Existing manuals and technical documents provide recommendations for planning and conducting a dam removal project (e.g., Graber et al., 2015; USSD (U.S. Society on Dams Committee on Dam Decommissioning), 2015; Randle and Bountry, 2017; Georgia Aquatic Connectivity Team, 2020). For any given project, consultation with local experts and regulators who can provide information appropriately tailored to local conditions is prudent. Below, we briefly outline the main issues for consideration when scoping a dam removal project.

- *Assembling a project and stakeholder team*. Regardless of the scope and complexity of the dam removal project, planning will involve both the creation of a project team and engagement with stakeholders who have an interest in project details. A project team will be multidisciplinary and likely include a manager, engineers and restoration designers, biologist, geomorphologist, outreach specialist, and construction-engineering specialist. The main goal of a project team will be to define project objectives, obtain necessary funding and permits, conduct the removal and any necessary mitigation and post-project monitoring. Larger, more complex projects may require several intermediate steps, including feasibility studies, preliminary design analyzes, and alternative scenario plans (e.g., no action, refurbishing, rebuilding). There could be many potential stakeholders, including local, state, tribal, and federal agencies who have legal jurisdiction. Other parties—public utilities, business and industry groups, environmental and watershed groups, heritage and historical societies, indigenous communities and residents—also have an interest and differing viewpoints on how ecosystem services may be impacted by the dam removal project. The success of many dam removal projects has depended upon successfully navigating such complex socio-political relationships through the building of successful partnerships and institutional coordination (Johnson and Graber, 2002).

- *Determining the ownership of the dam and surrounding lands upstream and downstream of the project*. The potential ownership of dams spans a gamut of possibilities, from privately owned structures to those owned by local, state, or federal entities. In less common situations, older dams may have been abandoned, and their ownership is unclear or unknown.
- *Assembling historical and technical details about the dam and its structure*. These include obtaining information and technical drawings (i.e., "as-built plans") or photographs showing how the dam was constructed, the history of any modifications or rebuilds, and the materials used in the dam's construction. This key information (albeit often lacking for older structures) is helpful for planning the mechanical removal of the structure, especially for determining equipment needs and methods for removal. Additionally, other infrastructure associated with the project (e.g., roads, bridges, utility lines, water intake structures) or within the influence of the dam removal project area should be identified in the early stages of planning. This information is necessary for determining levels of risk from the dam removal and potential liabilities and mitigation needs.
- *Understanding project scope, including river hydrology and sedimentation*. Determining the amount of sedimentation and the concentration of possible contaminants is vital, as these factors are perhaps the most significant drivers of project cost, complexity, and the strategy for conducting a dam removal (Randle and Bountry, 2017). Such reconnaissance will set the boundaries of the sediment management planning and any mitigation measures required to protect downstream resources. The length and width of the reservoir, coupled with the characteristics of the stored sediments, play a role in predicting how much sediment will ultimately erode from the reservoir during and following dam removal (Major et al., 2017). Hydrological conditions of the river, including the magnitude and seasonal variability of flows and the hydraulic capacity of the river to erode the reservoir sediment are crucially important, as this will determine the rate of scour, deposition, and river channel evolution in the former reservoir area and downstream river channel (Doyle et al., 2002). Providing additional context to the issues of hydrology and sediment, detailed geomorphological assessments upstream and downstream of the dam, including cross-section surveys and longitudinal profiles, can be vital for project planning.
- *Identifying needs for infrastructure and species protection*. Assessing the potential impacts to infrastructure or biological species of special concern within the project area is necessary, as this will influence the planning, permitting and conduct of the dam removal project. Many of the concerns surrounding infrastructure are focused upon how reservoir drawdown and sediment release will impact the function of existing water-related infrastructure. For example, development of reservoir shorelines can follow construction of a dam, creating infrastructure like wells, surface-water intake pipes, and septic systems. Once a reservoir is drained, concerns arise for this infrastructure. In their review of this topic, Tullos et al. (2016) noted that the effects of dam removal on wells were dependent upon whether the water table was hydraulically connected to the reservoir. For many locales, existing databases indicate the potential presence of sensitive aquatic species, including plants, fish, amphibians, invertebrates, and mammals, but additional local-scale surveys for potentially impacted taxa of concern may be necessary. For cases where sensitive species are present, actions may be required to reduce or eliminate potential negative effects. These include scheduling dam removal activities to avoid biologically sensitive times of year, utilizing abatement strategies to minimize noise from construction equipment, and relocating sensitive sessile and mobile animals from the project area into safer habitats.
- *Identifying regulatory statutes and environmental compliance mandates*. This includes obtaining the necessary permits to conduct the dam removal. Requirements vary among jurisdictions and consulting with local experts would be beneficial. In the United States, federal regulations that may apply to a dam removal project might include: (1) the Clean Water Act (Sections 401, 402, and 404) to protect water quality and regulate the discharge of dredged or fill material into navigable waters of the United States (administered by the U.S. Army Corps of Engineers and Environmental Protection Agency); (2) the Endangered Species Act (administered by either the National Marine Fisheries Service or the U.S. Fish and Wildlife Service); (3) the Magnuson-Stevens Act if commercial fish species are present in the project area, and (4) the Federal Power Act, which gives the Federal Energy Regulatory Commission (FERC) the exclusive authority to license non-federal hydropower projects. Some dams are designated as historical or culturally significant sites and may be protected by laws like the National Historic Preservation Act. State and local regulations may also apply.

Case-studies and conducting a dam removal

Once permitting and other logistical preparations are completed, the deconstruction phase of dam removal can proceed following one of three possible pathways—partial dam removal, instantaneous dam removal (also referred to as "sudden") or staged ("phased") dam removal. These pathways differ in the rate and extent of removing the structure from the river (given the needs and constraints of the project, as described above) and determine the time horizon of the project.

A partial dam removal is applied in cases where logistical (e.g., sediment retention) or socio-political (e.g., dam is a historically significant site) factors call for retention of some portion of the dam. For example, the portion of a dam blocking fish passage might be removed while other portions of the dam and related structures are left in place for historical preservation. Three different case-studies highlight the different factors that might lead to a partial dam removal. The first example involves the Kent Dam on the Middle Cuyahoga River in Ohio, where significant water quality degradation was caused by a dam no longer serving its intended purpose. Dam removal was considered necessary to improve the water quality status of the river. Yet, the historically significant dam was one of the oldest arch masonry dams in the U.S. and by creating a picturesque waterfall it was a culturally important feature for the citizenry (Tuckerman and Zawiski, 2007). A compromise was reached where a partial dam removal allowed part of the dam and its waterfall to be retained, while a bypass channel reconnecting the downstream and upstream portions of the river improved water quality.

A second example of a partial removal comes from Banff National Park in Canada. In this case, the town of Banff dug wells, thus negating the 8-m high water-storage dam's primary purpose, even as it remained a liability requiring costly annual maintenance and inspections. A flood washing out the dam's access road led to proposals for dam removal, but due to funding limitations the town managers decided to pursue a partial dam removal where only a portion of the dam was removed, but a bypass channel was engineered with both concrete and natural substrate that allowed fish passage (Sullivan et al., 2019). This was particularly beneficial for bull trout (*Salvelinus confluentus*), a protected migratory species in the province.

The final example of a partial removal comes from Taiwan, where a series of sediment retention check dams were limiting the available migration corridor of the land-locked Formosan salmon (*Oncorhynchus masou formosanus*). The most downstream and largest dam (Number 1 Dam, 16 m) on the Chichiawan River was slated for removal to increase connectivity for the last remaining population of this critically endangered fish species (Chang et al., 2017). Project planning identified that a main road would be impacted by full removal of the dam, but a partial removal allowed the western abutment to remain and protect the road while still restoring fish passage.

Full dam removals are cases where the dam is removed, the stream bed is returned to its original elevation and course, and all portions of the dam that could influence hydrological conditions of the river are removed. A full dam removal can be accomplished in two ways, differentiated mainly by the speed of the removal process and the rate of reservoir drawdown. In an instantaneous dam removal, reservoir draw down occurs in a matter of hours to days. Some of these projects are informally described as "blow and go," where a portion of the dam is first removed, sometimes with explosives, so that rapid and complete draining of the reservoir follows. Such instantaneous dam removal using explosives occurred with the 38-m high Condit Dam, on Washington State's White Salmon River, where a detonation of explosives in a tunnel bored out of the bottom of the dam caused a rapid and complete drawdown of the reservoir, releasing a large volume of sediment downstream. This minimized the duration of high sediment concentration experienced by fish populations downstream of the dam, limiting impact to a single spawning season instead of multiple seasons (as in some phased removals, see below). After the breach, the remains of the dam were mechanically removed in stages over the next 12 months. Note however that for smaller dams a rapid reservoir drawdown is usually achieved with more conventional methods using construction equipment.

A second type of full dam removal is staged dam removal which, by design, is drawn out over months or years. This is a method often used for taller dams where large amounts of sediment are contained within the reservoir, raising environmental or infrastructure concerns for accepting waters downstream. A staged removal allows the pace of reservoir drawdown to be controlled, which is a major determinant of the rate and timing of sediment mobilization. By maintaining the reservoir as the dam is removed in stages, the project managers can retain some level of control over the timing, duration, and amount of sediment released downstream. It also gives time for erosive processes and lateral channel migration to mobilize and redistribute sediment within the reservoir. Factors such as the presence of sensitive species and infrastructure, or a limited capacity of the receiving channel downstream to accept sediment, can initiate the need for a staged dam removal.

A good example of a staged dam removal comes from the Elwha River in Washington, where two dams were removed using two different staged dam removal strategies. The downstream Elwha Dam was a 32-m tall concrete gravity dam. Its staged removal was accomplished by alternating the river's flow through one of two constructed channels, using temporary coffer dams to route water through one channel at a time. The second dry channel was excavated to a lower elevation than the one with water, so that when the flow was switched between channels, the elevation of the reservoir was reduced by an amount equivalent to the difference in elevation between the wet and dry channels. A total of 10 channel switching events were used to remove the dam over an 8-month period. The taller 64-m Glines Canyon Dam was a concrete arch dam with a reservoir that contained about 75% of the 21 million m^3 of stored sediment contained behind both dams (Randle et al., 2015). Gradual removal of this dam was accomplished over a three-year period by notching the dam, at first mechanically with hydraulic hammers and then with explosives. The depth of each notch reduced the water elevation of the reservoir to a set amount, determined by limits of reservoir slope stability and levels of sediment to be released downstream to minimize negative effects to fish and their habitats. This incremental workflow also enabled project managers to control and manage sediment within the former reservoir, allowing the river time to erode, deposit, and redistribute sediment within the former reservoir.

Alternatives to the strategy of river erosion may be required when sediment cannot be released downstream. Removal of sediment, via dredging or mechanical removal, can minimize the downstream impacts or mitigate issues with contaminated sediments. However, this usually dramatically increases project cost because in addition to sediment dredging, project planners must find a location to dispose of the material and a method for transport. Mechanical sediment removal strategies were required to remove contaminated sediment stored behind the Milltown Dam on the Clark Fork River in Montana, a U.S. Superfund site, before dam removal could proceed (Brooks, 2015). In the case of the 32-m tall San Clemente Dam on the Carmel River in California, the aging dam was a safety risk, with a reservoir filled to 95% of its capacity with sediment. Dam removal was necessary, but the stored sediments posed a sediment management dilemma because downstream development, infrastructure, and limited channel capacity imposed unacceptable risks from a large sediment release. The creative solution involved leaving the reservoir sediments in place and constructing a bypass channel to reroute the river around the former reservoir reach. This approach allowed for sediment transport from river reaches upstream of the reservoir while sequestering reservoir sediment that may have created downstream issues for roads, houses, and other infrastructure (Harrison et al., 2018).

Physical and ecological outcomes of dam removal

As the number of dismantled dams has grown, the scientific community has increasingly studied the outcomes of dam removal (Table 1), including whether the environmental changes caused by dams can be reversed. Nearly 10% of the dams removed in the U.S. have been scientifically evaluated, through assessing changes to a suite of physical, water quality, and biological variables (Bellmore et al., 2017). Although many studies collect before and after dam removal data, some only collect post-removal data. Most of these studies, no matter their experimental design, have lasted for relatively short durations, and they have evaluated outcomes for a few years around the initiation of dam removal. Long-term evaluations are rare, as most studies have focused upon the time period where rapid physical changes take place in the upstream and downstream vicinity of the dam. As the number of case studies evaluating river outcomes has increased, synthesis of the physical and ecological responses has emerged alongside tools like numerical hydrodynamic and sediment modeling to allow predictions about how a river's condition will change over time following dam removal.

When conceptualizing responses to dam removal, it is helpful to segregate—in both space and time—the processes that affect the structure and function of the river ecosystem (Hart et al., 2002; Bellmore et al., 2019). Spatially, the most straight forward case involves a single dam that effectively creates three distinct zones that behave differently following dam removal. These zones are the river segment upstream of the reservoir, the reservoir section from the river inlet to the dam, and the reach downstream of the dam. Within each of these spatial domains, different sets of physical and biological factors and processes drive change, which collectively impact the shape of the ecological response trajectory following dam removal. This trajectory is also shaped by differences in temporal dynamics, as both short-term and long-term responses are dependent upon a suite of factors, including the size of the dams, amount of sediment, and ecological context (Fig. 1).

Changes to the upstream spatial domain are driven by restoration of connectivity following dam removal. The ability of organisms to travel past the dam location into upstream waters can increase species richness and life history diversity. This is especially true for migratory fish populations, which can be lost from upstream reaches following the placement of a dam unless significant mitigation (e.g., fish ladders for adults to pass the dam) is taken. Once passage is returned following dam removal, migratory fish from reaches downstream of the dam can swim up past the former dam, often rapidly repopulating upstream reaches, which over time can increase upstream species richness (Wippelhauser, 2021). Given the right conditions, in terms of environmental suitability and genetic memory, life-history diversity can re-emerge in upstream populations. This was seen when summer run Steelhead (*O. mykiss*) that were rare for decades prior to dam removal returned to the Elwha River following dam removal (Fraik et al., 2021). The return of fish to upstream reaches can also drive changes indirectly, as seen when Pacific Salmon (*Oncorhynchus* spp.) provide marine-derived nutrients to their freshwater spawning grounds. These marine-derived nutrients can be seen in both aquatic and terrestrial food webs (Tonra et al., 2015). Salmon can also transport freshwater mussel larvae to upstream areas and significantly alter the stream benthos through bioturbation disturbance from their spawning activity. A potential downside to restored connectivity occurs in cases where significant risk exists from invasive species migrating into upstream waters. This has deterred some potential dam removals, such as in streams draining into the Great Lakes in the U.S., where significant resources are directed toward eliminating Sea Lamprey (*Petromyzon marinus*), which spawn in rivers and as adults parasitize commercially important fish species in the lakes (Jensen and Jones, 2018).

The most dramatic changes to physical, biological, and ecological factors occur in the former reservoir reach. This spatial domain experiences a wholesale change from a lake-like (lentic) ecosystem to a river ecosystem (lotic). Once a dam is removed, the reservoir drains, stored sediment is transported downstream, and a new channel emerges within the former lakebed. Initially, the re-emergent river channel (or braided channels in wide reservoirs) is unstable. As the sediment interacts with hydrological flows, a stable channel will eventually reform. The pace of this physical transformation varies, depending on the size of the impoundment, stored sediment volume, and hydrological conditions. As the river channel reforms, the aquatic communities adapted to pelagic conditions and lentic fish species are replaced by benthic production and lotic fish species. For some systems, such species turnover can be considerable, but the absolute number of species may not change, and some generalist species can be found in the same area before and after dam removal (Bellmore et al., 2019). A driving force that determines the reassembly of species following dam removal is the "ecological memory" of the system, defined here as the current and future influence of the cumulative past impacts to

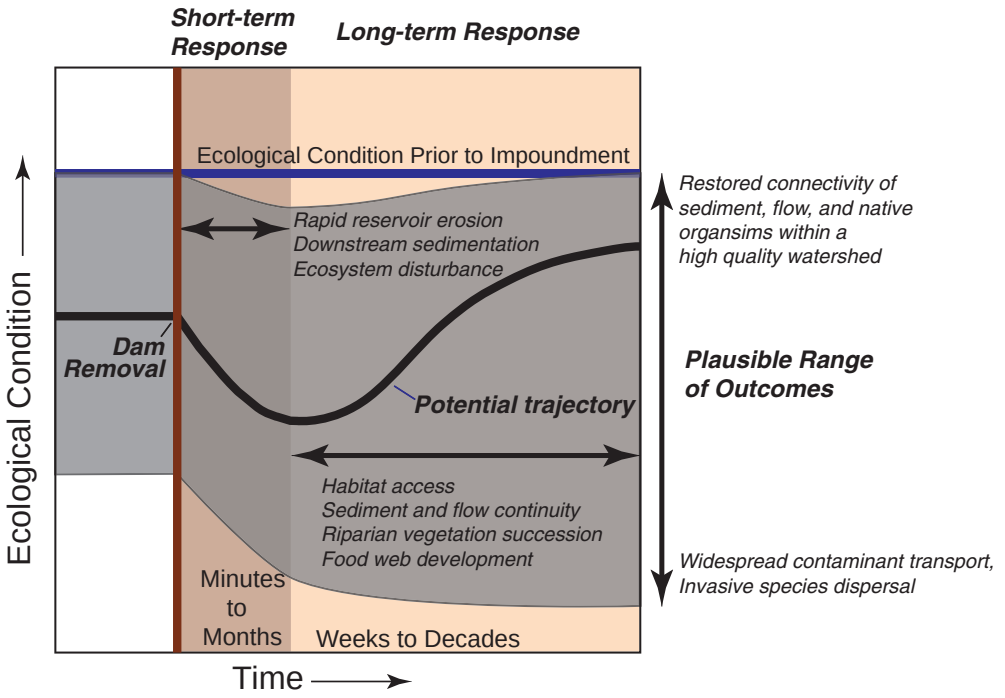

Fig. 1 Conceptual model of the ecological trajectory of a river following dam removal. Considerable variability exists in the condition of the river prior to removal (gray area to the left of the dam removal line). Following the initiation of dam removal, a short-term disturbance effect is caused by the dam removal, but conditions improve in the long-term as natural flow and sediment regimes are restored and habitat access in the former reservoir and upstream areas is resumed. A range of plausible outcomes (gray area to the right of the dam removal line) exists due to a suite of possible factors influencing the river condition outcome, such as existing watershed condition, size of the dam and sediment released, and strategy of dam removal From Foley MM, Bellmore JR, O'Connor JE, Duda JJ, East AE, Grant GE, Anderson CW, Bountry JA, Collins MJ, Connolly PJ and Craig LS (2017) Dam removal: Listening in. *Water Resources Research* 53: 5229–5246. Used with permission.

the ecosystem. In cases where upstream, downstream, and tributary reaches retain a high level of species and life history forms available for repopulating the reservoir reach, the system will more closely approach the pre-dam condition. Conversely, if these species and life history pools are diminished, due to the age of the dam or via other disturbances in the watershed, the river ecosystem might not approach the state that existed prior to dam placement (see Fig. 1). Natural revegetation within riparian and upland zones, sometimes assisted by seeding and planting, further stabilizes former reservoir surfaces, over time reducing erosion. With the return of riparian and upland vegetation, wildlife species also return and can further assist in normalizing habitat structure and function, as well as re-establishing trophic ecological interactions within the former reservoir reach.

Downstream of the dam, changes to the river are driven by fluxes of water, sediment, organic material, and nutrients caused by the dam removal. As the reservoir base level declines, either rapidly or in stages, fine sediments from the reservoir are eroded and transported downstream, even with modest river flows. Much depends on the amount of sediment stored in the reservoir, the characteristics of the sediment (e.g., bulk density, grain size), frequency and magnitude of floods, and the characteristics of downstream river reaches that are receiving and transporting the sediment (Major et al., 2017). Given the wide range of sediment volumes and dam conditions previously observed, a common theme among dam removal projects is that even large changes in geomorphology are relatively short-lived. A river will process the stored sediment, sometimes in amounts that are multiples of the river's naturally occurring annual sediment load, by transporting it downstream. Temporary changes in elevation, channel morphology, and grain size of the stream bed will occur. Over time, as supply from the reservoir diminishes to background levels, an equilibrium condition will emerge in the downstream reach to the point that the river channel approaches the pre-dam condition. From a physical standpoint, most rivers are resilient to the dam removal disturbance and largely recover their form and function soon after dam removal (Magilligan et al., 2021).

The downstream response of individual species, biological assemblages, and their trophic structure are also impacted by perturbations brought about by dam removal (Lake et al., 2007). The fluxes of water and sediment can have both direct and indirect effects on aquatic and riparian organisms, as well as significantly altering or entirely removing their habitats, at least for a time after the initial sediment pulse. Again, context—in terms of the size of the dam, amount of sediment released, dam removal strategy, and how altered the downstream ecosystem is from its pre-dam condition—matters (Foley et al., 2017; Bellmore et al., 2019). Burial of the benthos by sediment can directly impact organisms, particularly sessile organisms that cannot disperse to other less impacted areas. It is typical to see a rapid change in the species assemblage and the density of aquatic macroinvertebrates following dam removal (Carlson et al., 2018), with species tolerant of finer sediments and scour favored over sensitive taxa intolerant of such conditions. Also, sediment release usually increases the turbidity of the river, which reduces light availability and can affect the taxonomic composition of benthic primary producers and their capacity for production. Reductions in the densities of

benthic algae and invertebrate communities have been widely reported and are usually most significant in the reaches closer to the removed dam. These changes are often temporary, with recovery occurring once the dam removal effects diminish. Fish have been shown to be less directly impacted by sediment release from dam removal than organisms of the benthos, although mortality and damage to gills from abrasion are possible. Unlike sessile organisms or those with narrow habitat requirements, many fish species can avoid or move to refuges to escape the highest impacts associated with dam removal. Yet, indirect effects can affect fish and their habitats. A reduced food supply from reductions in benthic production, a diminished capacity to visually forage in high turbidity conditions, and diminished suitability of spawning habitat can all lead to decreased fitness of individual fish and reductions in population size during and following dam removal as the river processes the physical changes (Stanley and Doyle, 2003).

Despite the short-term disturbance caused by dam removal, a growing body of research suggests that rivers, given the opportunity, can recover substantially from having been dammed. However, the structure and function of the ecosystem may not be the same as what existed prior to dam emplacement. Changes in ecological communities caused by dams, such as extirpation of native species and harboring of invasive species, can limit the capacity for the ecosystem to reassemble into the pre-dam condition following dam removal (see Fig. 1). Moreover, land use, the presence of other dams, sediment contamination, climate change, and numerous other factors may constrain both physical and ecological trajectories. The ability to go back to a pre-dammed state will likely depend on how long the dam existed and the magnitude of its many-faceted effects on the ecosystem. Even if all elements of the ecosystem still exist, it is unlikely they will reassemble in the exact fashion that existed previously.

Future outlook of dam removal

It is likely that the number of dam removals and communities removing dams will increase into the future, for both practical and aspirational reasons. Given the immense number of dams and their age, there will be a number of candidates for removal, particularly dams that have aged beyond repair and outlived their usefulness. In places where the practice is well established, these dams (especially smaller dams) will continue to come down, probably with greater efficiency and less controversy. In regions or countries with few dam removals, translating the knowledge and experience gained from past projects could lessen the learning curve and institutional barriers to applying the practice where applicable. Coupling predictions about expected outcomes with a wide range of experience in conducting dam removal should see dam removal emerge as an accepted practice in areas where it is currently rare, especially when applied to dams that are beyond repair or pose a significant risk to life and property.

The opportunity to build on past successes and intensify river restoration efforts is gaining momentum, in terms of scientific expertise, practical experience, and public policy. This has led to a reassessment of policies and practices involved with the management of rivers. As an example, a recent joint statement from a working group representing the U.S. hydropower industry and the environmental and river restoration community recognized the need to remove dams that, "no longer provide benefits to society, have safety issues that cannot be cost-effectively mitigated, or have adverse environmental impacts that cannot be effectively addressed" (U.S. Hydropower: Climate Solution and Conservation Challenge 2020). The statement also acknowledges that hydropower is an important component of renewable energy strategies and that rehabilitating and retrofitting existing dams will also be important tools for addressing the myriad of challenges facing the wise use and conservation of the world's rivers.

Knowledge gaps

Considerable progress has been made in the field of dam removal over the last three decades. The action of physically removing a dam from particular river is a relatively straight forward construction-engineering process. Yet, additional knowledge and advances in key areas are still needed, largely in decision making and predicting the long-term outcomes of individual dam removal projects.

- Decision making
  - o Prioritization and optimization tools to aid decision making and selecting dam removal projects.
  - o Numerical modeling, in particular for tracking the fate of stored sediment and ecological outcomes.
  - o Tools for estimating the cost of dam removal projects.
- Outcomes of dam removal
  - o Assessing cumulative impacts of removing multiple dams from a single watershed.
  - o Long-term outcomes of river response and restoration
  - o Quantifying socio-economic effects, such as long-term outcomes to property values, economic trajectories of communities near dam removal projects (e.g., recreation, commercial fishing), cultural resurgence of indigenous peoples, communities, and river economies, as well as other societal benefits.

Conclusion/Synthesis

Dam removal is an important tool for river restoration and addressing aging infrastructure. It is an ongoing activity that will continue as a large number of aging dams that are no longer serving their original purposes, have become safety liabilities, or represent potential for significant restoration action are taken down. The increase in the number of dams removed has led to a

greater understanding about the outcomes to the river and its ecosystem. Rivers are resilient to the changes and disturbance that accompany the removal of a dam, with many of the changes occurring rapidly and representing an improvement in water quality, hydrological flows, and migratory movement of aquatic animals. Yet, some of the outcomes of dam removal may play out over longer time periods, depending on such factors as the life-history of key species or implementation of other complementary river restoration actions. In the future, as societies are faced with changing hydrologic and land-use drivers that influence water use and conservation, dam removal will be an important option for maintaining or enhancing the values and ecosystem services of the world's rivers.

Glossary

Anadromous Fish that migrate from salt water to freshwater to spawn including various salmonid species such as the Arctic charr (*Salvelinus alpinus*).
Arctic Council An international forum comprised of the Indigenous people and the eight countries of the Arctic that interact and coordinate on joint aims such as sustainable development and environmental protection of the Arctic.
Atmospheric transport The transfer of pollutants via the atmosphere such that these materials are dispersed and deposited large distances from their source.
Eurythermic Refers to organisms that live in a wide range of temperatures.
Freeze-up The process of a body of water freezing at the surface in winter.
Global distillation A process whereby volatile contaminants (e.g., persistent organic pollutants) evaporate and are transported from warmer to colder areas where the vapors condense and are deposited as precipitation (i.e., the "grasshopper effect").
Ice breakup The collapse of winter ice on rivers that can cause extreme flood events and often is an annual ecosystem reset event due to streambed and bank erosion.
Permafrost The thick layer of soil in polar regions that remains frozen throughout the year.
Stenothermic Refers to organisms that are only capable of living in a narrow temperature range.
Thaw slump Landslides that develop on hillslopes in areas of ice-rich permafrost that can deliver large volumes of sediments and organic debris downslope to stream channels.
Thermokarst Characteristic land-surface configuration in polar regions caused by subsiding ground due to thawing of ice-rich permafrost.
Tundra Biome where tree growth is limited by cold temperatures and short growing season with a characteristic vegetation of dwarf shrubs, sedges, mosses, and lichens.

Introduction

This chapter provides a broad overview of food web structure and composition in high latitude streams of the circumpolar Arctic and describes how the biota are affected by major environmental variables and the pressure of climate change. This region includes 12 major river basins that flow into the Arctic Ocean, and it can be subdivided into the Sub-, Low, and High Arctic. The Sub-Arctic is a boreal forest zone with discontinuous permafrost located immediately south of the treeline, the High Arctic is the most northerly region of the Arctic, characterized by barren tundra landscapes with continuous permafrost, and the Low Arctic is a transition zone between the forested region to the south and treeless polar region to the north (Fig. 1). Key environmental variables affecting Arctic river systems include the hydrological and ice regimes of cold-region environments, cold thermal conditions, and water quality

variables such as nutrients and sediments (Culp et al., 2021a). Our understanding of such stream ecosystems is nascent as much of the Arctic region is remote, sparsely populated, and relatively unstudied, as also noted by Huryn (2021). Given the breadth of the topic, this overview aims to provide an advanced introduction to the current knowledge of these systems.

The overriding environmental variable that establishes the abiotic template for biota in these rivers is related to water discharge, with the hydrological regimes of high latitudes varying significantly from those of temperate regions. This difference is related to the sources and pathways of snow and ice from a landscape often underlain by permafrost that limits infiltration below the land surface (Peters et al., 2021). Distinct cold-region hydrographs include (1) proglacial conditions with seasonally dominant spring snowmelt followed by runoff from glaciers and occasional rainstorms, and (2) nival hydrographs in regions of permafrost where spring snowmelt is the only major annual flow event (Peters et al., 2021). Winter flows of such high latitude rivers progressively decline from Sub- to High Arctic regions as discontinuous permafrost is replaced by continuous permafrost. Additional hydrologic regimes include (3) spring-fed environments that have more consistent flow throughout the year (Huryn, 2021), and (4) wetland conditions where spring snowmelt is followed by the summer and fall period where flow inputs from rainfall are greatly attenuated by the water-retaining capacity of muskeg.

A second critical driver of biotic pattern in high latitude rivers relates to the extreme cold temperatures and ice regimes of these ecosystems. Several investigations demonstrate that diversity of biota declines with latitude (e.g., Culp et al., 2019), with Lento et al. (2021) showing strong negative associations of macroinvertebrate diversity with decreasing temperature at higher latitudes. Across the circumpolar Arctic, macroinvertebrate composition of high latitude rivers is predominated by cold-tolerant macroinvertebrate taxa such as chironomids and oligochaetes. Similarly, Castella et al. (2001) found sharp decreases in species richness of glacial streams with increasing latitude.

Such extreme, cold thermal regimes lead to river ice playing a major role in affecting the physical and chemical environment of high latitude rivers. For example, headwater streams (<1–2 m in width) can be completely frozen in winter, while deeper channels downstream generally contain unfrozen water capped by floating ice (Huryn, 2021). Ice-covered rivers lack a direct exchange with the atmosphere and can experience substantial decrease in dissolved oxygen over the winter. Where streams freeze completely to the bottom, macroinvertebrate communities may be dominated by taxa with freeze tolerance or freeze avoidance traits, whereas fish typically employ seasonal migration to avoid freezing during these periods (Huryn, 2021). The annual breakup of river ice can cause streambed scour, extreme suspended sediment loads, and a rapid rise in water temperature, which together create an ecosystem reset event unique to these environments (Prowse and Culp, 2003). The resultant input of organic material and sediments, and post-breakup deposition of these materials, can reduce habitat quality and impair biological production. River ice breakup also adds nutrients (including phosphorus and nitrogen particulates) from the shoreline and floodplain. One study discovered that up to 30% of the annual phosphorus input to a small river in Alaska occurred during ice breakup (Whalen and Cornwell, 1985). Notably, ice breakup can also have important effects on the input and transport of contaminants, such as metals and organic compounds (Beltaos, 2018; Culp et al., 2021b).

As global warming progresses, the pressure of climate change will affect virtually all key environmental variables associated with river ecosystems. Climate change assessments indicate global warming is amplified at high latitudes (Box et al., 2019) and is occurring at twice the global average rate (Walsh et al., 2011). This climate shift is leading to permafrost thaw (Spence et al., 2020) and glacial retreat, which together modify downstream river environments, and to higher inter-annual variability in extreme precipitation events that modify hydrological regimes and exacerbate the growth of permafrost thaw slumps (Kokelj et al., 2015). Climate models predict that the Arctic will experience a reduction in snowfall and increase in precipitation falling as rain, including increased precipitation in the winter, which is expected to have strong effects on the hydrology of Arctic rivers (Box et al., 2019). Warming also affects the release of key nutrients from the terrestrial landscape such as dissolved organic carbon (DOC) and total phosphorus (Levenstein et al., 2018; Huser et al., 2020). Of importance is the increased occurrence of permafrost thaw slumps that augments sediment and nutrient input to high latitude rivers (Kokelj et al., 2015; O'Donnell et al., 2019; Huser et al., 2020), with sediment inputs in particular leading to shifts in the composition of river biota (Chin et al., 2016). Heino et al. (2020) conclude that most recent environmental changes in high latitude freshwater ecosystems are the result of human activities associated with climate warming, long-range transport of pollutants, and local or regional land use change. As these high latitude ecosystems continue to warm, it is expected that southern species will expand their ranges at the expense of cold-adapted species (Culp et al., 2012), resulting in changes to the biodiversity of these systems that will affect the ecosystem services on which Indigenous Peoples of the Arctic rely (Heino et al., 2020; Culp et al., 2021a).

Ecology of high latitude Rivers

Overview of abiotic and biotic structure and function

The physical-chemical environment of high latitude rivers forms an abiotic template for biotic activity that is vastly different than that of rivers in temperate regions. Freeze-up occurs in early fall, causing a reduction of light entering the water column and of oxygen exchange with the atmosphere (Prowse and Culp, 2003; Wrona et al., 2013). Cold thermal conditions dominate, with many smaller rivers of northern latitudes freezing completely to the streambed during winter (Peters et al., 2021). In contrast, larger rivers flowing north from temperate headwaters (e.g., Mackenzie River in Canada, Ob in Russia) can have significant discharge year-round (Peters et al., 2021), although they experience floating surface ice in winter. Winter flow can also remain continuous in springs, habitats that can be an important refuge for biota during winter (Wrona et al., 2013). Depending upon the latitude, these conditions combine with cold temperatures from fall through spring to either greatly reduce or halt biological activity during winter. Following the harsh winter, rapid warming produces the spring freshet that causes dynamic river ice breakup, which creates a short, but intense, physical disturbance that sorts the river substrate and affects river chemistry (Fig. 2). Such ice movement can cause substantial bank erosion and sculpting of the riparian zone. In addition, the concentrations of dissolved inorganic nutrients (including C, N and P) are generally extremely low due to low mineralization rates that result from the cold, Arctic temperature regime and because permafrost limits groundwater development (Huryn, 2021). This unique cold region regime produces a suite of environmental conditions that shape the diversity and biological traits of biota across all trophic levels.

Algae and bryophytes form an important basal component of food webs in Arctic rivers. Production and biomass of primary producers in these systems is typically low due to oligotrophic conditions (Peterson et al., 1985; Deegan et al., 1997). While animal diversity at higher trophic levels shows strong latitudinal declines (Culp et al., 2019; Laske et al., 2019), species richness of riverine benthic algae of the circumpolar Arctic is largely associated with nutrient concentrations and geology, with only weak negative associations with latitude (Lento et al., 2020). At the circumpolar scale, Kahlert et al. (2020) found that diatom community composition was lowest at the highest latitudes, but it was not dominated by endemic taxa. Rather, the strongest community shifts across the Arctic were associated with changes in substrate, velocity, alkalinity, pH, and the concentrations of several water quality variables, including nutrients, dissolved organic carbon and calcium. Bryophyte production in high latitude rivers also is limited by low nutrient concentrations; long-term nutrient enrichment experiments show bryophytes become the dominant component of autotrophic biomass in fertilized reaches of the Kuparuk River, Alaska (Bowden et al., 1994). However, macrophyte communities shift towards a greater dominance of bryophytes at the highest latitudes, which suggests that they are better adapted to the harsh

Fig. 2 Bank-to-bank ice rubble on the Mackenzie River, Northwest Territories near the mouth of the Arctic Red River, Northwest Territories, Canada. environmental conditions than are vascular plants (Lento et al., 2019). Both the abundance and community structure of benthic macroinvertebrate communities can be profoundly affected by bryophyte biomass (Stream Bryophyte Group, 1999).

A second important basal resource for food webs of cold region rivers includes energy sources flowing from microbial decomposition of terrestrial and aquatic carbon sources. For example, Peterson et al. (1985) demonstrated that in a tundra stream, heterotrophic processes dominated system metabolism with dissolved and particulate material from tundra soils being the predominant organic matter fueling the food web. Autotrophic carbon from aquatic primary producers also contributed carbon to decomposition pathways, with autotrophy becoming the dominant pathway when this stream was experimentally fertilized with phosphorus. Both rate and variability of decomposition of a standardized carbon source decline with latitude indicating that temperature limits this process at high latitudes. Recent studies show the following: soil organic carbon represents an important fraction of the organic carbon in rivers (Cole et al., 2007); biofilm communities can play a crucial role in the breakdown of this material; old carbon (5255 years before present to modern) from permafrost is incorporated into benthic biofilms; and, this carbon can be an important energy source for Arctic food webs (O'Donnell et al., 2019). Finally, Sub-Arctic rivers such as the Mackenzie River, Canada, can exhibit highly diverse microbial communities (Galand et al., 2006), the importance of which is only recently being revealed through the application of molecular techniques (Cavaco et al., 2019).

Benthic macroinvertebrate communities are a critical component of energy flow in high latitude food webs and are supported by the primary producer and decomposer trophic levels. The diversity of such macroinvertebrate communities decreases with latitude such that High Arctic rivers are dominated by the most cold-tolerant groups of dipterans (e.g., Chironomidae, Diamesinae, Tipulidae) and oligochaetes (Culp et al., 2019; Lento et al., 2021). These taxa are largely consumers of algal and detrital material associated with the streambed. In the Low Arctic, riverine invertebrate communities include many of the groups that dominate temperate streams including mayflies, caddisflies, and stoneflies (Lento et al., 2013, 2021). This northern decline in species richness is similar to the physiological thresholds observed along thermal gradients in glacial streams (Milner et al., 2001). Moreover, Culp et al. (2019) concluded that diversity declines with latitude were the result of the increased dominance of cold-tolerant taxa rather than being explained by the energy-richness hypothesis that links food limitation with latitudinal declines in richness (see Currie et al., 2004). Brittain et al. (2020) recently showed that the environmental drivers of macroinvertebrate communities of high latitude rivers in Fennoscandia are mainly related to climate variables including temperature and precipitation. However, both local and landscape scale environmental variables do play an important role in affecting alpha and beta diversity as also shown for Sub- and Low Arctic rivers in Northern Labrador, Canada (Lento et al., 2013). It is notable that these latitudinal trends in diversity and taxonomic composition of macroinvertebrates are mirrored in the harsh environment of glacial rivers, where cold thermal regimes, and low nutrient conditions dominate along a gradient from downstream to glacier snout (Milner et al., 2001).

High latitude rivers present harsh environmental conditions for fish survival (Wrona et al., 2013). Thus, the diversity of fish species that complete their entire life history in riverine environments of cold regions is low relative to lakes of this region (Wrona et al., 2013). For example, many species utilize small rivers for spawning but remain in lentic habitats for much of their life cycle. Such fish species utilize benthic macroinvertebrates for food. Riverine fish, such as the Arctic grayling (*Thymallus arcticus)*, also have the potential to modify food web structure through the top-down, cascading effects of predation on the benthos (Golden and Deegan, 1998). Although fish diversity is unrelated to latitude in the Sub- and Low Arctic regions (Lento et al., 2020), diversity decreases with latitude above 70°N as temperature regimes decrease. Moreover, richness of fish species is limited by historic or contemporary barriers to colonization (Laske et al., 2019). These discontinuities are caused by the ongoing species recolonization following Pleistocene glacial events and spatial gaps related to island geography (Wrona et al., 2013; Laske et al., 2019). Species

diversity in rivers of the High Arctic is often limited to landlocked Arctic char (*Salvelinus alpinus*), nine spine stickleback (*Pungitius pungitius*), as well as anadromous populations that can colonize islands via movement through the brackish water of coastal pathways (Laske et al., 2019).

Fish species in Arctic rivers, including Arctic char, inconnu (*Stenodus leucichthys*), Arctic grayling, Arctic cisco (*Coregonus autumnalis*), northern pike (*Esox Lucius*), and lake whitefish (*Coregonus clupeaformis*) are important food sources for Indigenous Peoples (Knopp et al., 2020). Indeed, research on Indigenous Knowledge indicates that various species of whitefish are a valuable food resource for the people of the Arctic Red River, Northwest Territories, Canada. Thus, although diversity and production of high latitude rivers is low relative to lake habitats, these rivers provide critical habitat for fish life cycle completion and production, and often are valued cultural locations.

Effects of climate change on biodiversity

Climate change has caused substantial alteration to Arctic freshwaters, with these shifts often occurring relatively rapidly and having long term ecological consequences (Heino et al., 2020). Increased temperatures and changes to the timing and magnitude of precipitation cause glacial retreat and hydrological shifts, and lead to permafrost thaw that increases sediment and nutrient levels (Fig. 3). These ecosystem shifts modify the biota of high latitude river systems through changes in the range distribution of biota and alterations in community structure and function.

Climate warming impacts

Cold temperatures are a defining feature of the Arctic and have been shown to limit diversity of freshwater organisms (Lento et al., 2019). For example, macroinvertebrate richness decreases in northern latitudes (Lento et al., 2021) and the lowest observed abundance of diatoms occurs at high latitudes (Kahlert et al., 2020). Fish species richness also follows this trend of low diversity at the highest latitudes, with species often limited to anadromous, cold stenotherms (Laske et al., 2019). Thus, climate-related water temperature increases are likely to cause directed changes in biotic composition of Arctic freshwaters as the physiological tolerances of stenothermic species are exceeded and eurythermic species adapted to warmer temperatures extend their range northward (Vincent et al., 2011; Culp et al., 2012).

An example of the mechanism that may lead to such biotic shifts with climate warming is related to how metabolic rates is affected by temperature (Lento et al., 2021). For fish and invertebrates, this relationship can modify ecological interactions such as

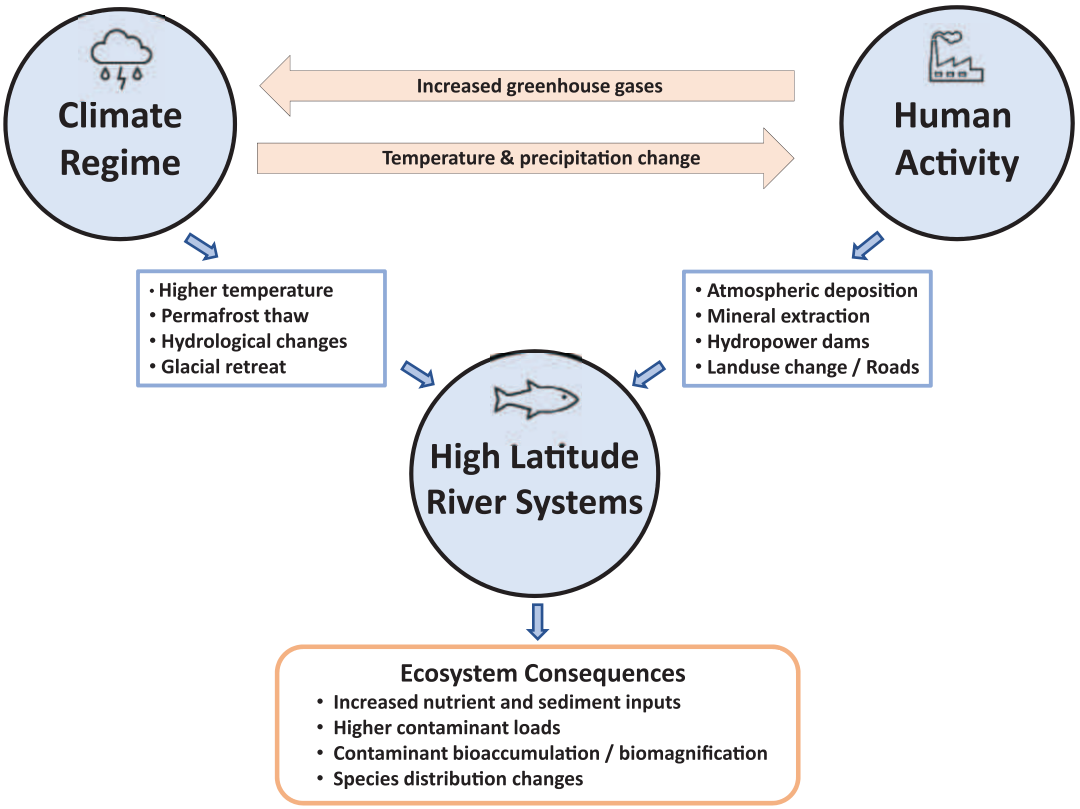

Fig. 3 Conceptual diagram showing the synergistic interactions between the pressures of climate change and human activity. These interactions result in modification of key environmental drivers that impact the physical and chemical environment of high latitude rivers and, ultimately, affect biological diversity.

competition and predation if body size changes with thermal regime, ultimately leading to shifts in species composition (Lento et al., 2021). As range expansion of southern species occurs, the loss of cold stenotherms that prefer temperatures $\leq$20 °C and have low physiological tolerances for higher temperatures may be coupled with increasing abundance of southern eurythermic species (Vincent et al., 2011). For example, model predictions for stream invertebrates suggest that species richness will rise at higher latitudes as warming progresses. Moreover, fish species such as Arctic char will likely be negatively affected by increasing water temperature, as well as by negative interactions with southern species that expand their range northward (Wrona et al., 2013). For example, analysis of long-term catch statistics from Iceland and Norway indicated a decrease in the relative proportions of Arctic char and concurrent increase in the relative proportion of brown trout (*Salmo trutta*) that was associated with increasing temperatures (Svenning et al., 2021). While there will be a net increase in species richness in Arctic areas, this change will cause the irreversible loss of unique Arctic biodiversity as 'climate change winners' replace 'climate change losers' (Heino et al., 2020).

Permafrost thaw impacts

One of the most important impacts of climate warming on high latitude rivers will result from permafrost thaw and the resultant mobilization of dissolved organic carbon (DOC), phosphorus, nitrogen, and major ions (Kokelj et al., 2015). This trend of warming is projected to continue (Wrona et al., 2013; Peters et al., 2021); thus thawing of thermokarst soils is anticipated to continue over all polar regions, impacting freshwater systems of the circumpolar Arctic (Spence et al., 2020). In low relief topography, or at a distance from rivers, the dominant effect of this thaw process will be from the release of large amounts of nutrients (e.g., DOC, nitrogen), ecosystem components that often are in short supply and that limit biological production. For example, Bowden et al. (2008) found that nutrient effects were confined spatially in some headwater streams, with biological uptake hypothesized as an important factor in restricting downstream export of nutrients. It is notable that the nutrient concentrations from thermokarst features were similar to those observed when experimental fertilization of an Alaskan stream increased benthic algal and macroinvertebrate production (Slavik et al., 2004).

In contrast, thawing of thermokarst soils in regions of steep topography or high ground ice content can lead to slope instability along stream valleys and significant input of terrestrial materials, with mud slurries flowing downslope into stream systems (Kokelj et al., 2015; Levenstein et al., 2020). A dramatic example of such slope failure is the case of retrogressive thaw slumps where large amounts of sediments, nutrients, soil organic matter (Chin et al., 2016), as well as contaminants (St. Pierre et al., 2018), flow into rivers and drastically alter these environments (Fig. 4). This phenomenon is predicted to increase in frequency and magnitude with increasing precipitation in the Arctic (Kokelj et al., 2015). This physical disturbance causes significant declines in benthic macroinvertebrate abundance (Chin et al., 2016) and periphyton biomass (Levenstein et al., 2018). Although the origin of thaw slumps is localized, the impact on the aquatic community can be observed at considerable downstream distances. For example, Levenstein et al. (2020) demonstrated that the sedimentation events associated with such slumps increased the relative proportion of

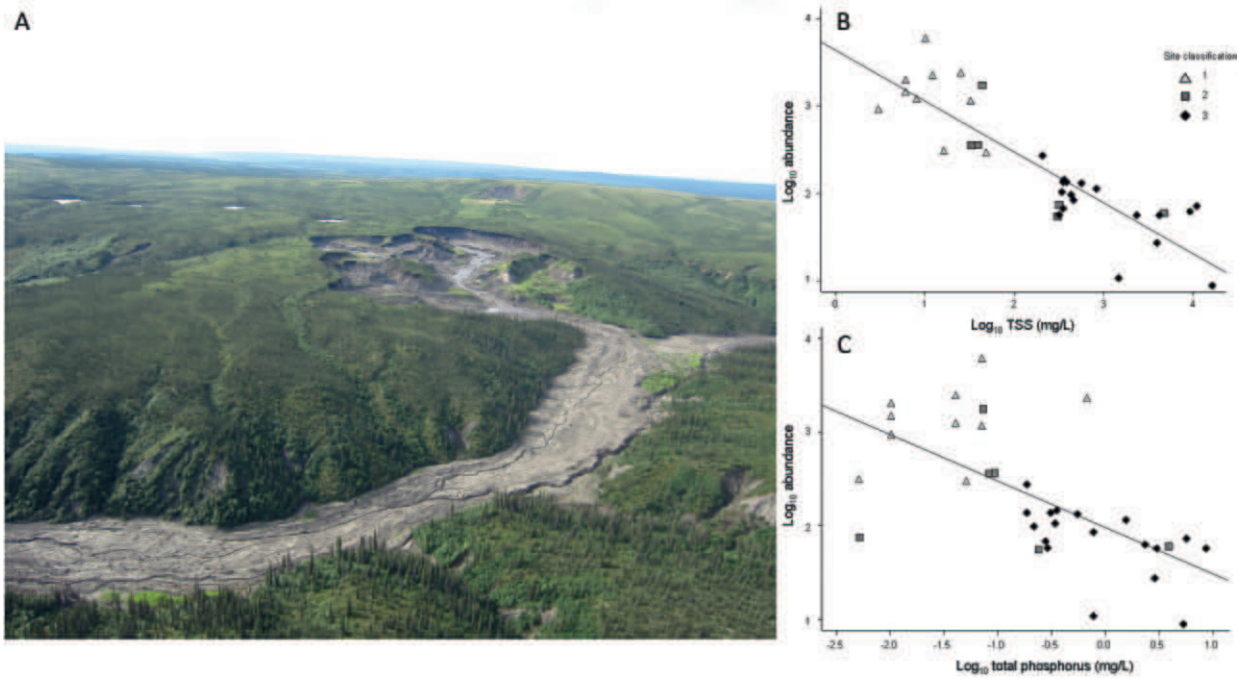

Fig. 4 Retrogressive thaw slumps can introduce large amounts of sediments, nutrients and soil organic matter to high latitude rivers (Chin et al., 2016). (A) Mega slump in the Peel Plateau region of the Northwest Territories with debris flow from the slump filling the river channel. Panels to the right show abundance of invertebrates in undisturbed (class 1), minimally disturbed (class 2) and heavily disturbed (class 3) streams in the Peel Plateau, plotted as a function of (B) total suspended solids (regression $p < 0.001$ and $r^2 = 0.76$) and (C) total phosphorus (regression $p < 0.001$ and $r^2 = 0.41$). Photo credit: J. Lento.

macroinvertebrates entering the drift even after prolonged (>3 years) exposure and lowered invertebrate abundance relative to upstream undisturbed sites. Finally, in several riverine environments, the impact of sediment loading appears to be more important than nutrient enrichment (Fig. 4). For example, suspended sediments were a more important driver of biotic change in a western Canadian river relative to nutrients, and algal biomass accumulation was more sensitive to thaw-slump sedimentation than was microbial decomposition (Levenstein et al., 2018).

Environmental change in glacial rivers

Glacier-fed rivers have a unique ecology that is shaped by longitudinal gradients in flow, temperature, nutrients and sediment load downstream of glacial inflow (Milner et al., 2001). These rivers are an important freshwater component in the Arctic with the largest global mass of glaciers occurring in Alaska, the Canadian Arctic and Greenland, and they are particularly susceptible to climate warming. Shifts in the abiotic template of high latitude, glacial rivers will produce structural changes in riverine flora and fauna, as well as modification of ecosystem functions. For example, both the diversity of species and their traits are predicted to increase as glaciers recede or as percentage of glaciers decrease in the basin, with these shifts mirroring existing downstream longitudinal patterns below glacial margins (Milner et al., 2001).

Effects of human development

Although Arctic ecosystems are often remote, these regions receive contaminants derived from external sources that are transported long distances from outside the Arctic region and deposited on the landscape, or that originate within the region from various sources including mineral extraction, landuse change, road development and hydropower generation (Gregor et al., 1998) (Fig. 3). Long-range transported compounds predominately arrive through atmospheric processes; however, northerly flowing rivers, such as those in Russia or Canada (Fig. 1), also can be important sources of contaminants bound to sediments or in water. In contrast, regional sources of such compounds are released directly in wastewater discharge from various industrial developments (e.g., mining, oil and gas), or within municipal waste waters (Gregor et al., 1998). Impacts to rivers of the above contaminants include biomagnification and toxic stress in biota, acid deposition and altered water chemistry that causes shifts in community structures, and nutrient enrichment that shifts community composition and biotic production (Culp et al., 2012). Importantly, contaminant stressors in Arctic freshwater are likely to interact with aspects of climate change such as increases in temperature and precipitation to produce cumulative impacts on ecosystems that will be difficult to predict (Wrona et al., 2013) (Fig. 3).

Long-range transport of pollutants

The long-range transport of contaminants has included persistent organochlorines (OCs) such as polychlorinated biphenyls (PCBs) and pesticides (e.g., DDT, chlordane, toxaphene), which are known to bioaccumulate in food webs of remote high latitude freshwaters, with examples for lakes being the most well studied (e.g., Kidd et al., 1998). Such contaminants can be extensively deposited across the catchment landscape or through air-water exchange (Gregor et al., 1998), and can bioaccumulate from primary consumers (invertebrates), to secondary Arctic char, nine spine stickleback and tertiary (lake trout, *Salvelinus namaycush*) consumers. Although the accumulation of contaminants in rivers is not well studied, OCs would be expected in riverine food webs because of the extensive connectedness of lake and river ecosystems in the Arctic.

Mercury is also a potentially toxic contaminant of concern that reaches high latitude freshwaters via long-range atmospheric transport, with enhanced atmospheric deposition occurring in spring and early summer as biological activity is increasing. Chételat et al. (2014) provide an extensive review of the cycling and fate of mercury in Canadian Arctic freshwaters, including detailed assessment of concentrations and processes in key ecosystem compartments of water, sediment, and food webs. An important finding is that large rivers transport considerable mass of aqueous and sediment-bound mercury, with concentrations increasing substantially in spring as tributary rivers erode and deliver material to downstream mainstem channels (e.g., Mackenzie, Yukon, Nelson, Churchill rivers). These sources of mercury provide opportunity for microbial transformation to the bioavailable and toxic form of methyl mercury in the environment (Chételat et al., 2014). Finally, research in the Mackenzie River Basin indicates that climate warming over the last 50 years appears to have mobilized mercury in this northerly flowing river system leading to striking increases of total mercury concentration in burbot (*Lota lota*), a food fish used by northern communities. Such mobilization of mercury will only increase as permafrost thaw slump frequency and magnitude increases.

Acid deposition through long-range atmospheric transport has also historically impacted high latitude freshwaters, primarily in Fennoscandia and northwest Russia (Moiseenko, 1994; Skjelkvåle et al., 2001). Acidification of freshwater systems in these regions led to the decrease of fish stocks, particularly in Norwegian lakes where Arctic char, brown trout, roach (*Rutilus rutilus*), and perch (*Perca fluviatilis*) were lost (Tammi et al., 2003). Legislation put in place to reduce sulfate emissions has led to large reductions in sulfate deposition in the region since the 1980s, and this was followed by the onset of recovery of water chemistry (Skjelkvåle et al., 2001). In parts of the southern Arctic such as Sweden, declines in sulfate deposition appear to increase the binding of phosphorus in soils, thereby reducing transport to freshwaters. In a recent circumpolar assessment, Huser et al. (2020) concluded that this process enhances terrestrial primary production at the expense of aquatic producers in the near and Sub-Arctic.

Regionally derived pollutants

Internally produced sources of contaminants in the Arctic region originate largely from mineral extraction (e.g., base metal mining, placer mining, oil and gas development), legacy effects such as abandoned mines, and municipal wastewater discharge. These types

of developments can affect food security of Indigenous communities and cause long-term environmental degradation that may be difficult to mitigate given the remote location of this activity and the unknown interactions of these impacts with climate change (Tolvanen et al., 2018). The expected responses of riverine biota to extraction activity includes the bioaccumulation and biomagnification of contaminants leading to selection for taxa more tolerant of contaminants, as well as nutrient enrichment (Culp et al., 2012). For example, input of heavy metals from mining operations is known to have negative effects on stream communities, with fish species in the Arctic being particularly vulnerable to heavy metals and associated contaminants in mine waste (Lemly, 1994). Placer mining for gold and other precious metals also impacts Arctic biota through substantial increases in sediment loading, with Reynolds et al. (1989) describing the avoidance by Arctic grayling of impacted stream habitats in Alaska, as well as reductions in carrying capacity for fish in summer. Explosives used in the mining process are also suspected to have increased nutrient concentrations in Sub-Arctic streams in northern Finland, resulting in changes in diatom and macroinvertebrate communities (Mykrä et al., 2021). Legacy effects of abandoned mercury mines in Alaska have been shown to raise contaminant concentration in Arctic grayling, Dolly Varden (*Salvelinus malma*) and northern pike, though the tissue mercury levels did not cause a health risk for humans (Gray et al., 2000). Finally, nutrient enrichment from wastewater discharges occurs in the relatively few urban areas in the High Arctic region, as well as from discharge associated with industrial and mining operations (Gregor et al., 1998). Classic experiments by Peterson et al. (1985) have highlighted the vulnerability of Arctic streams to nutrient addition, emphasizing that nutrient increases that may arise from municipal wastewaters released to high latitude rivers can shift these systems from heterotrophy to autotrophy and increase the size of dominant insects.

Hydropower dams

Hydropower generation and capacity have been expanding across the Arctic and Sub-Arctic including in Alaska, Canada, and much of Fennoscandia since 1980 (Cherry et al., 2017). This development has important environmental impacts that can cause striking regional change to the local landscape and riverine habitat. A key example of the environmental effects of hydropower impoundments on high latitude rivers is the dramatically altered discharge regime downstream, with reduced summer flows and enhanced winter flows in basins of Siberian Russia (Yang et al., 2004). Moreover, such modification of flow regimes and dynamic ice breakup in spring can reduce the periodic inundation of biologically important floodplain areas, such as perched wetlands of the Mackenzie River Basin, far downstream from impoundments (Peters et al., 2021). Further information on the importance of defining the required environmental flows to sustain the aquatic ecosystem in permafrost regions is provided in Peters et al. (2021). Hydropower regulation also modifies the water quality regime as materials transport is shifted from the spring flood pulse to winter with potential consequences to the riverine food web (Siergieiev et al., 2014).

The biological effects of hydropower include impacts at multiple trophic levels. A global synthesis of dam impacts on river macroinvertebrates found declines in taxonomic richness in relation to dams, with the strongest evidence of this pattern found in cold regions (Wang et al., 2020). Furthermore, Wang et al. (2020) noted that stoneflies, caddisflies, and true bugs were most affected by the presence of dams. Other studies have found that fish growth is negatively affected by hydropower reservoirs because of lowered ecosystem productivity (Milbrink et al., 2011). Habitat for juvenile salmon is often degraded or eliminated as observed for rivers in Finland, and restoration efforts to restore stream substrate quality as well as the installation of fish ladders are applied to increase fish stocks (Erkinaro et al., 2011). As hydropower development increases at high latitudes, it will be necessary to further examine the potential impacts on the ecological function of high latitude rivers.

Conclusion/synthesis

High latitude rivers present extremely harsh environments to aquatic species. The cold temperatures that occur much of the year limit dissolved nutrient concentrations required by basal producers and restrict biological production of river food webs. Moreover, these rivers are ice-covered for up to 8 months with many smaller, headwater streams freezing to the bed. Atmospheric reaeration of oxygen is also reduced during winter ice cover (Peters et al., 2021). Much of the landscape is underlain by permafrost, which is a major driver of river flow and greatly limits groundwater formation (Peters et al., 2021) and rates of mineralization of key elements (e.g., phosphorus). Environmental harshness is exacerbated in spring when river ice breakup often causes a major annual disturbance that resets many ecosystem processes by resorting the substrate and causing bank erosion that reintroduces deposited materials including key nutrients required for basal metabolism (Prowse and Culp, 2003). Following the spring freshet, biological production can increase quickly as temperatures rise reaching a peak in late summer prior to fall freeze-up. This harsh abiotic template of high latitude rivers restricts basal production by algae and microbes and limits biological diversity at all trophic levels, with many fish and other aquatic organisms being cold adapted (Lento et al., 2019). The harshness of the physical-chemical environment tends to increase with latitude (Culp et al., 2019), a gradient that mirrors the environmental regime observed for glacial rivers where production and diversity are at a minimum near the glacier terminus (Milner et al., 2001). Due to the remoteness and seasonal extremes of high latitude rivers across the circumpolar Arctic, our knowledge of these systems is poor relative to rivers of other geographical regions (e.g., temperate ecosystems).

The accelerated warming of Arctic landscapes will cause substantial change to high latitude river ecosystems. Because temperature is a primary driver of biodiversity in the Arctic freshwaters (Lento et al., 2020), climate-related warming will lead to modification of biotic composition of all trophic levels as cold adapted stenothermic species are replaced by southern eurythermic species that extend their range northward (Culp et al., 2019). Thus, while an overall increase in future biodiversity is expected, there will be an irreversible loss of unique Arctic biodiversity as 'climate change winners' replace 'climate change losers' and changes in

ecosystem functioning (Heino et al., 2020). Finally, permafrost thaw produced by climate change will mobilize various nutrients (e.g., DOC, phosphorus, nitrogen) that can alleviate nutrient limitation in some river systems (e.g., regions of low relief topography). However, in regions with steep valley slopes, thaw slumps and the downslope movement of substantial sediment input will degrade river habitat.

High latitude rivers are under further threat from increased human development, facilitated by climate shifts, and this increase in development may contribute regionally derived pollutants (Fig. 3). These remote environments also receive contaminants from distant sources through the processes of global distillation of persistent organic pollutants (POPs) transported from warmer regions, and the cumulative effects of pollutants and climate warming are likely to cause substantial environmental stress that will be difficult to forecast. A common plea from assessments of Arctic freshwaters is that there is an urgent need for improved coordination and standardization of the monitoring of physical-chemical and biological components of these ecosystems (Heino et al., 2020; Culp et al., 2021b). Improved monitoring approaches also need to fully engage Indigenous Peoples of the region to integrate their knowledge and perspectives of climate-induced change, thereby developing more rigorous assessments. With greater effort and focus on monitoring approaches and circumpolar Arctic cooperation via institutions such as the Arctic Council (https://arctic-council.org), our baseline knowledge of these understudied ecosystems will improve substantially. The result of these actions will be the increased ability to model the future state of these systems, which will improve planning, the conservation of biodiversity, and the associated ecosystem services provided by high latitude rivers.

Knowledge gaps

- Knowledge of the energy flow of high latitude food webs is in a nascent form. This gap requires determination of the relative importance of carbon supplied to consumers by algae and aquatic plants compared to that of microbial decomposition.
- Climate warming is predicted to increase the biodiversity and productivity of high latitude rivers. Will such increases lead to a greater or lesser importance of top-down predation versus bottom-up stimulation of basal food resources as drivers of food web structure and function?
- Improved models are required to predict the rate of northward expansion of southern species into high latitude rivers, the potential extirpation of cold adapted species related to this range expansion, and the effects these changes in biodiversity will have on ecosystem services on which Indigenous Peoples of the Arctic rely. These models must consider the extent to which spatial discontinuities (e.g., Arctic islands) will hinder the northward range expansion of taxa.
- Permafrost thaw will continue to accelerate as climate warming progresses, thereby releasing nutrients, sediments, and contaminants. The relative importance of these environmental stressors is poorly known, requiring investigation to better understand and predict landscapes where effects of each stressor will predominate (e.g., steep versus low gradient topography, role of ground ice composition).
- As permafrost thaw progresses, what will be the effect of the release of old carbon from ancient soils on decomposition pathways and ecosystem productivity?
- Future contaminant loading to high latitude rivers will increase through long-range transport and regional release of pollutants. What specific predictions can be made related to the cumulative effects of such pollutants and climate change? There is a need to produce improved models that can forecast change to riverine community structure and function.
- For the various biological, physical, and chemical impacts associated with climate change and human development, it will be important to determine critical ecological thresholds where abrupt change in ecosystem structure and function may occur.
- Monitoring at high latitudes must become routine to establish time series observations and allow for the detection of temporal changes in biodiversity and habitat conditions, as well as address questions related to range expansion of taxa and shifts in the boundaries of Arctic regions. Improved monitoring approaches can provide important baseline information for modelling and should fully engage Indigenous Peoples of the region.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Alpine zone The zone above the treeline.
Braided channel A network of river channels separated temporary by islands of unconsolidated sediment (called braid bars), usually occurs on glacial floodplains.
Cryosphere Regions of the Earth's surface where water is in solid form (i.e., snow or ice).
Discharge The volume of water moving past a given point in the river per unit time (usually liters per second).
Meltwater Water (specifically runoff) that has come from melting snow or ice.
Permafrost Any ground that remains completely frozen for at least 2 years consecutively.
Water source A distinct source of water that generates river flow (e.g., groundwater, snow or ice).

Introduction

Alpine streams and rivers are found on all the Earth's continents. The alpine zone is located above the treeline in mountain ranges but below the permanent snow-line (Körner et al., 2003). The term "alpine stream" is often applied where glacier-fed streams extend below treeline, as occurs in many large mountain ranges. The geomorphology of alpine regions is a product of glacier activity over millennia. Significant ice movement during Quaternary glaciations has created a landscape characterized by U-shaped valleys, hanging valleys and over deepening of valley floors. These landscapes host poorly developed soils interspersed with bare rock, where vegetation typically forms herbaceous meadows with a high diversity of endemic plants and shrubs. However, at higher altitudes, vegetation is sparse, valley slopes are steep and snowpacks and glaciers become a major feature of the alpine zone.

Alpine running waters are diverse, ranging from turbid torrents fed by glacier melt to small groundwater-fed springs (Fig. 1A). There are four key hydrological stores in the alpine zone—permafrost, glacier ice, snow and groundwater—individually and jointly water sourced from these stores produces characteristic discharge regimes and a distinctive suite of physicochemical habitat properties (Brown et al., 2003). Spatiotemporal variability in the magnitude, timing and duration of meltwater production and groundwater recharge leads to mixing of these water sources in differing proportions, producing gradients of habitat harshness

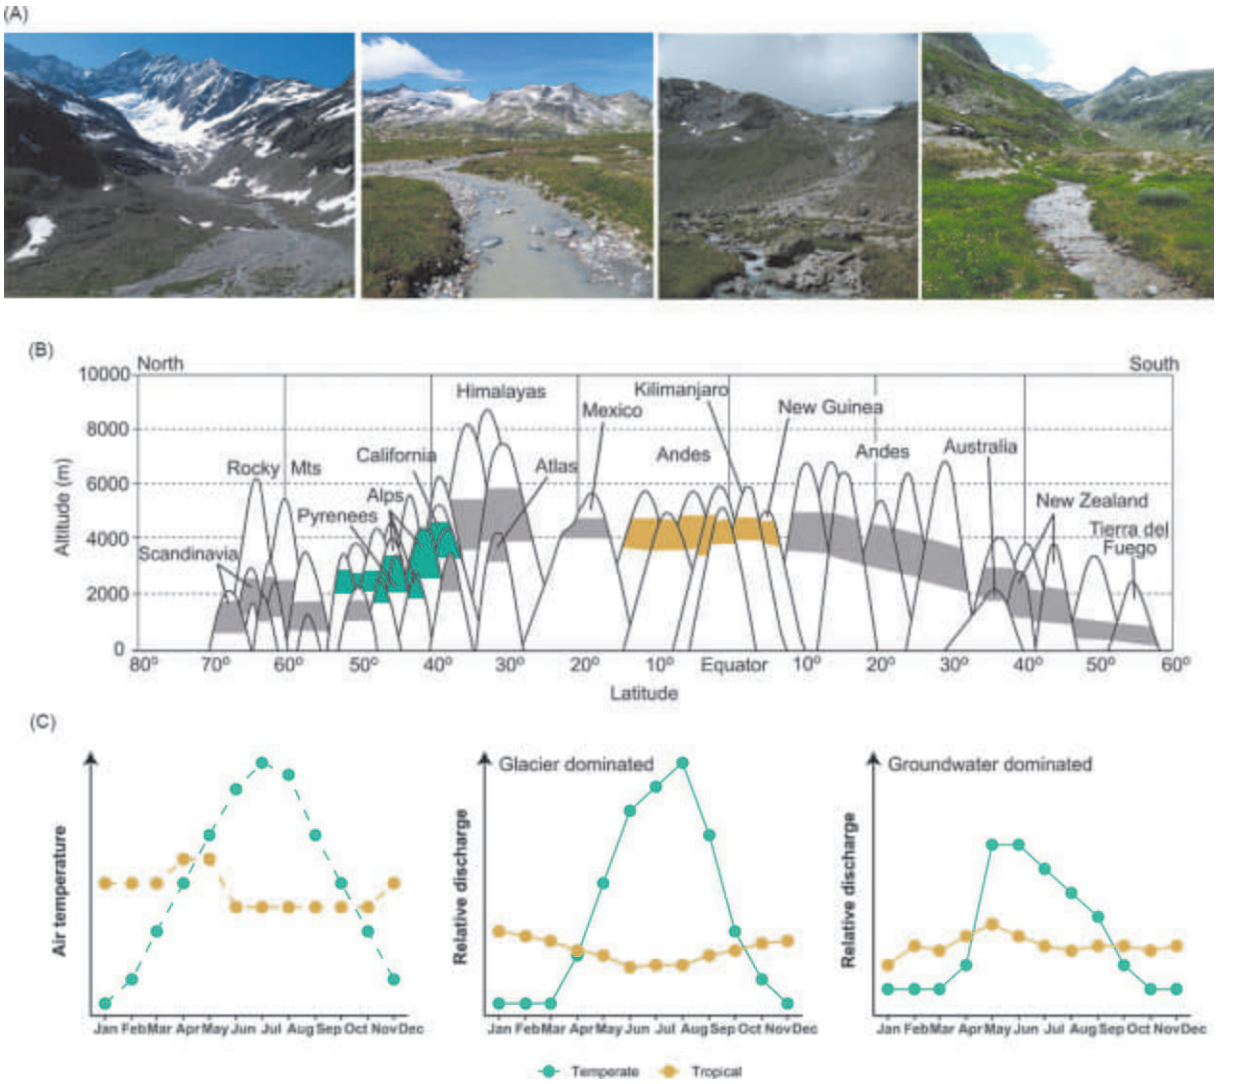

Fig. 1 (A) Images of glacier-fed streams (left and left-center; Austrian Alps), snowmelt fed (right-center; Austrian Alps) and a groundwater dominated stream (right; Austrian Alps). (B) The distribution of the alpine zone (gray shading) across a global latitudinal gradient. (C) Schematic representation of seasonal air temperature and discharge for a temperate (e.g., Alps) and tropical (e.g., Equatorial Andes) alpine region. Hydrographs are displayed for glacier-fed and groundwater dominated streams. (B) Modified from Körner C, Paulsen J, and Pelaez-Riedl S (2003) A bioclimatic characterisation of Europe's alpine areas. In: Alpine Biodiversity in Europe. Berlin: Springer, pp. 13–28.

(e.g., variations in thermal maxima, turbidity, primarily productivity and river bed and channel stability). This gradient can, at the river basin or regional scale, be conceptualized as a harsh (pure glacial meltwater)—benign (pure groundwater) gradient with mixtures of different stores creating intermediate harshness (Khamis et al., 2016). Permafrost can complicate this harsh-benign gradient though, with meltwater outlet streams that are often small and stable hydromorphologically, but with very low water temperature (Brighenti et al., 2021). The strong gradients in habitat properties create high species turnover between sites (beta diversity), with increasing specialization of aquatic fauna in meltwater-dominated streams and isolated spring brooks.

In many regions, particularly (semi)-arid, the generation of river flow in alpine regions is important for ecosystem functions and services downstream, such as hydroelectric power, irrigation and water supply (Milner et al., 2017). Given the high climate sensitivity of alpine regions and the cryospheric processes that dictate streamflow, understanding the structure and function of alpine river systems is particularly important as anthropogenic pressures intensify and the cryosphere shrinks.

This chapter provides an overview of current understanding of alpine stream and river ecosystems. The global distribution of alpine rivers and streams is discussed initially. The different stream types and associated habitats and the concept of dynamic water source contributions (snow, ice, groundwater) are introduced, followed by current knowledge of biodiversity patterns and ecological processes. A discussion of anthropogenic threats and future predictions for alpine rivers concludes the chapter. Examples are drawn from a broad range of biogeographical zones, from temperate to tropical/equatorial regions.

Alpine lotic ecosystems: Links between climate and habitat

Distribution

The alpine zone has a broad geographic coverage—from temperate to tropical mountains (Fig. 1B). In undisturbed areas, the treeline approximates the 10 °C July (Northern Hemisphere) or January (Southern Hemisphere) mean temperature isotherm (Remmert, 1980). Hence, the elevation of alpine streams can vary markedly according to location, from near sea level at high latitudes to >4000 m a.s.l (meters above sea level) near the tropics (see Fig. 1B).

Hydroclimatological conditions

There is strong seasonality in temperate alpine zones with predictable shifts in hydroclimatology. During winter, air temperature is low with precipitation in the solid phase and accumulation of snow and ice is apparent (Fig. 1C). When temperature and solar radiation increase during late spring and summer, snowpack and glaciers melt and feed stream flow and recharge groundwater (Milner et al., 2009). A characteristic annual hydrograph for temperate alpine streams, with a summer peak and winter minimum is evident (Fig. 1C). For example, the main glacier-fed channel of the Val Roseg in Switzerland (46°N, ~2100 m a.s.l) is perennial, but a difference in discharge of two orders of magnitude exists between the winter (<0.5 $m^3 s^{-1}$) and summer peak (>10 $m^3 s^{-1}$). Similar patterns have been recorded for the Upper Rhone catchment (46°N, ~2000 m a.s.l) with <0.2 $m^3 s^{-1}$ recorded during winter and >10 $m^3 s^{-1}$ in summer (Uehlinger et al., 2003). While the difference between winter and summer is not as extreme for groundwater streams, shallow alpine aquifers are recharged by snowmelt and hence peak flow is observed in late spring/early summer. Catchment storage is sufficient for most springs to maintain baseflow during winter months when precipitation falls primarily as snow (Mackay et al., 2020).

Tropical alpine regions experience less hydroclimatological variability over the year due to relatively constant solar input, but daily variability in meteorological conditions (particularly air temperature) can be extreme. Precipitation can occur year-round but with distinct wet and dry seasons depending on latitude (Buytaert et al., 2011). Local elevation and topography are important; for example, there are strong gradients across the equatorial Andes from less than 500 mm $year^{-1}$ on the dry eastern slopes to more than 3000 mm $year^{-1}$ on western slopes (Buytaert et al., 2011). In contrast, in the East African Rift Valley precipitation is related inversely with elevation. Accumulation usually exceeds melt during the wetter seasons with differences between dry and wet season flows, but these are less pronounced than seasonal variability for temperate regions (Jacobsen, 2009). While discharge records for equatorial and tropical alpine streams are limited, a few monitoring sites have captured marked annual flow variability. For example, differences between dry and wet season flow were apparent for the glacier-fed River Mubuku, Uganda (0.2°N), 0.002 vs. 0.017 $m^3 s^{-1}$, and runoff from the Zongo Glacier, Bolivia (16°S), 0.07 vs. 0.21 $m^3 s^{-1}$ (Taylor et al., 2009; Wagnon et al., 1999).

Climate-habitat-ecology linkages

Regardless of elevation or latitude, alpine rivers exhibit some general features that differentiate them from lower altitude streams. Within the river channel, there is typically a lack of woody debris and allochthonous matter due to limited riparian vegetation and low in-channel retention. Alpine streams typically accumulate fewer annual degree days, have a shorter growing season and contain limited nutrients, all of which result in low relative stream productivity (Ward, 1994). There is also a strong coupling between meteorological, cryospheric, hydrological and ecological conditions in alpine regions. These links can be conceptualized as a deterministic process chain with climate dictating the contribution of the major hydrological stores to runoff (Hannah et al., 2007). These differing water sources impart a distinct signal in the river habitat (sediment, habitat stability, flow variability) and thus structure the species assemblages and ecological functioning (Fig. 2). However, it is important to consider regional and local conditions that potentially modify the relationships between different stages in the process chain. These can be either natural (e.g., geology, river basin aspect, topography and biogeography) or anthropogenic (e.g., land use change, flow storage alteration, livestock grazing, and species introductions). For example, in the Southern Alps in New Zealand, storms are often so intense that the summer part of the hydrograph for many alpine glacier-fed rivers is totally dominated by rainfall events (Anderson et al., 2016).

Changing flow regimes

Anthropogenic warming is generally strongest at high altitudes and latitudes. Alpine hydrology is changing in response to this warming, and model predictions suggest major changes in flow magnitude, timing of peak and water source contributions. However, the amplitude of this seasonal cycle is currently increasing under climate change, with higher summer air temperature increasing meltwater production and stream discharge. Over longer timescales (decades) as negative mass balance dominates (summer melting of snow and ice exceeds winter accumulation), the volume of runoff generated by glaciers and permanent snowpacks will decline and consequently the magnitude of the summer discharge peak will diminish and shift to earlier in the season (Hock et al., 2019; see Fig. 3). Rainfall patterns are likely to become less predictable seasonally, and the frequency and magnitude of extreme events are also expected to increase. These patterns are already becoming apparent for many regions as a reduction in cryospheric water stores in alpine basins will potentially lead to low flow periods during late summer and a less predictable flow regime that is influenced more by episodic precipitation as buffering by the cryosphere (meltwater production) is reduced (Milner et al., 2017).

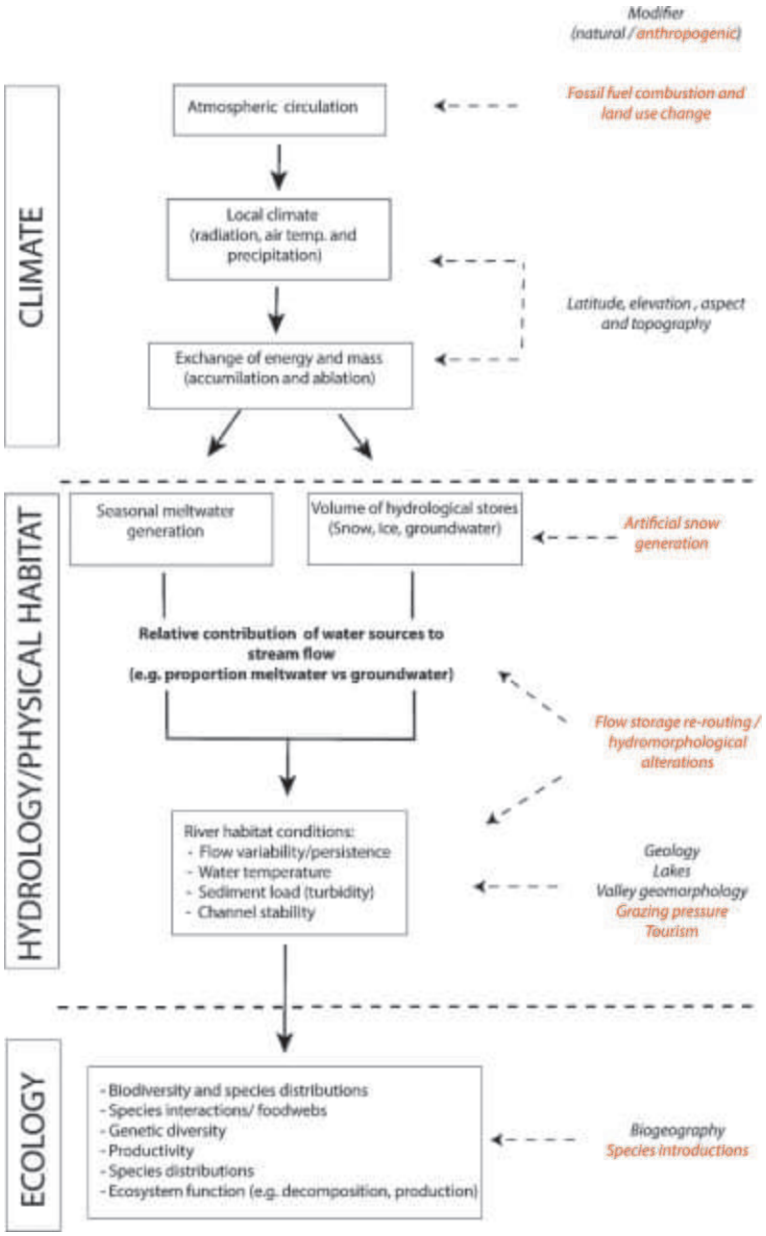

Fig. 2 Flow diagram depicting the conceptual linkages in the climate-hydrology-ecology process chain. Potential modifiers to the links are highlighted in italics (black for natural and red for anthropogenic).

Alpine stream types

Traditional approach to alpine stream classification

In alpine regions, water source is a major control on stream flow dynamics, habitat properties and biotic communities. Early approaches to group or classify alpine stream types were based on perceived water source, with three general stream biotypes: *kryal* or glacier-fed, *krenal* or groundwater fed and *rhithral* or seasonal snowmelt fed (Fig. 1A; Ward, 1994). There are distinct differences in physicochemical habitat properties associated with *kryal*, *krenal* and *rhithral* streams, particularly regarding water thermal regimes, discharge, suspended sediment dynamics, solute concentrations and bed/channel stability (Table 1). While there is increasing evidence that permafrost is an important water source in alpine regions (Brighenti et al., 2021), more research is needed to constrain conceptual understanding of associated habitat conditions. In addition, most permafrost melt provides recharge for local groundwater.

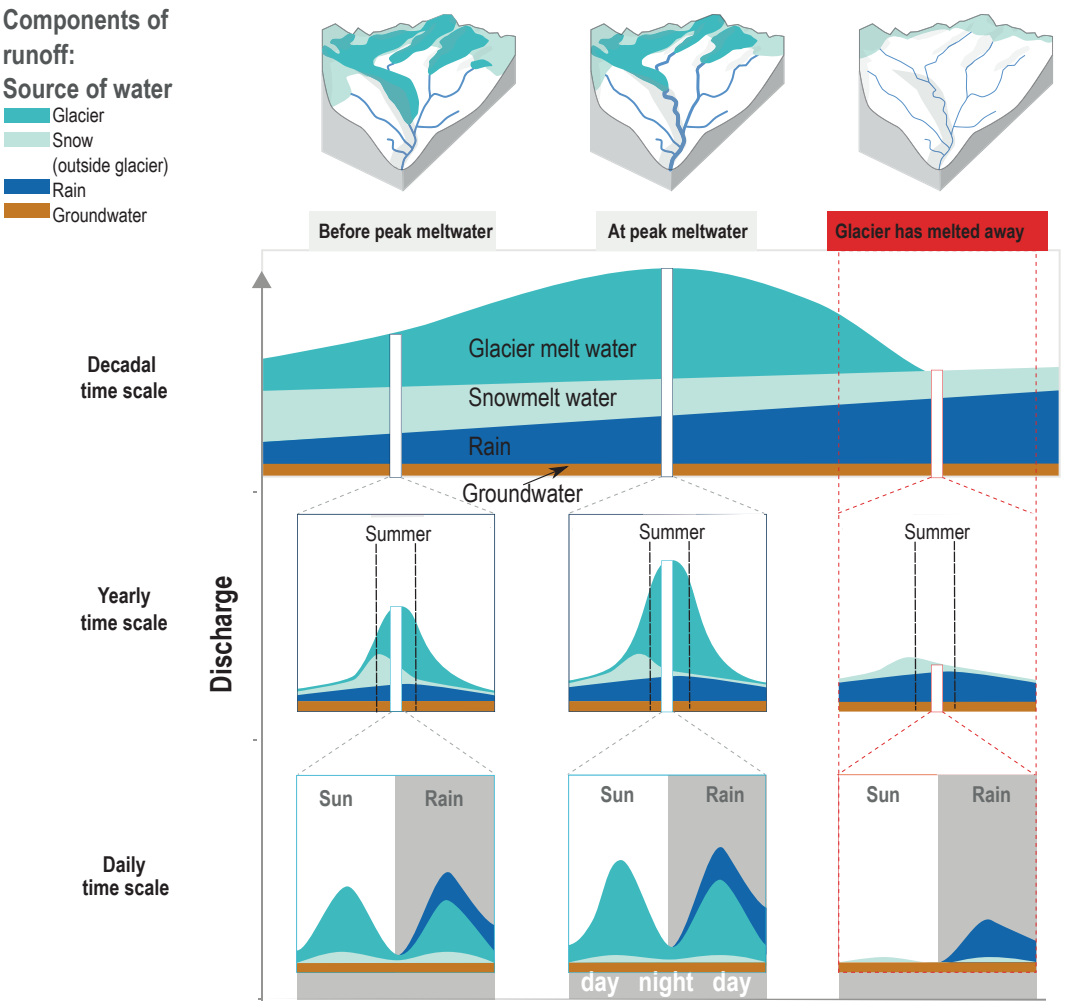

Fig. 3 Conceptual representation of the predicted changes in discharge and water source contributions across a gradient of cryosphere shrinkage. Note that the summer pattern for temperate alpine zones reflects the year-round pattern for aseasonal equatorial alpine regions, both at the annual and daily time scales. Modified from Hock R, Rasul G, Adler C, et al. (2019) High Mountain Areas. In Pörtner HO, Roberts DC, Masson-Delmotte V, et al. (eds.). *IPCC Special Report on the Ocean and Cryosphere in a Changing Climate*. Geneva, Switzerland: IPCC.

Table 1 Physical and chemical properties of the three major stream types in alpine environments based on water source.

Variables	*Kryal (glacier fed)*	*Rhithral (snowmelt fed)*	*Krenal (groundwater fed)*
Discharge	Summer peak, diurnal variations sustained through melt season	Spring snowmelt causes peak flow. Also, peaks following rainfall events	Relatively constant but attenuated peaks following precipitation events
Channel stability	Frequently unstable, braided or wandering. Stability a function of distance from glacier and time since deglaciation	Typically more stable and less braided	Stable, single thread channels. With significant riparian vegetation
Water temperature	Diurnal variability lower than rhithral; <2 °C close to glacier margins, increases with reducing glacier influence	High in summer, range from 0 °C to 12 °C. Large diurnal variation	Related to air temperature at source, typically low diurnal and seasonal variation
Suspended sediment	High suspended sediment concentrations during summer melt season with peaks over 500 mg L^{-1}	May be elevated during high flows, but much lower than kryal	Low suspended sediment concentration
Hydro-chemistry	Conductivity usually low but sulfates can be elevated due to erosion processes	Ionic enrichment related to snowpack concentrations of solutes. Intermediate between kryal and krenal	Generally high conductivity. Chemistry related to the geology of groundwater store but usually enriched in carbonates and silicates
Macro-nutrients	Phosphorus concentration can be high and dissolved organic carbon (DOC) concentration low but highly labile	Generally low nutrient concentrations but nitrate can be high during initial snow melt	Low nutrient concentration, particularly phosphorus and DOC

Adapted from Brown LE, Hannah DM and Milner AM (2003) Alpine stream habitat classification: An alternative approach incorporating the role of dynamic water source contributions. *Arctic, Antarctic, and Alpine Research* 35: 313–322.

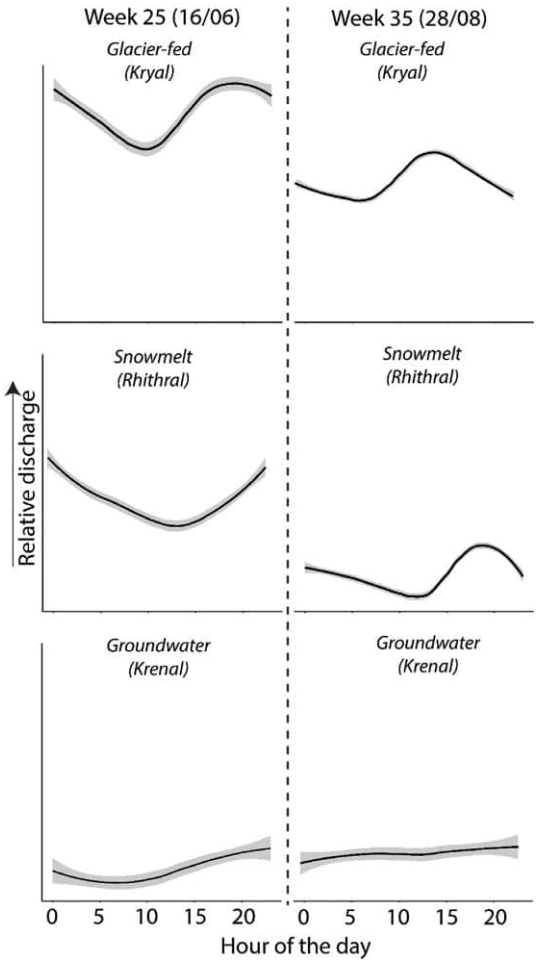

Fig. 4 Locally weighted smoothing (LOESS) of daily discharge recorded for the Taillon glacier-fed stream (French Pyrénées, 42°N) a snowmelt dominated stream Vignemale (French Pyrénées, 42°N) and groundwater spring (Austrian Alps, 47°N). Note that the curve is based on the daily pattern over a week (gray band = 95% CI) during early melt season (week 25) when snow cover is extensive and during late summer (week 35) when extensive glacier ablation is apparent.

Kryal streams can be considered more environmentally "harsh" in terms of habitat properties when compared to *krenal* and *rhithral* streams, with lower water temperature, more unstable riverbeds and channels, less riparian vegetation, and higher suspended sediment loads (Table 1). The daily variation in flow is particularly pronounced for *kryal* streams and is always greater than observed in stable *krenal* streams but can be comparable to *rhithral* streams in summer before seasonal snowpacks have melted (Fig. 4). *Krenal* streams can be considered the most stable stream type in terms of habitat characteristics but this can vary with aquifer volume and recharge dynamics. *Rhithral* streams are generally intermediate between *krenal* and *kryal* (Table 1).

For equatorial mountains, the discharge regime of *kryal* streams varies on a diurnal basis due to diurnal melting and nocturnal freezing. Seasonal variability in the amplitude of diel (24 h) cycles is less pronounced than for temperate streams and is a function of air temperature/solar radiation input (control on meltwater generation), precipitation (increased albedo due to snowfall) and wind (sublimation). For *krenal* streams groundwater recharge is not strongly seasonal with inter-annual variability more pronounced than annual changes in flow. Hence, variability is more a function of longer-term changes in climate, such as El Nino cycles (Jacobsen, 2009). Equatorial *rhithral* streams have a more stochastic flow regime with no seasonal snow accumulation apparent and rain showers occurring throughout the year.

Novel stream classification approaches

The stream classification approach outlined above provides a basis for understanding alpine stream habitats, but it is static temporally in that the seasonally dynamic nature of water source contributions to flow are largely ignored, and some water sources such as permafrost or cold rocky landforms (CRL; Brighenti et al., 2021) are not explicitly incorporated. There have been some efforts to create sub-groupings within these broad classifications, e.g., groupings based on the presence of lakes or macroinvertebrate assemblage composition (e.g., *metakryal* vs. *hypokryal* based on chironomid community composition). Other approaches have

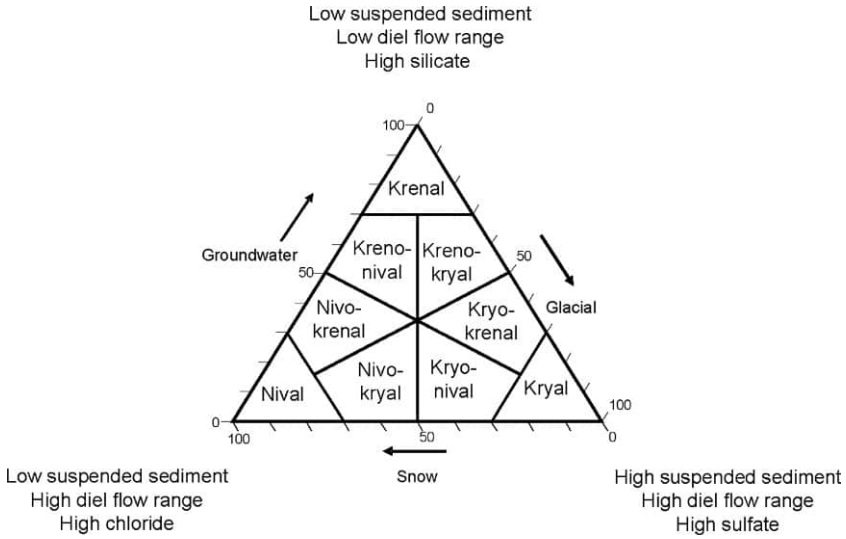

Fig. 5 Alpine stream classification system based on water source contributions. Key physicochemical characteristics of the water source end members (snow/glacier/groundwater) are highlighted in gray boxes. modified from Brown LE, Hannah DM and Milner AM (2003) Alpine stream habitat classification: An alternative approach incorporating the role of dynamic water source contributions. *Arctic, Antarctic, and Alpine Research* 35: 313–322.

considered the importance of quantifying the influence of glacial runoff on a given river reach based on estimation of glacier cover in the upstream catchment (aerial imaging; Jacobsen et al., 2012) or through the calculation of indices based on habitat conditions (e.g., suspended sediment, water temperature and river bed stability) or periodicity in diel flow variability (Cauvy-Fraunié et al., 2013).

An alternative classification system was proposed (ARISE: a classification tool for Alpine RIver and Stream Ecosystems) based on the premise that streams are not fed by a single water source but over time can have a combination of sources. Hence, alpine streams can be grouped based on quantification of these relative water source contributions to streamflow at a given point in space and time (Brown et al., 2009b). Building on the three groupings outlined above (*kryal*, *krenal*, *rhithral*), streams can be placed into nine categories based on the relative contribution of glacier melt, groundwater and snowmelt (Fig. 5). These categories relate water source contributions with physicochemical habitat variables such as stream discharge, suspended sediment concentration and hydrochemistry. As this approach involves quantitative measurement of water source contributions through use of mixing models there is potential for accurate comparisons between stream reaches across different river basins, regions and climate zones. ARISE does not, however, consider flow generated from rainfall, a feature that becomes more of an issue in basins with less snow and ice cover (i.e., climate change and glacier retreat). Furthermore, permafrost contributions are still absent from this model but rivers fed predominantly from this source are likely to exhibit characteristics of *kryal-krenal* streams (Brown et al., 2009b).

Intermittent alpine streams

There are other modifiers to the expected patterns based on water source contribution which need to be considered. Lakes, have a significant influence on the physicochemical properties of alpine streams. For example, in glacier-fed streams, lakes increase channel stability, thereby buffering flow variability and reducing suspended sediment load (Milner et al., 2001). It is also important to consider the interaction between water source and geomorphic/landscape properties (Weekes et al., 2012). For example, valley scale depositional processes can influence streamflow regimes and water temperature dynamics in ways that depart from expectations based on water source (Weekes et al., 2015). Flow intermittency occurs naturally in alpine environments and while it is a feature of significant ecological importance, it has only been relativity recently that the occurrence of natural intermittent rivers and ephemeral streams (IRES) have been assessed systematically (Paillex et al., 2020). The seasonal variability in climate and water source availability are important drivers of seasonal intermittency, with the landscape heterogeneity and limited storage potential/shallow aquifers contributing to the relatively high proportion of IRES in temperate alpine regions (see Robinson et al., 2016). Conceptually, the dominant water source of streamflow can provide an indication of intermittency likelihood (Fig. 6). Despite this, it remains difficult to generalize patterns of intermittency across basins with contrasting climate, geology and geomorphology. The occurrence of IRES in tropical/equatorial alpine regions remain largely unknown but it is likely that the frequency will increase with climate change.

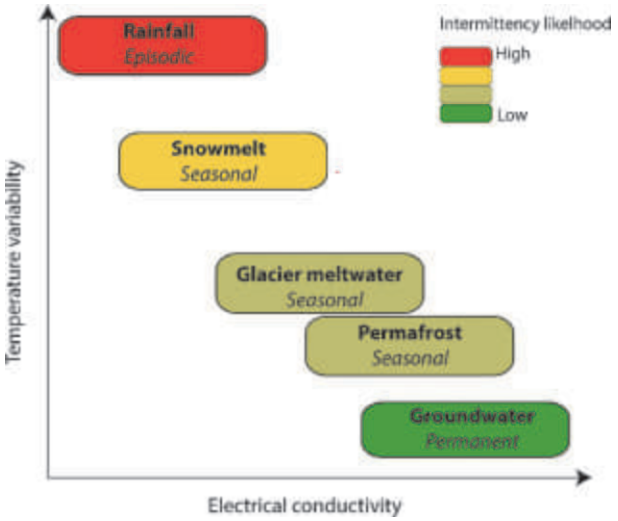

Fig. 6 Conceptual representation of the relationship between water source and intermittency for temperate alpine streams. Electrical conductivity and water thermal variability are the physicochemical habitat variables that display the greatest variability over the flow permanence gradient. Adapted from Paillex A, Siebers AR, Ebi C, et al. (2020) High stream intermittency in an alpine fluvial network: Val Roseg, Switzerland. *Limnology and Oceanography* 65: 557–568.

Ecological structure of alpine streams

Alpine streams support a unique flora and fauna with high levels of endemism (Brown et al., 2009a) due to isolation and marked changes in environmental gradients over short spatial scales. Despite having relatively low local diversity (alpha diversity), alpine streams contribute significantly to regional scale biodiversity (gamma diversity). Equatorial and subtropical—tropical regions potentially have high levels of endemism and rarity, e.g., in Japan over 50% of the freshwater taxa are endemic, many in alpine streams (Yoshimura et al., 2005). However, taxonomic limitations in many other countries prevent a full understanding of the true diversity.

Across different biotic groups and trophic levels, some general patterns of biodiversity are apparent across alpine stream types. Alpha diversity is generally lowest for high meltwater sites (particularly those close to glaciers), and generally peaks at intermediate to low meltwater contribution or glacier influence. This pattern is associated with decreasing environmental harshness and mass effects (more upstream sources of colonists). Community structure in groundwater sites is more varied and is driven by biotic interactions and flow permanence (Brown et al., 2007). Despite low alpha diversity, high meltwater sites support a unique, specialized flora and fauna and thus make a significant contribution to beta diversity (turnover between sites). Historically, macroinvertebrate communities have been the focus of study in alpine regions, however, surveys of algal and microbial diversity have increased in recent years (Fell et al., 2017). In the following sections, we consider community structure, diversity and distribution of major taxonomic groups across the alpine stream types identified above.

Microbes and fungi

Alpine streams are important repositories for microbial diversity with communities associated with either attached biofilms (epilithic) or the water column. In alpine glacier-fed streams, bacterial diversity generally increases with distance from the glacier margin, with Proteobacteria, Cyanobacteria, Bacteroidetes and Actinobacteria dominating the benthic communities (Freimann et al., 2013; Ren et al., 2017a). The stream water column has greater species richness than attached biofilm communities, likely due to mass effects and the influx of cells from a variety of sources (e.g., cryoconite holes, glacial ice, groundwater and the adjacent terrestrial environment). However, only a subset of taxa recorded in the water column are able to successfully colonize benthic biofilms principally due to short water residence time and transient environmental conditions (Wilhelm et al., 2013). Nevertheless, bacteria within the phyla Firmicutes and Tenericutes are typically only found in glacier-fed channels in alpine regions. Furthermore, rare taxa are particularly important components of biofilms in glacier-fed streams (Wilhelm et al., 2014), with significant turnover of community composition in space (i.e., longitudinal) and time (i.e., optimal environmental conditions in spring or summer).

Average microbial biomass, carbon production and diversity are higher in groundwater-fed tributaries compared with glacier-fed streams (Battin et al., 2004), with bacterial diversity correlated positively with water temperature. Taxonomic diversity in snowmelt channels is comparable to groundwater channels, with bacterial biomass and abundance being lower than groundwater but higher than glacier-fed channels (Hotaling et al., 2019). Icy seeps or outflows from rock glaciers also represent important habitats for microbial communities, particularly cold water specialists, and they may represent refugia as glaciers and permanent snow packs recede and disappear (Hotaling et al., 2019). There is limited data regarding the microbial communities associated with tropical or equatorial alpine rivers. However, studies from the glacier ice of Mt. Kilimanjaro have identified rich bacterial assemblages with a particularly high diversity of endemic taxa, suggesting the river networks may also have unique microbial communities (Vimercati et al., 2019).

Aquatic hyphomycetes dominate alpine-river fungal communities often as a component of complex microbial biofilms. They represent an important functional component of alpine riverine communities, acting as a nutrient source for higher trophic levels and as the principal microbial decomposers of allochthonous organic-matter inputs (Gessner and Robinson, 2003). Some specialists show adaptation to cold water temperature and high suspended-sediment concentrations, with biomass, taxonomic richness and diversity in glacier-fed rivers comparable to temperate rivers (Gessner and Robinson, 2003). Recent large-scale studies have linked OM decomposition rates to specific fungal taxa, saprotrophic groups (those that obtain nutrients from the decomposition of detritus) and functional genes (Fell et al., 2021). Over 1000 unique fungal Operational Taxonomic Units (OTUs) were identified from a study spanning mountainous regions of Alaska, Austria, Ecuador, France, New Zealand and Norway (Fell et al., 2021). Reductions in catchment glacier cover were associated with increased fungal (ITS) abundance across all mountain river sites. A total of 294 fungal OTUs was found exclusively in rivers with >52% catchment glacier cover, highlighting the potential vulnerability of fungal diversity to ice loss. Decomposition rates of organic matter increase in rivers as glacier cover decreases (Fell et al., 2021), reflecting increases in temperature, channel stability and reduced sediment transport. Responses of fungi and other biofilm species to glacier retreat are also thought to be mediated by local factors including nutrient supply and hydrodynamics (Battin et al., 2004; Wilhelm et al., 2013).

Algae

As alpine streams are predominantly located above treeline, their allochthonous organic inputs are typically low. Hence, primary producers (autotrophs) represent the main energy source, particularly in glacier-fed stream ecosystems. Yet, despite alpine springs having been identified as hotspots of benthic algal biodiversity, there is a relative paucity of knowledge regarding algal communities compared to groups such as invertebrates (Fell et al., 2017).

Strong seasonal variations in stream discharge, channel stability, turbidity, water temperature and hydrochemistry are recognized as the key drivers of fluctuations in benthic algae biomass. Biomass typically peaks during spring when nutrient input from snowpacks and water clarity is highest. This period represents a "window of opportunity" for primary producers in the otherwise highly turbid and unstable glacier channels (see Milner et al., 2001). For example, the golden alga, *Hydrurus foetidus*, can dominant in glacier-fed rivers in early summer (Rott et al., 2006). Rapid growth at this time of low water temperature (<1 °C) indicates *H. foetidus* growth is not temperature limited, and that it resists increased river flows by forming a gelatinous cover on the substrate. Other taxa with differing growth strategies are also found, such as the patch-forming cyanobacterium *Phormidium autumnale* and less frequently the tubular tissue-forming red alga *Lemanea fluviatilis* (Rott et al., 2006).

In alpine streams, benthic diatoms are often the most species rich component of the algal community, and they play a major role in primary production and energy transfer to higher trophic levels (e.g., major food source for macroinvertebrates; Clitherow et al., 2013). The diatom community of glacier-fed rivers across the Northern Hemisphere is dominated by *Hannaea arcus* and taxa from the genera *Achnanthidium*, *Fragilaria* and *Odontidium* (Cantonati et al., 2001). At the species level, diatoms show a range of responses to catchment glacier cover reductions; for example, *Eunotia trinacria*, found exclusively in European Alps rivers with ≥52% glacier cover, may be affected negatively by loss of glacier ice. In contrast, seven taxa found only at sites with no glacier cover, including *Gomphonema calcareum*, may benefit (Fell et al., 2018). However, new species are being recorded (for example *Odontidium* spp. in the Himalayas) as sampling efforts have increased for alpine streams in recent years (Jüttner et al., 2017). Species richness (alpha diversity) is generally highest at sites with low glacier/meltwater influence and community composition divergence is greatest. Cold adapted specialists that can thrive in oligotrophic conditions are well represented across a range of stream types. However, *Achnanthidium* spp. are found closest to the glacier margin as they can also tolerate stream bed instability. Conversely, taxa from stable channels with low glacier influence exhibit a greater range of growth strategies; for example, chain-formation (e.g., *Staurosirella pinnata*) and motility (e.g., *Nitzschia soratensis*) are common. A study from the Austrian Alps (Fell et al., 2018) found that there was a high proportion of Red List species (rare or threatened taxa) at groundwater or low glacier influenced sites and two taxa, *Fragilariforma constricta* and *Staurosira construens*, were exclusively found at sites with higher glacier influence (>28% glacier cover in the catchment).

Invertebrates

There has been significant interest in the longitudinal zonation of invertebrate assemblages downstream from glaciers. Studies from both temperate and tropical regions highlight consistent increases in species richness with increasing distance from the glacier margin (Crespo-Pérez et al., 2020; Kuhn et al., 2011; Milner et al., 2001). This pattern has been linked to increasing channel and bed stability, water temperature, groundwater input and basal resource retention. However, longitudinal patterns can be punctuated by tributary inflows with biotic diversity responses depending on water source of the input (e.g., a high groundwater tributary increases diversity while a high meltwater tributary may decrease diversity) or the presence of lakes. This change in habitat conditions (and associated community changes) can be conceptualized across the continuum of stream types in alpine environments from meltwater to groundwater dominated as a gradient of environmental harshness (Khamis et al., 2016; Fig. 7).

Relatively predictable downstream changes in community composition have been observed for macroinvertebrates of temperate streams in the Northern Hemisphere. Chironomids are generally the most abundant and diverse family in glacier-fed streams. Species of the sub-family Diamesinae are found closest to the glacier margin (i.e., *Diamesa* spp.) and can complete their lifecycle even when channels are unstable and maximum water temperature is <2 °C; due to minimal competition and predation these

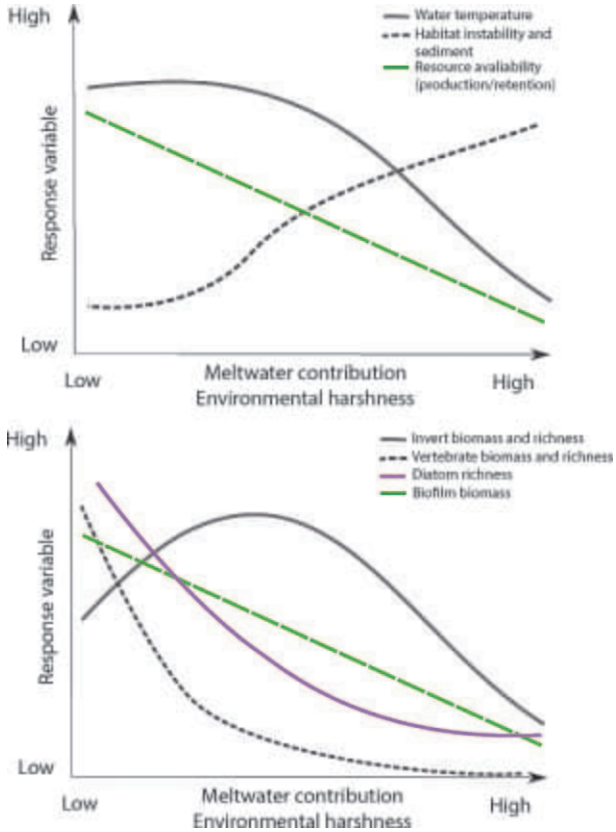

Fig. 7 Conceptual representation of alpine benthic habitat properties and biota responses along the meltwater (glacier influence) gradient. Curves are based on data from Khamis et al. (2016) and Fell et al. (2017).

species are often very abundant. Orthocladiinae can also tolerate low channel stability where water temperature reaches 4 °C, whereas Oligochaeta and other Diptera (e.g., Tipulidae and Empididae) can colonize more stable channels at these temperatures (Milner et al., 2001). Further from the glacier snout Ephemeroptera, Plecoptera and Trichoptera (EPT) taxa become increasingly abundant and diverse along with Simuliidae and other chironomids (e.g., Chironominae). In the Southern Alps (New Zealand), *Diamesa* spp. are absent due to biogeographical constraints, and here *Deleatidium* spp. (Ephemeroptera: Leptophlebiidae), are found near to glacier margins at low temperatures. (Fig. 8A; Cadbury et al., 2011). Similar longitudinal patterns are apparent in equatorial glacier-fed systems, with an increase in EPT taxa correlated to distance from the glacier, while a notable difference is the presence of Podonominae and absence of *Diamesa* spp. at sites closest to the glacier margin (Jacobsen et al., 2010). Thus, differences are largely attributed to biogeographical variability in the regional species pool (Fig. 8B). Although less is known about meiofauna communities, diversity patterns for copepods, tardigrades and rotifers broadly follow macroinvertebrates (e.g., increasing diversity at sites of decreased glacier influence; Eisendle-Flöckner et al., 2013).

Differences in habitat conditions between streams fed by different water sources is a key control structuring the associated macroinvertebrate assemblages. Generally, abundance and total taxonomic richness is higher (2–8 ×) in groundwater-fed streams. Alpine spring-fed systems are often associated with a unique fauna (Brown et al., 2009a). For example, in the Val Roseg, Switzerland, Heteroptera, Coleoptera, Gastropoda and Bivalvia were restricted to spring-fed streams. Similarly, of five endemic Pyrénéan species found in the Taillon-Gabiétous basin, French Pyrénées, four were strongly associated with groundwater streams (Brown et al., 2006). Sites with more stable physicochemical habitat variables (e.g., groundwater-fed streams) may not necessarily support the most stable communities though, perhaps because species abundance patterns are influenced more by changes in resource availability and biotic interactions. These studies suggest alpine groundwater springs and streams are important contributors to biodiversity. Furthermore, groundwater-fed streams may be potential sources of macroinvertebrates for the more physically disturbed meltwater-fed streams (Robinson et al., 2004). Groundwater streams can even act as refugia for specialized cold-water macroinvertebrates providing the thermal conditions are suitable (Muhlfeld et al., 2020). A comprehensive survey of streams in Glacier National Park (Montana, USA, 48.7°N) identified most of the regional species pool in non-glacial channels (110 of 113 species) suggesting few glacier obligate species (Muhlfeld et al., 2020). This highlights the need for increased sampling effort in alpine regions to better constrain species distributions and ultimately help guide targeted conservation efforts.

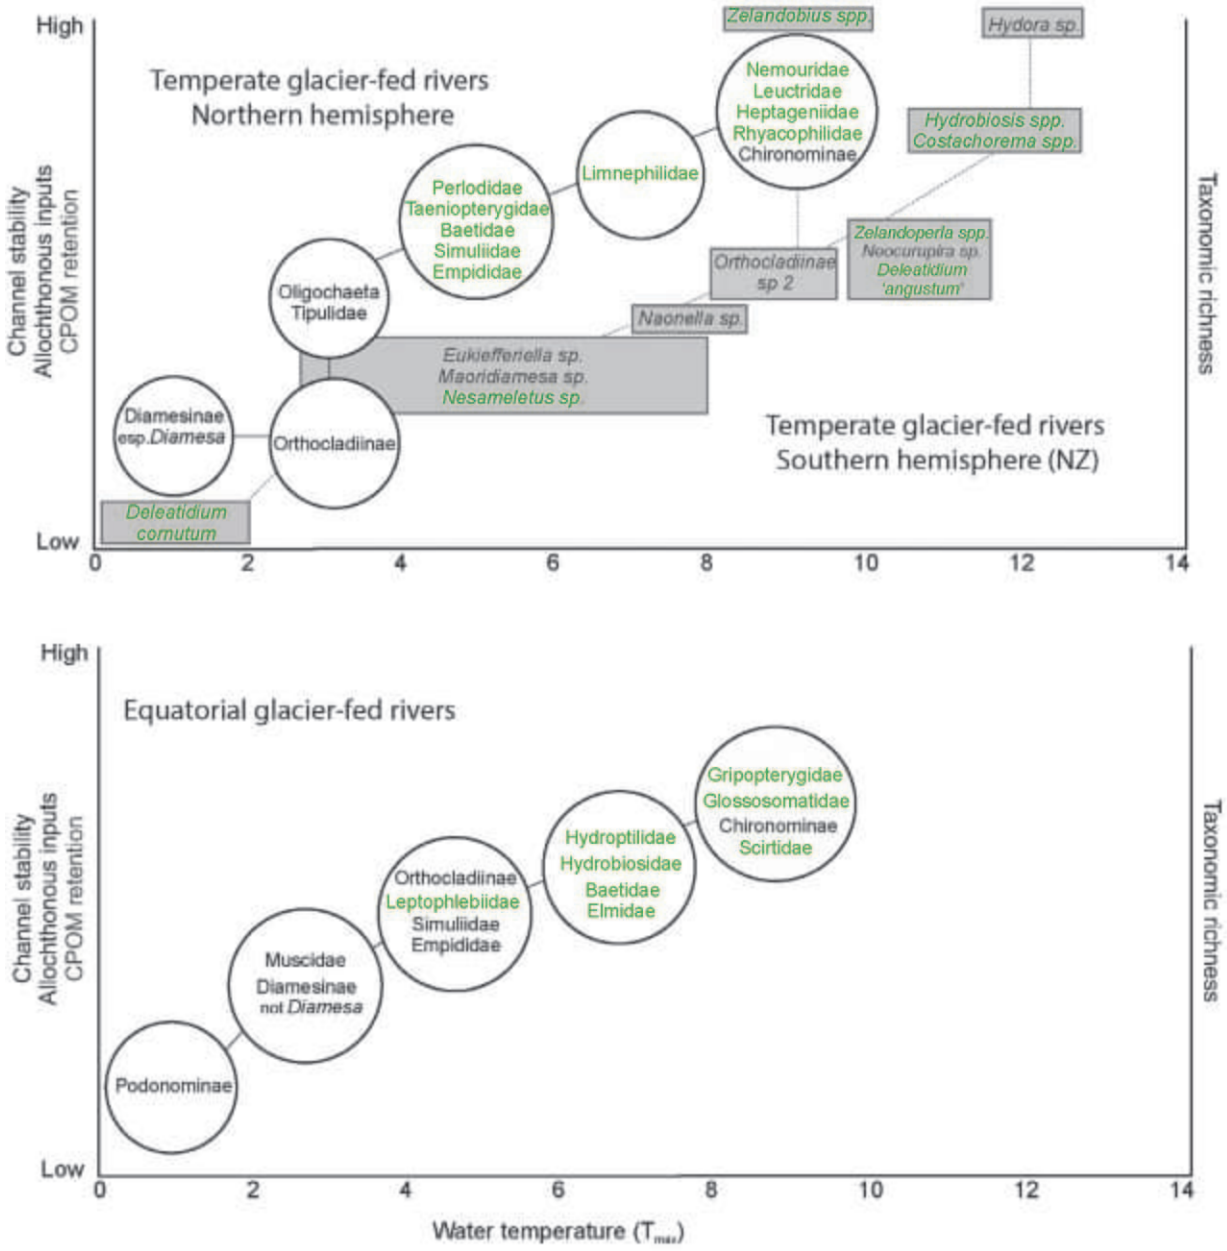

Fig. 8 Conceptual representation of macroinvertebrate community composition patterns in glacier-fed streams in relation to water temperature, channel stability and organic matter retention. The top panel represents temperate regions in the Northern and Southern Hemisphere after Fell et al. (2017) and Milner et al. (2001). The lower panel represents community patterns in equatorial streams based on Kuhn et al. (2011) and Crespo-Pérez et al. (2020). Green text is used for non-dipteran taxa (Ephemeroptera, Coleoptera, Plecoptera, Trichoptera) taxa. Gray fill on the upper panel represents patterns for streams in New Zealand.

The increasing use of molecular and genetic techniques in ecology are identifying significant cryptic diversity among invertebrates in mountainous and alpine regions. This is particularly prevalent where refugia communities have persisted during Pleistocene glaciation. For example, the mayfly *Baetis alpinus*, a well-studied species in temperate regions, has been shown to consist of reproductively isolated units in the Alps and Pyrénées, with limited genetic overlap between sites of high and low glacier influence (Finn et al., 2014). This suggests subspecies with distinct evolutionary histories are likely linked to extreme environmental differences between sites. Interestingly, these patterns have not been identified in tropical alpine streams in the High Andes, with gene flow apparent between groundwater and glacier melt streams for *Andesiops peruvianus*, a baetid mayfly. This is thought to reflect the legacy of volcanic activity in the region leading to environmental and demographic instability on evolutionary time scales (Finn et al., 2016).

Fish

Few native fish species are able to colonize and inhabit alpine rivers due to the harsh environment and cold water temperature (Milner et al., 2009). In the Colombian Andes only six species were found above 1250 m and diversity decreased at higher elevations (Carvajal-Quintero et al., 2015). In Europe, the dominant native alpine fish are brown trout (*Salmo trutta*), in eastern North America brook trout (*Salvelinus fontinalis)*, and in western North America the cutthroat trout (*Oncorhynchus clarkia*) and the bull trout (*Salvelinus confluentus*). In New Zealand, alpine galaxias species are native in alpine rivers. However, non-native cold stenothermic species have been introduced, in particular European brown trout for sport fishing, which have eliminated or severely reduced the range of native species (Boddy and McIntosh, 2017).

Climate change has and will affect cold stenothermic alpine fishes markedly, due to warmer water temperatures and to downstream fishes expanding their range and out-competing species at higher elevations (Bruno et al., 2019). In addition, contraction of suitable range habitat also occurs as species cannot migrate upstream into colder waters due to barriers such as dams. Conversely dams may restrict upstream movement of downstream cool water fishes. Interestingly rock glaciers are ubiquitous in alpine environments and their springs can reduce maximum daily water temperature by up to 5 °C, thereby providing a cold water refugia (Harrington et al., 2017).

Biogeochemical and ecological functioning

Nutrient cycling and microbial processes

Glaciers play an important role in the carbon cycle, both storing and transforming organic carbon. Much of the carbon exported from glaciers is "ancient" with radiocarbon dating estimates suggesting ages of 600–8500 year BP (Singer et al., 2012). Interestingly, carbon age is related positively to bioavailability (i.e., readily available fuel for microbial processes; Hood et al., 2015). The highest DOC concentrations are usually found in basal ice and cryoconite (surface sediment) holes reflecting localized accumulation of organic material from deposited material and in situ production (Singer et al., 2012). Local soils and vegetation are the primary source in high altitude systems with longer distance atmospheric transport of aeolian dust (e.g., Saharan dust to European Alps) and anthropogenic aerosols (e.g., polycyclic- aromatic carbon—a measure for black carbon associated with industrial emissions). Rock glaciers and permafrost represent important stores of labile carbon with potential to provide bioavailable DOC to alpine rivers over the coming decades (Fegel et al., 2019). For groundwater channels DOC concentration is generally higher than for glacier channels (Tockner et al., 2002) and is likely to increase with permafrost melting. The depth of the aquifer channel is an important control with streams fed by deeper groundwater flow paths displaying lower DOC concentrations that are more refractory than those fed by shallow karst systems or with connections to the soil layer/riparian zone (Boix Canadell et al., 2019).

The flux of DOC from snowmelt or runoff channels (cf. Jacobsen, 2009) is highly seasonal—during winter and spring soluble organics accumulate beneath the snowpack and are preferentially flushed during the early melt season from the upper soil horizons. This first flush or snowmelt freshet is associated with complex humic carbon (aromatic) reflecting the terrestrial origin. As the melt season progresses a reduction in DOC concentration and aromaticity is apparent as connectivity between the stream channel and surface soils is reduced and flow paths become associated with mineral layers (Hood et al., 2003). The transport of glacier carbon to the stream network is limited to the summer melt season and is controlled by atmospheric forcing (e.g., air temperature, solar radiation and precipitation). Hence, labile carbon can only provide a stimulus for downstream heterotrophic activity in glacier-fed streams during summer melting. However, seasonal differences in carbon composition exist with terrestrial, vascular plant-sourced material dominating during the early melt season and shifting to a more microbial protein-dominated signal as supraglacial channels link cryoconite holes to the drainage network (Hood et al., 2015). Despite seasonal shifts in composition, the age of the exported carbon remains relatively consistent across seasonal melt cycles.

While nutrient concentrations are generally low in alpine streams, there are distinct seasonal dynamics associated with the predictable shifts in water sources (Tockner et al., 2002). It is thought that most nutrients (N, P and C) are linked to short term atmospheric deposition. This results in the seasonal snowpack representing the major nutrient source (Mladenov et al., 2012). Hence, the mass associated with fluxes varies spatially but the mechanism by which the nutrients are delivered—i.e., through snowmelt—is consistent. This results in distinct seasonal pulses of nutrient release into the alpine river network (Fig. 9). Soluble Reactive Phosphorus (SRP) concentrations are generally highest in glacier meltwater and associated with phosphorus release via glacier rock weathering and reduced potential for instream uptake (Hood et al., 2009). Glacier runoff can also act as a source of N and may be associated with ammonium (NH_4^+) sorption to suspended sediments (Milner et al., 2017). Studies assessing nutrient uptake in alpine streams are limited; however, a study by Scott et al. (2010) found that N and P travel conservatively in supra glacier-fed streams, suggesting demand for nutrients was either limited or saturated. In snowmelt and groundwater dominated alpine streams in N. America, uptake velocities of N and P were comparable to those observed for headwater streams in lowland regions but N uptake was reduced when lakes were present (Arp and Baker, 2007).

Primary production does not appear to be N-limited in temperate alpine regions and is generally only P-limited during spring (Robinson et al., 2002). During the summer melt season physical factors (e.g., turbidity, scouring and bed stability) appear to override any nutrient effects on primary production in snowmelt and glacier-fed streams. Hence, water source can be seen as the key control on metabolic regime of alpine streams (Fig. 10; Canadell et al., 2020), with a distinct window of opportunity for benthic production in meltwater streams apparent in early and late melt season when turbidity and bed movement are lower

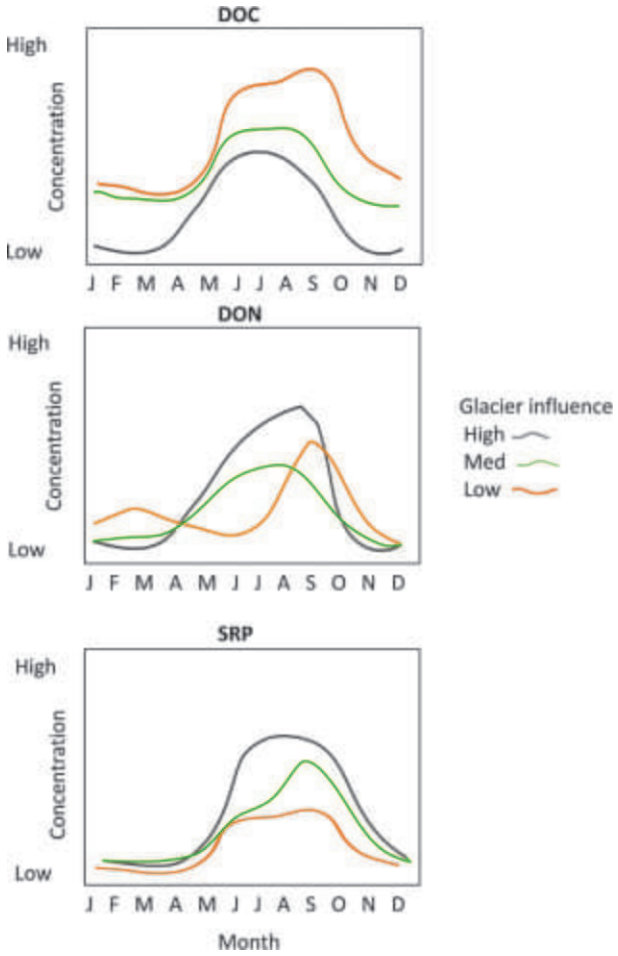

Fig. 9 Conceptual representation of the release of nutrients in alpine rivers with high (~50%), medium (~25%), and low (<1%) glacier cover in the upstream catchment. SRP = soluble reactive phosphorus, DON = dissolved organic nitrogen and DOC = dissolved organic carbon.

(Milner et al., 2001). Similarly, for decomposition of particulate organic matter (larch needles), groundwater-fed streams display faster breakdown rates than meltwater dominated channels (Robinson et al., 2000). This pattern of increasing breakdown with decreasing meltwater appears to be due to more rapid colonization by aquatic hyphomycetes and shredding macroinvertebrates. A study by Fell et al. (2021) found cellulose decomposition increased with decreasing glacier cover and was largely associated with changes in the fungal community, particularly an increase in the abundance of fungal a cellulose-degrading gene. While detailed microbial functional data remain limited, some patterns are emerging highlighting that glacier loss could increase the activity of bacterial functional genes important for N cycling (e.g., denitrification, nitrification, and anammox; Ren et al., 2017b). Bacteria associated with glacier-fed streams displayed highly specialized enzyme activity, whereas krenal sediments were dominated by generalists that displayed enzyme activity more similar to communities from lowland streams (Freimann et al., 2013). This loss of specialization in enzyme activity provides an interesting analogy to the biotic homogenization expected for higher organisms (e.g., macroinvertebrates) as glaciers retreat under climate warming (Milner et al., 2017).

Species interactions and food webs

Alpine river food webs reflect the diversity of feeding interactions between trophic groups characteristic of mountain streams and from the emergent properties that arise from complex ecosystem networks (Fell et al., 2017). They are predominately supported by primary production, with the majority of feeding linkages occurring between macroinvertebrate and fish consumers and epilithic diatom and algal resources (Füreder et al., 2003). As the availability of these resources is often patchy and constrained by the low water temperature of mountain streams, alpine aquatic macroinvertebrates adopt highly variable feeding strategies to opportunistically exploit resource availability (Clitherow et al., 2013), which itself fluctuates with season, water source (Sertić Perić et al., 2021) and flow intermittency (Siebers et al., 2021). For example, detritus (particularly the attached fungi) is a variable but often significant source of nutrients, particularly in many groundwater-fed streams, and the ancient carbon released from melting ice can contribute

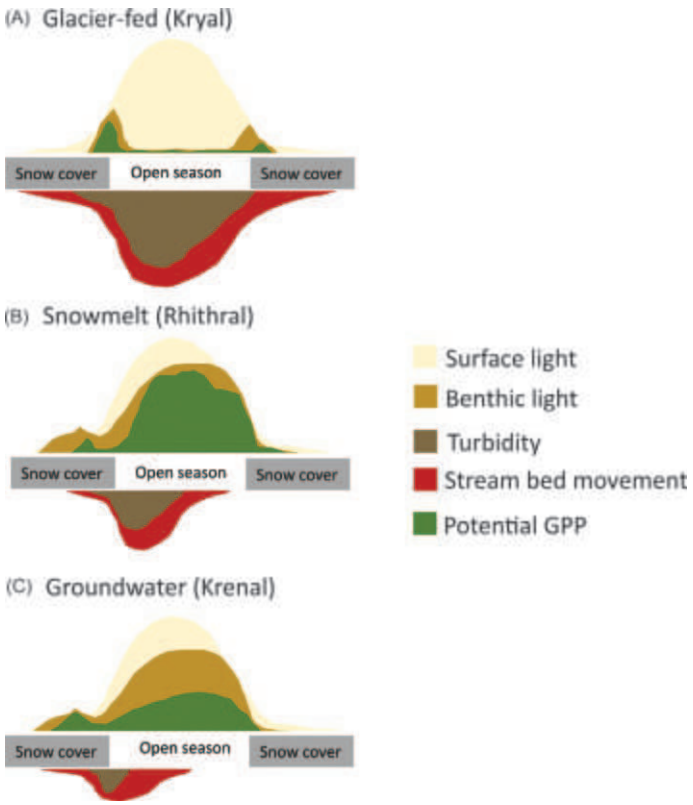

Fig. 10 Conceptual model of productivity regimes and physiochemical controls for the major stream types in alpine regions: (A) glacier-fed, (B) rhithral and (C) krenal stream. Modified from Canadell MB, Gómez-Gener L, Clémençon M, et al. (2020) Daily entropy of dissolved oxygen reveals different energetic regimes and drivers among high-mountain stream types. *Limnology and Oceanography* DOI: 10.1002/lno.11670.

to the diet of microbial consumers in glacier-fed waters (Zah et al., 2001). These opportunistic, generalist and omnivorous feeding behaviors were identified through stable isotope studies (e.g., Zah et al., 2001) and then confirmed by gut contents analysis. A meta-analysis of food webs from a wide range of river ecosystems found the highest directed connectance (proportion of possible feeding connections) in a glacier river food web from the Austrian Alps (Clitherow et al., 2013). This suggests the effects of local extinctions will rapidly propagate through food webs in glacier-fed rivers.

Cold water temperature, turbidity and bed instability of alpine streams typically limit productivity (Fig. 10) and associated abundance and biomass of many taxa, ensuring that alpine river food webs have low numbers of nodes and feeding linkages (Clitherow et al., 2013). This is particularly the case for glacier-fed rivers, where colonization by large predators is minimized by low temperature, repeated channel shifting disturbances and low availability of prey (Fell et al., 2017). As a result, many alpine river food webs are characterized by shorter mean food chain lengths and weaker size structuring when compared to streams and lakes from lower elevation (Clitherow et al., 2013). As glaciers retreat and the relative contribution of groundwater, springs, and precipitation increase as post peak-flow ice melt inputs decline, alpine river food webs can be expected to have increased number of nodes, links, and chain lengths (Niedrist and Füreder, 2017; Fig. 11). However, additional gut contents studies are required to determine the implications for species-level interactions (Fell et al., 2017). Changing water sources may also have implications for body mass as glacial-river specialists (*Diamesa* spp.) are larger in glacier dominated streams than more benign groundwater streams. This difference in body mass is likely due to the environmental conditions in glacier-fed streams limiting colonization by potential competitors and adaptation of *Diamesa* to the cold water temperature (Niedrist et al., 2018).

Anthropogenic threats and conservation priorities

Alpine regions are considered sentinels of global change that are generally more "pristine" than lowland regions and more sensitive to environmental variability (Hannah et al., 2007). The cryospheric component of alpine regions is particularly important for alpine river ecosystems (see Fig. 2), but it is also particularly sensitive to climate change. Alpine regions across the globe have reported a shrinking cryosphere with declines in snow, ice and permafrost extent impacting seasonality and river flow volume (Hock et al., 2019). Changing flow regimes have implications for a range of ecosystem services ranging from irrigation and water supply to hydropower production and fisheries (Milner et al., 2017). As the flow regime becomes more unpredictable, and the frequency and magnitude of extreme high and low flow events increases, specialist cold stenotherm taxa are likely to go extinct or see substantial

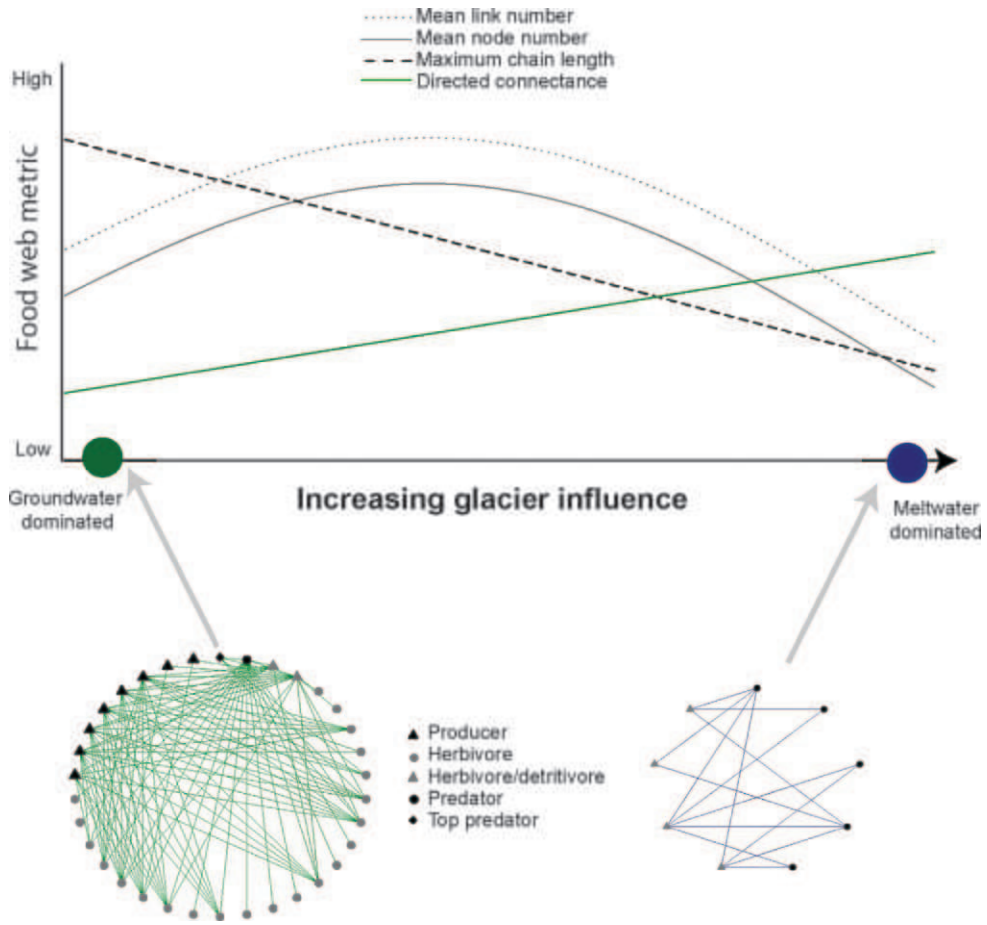

Fig. 11 Schematic representation of changes in river food-web connectance and web metrics as a function of increasing glacier melt contribution to bulk discharge. Observed connectance food webs are displayed for sites along a gradient from low to high glacier influence. Modified from Fell SC, Carrivick JL and Brown LE (2017) The multitrophic effects of climate change and glacier retreat in mountain Rivers. *BioScience* 67: 897–911.

reductions in range (Muhlfeld et al., 2020). Warmer temperatures and lower flows are likely to result in an increase in emission of CO_2 to the atmosphere from in-stream processes (Fell et al., 2021) and a reduction in transport of autochthonous organics to downstream ecosystems (Ulseth et al., 2018). Legacy contaminants (e.g., black carbon, mercury, pesticides, and other persistent organic pollutants) locked in glacier ice have increased downstream as glaciers recede, but their impacts are largely unexplored (Milner et al., 2017).

Hydropower developments are prominent features of alpine regions in Europe, North America and Asia and, while a renewable energy source, they result in the unsteady release of water to rivers (i.e., hydropeaking). This has significant implications for both the physical habitat and biotic communities with potential to have major impacts on ecosystem structure and function (Bruno et al., 2019). However, recent work has highlighted that water abstraction alone can improve habitat conditions further downstream through an increase in the relative contribution of less turbid and groundwater sources (Gabbud et al., 2019), but habitat directly below the intakes (~1 km) is devoid of fauna. Furthermore, intake flushing that generates sediment-laden flows can destabilize large areas of stream bed with significant impacts on macroinvertebrate abundance and diversity. As alpine glaciers retreat they will provide new opportunities for damming and hydropower (Milner et al., 2017) so careful management of operations are required to optimize energy production while minimizing environmental impacts.

Seasonal tourism in alpine regions has obvious implications for water quantity associated with peak water demand during winter coinciding with the period when water availability is lowest (Vanham et al., 2008). Implications for water quality have also been noted with increased concentrations of pharmaceuticals and personal care products recorded in streams close to major tourist resorts (Mandaric et al., 2017), with the impact on river water quality most pronounced in winter when stream flows are lower. In addition, the increased use of salt to de-ice roads and other impervious surfaces to facilitate winter tourism results in increased salinization of alpine river systems with currently unknown impacts on biota (Niedrist et al., 2021).

Given the complex nature of climate change impacts on alpine ecosystem structure and function, current legislative and conservation policy mechanisms need to be realigned. In particular, a shift in focus towards holistic ecosystem functioning conservation is required (Khamis et al., 2014). Due to limited potential for preventative intervention in these systems, conservation

strategies should focus on: (i) the maintenance and enhancement of connectivity within and between alpine river basins, (ii) protecting refugia for cold stenotherm (e.g., rock glacier-fed streams), (iii) improvement of hydropower operations to minimize impacts on river ecosystems, and (iv) where possible control and reduction of additional anthropogenic stressors such as erosion associated with ski-run creation and water pollution from tourist resorts.

Conclusion/Synthesis

This chapter has provided an overview of the varied nature of alpine river ecosystems from small stable springs to turbid glacier-fed torrents and has highlighted the important linkages between climate, hydrology and ecology. As a consequence of the strong coupling between climate and hydrology in alpine regions, the stream and river ecosystems are particularly sensitive to climate change. Currently biodiversity patterns (across multiple groups of organisms) are largely deterministic with meltwater contribution to flow a major control on alpha diversity and community structure. However, reductions in meltwater generation will have implications for stream habitat properties and could promote biotic (and functional) homogenization, a reduction in beta diversity and loss of cold stenotherms. The cryosphere melt dynamics in alpine regions are an important control on solute and nutrient concentrations, with loss of ice likely to lead to increased DOC export but a reduction in SRP and N. This change in water source will also have important implications for stream metabolism as the open season or "window of opportunity" for algal growth is extended, which in turn can facilitate an increase in secondary production and food web complexity. Beyond climate induced cryosphere shrinkage and the associated changes in water source dynamics, a number of other threats to alpine stream ecosystems have been identified. The most poignant of these threats are associated with the expansion of infrastructure for hydropower generation and tourism. As we move into an era of accelerated environmental change and biodiversity loss there is a clear need to realign legislation and conservation efforts for alpine streams, focusing on enhancing connectivity between and within river basins, promoting better management of hydropower activities and development for tourism. An additional challenge to implementing successful conservation strategies is linked to gaps in knowledge of ecosystem functioning, largely due to the logistical challenges associated with sustained monitoring campaigns, particularly during the winter months, or at the high altitudes associated with equatorial alpine environments.

Knowledge gaps

Despite increased research interest in alpine stream ecology over the last 30 years, gaps in our knowledge and understanding still exist. These can be split into four key groups with some of the most poignant questions outlined below.

Biodiversity and zoology. What is the extent of cryptic biodiversity in alpine streams (particularly among invertebrates) and is it more pronounced for equatorial regions? What is the distribution of aquatic alpine mammals and amphibians and are these ranges shifting with climate? How important are under snow/winter dynamics and processes for maintaining biodiversity?

Ecosystem function and species interactions. Do we see consistent patterns in connectance based food webs across latitudinal gradients, and do inferences made from quantitative assessments of energy transfer provide new insights into community resilience? Does the biofilm function and nutrient cycling of a given stream reach follow predictable patterns based on habitat conditions? To what extent does our understanding of ecosystem structure and function from temperate regions hold for alpine regions in the tropics/sub-tropics?

Impacts of anthropogenic activity. What is the impact of legacy contaminants (i.e., those released from melting glaciers) on biodiversity and ecosystem function? What are the implications of extinction of cold stenotherms for species interactions in alpine streams? How are the suite of anthropogenic pressures modifying the climate-environment-ecology cascade outlined in this chapter?

Methodological. Are there implications of making inferences based on time-series vs. chronosequences and do these vary with latitude? How well have we constrained the uncertainty associated with projections of change and what does this mean for conservation activity?

Glossary

100-year flood A storm event that has less than a 1% chance (frequency) of being exceeded in intensity (rainfall rate) and duration (length of storm) in any given year.
Aridity index Numerical index of the degree of dryness of a region's climate, or, mathematically, the ratio of the average annual precipitation to the potential evapotranspiration.
Dryland river A river that occurs in regions that have an aridity index <0.65.
Ephemeral A non-perennial river or stream without a substantial groundwater connection that flows for a short period of time, typically only after precipitation events. These waterways are hydrologically losing surface water the majority of the time when considering long-term flow patterns.
Hydrological persistence Significant temporal dependence between flow observations over a long time span in a river.
Intermittent A non-perennial river or stream with a considerable connection to the groundwater table, having variable cycles of wetting and flow cessation, and with flow that is sustained longer than a single precipitation event. These waterways are hydrologically gaining surface water most of the time when considering long term flow patterns.
Non-perennial Any lotic, freshwater system that periodically ceases to flow and/or is dry at some point in time and/or space.
Perennial A continually flowing system.
Potential evapotranspiration (PET) The amount of evaporation and transpiration from a surface to the atmosphere that would occur given sufficient water availability (e.g., ground saturation).

Introduction

Dryland rivers are those that occur in hyper-arid, arid, semiarid, and dry-subhumid climates of the world, or regions that have an aridity index of <0.65 (U. N. E. P., 1992). Drylands make up 40–50% of the Earth's surface and sustain 30–40% of Earth's population (United Nations, 2016; Heritage et al., 2019). The term "dryland rivers" has historically been used to describe lotic

 https://doi.org/10.1016/B978-0-12-819166-8.00156-0

ecosystems that do not continuously flow, but this is a misnomer as non-perennial rivers and streams are not unique to drylands and exist in all climates and biomes (Busch et al., 2020). Further, perennial waterways are present and important in dryland climates. For our purposes, we use the definitions for "non-perennial," "intermittent," and "ephemeral" rivers as recommended by Busch et al. (2020), who based this terminology on a systematic literature search of all terms used to describe these types of non-flowing rivers and distinguish them from flowing rivers (see *Glossary* for definitions).

The major driving force that generates and maintains drylands is the climate of these areas, particularly the temporal dynamics of water gains and losses. Water is a key currency in drylands (Allen et al., 2014) and plays four key roles in dryland environments: (1) maintenance of biodiversity, (2) chemical solvent for other substances, usually salts, (3) medium of mass transport, and (4) direct energy source, which can govern runoff by impacting infiltration (Thornes, 2009). High-pressure and dry air masses dictate the regional climate by impeding low-pressure, precipitation-bearing air masses. Topographic barriers also form drylands by constraining these air masses and creating rainshadows (e.g., deserts in the southwestern U.S. and on the Tibetan plateau). In addition, drylands can be formed in the center of large continents (e.g., Eurasia) due to large distances from oceanic moisture. Storms in drylands are often characterized as explosive, localized convective systems due to uneven surficial heating. But frontal systems can also be dominant, as seen in Western Australia (Cordery et al., 1983) or in northern and central Australia, where monsoon incursions from the Indo-Pacific basin dominate precipitation patterns (May and Ballinger, 2007). Irregular oscillations of sea surface temperatures, such as El Niño–Southern Oscillation (ENSO) (Evans and Boyer-Souchet, 2012) and the Indian Ocean Dipole (Ashok et al., 2003), can be the main contributors to shifts of rain- or snow-bearing systems on many continents. In regions where rainfall is relatively high, the even higher potential evapotranspiration (PET) becomes the first-order control in forming drylands (Bull and Kirkby, 2002). Here, the sheer deficit between precipitation and PET, along with their pronounced temporal variability, often makes rainfall run off quickly, leaving these rivers dry for many months at a time.

Even though deserts are not considered global biodiversity hotspots (Durant et al., 2012), they have high endemism (Sosa et al., 2020). Within these arid biomes, dryland rivers (especially perennial dryland rivers) house a disproportionate amount of the regional biodiversity (Stromberg et al., 2009). Because water is such a severely limiting resource in these systems (Allen et al., 2014), the structure and functioning of intermittent rivers and ephemeral streams (IRES) in drylands are governed by the timing and magnitude of water delivery (Datry et al., 2018a), with dramatic increases of ecosystem productivity (Fisher et al., 1982) and local recruitment (Boulton and Lake, 1992) after hydrological events.

Dryland rivers are unique from perennial, intermittent and ephemeral streams in more mesic biomes (Fig. 1). First, dryland rivers are some of the most variable and unpredictable systems in the world (Bunn et al., 2006a; Petts, 2017). Second, these rivers

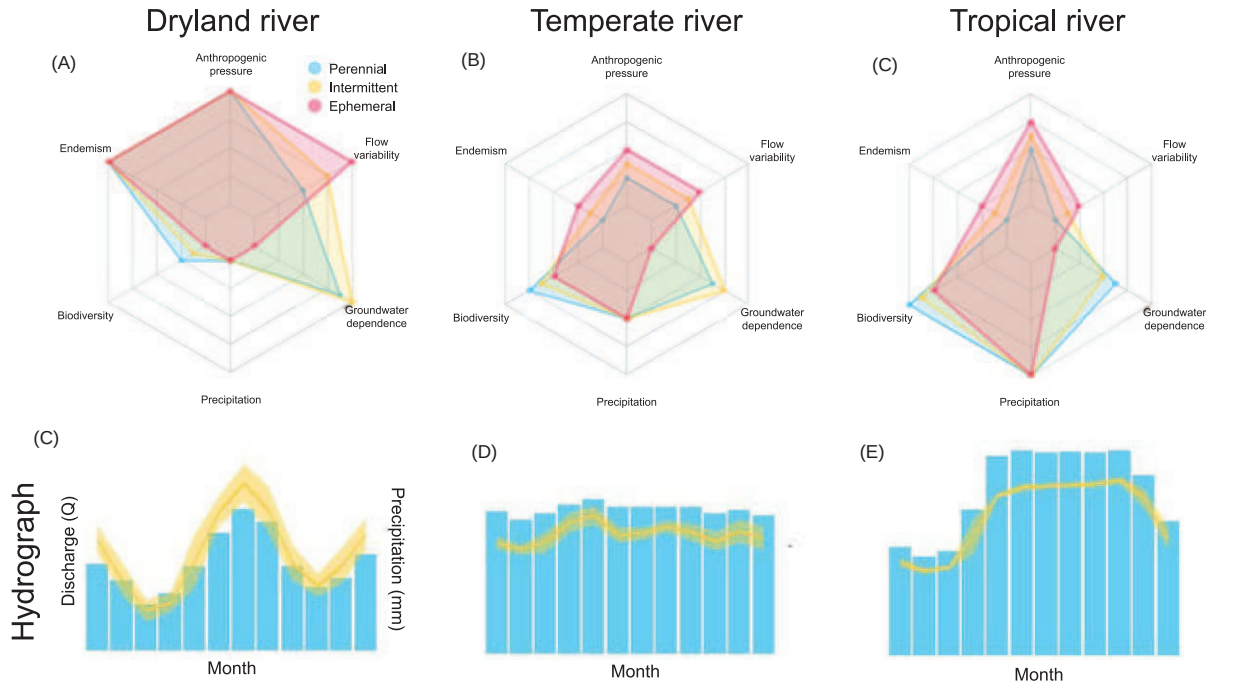

Fig. 1 Conceptual radar plots of key features of typical perennial (blue), intermittent (yellow), and ephemeral (red) rivers in dryland (A), temperate (B), and tropical (C) regions. Axes depict relative values of each variable for each river type and include flow variability (measured on an annual scale), groundwater dependence (or the proportion of stream flow that is supported by groundwater sources), precipitation (or the relative annual precipitation for a given watershed), biodiversity (associated with the stream and surrounding riparian zone), endemism (or the number of unique species in the watershed), and anthropogenic pressure (measured as the degree to which human activities are currently impacting these systems globally). Values increase moving out from the center of each radar plot. Overlapping colored contour lines highlight key differences in perennial, intermittent, and ephemeral streams within each region. Conceptual hydrographs depicting typical 20-year flow regimes for dryland (D), temperate (E), and trophic (F) rivers, including monthly precipitation (blue bars) and discharge (yellow lines with 95% CI bands).

have a higher dependence on aseasonal factors (e.g., catchment area, ENSO) compared to perennial rivers (Puckridge et al., 2000; Walker et al., 1995). Consequently, these rivers are likely to experience more intense effects of natural and anthropogenic disturbances, such as climate change. Dryland rivers also provide important ecosystem services, such as water security in arid regions (Petts, 2017). They provide water supply for agriculture, and their wetlands protect cities from the frequent, high magnitude flash floods to which these systems are prone. Pressure to develop water resources in dryland regions is increasing, threatening their under-appreciated resources and services (Kingsford et al., 1998; Petts, 2017). This pressure has led to some of the greatest examples of hydrological interference by humans, with large over-allocation of these resources for human uses in the 1970s, including in Australia (Petts, 2017) and the western United States (Young, 2014).

Here, we outline the key features of dryland rivers that distinguish them from temperate and tropical rivers and explore knowledge gaps in our understanding of how these systems function. Specifically, we outline the unique geomorphology, hydrology, biogeochemistry, and biology of these systems, highlighting key differences (e.g., flow variability, groundwater dependence, annual rainwater inputs, biodiversity, and endemism) in relation to temperate and tropical systems (see Fig. 1). Next, we detail how anthropogenic drivers will impact these systems (e.g., urbanization and climate change; collectively "Anthropogenic pressures," Fig. 1), and how these systems can be used as ecological laboratories to understand and advance fundamental research in metacommunity theory. Finally, we identify key knowledge gaps and provide a conceptual framework synthesizing key aspects of these systems, how their unique geomorphology, hydrology, biogeochemistry, and biology interact to influence their provisioning of ecosystem functions and services, and how global change is expected to alter these systems (Fig. 2).

Geomorphology of dryland rivers

The fluvial geomorphology of rivers differs by climate, with large differences between tropical, periglacial, and dryland rivers (Graf, 1988). Yet, few morphological features are unique to dryland rivers (Powell, 2009). This lack of distinctive features, coupled with the high amount of variation in their geomorphic forms that range from high-energy, high-gradient upland rivers prone to flash flooding to low-energy, low-sediment-load lowland systems with languid flows, makes classifying these systems difficult (Powell, 2009). The features that do make these systems distinct result from the variability and magnitude of their flow regime.

Flow variability is a key aspect of the flow regime shaping geomorphology (Graf, 1988). Highly variable flow regimes, which are typical of dryland rivers (McMahon, 1979), create geomorphic complexity and greater in-channel complexity (Thoms and Sheldon, 2002). For example, increases in extreme floods (i.e., magnitude and/or frequency) could trigger geomorphological state changes from mixed bedrock-alluvial systems with high geomorphic and ecological diversity to bedrock dominated channels with lower diversity and altered ecosystem function (Heritage et al., 2019; Milan et al., 2018). Further, since infiltration is a major threshold in dryland morphological development (Thornes, 2009), variability in delivery of flow to these systems leads to further morphological distinction and heterogeneity. Collectively, these aspects of flow variability and heterogeneous geomorphology lead to high levels of habitat patchiness and variable connectivity in space and time, supporting biodiversity (Quinn et al., 2000).

The magnitude of high-flow events also structures the geomorphology of dryland rivers. Because there is frequently little vegetation to buffer runoff from the surrounding landscape, dryland rivers worldwide are subject to episodic, extreme flood events, with channel scouring and stripping of streambed sediments. Flash flooding influences the architecture of dryland river deposits, and frequent, local, deep-scour events dramatically alter their geomorphic structure within short periods of time, making them difficult to study (Carling and LeClair, 2019). These restructuring events provide physical refugia important for sustaining biota through long-duration dry spells and sporadic precipitation events. Further, flood-flows enhance the relationship between flow variability and in-channel complexity (Thoms and Sheldon, 1997). The intensity of flow events dictates the transport of sediment downstream, with large flash floods capable of moving large bedloads for long distances in a short time. This means that the geomorphic structure of dryland river channels can change rapidly, and in extreme events leading to an entire rerouting of the channel (Field, 1994).

Hydrological regimes of dryland rivers

The high flow variability of dryland rivers is controlled by a climate characterized by extended dry periods that are punctuated by intense storm seasons (e.g., monsoons), or episodic events that provide most of the annual moisture during relatively short periods of time (Dare et al., 2012; McGrath et al., 2012; Fig. 1D). The hydrological inputs can be similar for dryland rivers as for other systems, but the relative importance of these factors can vary greatly compared to those of temperate systems, and their relative roles can change much more spatiotemporally compared to temperate systems (Thornes, 2009). In dryland rivers, gross water inputs occur at high intensities, but low relative volumes, with rain events coming at irregular intervals and exhibiting strong seasonal and interannual variability (Thornes, 2009). Low volume rain events and low soil moisture coupled with patchy vegetation adapted to rapidly uptake moisture means that interception rates (i.e., rates at which water is stored above the ground surface, primarily in vegetation) are low and variable in dryland systems, meaning that these systems are particularly vulnerable to changes in moisture patterns.

Dryland rivers exhibit unique characteristics compared to rivers in more humid regions. The primary trademark of dryland rivers is a flashy hydrograph with steep rising limbs, with delayed but sharp peaks, followed by steep falling limbs. The steep rising limbs mostly result from the explosive, convective rainfall typical of dryland areas. High evapotranspiration causes low antecedent soil moisture content, and thus a high initial abstraction into low-moisture soil, which can delay runoff responses to rainfall, especially low- or moderate-volume events. This results in a low runoff coefficient (i.e., total runoff volume divided by total rainfall). Another contributing factor is re-infiltration, a signature process in dryland hydrology, where upstream surface runoff is routed to and then infiltrates the dry streambed of downstream river sections (Nahar et al., 2004). Re-infiltration leads to transmission loss, or abstraction into the dry streambed, shortening the period of runoff, as reflected by the steep falling limbs of hydrographs. Re-infiltration is also important because the intense storms in dryland areas are often very localized, which means rainfall only occurs in a fraction of the whole watershed, and dry, downstream sections reduce those flows through re-infiltration. Because much of the excess surface water is directly lost to evaporation, inputs into dryland rivers are generally low and sub-alluvial aquifers (i.e., those just below the streambed that are often connected to groundwater sources) assume a more significant hydrological role in these systems, especially for non-perennial streams (Thornes, 2009). The infiltration that does occur in dryland rivers is largely controlled by soil and bedrock surface characteristics, and systems dominated by hard bedrocks and clay soils, for example, are prone to flash flooding; consequently, channel flow through these systems can range widely based on the frequency and magnitude of precipitation events as well as the channel geology and boundary conditions, including saturation of alluvium (Thornes, 2009).

Previous researchers used three major approaches individually or jointly to characterize intermittent flow regimes: in-situ monitoring, remote sensing, and hydrological simulation. In general, the first two estimates are essentially visual observations that lack spatial and temporal continuity (Zimmer et al., 2020). Given the highly varied nature of rainfall processes, hydrological modeling—when validated by in-situ and/or remotely sensed observations—promises to bridge the spatio-temporal gaps in assessment of these flow regimes in dryland areas.

Biological properties of dryland rivers

Environmental flows and the maintenance of biodiversity

Flow regulation—or the process of controlling stream flow through diversions, dams, and impoundments—is a common practice in dryland regions of the world, both for flood mitigation and water storage. Flow regulation in dryland rivers is highly divisive, providing both an important role in maintaining water supply for human use (e.g., irrigation) but also representing one of the most hydrologically destructive impacts in these sensitive ecosystems (Petts, 2017). For example, over 90% of the exploitable flow of the Murray-Darling river (south-eastern Australia), generated from only 21 mm of annual runoff, is often extracted for irrigation use within the basin, causing significant ecological impacts (Wedderburn et al., 2017). Indeed, dryland systems are more sensitive to flow alteration than perennial systems because of the ecological interplay between their hydrology and biology (Kingsford et al., 1998; Leigh et al., 2010).

The unique geomorphic and hydrological characteristics of dryland rivers are important for maintaining and regulating ecological interactions in these systems. For example, flow variability and flood timing are critical for sustaining biodiversity across the river-floodplain mosaic (Leigh et al., 2010). Biodiversity in these systems is strongly linked to rainfall-driven pulses (Free et al., 2013), which can cause dramatic booms in secondary production (Leigh et al., 2010; Free et al., 2013) that sustain aquatic and terrestrial biota over large spatial scales (Bunn et al., 2006b). Another ecologically important feature of the dryland river hydrological regime is hydrological persistence, or the significant dependence between flow observations a long time span apart (see Puckridge et al., 2000). Thus, the patchy wetted habitats that persist during dry periods require periodic hydrological recharge to replenish downstream nutrients and production (Petts, 2017), thereby sustaining biodiversity in these systems (Puckridge et al., 2000). Indeed, organisms in dryland systems often display traits that respond to periodic delivery of water and dissolved nutrients (e.g., increased ability to tolerate dry periods as well as strong dispersal ability; Sheldon et al., 2010). Further, hydrological persistence can play a role in exotic species invasions, as serial flooding favors recruitment of native species that are adapted to these highly variable flow conditions (Puckridge et al., 2000). Collectively, the biota of dryland systems are particularly susceptible to hydrological alterations that abstract river flow or reduce high flow variability.

With increasing human demand and climate change leading to increasing water stress, there is a clear need to better manage the water resources provided by highly stressed dryland systems, to minimize the negative social-ecological outcomes of water management. By directly integrating the different components of the hydrological regime—quantity, timing, and variability of flows—environmental flows aim to sustain and promote both the health and function of aquatic ecosystems and their biodiversity as well as the human cultures, economies and livelihoods that rely on these systems (Poff et al., 2010; Arthington et al., 2018). The move toward more integrated approaches to managing water is even more critical within dryland environments: the successful development and implementation of these frameworks reflects a collaborative approach that includes discussion of risk and balance of water needs (e.g. Chen and Olden, 2017; Conallin et al., 2018). These frameworks come with a clear need for consistent and long-term monitoring, but effective methods are not always in place for dryland rivers which limits their formal assessment (Chessman et al., 2010).

Ecosystem function and biogeochemical processes

Overview and processes in flowing systems

Biogeochemical processes in dryland watersheds are controlled by the degree of hydrological connectivity through the stream network. Variation in hydrological connectivity across dryland watersheds controls the downstream movement of dissolved oxygen, organic matter, nutrients, and microbial colonizers. Low allochthonous inputs and high light availability make many flowing desert streams autotrophic (i.e., gross primary production > ecosystem respiration) and net exporters of organic matter (Fisher et al., 1982; Fellows et al., 2009). A paucity of allochthonous organic matter means that ecosystem respiration in dryland systems can be highly linked and dependent on organic matter released from primary producers (Fellows et al., 2007; Townsend et al., 2011). Aerobic respiration occurs in porous hyporheic and parafluvial zones that are well connected to the stream surface and thus oxygenated, but anaerobic processes such as methanogenesis can occur in less well-connected bank sediments (Jones et al., 1995). Further, spring and groundwater inputs of bioavailable dissolved organic carbon (DOC) and dissolved inorganic nitrogen (DIN), can stimulate both rapid mineralization and algal growth (Burrows et al., 2020; Fellman et al., 2014).

Ponded and dry phases

Flow cessation has large impacts on the ecosystem function and biogeochemistry of dryland rivers. Gross primary production can remain high in residual pools (Fellows et al., 2007), but high turbidity can limit algal production to a narrow littoral band (Bunn et al., 2003). However, even small inputs of allochthonous resources can induce heterotrophy, particularly in nutrient-poor pools (Siebers et al., 2020). As aquatic environments recede and benthic sediments become exposed, particulate organic matter breakdown may decrease (McIntosh et al., 2017) and CO_2 released (Keller et al., 2020). Evaporative processes often control biogeochemical dynamics in ponded systems (Townsend, 2002), but the degree of groundwater-surface water connectivity can moderate this through dilution. For example, in the semi-arid northwest region of Australia, pools with higher evaporative losses and lower alluvial connectivity had higher nutrient (C, N, P) concentrations and higher proportions of humic and protein-like organic matter than pools with greater alluvial connectivity (Siebers et al., 2016).

Flow pulses after dry and low-flow phases

Flow pulses play a major role in shaping ecosystem metabolism, biogeochemical characteristics, and ecosystem processes of dryland rivers. Flow velocities and turbulence can drastically reduce primary productivity over days to weeks by scouring benthic surfaces (Fisher et al., 1982) and increasing water-column turbidity (Bunn et al., 2006a). Further, high-flow periods can cause a temporary increase in allochthonous DOC concentrations by increasing hydrological connectivity of the watershed (Wise et al., 2019). Although flow pulses can temporarily suppress algae production and alter biogeochemical conditions, they also reconnect isolated waterholes and floodplains, delivering water and dissolved and particulate resources that are key to the long-term persistence of dryland river ecosystems (Bunn et al., 2006a). Further, particulate organic matter accumulated in channels during dry phases, or delivered during flow pulses, can be subject to enhanced microbial activity upon wetting and lead to significant CO_2 fluxes to the atmosphere from dryland rivers at local scales (Datry et al., 2018b).

Food web dynamics

Due to the combination of extreme hydrological variability and opportunistic biotic responses to flood pulses, dryland rivers have unique food webs. Primary productivity and heterotrophy are important for sustaining food webs in these systems (McIntosh et al., 2017; see also "Biological properties of dryland rivers" section). Yet, because flows that provide rewetting and the delivery of upstream dissolved and particulate resources are episodic, autochthonous production often occurs in dramatic booms that generate a large biomass in a short time (Bunn et al., 2006a). This biomass boom can translate to high amounts of secondary production; in fact, one of the highest estimates of stream annual secondary production ever measured (i.e., 120.9 ± 18.0 g m^{-2} $year^{-1}$) occurred in Sycamore Creek, Arizona USA (Jackson and Fisher, 1986).

Consumers in dryland systems are often generalists that have adaptations to exploit pulses in resources that correspond with the changes in resource availability. Most consumers in dryland rivers have traits either allowing them to capitalize on a wide range of resources or to persist until favorable conditions and resources return. For example, traits like desiccation tolerance or burrowing can allow some organisms to persist during drying conditions, while strong dispersal ability can enable mobile predators (e.g., dragonflies) to track resource availability and boom cycles (Boersma et al., 2014; Bogan et al., 2014). Many consumer trophic interactions (e.g., fish predation) are excluded by temporary flow regimes, making these interactions less important in dryland rivers lacking fish, causing many of these systems to be driven by bottom-up trophic forces. Even in perennial dryland rivers, the effects of fish predation are likely to be weaker than in temperate systems. For example, in many perennial, low-gradient dryland rivers, waters are turbid due to large influxes of sediment, especially during the wet or monsoon season, and these systems naturally lack the large, visual predators typical of rivers in more temperate regions.

Yet the interactions that do exist in dryland rivers are likely to be strong given their adaptations to variable flow regimes characterized by periods of zero flow and drying. Whereas organisms in perennial streams are subject to faunal devastation during droughts (Hynes, 1958) that can lead to trophic rewiring (Lu et al., 2016), organisms in dryland rivers are adapted to extended periods of drying. There is some evidence that while the food webs in these systems contract during these periods, core ecological interactions persist, resulting in similar topologies as regional food webs (Peralta-Maraver et al., 2020). Additionally, aquatic

consumers in dryland rivers can exhibit relatively strong trophic connections to terrestrial food webs. This is, in part, because as drying intensifies, more and stronger linkages with terrestrial systems are created (McIntosh et al., 2017). Experimental evidence suggests that aridity enhances terrestrial consumer responses to water additions (Sabo et al., 2008; Allen et al., 2014), which has led to the idea of water as a "trophic currency" in drylands (Allen et al., 2014). Collectively, this evidence suggests that dryland river food webs might have resistant "multiscale backbones" (sensu Serrano et al., 2009) that enable core ecological functions to persist in these systems during drought conditions, but more research is needed to test this hypothesis.

Dryland river riparian ecosystems

The presence of a river can have profound consequences for dryland terrestrial landscapes. Riparian ecosystems are the portion of a terrestrial landscape immediately surrounding rivers and streams. Although riparian systems are important habitats everywhere (Selwood and Zimmer, 2020), they are especially unique in dryland climates (Free et al., 2013; Selwood et al., 2017). The presence of water in the river channel and its shallower water table can lead to a drastic difference in the dominant terrestrial vegetation in riparian compared to upland ecosystems. For example, in the drylands of the southwestern US, riparian areas are marked by mesic cottonwood and willow species that can access shallow groundwater through deep taproots. These trees create gallery forests in dryland streams that are vastly different from the scrub habitats upslope of the floodplain, which are dominated by more xeric shrub, grass, and succulent species (Lite et al., 2005).

Riparian zones in drylands can be of paramount importance to terrestrial animals. They are typically more productive habitats than uplands, and therefore have elevated energetic resources for consumers. Many bird species rely on riparian corridors in drylands. In the arid Southwestern US, for example, riparian zones in desert areas are key stopover sites for migrating birds during the spring, as woody riparian vegetation offers more perching sites than upland scrub vegetation and provides increased water and energetic resources (Skagen et al., 1998, 2005). Further, mammals often preferentially forage in riparian areas, even those that live in upland areas. For example, in drylands, mammalian carnivores have been shown to prefer riparian areas during especially dry times of year when productivity of upland habitats is limited (Soykan and Sabo, 2009). Finally, terrestrial invertebrates can be more abundant and diverse in riparian than upland habitats due to the availability of aquatic insect resource subsidies that many riparian arthropods prey upon (Ramey and Richardson, 2017). Within the riparian zone, river drying can alter the composition of terrestrial arthropods and lower their diversity (McCluney and Sabo, 2012). Because of the importance of riparian habitats to many different terrestrial taxa, they are often a high value area for conservation and management (Riis et al., 2020).

Environmental factors that influence water availability in floodplains and riparian zones are important determinants of riparian plant community composition and abundance. Accordingly, variation in streamflow in the river itself is a critical factor for riparian ecosystems at both ends of the hydrological spectrum. Flood magnitude, duration, and timing can be critical for the recruitment of certain pioneer riparian plant species. For example, in western North America cottonwood seed dispersal generally occurs after peak streamflows in the spring, and the receding stream exposes bare, moist soils in banks and bars where seeds germinate (Mahoney and Rood, 1998). But the vast majority of seedlings die if water table declines outpace root growth, such that only floods large enough to scour and generate bare soil, but also have gradual streamflow declines after the peak flow, allow cottonwoods to successfully recruit (Mahoney and Rood, 1998).

On the dry end of the hydrological spectrum, the lack of continuous surface flow can also be important for riparian ecosystems. Surface-flow permanence is related to groundwater table depth, such that when the river dries the groundwater table lowers as well. Some riparian tree species may require the presence of shallow groundwater, whereas other species may be able to access much deeper groundwater with longer taproots (Lite and Stromberg, 2005). Because water table depth typically varies with streamflow, this can lead to different riparian plant communities at continuously flowing river reaches versus those that are not. For example, in the Sonoran Desert in the US Southwest, riparian vegetation along perennial streams is more diverse compared to intermittent riparian plant communities, which are dominated by a less diverse assemblage of herbaceous and shrub species (Stromberg et al., 2007). These differences can reverberate throughout the rest of the riparian ecosystem. For example, changes in riparian plant communities associated with groundwater declines led to reduced avian diversity in one study (Merritt and Bateman, 2012), and another showed that ground-dwelling arthropods varied with riparian vegetation type at perennial vs. non-perennial reaches of the same river (Allen, 2016).

Despite their ecological importance, dryland riparian ecosystems are among one of the most imperiled ecosystems worldwide. One of the most common threats to these systems is invasive plant species, which can impact both riparian and stream ecosystems. For example, nonnative *Tamarix* spp. (salt-cedar) is widespread in riparian areas across the western US, and this species has been shown to alter the composition of riparian lizard, small mammal, and bird communities (Bateman and Ostoja, 2012; Fleishman et al., 2003). As discussed earlier, riparian vegetation and its inputs of leaf litter into the stream are critical to the food web and biogeochemical dynamics in streams, so changes in dominant riparian vegetation species can influence these aspects of stream ecosystems as well. Russian olive (*Elaeagnus angustifolia*) is another invasive riparian tree species in the western US, and its presence is associated with 25 times more leaf litter input to streams, increasing benthic organic matter storage while decreasing the efficiency of stream respiration relative to organic matter input (Mineau et al., 2012). In-stream nutrient dynamics are also affected by the Russian olive as it is a nitrogen-fixer, and stream reaches invaded by it have greater N concentrations and reduced N limitation of

stream biofilms (Mineau et al., 2011). Dryland riparian ecosystems are also being negatively impacted by changes in streamflow. Indeed, flow modification by dams typically reduces the frequency and magnitude of floods, this can prevent cottonwood recruitment and alter riparian vegetation community structure (Goodale et al., 2002; Stromberg et al., 2007). Water withdrawals and diversions that reduce stream flow can impact riparian vegetation, but efforts to restore streamflows have shown that flow resumption can reverse these effects and restore riparian habitat (Bigelow et al., 2020; Hillman et al., 2016).

Dryland rivers provide ideal case systems for advancing metacommunity theory

Temporal and spatial changes in aquatic habitat availability drive population and community dynamics not only locally but also regionally, as species interact within a river network or a landscape as part of a metapopulation and metacommunity, respectively. Metacommunity theories assume that changes in population trajectory or community composition are driven by interacting local (e.g., species interactions, environmental changes) and regional (e.g., dispersal of individuals) drivers.

In drylands, where aquatic habitats are scarce, dispersal and connectivity between remnant aquatic habitats is likely central in determining population and community structure of, for example, fishes (Jaeger et al., 2014) and invertebrates (Cañedo-Argüelles et al., 2015). Although the main pathways of recolonization post-drying are still debated, dry temporary streams can serve as dispersal corridors linking aquatic habitats, particularly for flying insects (Cañedo-Argüelles et al., 2015). Some invertebrates (Stubbington et al., 2019) and fishes (Rodríguez-Lozano et al., 2019) can also migrate vertically to the hyporheic zone where moisture is preserved and where they can persist during the dry season to recolonize when water resumes. Aquatic organisms typically are little resistant to drying; however, some strategies, such as diapause or dormancy (e.g., the burrowing tree frog, *Cyclorana alboguttata*, that can exist for years buried in mud in a state of torpor), can allow species to persist locally and maintain diversity under drying conditions (Boersma et al., 2014). These resistance strategies can be considered as "temporal dispersal" since dormant forms can persist in situ, sometimes for years and develop after local conditions become favorable (Buoro and Carlson, 2014). Local persistence and colonization capacity from refuges are thus key in determining dryland communities, but it remains unclear which of the temporal and spatial dispersal strategies maintain diversity in different locations within the landscape and among hydrological phases.

Learning from these approaches, management strategies should focus on preserving the aquatic habitats central to the metasystems, which provide sources of spatial and/or temporal colonizers (Ruhí et al., 2017). A better understanding of the pathways connecting populations and communities – and the effect of fragmentation on those – could also help in designing integrative management plans which sustain regional diversity under climate change.

Dryland rivers in urban systems

The behavior of rivers and streams in urban areas is regulated by human activities, including land cover, and infrastructure, especially stormwater management infrastructure. Until the late 20th century, with the adoption of the U.S. Clean Water Act in 1972, urban stormwater systems functioned primarily to shed water from the landscape as quickly as possible through drainage infrastructure consisting of concrete and pipes, often replacing natural riparian zones and ecosystems with concrete-lined channels optimized for maximum flow (Shuster et al., 2005). These developments increased discharge of roadway and urban pollutants into rivers (Booth and Jackson, 1997), reduced riparian areas (Walsh et al., 2005), and increased the velocity of runoff flows through the system, among other problems (Miller et al., 2014). In the USA, the intensity-duration-frequency (IDF) framework (Hershfield, 1961) for design of urban river and drain systems has led to systems that can shed or retain discharge from 100-year floods. Because much of the land development in the United States has occurred in drylands since the introduction of regulations associated with Low Impact Development (LID, Dietz, 2007) and Green Infrastructure practices (Fitzgerald and Laufer, 2017), newer southwestern dryland cities tend to support relatively modern, ecologically adapted riparian systems compared with older, well-watered eastern cities.

A remarkable feature of rivers, streams, and wetlands in dryland cities is the phenomenon of artificial riparianization, in which the large volumes of water delivered to dryland cities are released into dryland stream channels through wastewater discharge, causing perennial wetlands and streams to appear (Palta et al., 2017). This artificial riparianization process alters the hydrologic regime and thus species composition and ecosystem function. Additionally, it enables species that are uncommon in arid environments to establish in these ecosystems. These "accidentally restored" systems can serve as biodiversity hotspots in their own right, maintaining other ecosystems in decline (Bateman et al., 2015).

Dryland rivers in a changing world

Dryland rivers, which are among the most variable, unpredictable rivers in the world (Bunn et al., 2006a), are also subject to some of the most intense pressures from anthropogenic disturbances (Jaeger et al., 2014; Burrell et al., 2020). A major reason for this is water security. Not only are dryland rivers a source of water for a growing number of people (e.g., due to people disproportionately

moving to warmer, drier climates; Samson et al., 2012), but they also ensure food and economic security in arid regions by providing water for agriculture. Consequently, some of the most dramatic examples of hydrological interference can be seen in these systems (Petts, 2017).

Given the tremendous pressures on dryland rivers, there will likely be major impacts on the biodiversity of these systems and the services they provide. Because biodiversity in these systems is adapted to unpredictable, dynamic hydrological events, organisms endemic to these systems will likely be disproportionately affected by hydrological alterations (Ruhí et al., 2016). For example, flow regulation homogenizes flow regimes of these systems, which has been linked to factors that impact endemic species, including disrupting natural environmental cues native organisms use for reproduction and emergence (Ruhí et al., 2015). Mismatches in environmental cues, for example, can result in failed recruitment events in fish (Perkin et al., 2019) and alter consumer-resource linkages (Asch et al., 2019), which themselves link aquatic and terrestrial food webs (Nakano and Murakami, 2001). Moreover, many of the water column changes that impact endemic species favor invasive species, making it easier for species invasions to further threaten and reduce local biodiversity (Propst et al., 2008).

In conjunction with these anthropogenic pressures, climate change is expected to have disproportionate effects on systems in extreme environments (e.g., high latitude ecosystems, high-elevation deserts), including arid regions where climate change has already been associated with extreme changes (Birrell et al., 2020; Vincent, 2020). While the long-term average of climatic variables defines and characterizes dryland environments, unpredictable short-term variability (i.e., intra-annual variability) may be even more important for shaping river intermittency and altering river forms in diverse ways (see "Geomorphology of dryland rivers" section).

These complications require that climate change effects in dryland rivers be studied in context of predictions of increasing temperature and less frequent, higher magnitude flood events, as well as under different scenarios of change. These considerations are especially important given the profound, nonlinear changes expected for both ecosystems and human populations in dryland regions (Koutroulis, 2019). Additionally, intensifying droughts coupled with increasing water withdrawals is expected to decrease connectivity in dryland rivers, potentially altering fish dispersal and stocks, both seasonally and in the long term (Jaeger et al., 2014). Collectively, more extreme drying and flooding events will test the phenotypic plasticity (i.e., genetic-independent changes to an organism's behavior, morphology, or physiology in response to environmental change) of dryland river organisms to endure extreme changes, which in many cases are happening too fast for them to adapt (Woodward et al., 2010). Finally, with climate change expected to enhance the duration and intensity of drying in arid regions while increasing the frequency and duration of large magnitude floods, this uncertainty will lead to an intensifying struggle among stakeholders with competing interests, including those of indigenous peoples who use dryland rivers for social, cultural, and economic reasons (Barber and Woodward, 2018; Poelina et al., 2019). These issues will require proactive forms of inclusive communication and legislation to ensure environmental justice among all stakeholders (Shiva, 2016).

Conclusions and synthesis

Dryland rivers are highly variable, unpredictable systems that provide critical ecosystem functions and human services. Given that these systems have historically been understudied, and that their biodiversity has likely been underestimated (Ruhí et al., 2017), more focus on these systems is warranted, especially in context of how climate change will disproportionately affect them and interact with other anthropogenic disturbances to affect biodiversity and human wellbeing in the decades to come. Key knowledge gaps about dryland rivers include (1) how geomorphic (e.g., sedimentation, surface-groundwater exchanges) and biotic processes (e.g., dispersal and recruitment of organisms, food web dynamics) interact in these systems, particularly in high gradient systems prone to flash flooding, and (2) how these interactions relate to metacommunity dynamics, ecosystem functioning, and the provisioning of ecosystem services, and (3) understanding dryland rivers occurring in high latitude and high elevation regions, including in high- and low-elevation deserts and arctic regions, especially since these regions are expected to be disproportionately impacted by climate change (Birrell et al., 2020; Vincent, 2020).

Despite these knowledge gaps, progress can be made to better manage dryland rivers through better integration of knowledge we do have into adaptive management plans, which will require better communication among scientists and other stakeholders. Dryland rivers lack large-scale, long-term adaptive management programs, and there has been a general failure to integrate dryland rivers in whole-watershed management plans (Petts, 2017). Further, recent policy changes threaten the health and service provisioning of dryland rivers, including efforts to change the classification of dryland rivers to relax their environmental regulation (Popovich et al., 2021). These problems are compounded by piecemeal regulation across state, provincial, and national boundaries, which is particularly problematic for dryland rivers reliant upon infrequent pulses of water and nutrients (Kingsford et al., 1998).

Given the need for a of more holistic, collaborative resource management for dryland rivers, including management that crosses political boundaries and includes all stakeholders in management decisions (Kingsford et al., 1998), we propose an integrated nested-DPSIR framework (sensu Atkins et al., 2011) for understanding and adaptively managing these systems in the face of climate change and other anthropogenic pressures (Fig. 2). The DPSIR framework includes drivers (human activities impacting a system), pressures (causes of the human problems), state changes (the change in background status), impacts (impacts on ecosystems, ecosystem services, and human society), and responses (the human response). Key anthropogenic drivers causing pressures, state changes, and impacts to dryland river systems include (but are not limited to) urbanization, flow regulation, agricultural practices,

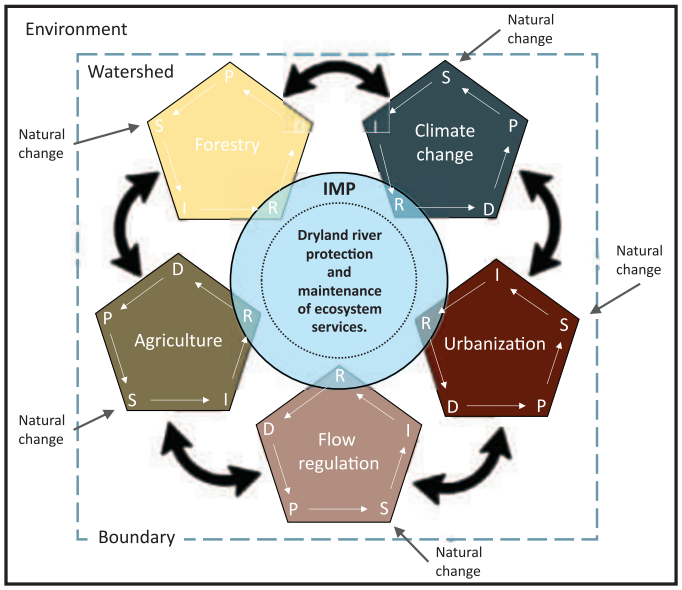

Fig. 2 Adaptive management framework for dealing with key anthropogenic system drivers expected to affect dryland rivers. This nested DPSIR framework shows the relationship of five key system drivers (D) and associated pressures (P), state changes (S), and impacts (I), which require management in the form of human responses (R). The dashed blue line depicts the watershed boundary, with everything outside this line representing the natural environment and changes associated with natural processes. Pentagons within the watershed boundary depict five key anthropogenically driven processes impacting dryland rivers. Effective management of dryland river systems will require adaptive human responses (to these and other drivers) and consider these processes together in a single, integrated management plan (blue circle). Modified from Atkins JP, Burdon D, Elliott M, and Gregory AJ (2011) Management of the marine environment: Integrating ecosystem services and societal benefits with the DPSIR framework in a systems approach. *Marine Pollution Bulletin*, 62(2): 215–226.

forestry practices, and climate change, which themselves are impacted by natural environmental change (Fig. 2). The adaptive, nested-DPSIR approach integrates existing management practices for key impacts to dryland river systems, while remaining flexible to the rapid accrual of basic knowledge about these systems that is important for proper management and protection in the context of an uncertain, changing world.

Intermittent Rivers and Ephemeral Streams

Thibault Datry[a] **and Rachel Stubbington**[b], [a]INRAE (French National Research Institute for Agriculture, Food and Environment), UR Riverly, Centre de Lyon-Villeurbanne, Villeurbanne, France; [b]Nottingham Trent University, Nottingham, United Kingdom

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Disturbance An event in which physical forces alter habitats, change resources and cause a biotic response characterized by the loss of organisms. Floods and drying are common disturbances in rivers.
Dry phase A period of time in which a channel has no flowing surface water, although isolated pools can persist, and water may be present beneath the sediment surface.
Ephemeral A flow regime in which flowing water occurs only in response to rainfall events, and flowing phases are thus unpredictable and typically short, lasting hours to weeks.
Flow cessation The point at which water in an IRES channel stops flowing from upstream to downstream.
Intermittence The state or quality of being *intermittent*, *ephemeral*, or having any other flow regime in which surface water sometimes stops flowing.
Intermittent rivers and ephemeral streams (IRES) Rivers and streams with ephemeral, intermittent or other flow regimes in which surface water sometimes stops flowing and is often partly or completely lost, resulting in channel drying, with or without isolated pools.
Intermittent A flow regime typically characterized by relatively long, predictable flowing phases and shorter, seasonal dry phases. Intermittent flow typically resumes in autumn/winter and continues until spring/summer, reflecting changes in precipitation and temperature.
Perennial rivers and streams Rivers and streams in which surface water never stops flowing from upstream to downstream.
Resilience The capacity of a biological entity (e.g. a species) to recover by colonization after a disturbance (such as drying, for an aquatic organism) ends.
Resistance The capacity of a biological entity (e.g. a species) to tolerate a disturbance (such as rewetting, for a terrestrial organism) in situ.

Intermittent rivers and ephemeral streams: Dynamic aquatic-terrestrial ecosystems

Intermittent rivers and ephemeral streams (IRES) are all rivers and streams in which water sometimes stops flowing, and many dry in part or completely (Datry et al., 2017a). The world's most widespread type of river ecosystem (Messager et al., 2021), IRES range from small ephemeral streams that occasionally flow for a few days after heavy rain to large intermittent rivers that recede to isolated

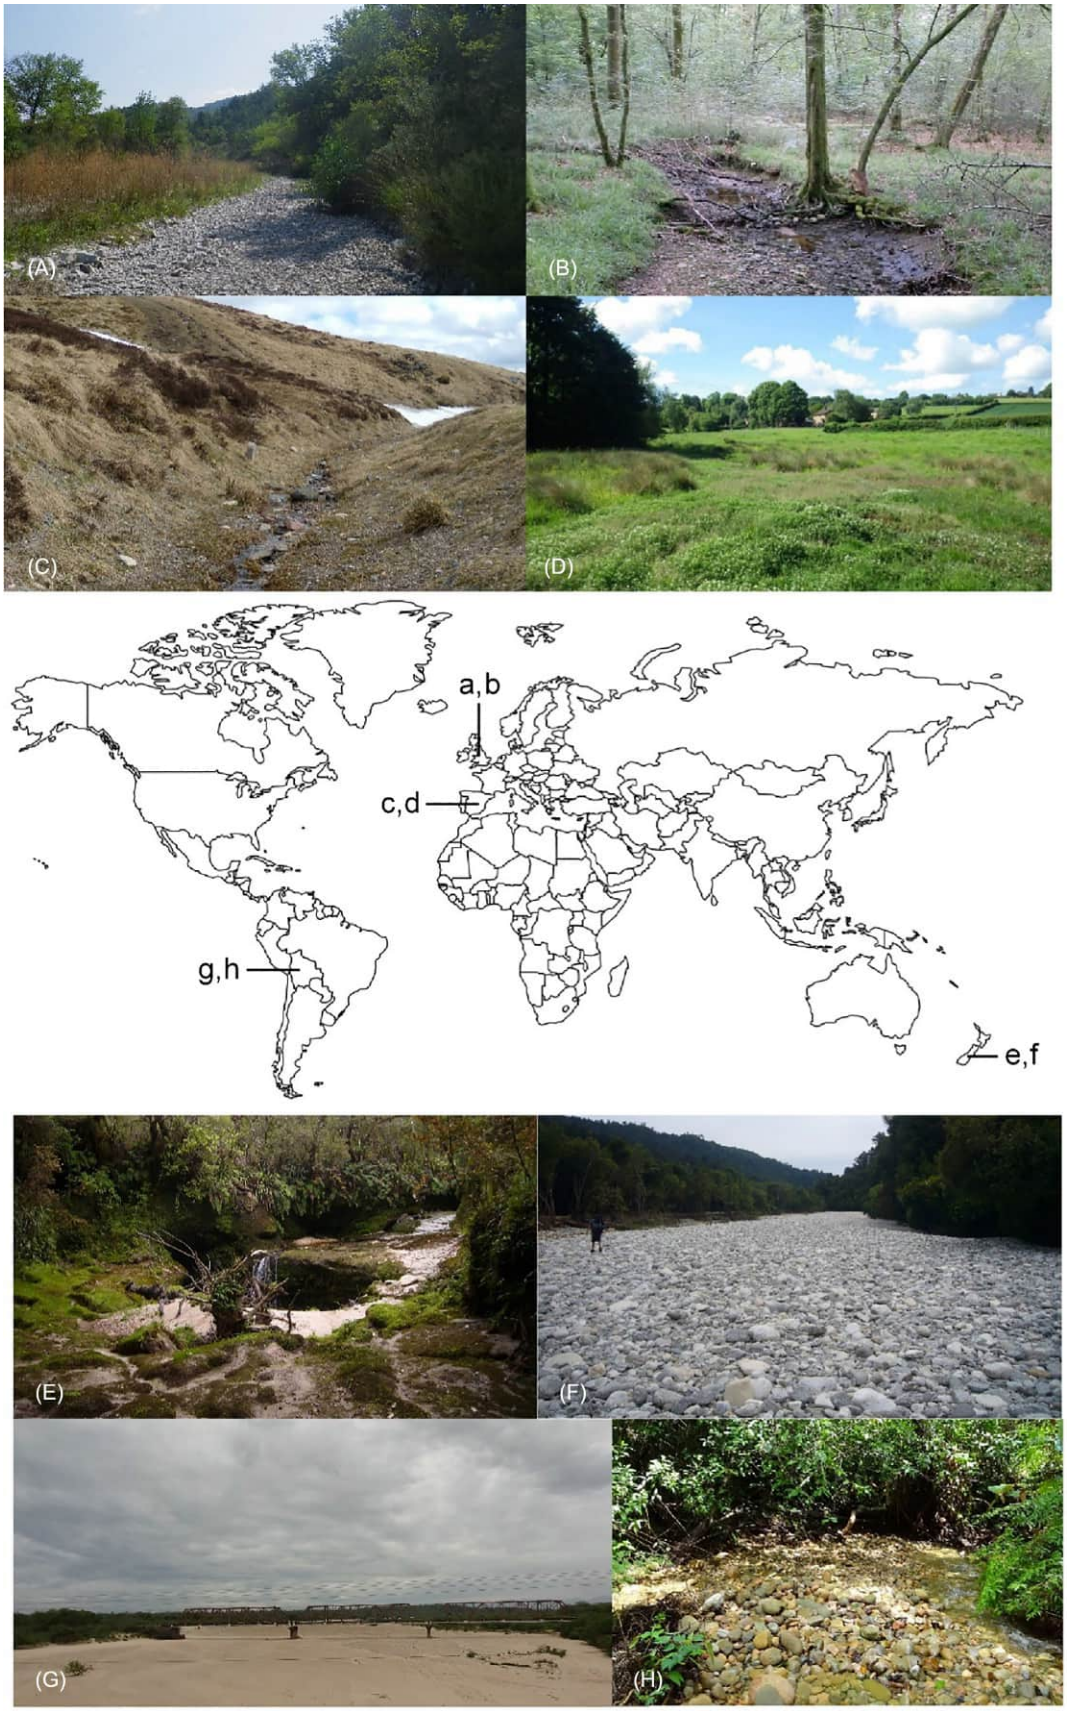

Fig. 1 Intermittent rivers and ephemeral streams are dynamic ecosystems in which habitat diversity varies within and among regions. Dry phases are shown in: (A) an alpine system and (B) a wooded Jura mountain stream, France; (C) a near-dry channel in the uplands of Scotland as snow recedes and (D) a vegetated 'winterbourne' stream in the lowlands of England, United Kingdom; (E) a karst limestone stream and (F) an alluvial cobble-bed river, New Zealand; and (G) a sand-bed channel and (H) an Amazonian stream, Bolivia. Photos: (A–B) and (E–H) T. Datry; (C) C. Macadam; (D) © Environment Agency of England; map © J. Bruce Jones (2019).

pools or dry only during severe droughts (Datry et al., 2017a). Also known globally as temporary or non-perennial rivers, the local names for IRES that exist around the world—such as arroyos, ramblas and winterbournes—highlight the physical diversity and cultural importance of this biome to people living in IRES basins (Steward et al., 2012). Several studies have assigned names to IRES classes in which flow ceases for differing durations and with varying predictability (e.g., Uys and O'Keeffe, 1997; Williams, 2006; Gallart et al., 2012), but terminology remains inconsistent, due to the considerable environmental variability within and between IRES subtypes (Fig. 1; Datry et al., 2017a; Shanafield et al., 2020; Zimmer et al., 2020).

IRES show complex alternations between aquatic and terrestrial conditions in both space and time, with important consequences for physical and biological processes (Datry et al., 2017a). They thus comprise dynamic, shifting mosaics of flowing, ponded and dry habitats, the extent and connectivity of which continually vary across drainage basins in response to groundwater levels and/or surface runoff and thus river discharge (Stanley et al., 1997; Datry et al., 2014; Jaeger et al., 2014). During long, uninterrupted flowing phases, physical habitats and ecological communities can become increasingly similar to those in nearby perennial rivers or streams. Equally, drying can have effects on communities and ecosystem processes that persist long after flow resumes (e.g., Datry et al., 2011; Piano et al., 2019), due to the replacement of drying-sensitive species by those with adaptations to drying (Armitage and Bass, 2013). After flow ceases, lentic waters ranging from extensive ponded reaches to tiny isolated pools are soon colonized by aquatic species from nearby surface waters such as ponds (Argyroudi et al., 2009). During dry phases, although riverbeds can remain distinct from adjacent soil-based environments (Arce et al., 2019), they can support a diverse range of terrestrial organisms.

In this chapter, we explore the hydrological, biogeochemical and ecological features that characterize a diverse range of IRES. We first present the global distribution and diversity of these ecosystems and outline their flow permanence regimes, including shifts between flowing, ponded and dry phases. We then explore how spatial and temporal heterogeneity in environmental conditions influence biogeochemical processes, aquatic and terrestrial communities and thus ecosystem functioning in IRES. Lastly, we identify major knowledge gaps, to stimulate further research that advances our understanding of, and thus our ability to protect, these unique ecosystems.

The global diversity of IRES ecosystems

IRES occur on all continents and dominate arid, semi-arid, and dry sub-humid regions, which represent more than half of the Earth's land surfaces (Messager et al., 2021). For example, 70% of Australian rivers are IRES (Sheldon et al., 2010), as well as up to 94% of river lengths in southwestern USA (i.e., Arizona, California, Colorado, Nevada, New Mexico and Utah; Levick et al., 2008). IRES also occur across alpine, boreal, continental, mediterranean, oceanic, polar and tropical regions (Datry et al., 2017a; Stubbington et al., 2017b). It is likely that every river network includes IRES, because small headwater streams—which are estimated to represent more than 70% of the total river network length—typically experience flow cessation and drying events (Benstead and Leigh, 2012).

IRES are increasing in space and time due to interactions between climate change and other human impacts (Larned et al., 2010; de Graaf et al., 2019). Climate-driven shifts from perennial to intermittent flow are predicted in the next decades for streams and rivers across global regions including Australia, Brazil, the southwestern USA, the Caribbean, southern and western Africa and the Mediterranean Basin (Döll and Schmied, 2012). In addition, in many natural IRES, dry phases are increasing in duration, frequency and spatial extent (e.g., Larned et al., 2011). Conversely, some natural IRES are predicted to become perennial in the Alps, Siberia, Canada and Alaska due to warmer winters, snowmelt and glacial melting (Döll and Schmied, 2012; Paillex et al., 2020).

The hydrological template of IRES

IRES are dynamic mosaics of lotic (aquatic, flowing), lentic (aquatic, ponded) and dry (terrestrial) habitats (Fig. 2). Integrating concepts and methods from lotic, lentic and terrestrial ecology can therefore enhance understanding of these unique ecosystems (Datry et al., 2014; Stubbington et al., 2017a,b).

Changing in-channel conditions: From wet to dry

Following a decline in surface runoff and/or groundwater levels (Fig. 2A), flow ceases and aquatic habitats within IRES channels typically fragment into pools (the ponded phase, Fig. 2B). The loss of flowing water exerts a strong pressure on biogeochemical processes and associated biota (Boulton, 2003). In isolated pools, water quality can quickly decline due to high temperatures, low dissolved oxygen and high nutrient concentrations (von Schiller et al., 2017), especially in pools without a connection to subsurface flow. Isolated pools often disappear as the duration of the dry phase increases, resulting in the complete loss of surface water (Fig. 2C). From this point, the surface channel no longer includes aquatic habitats, although it rarely resembles adjacent terrestrial habitats, instead retaining riverine characteristics (von Schiller et al., 2017; Arce et al., 2019). Sometimes, the subsurface sediments can remain saturated throughout a dry phase, offering a potential refuge in which aquatic organisms can survive (Stubbington, 2012). However, these subsurface sediments typically dry—but may retain moisture in interstitial spaces, especially in regions with year-round rainfall, enabling them to support aquatic organisms with some degree of desiccation tolerance (Boulton, 2003; Stubbington and Datry, 2013; Pařil et al., 2019). This sequence of in-channel changes crosses several critical thresholds, notably the loss of flowing water and subsequent loss of surface water (Boulton, 2003), although drying can also be considered a 'ramp' disturbance in which conditions gradually intensify over time (Lake, 2003).

Fig. 2 (A–D) Intra-annual and (E–H) interannual variability in dry, ponded and flowing phases in IRES. Alternating wet and dry phases in the Calavon River, southern France, in 2016: (A) a flowing phase in April; (B) a ponded phase in June; (C) a dry phase in August; and (D) just after rewetting in November. Within-season hydrological conditions can vary at single sites between years: a 'winterbourne' chalk IRES, United Kingdom, during: (E) winter flowing; (F) winter dry; (G) summer low-flow; and (H) summer dry phases. Changing in-channel conditions: Flowing water returns

In many IRES, rewetting extends from upstream to downstream as inputs from surface runoff and groundwater springs increase, but where the water table rises above the bed, rewetting can occur locally then extend in either direction (Arscott et al., 2010). Rewetting can coincide with the rapid onset of sustained flow or be a slower process in which isolated pools first fill then gradually become linked by surface flow (Fig. 2D; Jaeger and Olden, 2012, Godsey and Kirchner, 2014). Rewetting is typically more rapid than drying, although some IRES experience 'false starts' in which flowing surface water is fleetingly present or pools repeatedly fill and dry for weeks or months before flow establishes in earnest (e.g., Corti and Datry, 2012; Bhamjee et al., 2016). Sometimes, rewetting coincides with floods that generate novel habitats and scour mats of desiccated benthic algae and leaf litter, washing them downstream (Corti and Datry, 2012; Rosado et al., 2015).

Drying and rewetting patterns occur at multiple spatial scales

Drying and rewetting patterns in IRES occur at multiple spatial extents from the microhabitat to the regional scale (Costigan et al., 2016; Hammond et al., 2021). At regional scales (i.e., biogeographical regions), patterns are determined by interacting environmental factors including climate and geology, with greater evapotranspiration to precipitation ratios promoting intermittence as aridity increases (Fig. 3A; Costigan et al., 2016, Messager et al., 2021). Permeable surface geologies that enable infiltration and groundwater recharge after rainfall subsequently deliver water that sustains surface flow, whereas impermeable geologies rapidly deliver water to channels, creating short flow pulses separated by long dry periods (Costigan et al., 2016, Hammond et al., 2021). However, substantial variation in IRES flow regimes occurs both within and among regions and climatic zones, often preventing robust generalizations (Boulton et al., 2017).

At intermediate scales (i.e., from the river segment to river basin), rainfall can increase sediment moisture or cause rewetting and flow resumption in some streams while adjacent channels stay dry, and the predictability of flow is particularly low in arid and semi-arid regions (Boulton et al., 2017). Such spatial variability in flow varies among events, seasons and years, which contributes to IRES habitat heterogeneity (Figs. 2 and 3B; Costigan et al., 2016). Differences in patterns and rates of drying and rewetting also occur in response to spatial variability in bedrock, overlying sediments and climatic conditions, which collectively influence infiltration and evapotranspiration and thus transmission losses along channels (Boulton et al., 2017).

At local scales (i.e., within reaches), drying and rewetting can be asynchronous among adjacent habitats due to local variation in channel microtopography and sediment permeability: low-lying, fine-grained microhabitats fill earlier, hold water for longer, and dry more slowly than coarse-grained riffle crests (Costigan et al., 2016). These fine-scale patterns generate heterogeneous mosaics of habitat patches of varying size and permanence, and with varying physicochemical, biogeochemical and biological conditions (Fig. 3C; Boulton et al., 2017).

The biogeochemical template of IRES

River networks transport a variety of dissolved and particulate materials such as inorganic nutrients (e.g., nitrogen and phosphorus) and organic matter, which constitute the base for stream food webs and thus support wider ecosystem functioning. River networks play key roles in global biogeochemical cycles (Raymond et al., 2013), but the occurrence of ponded and dry phases alters processes in IRES, and our understanding of their contribution to global cycles is still developing (von Schiller et al., 2017). Most biogeochemical cycles, which result from the input, transformation, production, export and removal of dissolved and particulate materials, are controlled in IRES by factors such as free water availability and sediment humidity, temperature, and flow velocity (Shumilova et al., 2019). Shifts between dry and wet phases generate pulsed nutrient and organic matter inputs, processing periods, and transport events (Fig. 4; von Schiller et al., 2017, del Campo et al., 2021).

Biogeochemical responses to changing in-channel conditions: Ponded and dry phases

When flow ceases, so too does the transport of dissolved and particulate materials from upstream to downstream. Particulate matter is deposited and accumulates in pools and on dry sediments (Datry et al., 2018), potentially including leaf litter from riparian plants and stranded aquatic organisms such as fish and invertebrates (Fig. 4). Evapotranspiration continues during ponded and dry phases, further reducing water levels in surface pools and consequently increasing concentrations of dissolved substances including inorganic nutrients, supporting algal growth.

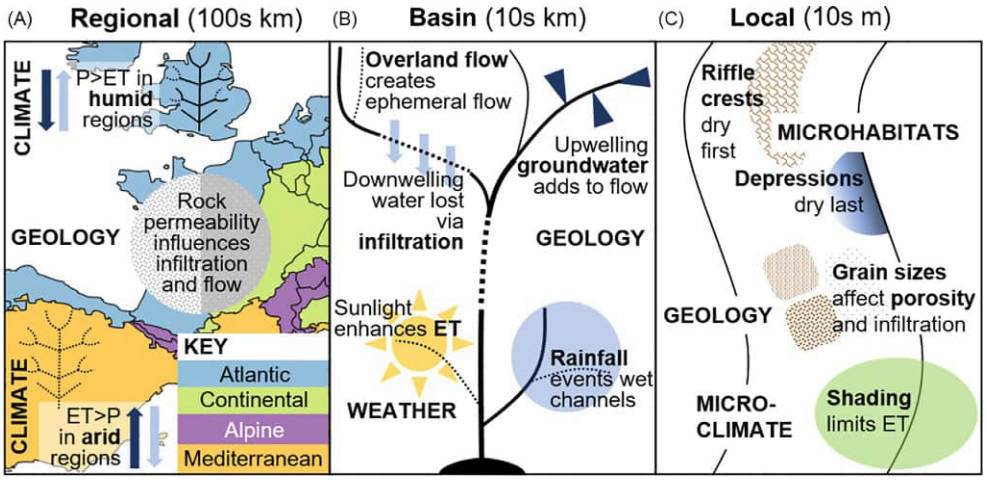

Fig. 3 Geology and climate are the key natural drivers that influence flow intermittence at multiple, nested spatial scales from (A) large, regional scales to (B) intermediate, segment-to-basin, scales and (C) local, reach scales. Reis, 2006, CC BY-SA 3.0 (https://creativecommons.org/licenses/by-sa/3.0/).

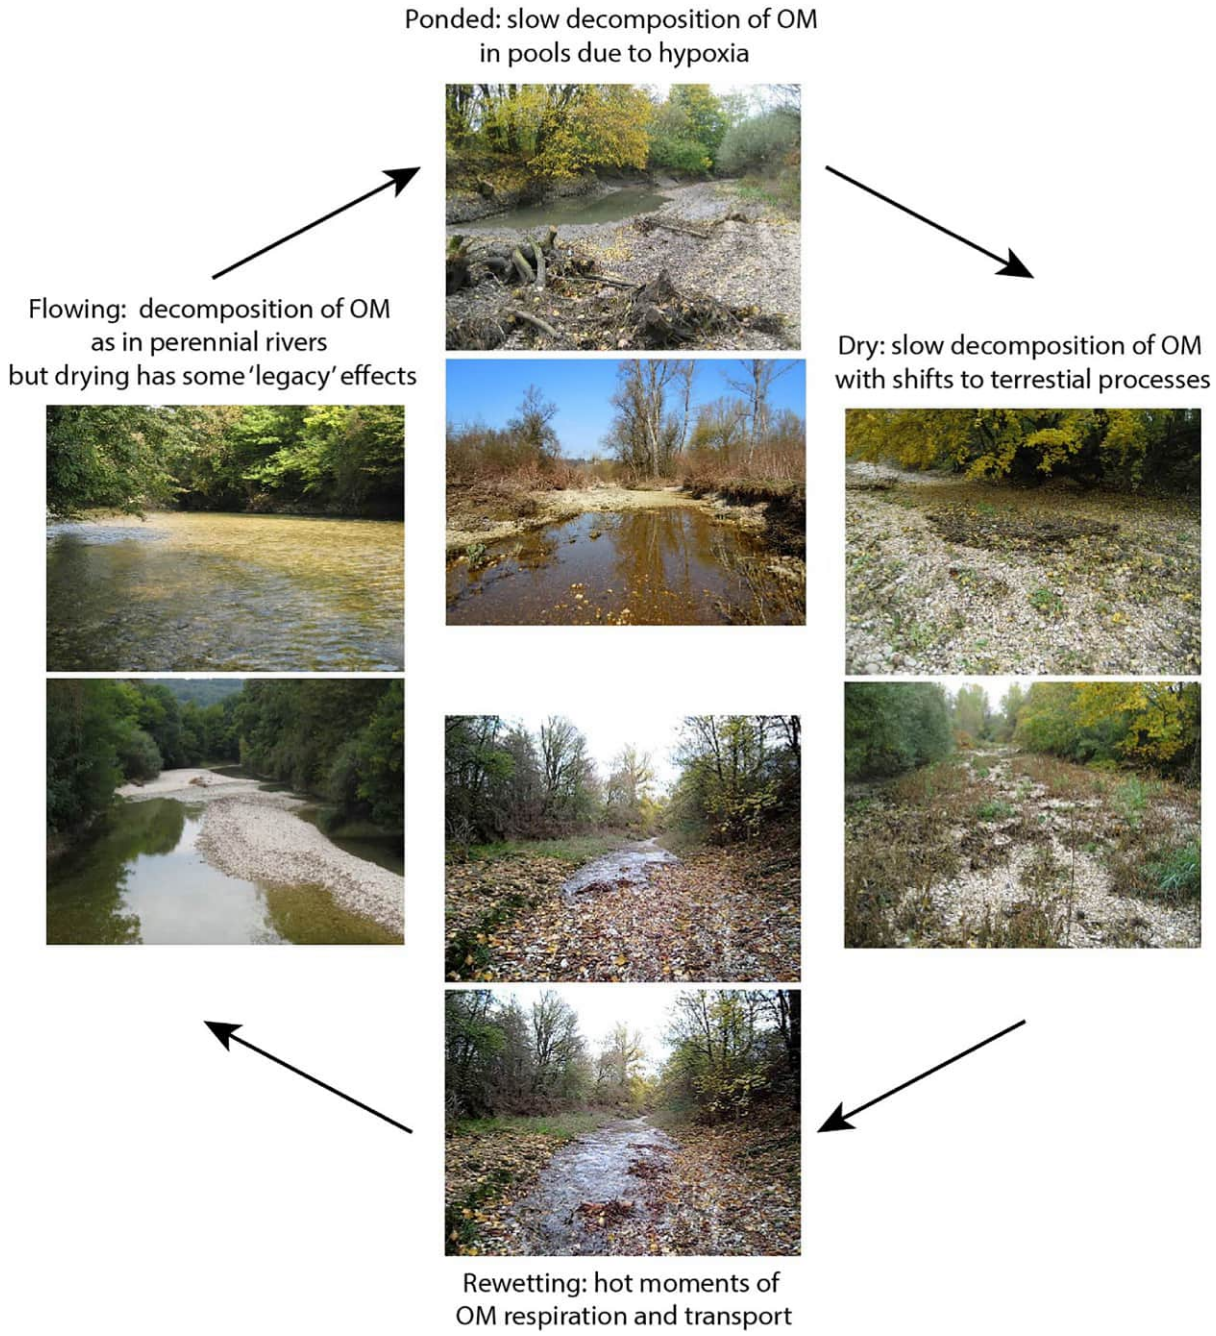

Fig. 4 Changes in the rates and modes of organic matter (OM) decomposition in the Albarine River, France, during flowing, ponded, dry and rewetting phases. The temporal sequence can vary (e.g., some IRES do not have ponded phases). Photos: T. Datry.

Biofilms associated with 'dry' sediments may slowly continue to process organic matter and nutrients, with rates limited by sediment moisture (von Schiller et al., 2017). Organic matter is decomposed very slowly during dry phases, due to reduced activity of aquatic invertebrates and microorganisms (Fig. 4; Corti et al., 2011, von Schiller et al., 2017). However, when exposed to solar radiation, organic matter on the dry riverbed can be partly decomposed by photodegradation (von Schiller et al., 2017). In addition, the activities of terrestrial animals (e.g., insects and mammals) and plants that colonize dry riverbeds can modify the quantities and types of organic and inorganic resources (Fig. 4; Steward et al., 2017, Masese et al., 2020).

In pools and in saturated and/or moist sediments beneath dry riverbeds, the activity of some anaerobic microbes can continue, leading to spatial and temporal variation in the concentrations of inorganic nutrients (Merbt et al., 2016). Accumulations of organic matter can also promote high respiration rates in isolated pools, depleting dissolved oxygen as temperatures rise, and generating

hypoxic conditions that cause shifts in biogeochemical processes (von Schiller et al., 2017). For example, methanogenesis can replace aerobic respiration when dissolved oxygen concentrations become low (Gómez-Gener et al., 2016, 2021). Hypoxia can also promote denitrification processes in pools, with the reduction of nitrate ions associated with an increase in ammonium concentrations (von Schiller et al., 2017; Gómez-Gener et al., 2021).

Biogeochemical responses to changing in-channel conditions: Flowing water returns

When flow resumes, rewetting of dry organic materials and riverbed sediments reactivates dormant organisms within biofilms, triggering pulses of microbial activity (Fig. 4; von Schiller et al., 2017). Experimental inundation of dry sediments (Shumilova et al., 2019; von Schiller et al., 2019) and accumulated terrestrial leaf litter (Datry et al., 2018) has shown that rewetting is associated with high respiration rates and thus rapid leaching of nutrients from dry organic matter. Acting as 'hot moments' of metabolic activity, these rewetting events can emit considerable CO_2 to the atmosphere (Fig. 4; Datry et al., 2018; Keller et al., 2020). These periods of intense microbial respiration can also send pulses of anoxic waters downstream, killing animals including fish (von Schiller et al., 2017) and reducing water quality in receiving waters including reservoirs, large rivers and estuaries.

The aquatic-terrestrial biodiversity of IRES

Diverse aquatic and terrestrial communities inhabit IRES during wet and dry phases, respectively, including representatives of all major taxonomic groups: vertebrates encompassing fish, amphibians, reptiles, birds and mammals; macroinvertebrates and microinvertebrates; plants including flowering plants and bryophytes; and microorganisms (Datry et al., 2017a). Macroinvertebrates are particularly abundant, diverse and well-studied, and have important ecological roles. This group includes mollusk, flatworms, worms and arthropods, the latter including major contributors to the IRES fauna, namely insects, crustaceans and arachnids (Steward et al., 2017; Stubbington et al., 2017a,b). Microorganisms also make notable contributions to IRES ecosystem functioning, with the biofilms that cover IRES substrates including algae, with particular biodiversity noted for diatoms; bacteria, including a diverse range of cyanobacteria; and fungi and archaea, although these two groups are poorly known (Sabater et al., 2016; Romaní et al., 2017).

Resistance and resilience traits promote species persistence in IRES

IRES communities experience profound shifts in composition between flowing, ponded and dry phases, encompassing species across a continuum of environmental preferences from obligate aquatic to fully terrestrial (Stubbington et al., 2017a,b). Although often predictable, dry and wet phases represent disturbances that disrupt aquatic and terrestrial biotas, respectively. As such, all IRES inhabitants require adaptations that enable their use of these dynamic habitats. Adaptations can be considered as functional traits that promote resistance, defined as the capacity to tolerate a disturbance—i.e., dry and wet conditions for aquatic and terrestrial species, respectively—in situ, and those confer resilience, which describes the capacity to recover after a disturbance (McGill et al., 2006; Bogan et al., 2017). Both resistant and resilient organisms thus contribute to post-disturbance community recovery. Traits promoting resistance typically involve physiological tolerance of either inundation or drying, whereas resilience is enhanced by behaviors enabling refuge use during unfavorable conditions and/or facilitating dispersal after favorable conditions return (Bogan et al., 2017).

Biotic responses to changing in-channel conditions: Flowing water returns

When a dry channel rewets and flow resumes, mobile terrestrial organisms with behavioral adaptations can avoid advancing wetted fronts; for example, many adult ground beetles (Carabidae) are winged and can escape by flight (Bonn, 2000). Others are engulfed by water and are either washed downstream or stranded in inundated sediments (Corti and Datry, 2012), alongside the submerged roots of terrestrial plants. Here, terrestrial organisms that lack escape mechanisms or inundation tolerance will die and can become prey for aquatic scavengers and generalist feeders (Nakano et al., 1999).

Concurrent colonization by aquatic organisms can be rapid (Bogan et al., 2017). First, water triggers the development and emergence of resistant organisms such as desiccation-tolerant microorganisms in dry biofilms and lifeforms within aquatic invertebrate 'seedbanks' (see below). At the same time, resilient species with strong dispersal abilities colonize from nearby refuges, including drifting diatoms, actively swimming fish and flying insects, which arrive from upstream, downstream and nearby perennial waters, respectively (Peterson and Bayley, 1993; Robson et al., 2008; Bogan and Boersma, 2012). Others migrate short vertical distances from saturated subsurface sediments (Kawanishi et al., 2013; Vander Vorste et al., 2016). Over time, as flowing phases continue, communities become increasingly similar to those in nearby perennial rivers if species with weaker dispersal abilities join the early colonists (Stubbington et al., 2017a,b). However, communities remain distinct where colonist sources are limited by widespread drying (Davey and Kelly, 2007) or are disconnected from rewetted reaches by barriers (Labbe and Fausch, 2000). IRES biodiversity thus typically remains lower than in perennial streams when peak aquatic taxonomic richness is compared at small spatial scales (Soria et al., 2017), because the absence of drying-sensitive species that fail to colonize after water returns (Davey and Kelly, 2007; Chadd et al., 2017) is offset by the localized occurrence of just a few IRES specialists (Armitage and Bass, 2013).

Biotic responses to changing in-channel conditions: Flowing waters recede, dry habitats expand

Perhaps days later in some ephemeral streams but months later in intermittent rivers, water depths decline, submerged habitats shrink, and mobile aquatic organisms become concentrated in remaining wetted areas (Boulton, 2003), causing a brief increase in population densities during flow recession (Stubbington et al., 2011). The loss of flow represents a critical ecological threshold that imperils obligate lotic species, such as invertebrate filter-feeders that consume fine particles of organic matter delivered by flowing water (Boulton, 2003). As ponded reaches contract into connected then isolated pools, the decline in water quality—and in particular, low dissolved oxygen concentrations—can kill sensitive species including fish and mayfly and stonefly juveniles (Chadd et al., 2017; Kerezsy et al., 2017). At the same time, biotic interactions intensify, with predators feasting on oxygen-deprived prey (Boulton, 2003). These predators include persisting lotic species with broad environmental tolerances such as gammarid amphipods, lentic species such as dragonfly juveniles, and terrestrial species, notably piscivorous birds and mammals such as herons and otters (Steward et al., 2017). Despite these interacting abiotic and biotic pressures, pools are an important refuge for groups including aquatic invertebrates (Bogan et al., 2017), fish (Rodríguez-Lozano et al., 2019) and turtles (Leidy et al., 2016).

The shrinkage of submerged habitats equates to the expansion of exposed, drying sediments, and mobile terrestrial organisms soon arrive to exploit resources including subsurface water (Kiss, 2016), stranded aquatic organisms (Paetzold et al., 2005) and humid microhabitats (Langhans and Tockner, 2014). Many colonists are resilient and originate from marginal, riparian and wider terrestrial habitats, but others may persist in situ during wet phases as inundation-resistant forms (Steward et al., 2011; Corti and Datry, 2016). Predatory invertebrates including ground beetles prowl the surface of drying sediments, devouring stranded dead and dying aquatic invertebrates (Fig. 5; Paetzold et al., 2005); fish carcasses may also attract terrestrial organisms from fungal decomposers to vertebrate scavengers (Steward, 2012). Springtails span the surface and subsurface sediments, feeding on newly exposed biofilms (Langhans and Tockner, 2014), and themselves becoming prey for ground beetles—some of which are specialist springtail predators (Riddick, 2008). This transfer of aquatic-derived energy through trophic levels into mobile animals might create dry-phase food webs that extend deep within the beds of riverine ecosystems and far into their surrounding basins (Paetzold et al., 2005; O'Callaghan et al., 2013). As well as energetic resources, IRES channels can represent relatively cool, humid corridors that

Fig. 5 Terrestrial animals use the resources in IRES channels: (A) a wild elephant digs to access subsurface water resources in South Africa; (B) a domesticated cow drinks from a ponded reach in England; (C) a deer walks through a shaded channel in France; (D) a predatory lycosid spider searches for stranded aquatic prey in drying sediments. Photos: (A) © Gabriella Kiss; (B) © Environment Agency of England; (C) B. Launay; (D) T. Datry.

attract terrestrial vertebrate and invertebrate animals seeking shelter from heat and access to drinking water in either surface pools or subsurface sediments, in particular during long migrations (Fig. 5; Langhans and Tockner, 2014, Kiss, 2016, Sánchez-Montoya et al., 2016).

Biotic responses to changing in-channel conditions: Surface water is lost

With or without the persistence of scattered pools, the loss of surface water is a fundamental threshold in the drying process, at which many aquatic organisms die (Boulton, 2003). However, where subsurface sediments remain saturated, many invertebrates (Vander Vorste et al., 2016) as well as vertebrates including fish (Kawanishi et al., 2013; Rodríguez-Lozano et al., 2019) and juvenile salamanders (Feral et al., 2005) may respond to surface drying by migrating downwards into saturated interstices—if sediment characteristics permit (Stubbington, 2012). If interstices remain saturated, long-term survival then partly depends on whether abiotic factors such as oxygen concentrations remain tolerable for the days, weeks or months for which a dry phase continues.

Many aquatic species survive in sediments that have lost free water but remain humid (Strachan et al., 2015; Pařil et al., 2019). IRES biofilms commonly support desiccation-tolerant organisms including cyanobacteria and algae whose metabolism slows in accordance with interstitial humidity (Romaní et al., 2017). In addition, some eggs, juveniles and adults of aquatic invertebrates have some degree of desiccation tolerance, and a diverse range of insects (including beetles, and true fly and caddisfly juveniles), crustaceans, molluscs and mites thus form a so-called 'seedbank' or egg bank (Stubbington and Datry, 2013). The moisture requirements of some active seedbank residents are surpassed as dry phase durations increase, and they perish (Datry et al., 2012; Stubbington and Datry, 2013). Others—in particular microcrustaceans from the Cladocera, Copepoda and Ostracoda—become the 'living dead', entering dormant states in which water requirements are minimized by slowing metabolism to below detection levels (Ricci and Fontaneto, 2009). In IRES that have experienced seasonal drying over evolutionary timescales, vertebrates have also evolved desiccation tolerance. Notably, killifish (order Cyprinodontiformes) persist for months as desiccation-tolerant diapausing eggs in the dry sediments of African IRES (Furness, 2016).

As dry habitats extend in space across the channel, from upstream to downstream and sometimes into the subsurface, and as dry durations increase from hours to years, terrestrial colonists may collectively form complex assemblages. Terrestrial invertebrates are the best-known group, with common dry-channel inhabitants including springtails; ants; spiders, in particular wolf spiders; and beetles, especially ground and rove beetles (Steward et al., 2017). Collectively, these taxa may make a greater contribution to overall channel biodiversity than the aquatic invertebrates active during wet phases (Corti and Datry, 2016). However, biodiversity estimates to date have typically been constrained by coarse, variable taxonomic resolution (but see Sánchez-Montoya et al., 2020). In addition, we know little about how the structure and functioning of dry-phase communities respond to environmental variability. In particular, biotic responses remain uncharacterized for a fundamental habitat transition: from the dry riverine channels of intermittent systems with short dry phases, to the terrestrialized channels of ephemeral streams in which drying is extensive enough to support sediments and vegetation characteristic of adjacent riparian habitats (Arce et al., 2019).

Responses to changing environments create high biodiversity

Despite their lower aquatic alpha diversity (Soria et al., 2017), IRES have higher spatial and temporal habitat heterogeneity than perennial rivers and streams, due to the occurrence of flowing, ponded and dry habitats at multiple points throughout a river network. This heterogeneity enables these dynamic ecosystems to support ever-changing assemblages of species with a wide range of environmental preferences (Larned et al., 2010; Stubbington et al., 2017a,b). This compositional variability in space and time (i.e., spatial and temporal beta diversity) may enhance both the aquatic biodiversity of IRES compared to equivalent perennial systems (Datry et al., 2016; Tonkin et al., 2017) and their terrestrial biodiversity compared to that in the surrounding land (Sánchez-Montoya et al., 2020). However, further research is needed to quantify how intermittence affects regional (i.e., gamma) biodiversity in riverine networks with varying extents of IRES reaches (Sarremejane et al., 2020).

IRES communities interact within meta-ecosystems

Much research characterizing biotic responses to flow intermittence has considered communities sampled at local spatial scales, i.e., at a few sites within one IRES. In contrast, recent conceptualizations have positioned populations, communities and ecosystems within meta-populations, meta-communities and meta-ecosystems linked by dispersal (Datry et al., 2017b; Cid et al., 2020). In IRES, flowing phases that extend throughout river basins create landscape-scale networks of longitudinally connected habitats in which aquatic biota can move (Fig. 6C), but which may represent barriers to lateral migration of ground-dwelling terrestrial organisms (Fig. 6A). Accordingly, surface water loss can restrict movement by obligate aquatic species to the subsurface sediments (Fig. 6D) while creating opportunities for ground-dwelling terrestrial organisms to venture across channels that dissect terrestrial habitat patches when wet (Fig. 6B; Stubbington et al., 2017a,b).

Meta-community dynamics thus influence community resilience, with local communities situated within well-connected meta-communities recovering most rapidly after a disturbance ends, then experiencing reductions in spatial beta diversity due to community homogenization (Datry et al., 2017b). For example, after rewetting in IRES reaches positioned between perennial upstream and downstream waters, aquatic communities soon resemble those in adjacent reaches (Storey and Quinn, 2008; Datry et al., 2014). Equally, aquatic communities in isolated headwaters may return to a pre-drying state more slowly after flow resumes,

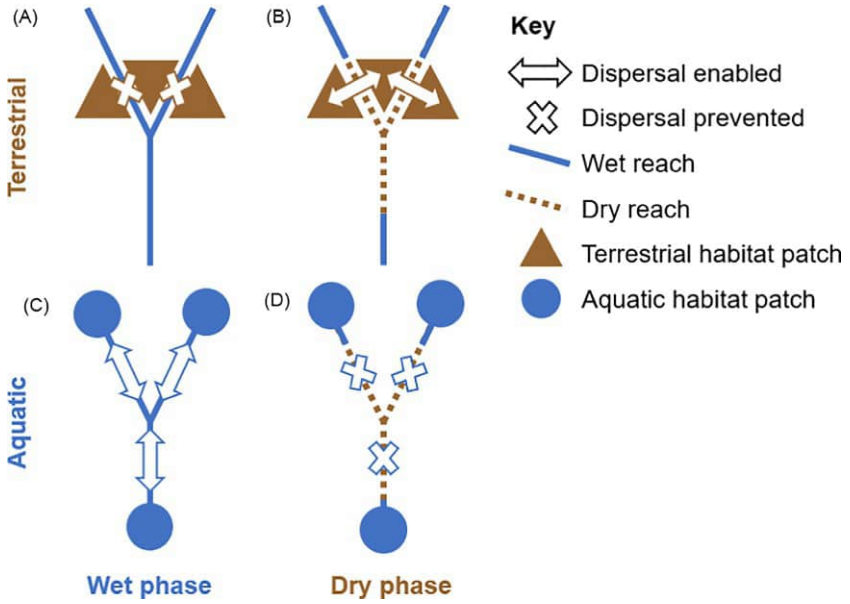

Fig. 6 A conceptual model comparing the effects of wet and dry phases on the dispersal of fully aquatic and ground-based terrestrial organisms among comparable habitat patches within meta-ecosystems: dispersal of terrestrial organisms is prevented (A) and enabled (B) during wet and dry phases, respectively; conversely, aquatic dispersal is enabled (C) and prevented (D) during wet and dry phases, respectively.

and then remain distinct from those at perennial sites—as well as from nearby IRES, if early colonists have a long-term influence on community assembly (Davey and Kelly, 2007). The role of drying as a source of fragmentation in river networks that alters dispersal is still poorly explored, but it could be as important a determinant of riverine biodiversity as the effects of local drying on local communities (Phillipsen and Lytle, 2013; Gauthier et al., 2020).

Because drying facilitates dispersal by ground-dwelling organisms, terrestrial meta-community succession and associated heterogeneity can be overridden by mass effects in dry riverbeds (Steward et al., 2017). Mass effects may be amplified as channels dry if resources including stranded aquatic prey motivate riparian predators and scavengers with strong ground-based dispersal abilities to enter habitats that otherwise align poorly with their environmental preferences (Corti and Datry, 2016). Mass effects may also introduce passive aerial dispersers such as spiders into channels, and gravity may then impede their windblown return to riparian habitats (Tonkin et al., 2015). The temporal trajectories that in-channel terrestrial communities follow as dry phases extend in time remain uncharacterized (but see Corti and Datry, 2016, Sánchez-Montoya et al., 2020), with variability expected from diurnal to seasonal scales, as well as in response to changing habitat conditions (Steward et al., 2017). Differences in both the spatial and temporal organization of colonist sources within IRES, their riparian corridors and the wider landscape are therefore likely to have contrasting effects on aquatic and terrestrial meta-community dynamics, with consequences that reverberate through aquatic-terrestrial food webs. Whereas the terrestrial predators that consume aquatic prey in dry riverbeds transfer trophic resources from in-channel to riparian habitats during dry phases (Corti and Datry, 2016), terrestrial organisms engulfed by advancing wetted fronts supply energy to aquatic organisms (Corti and Datry, 2012; Rosado et al., 2015). Further research is needed to determine how these shifts in trophic interactions influence the flow of energy through IRES meta-ecosystems.

Towards better understanding and protection of IRES

Although our understanding of IRES has advanced considerably in recent years (Larned et al., 2010; Datry et al., 2017a; Stubbington et al., 2017a,b; Allen et al., 2020), knowledge gaps still limit our capacity to manage these diverse ecosystems (Datry et al., 2017c). First, locating and mapping IRES remains challenging because discharge gauging networks are strongly biased towards perennial rivers and streams (Beaufort et al., 2018), although alternative methods are emerging, such as citizen science initiatives (e.g., Allen et al., 2019), spatial interpolation based on point measurements (e.g., Beaufort et al., 2018) and remote sensing technologies (e.g., Borg Galea et al., 2019). The lack of continuous discharge data also limits our ability to classify the considerable diversity within IRES flow regimes and identify the underlying drivers of intermittence (Costigan et al., 2016; Hammond et al., 2021), hindering the implementation of environmental flows in IRES (Acuña et al., 2020).

Second, IRES aquatic-terrestrial biodiversity is still poorly explored at regional scales (Soria et al., 2017). Interactions between aquatic and terrestrial organisms are a major feature of perennial rivers (e.g., Baxter et al., 2005) and are probably even more significant in IRES, particularly during drying and rewetting phases (Steward et al., 2017). This includes exchange of materials and

energy through reciprocal subsidies and intertwined food webs between channel and riparian habitats. The extent to which our developing knowledge of biodiversity in natural IRES can be applied to new, artificial IRES is also unclear, but contrasting responses may be observed for biotas experiencing flow cessation and drying for the first time due to climate change and other anthropogenic drivers (Pařil et al., 2019; Crabot et al., 2021). Equally, ecological responses to artificial flow perennialization (Hassan and Egozi, 2001; Steward et al., 2012), notably caused by wastewater effluent releases (Luthy et al., 2015), have not yet been quantified.

Third, the role of IRES in global biogeochemical cycles remains poorly understood, although some studies have suggested that IRES could contribute disproportionally to carbon cycles due to the hot moments of carbon processing that occur during rewetting events (Datry et al., 2018; von Schiller et al., 2019; Keller et al., 2020). The consequences of the pulsed processing of carbon, nitrogen and phosphorus within IRES require exploration, in particular to inform the management of IRES in urban areas (Luthy et al., 2015). How flow intermittence shapes biodiversity-ecosystem function relationships is also a promising and timely research avenue, with IRES representing model ecosystems in which to examine the effects of disturbance on these relationships, which is still an open question in ecology (Gamfeldt and Roger, 2017; Barnes et al., 2018).

Finally, despite recognition of widespread degradation due to human activities, the legislative status of IRES remains ambiguous, inadequate or non-existent across nations, which contributes to their ongoing degradation (Acuña et al., 2014; Fritz et al., 2017). For example, the future legislative protection of most IRES remains uncertain in the USA (Marshall et al., 2018, United States Environmental Protection Agency, 2021), and in Europe, IRES challenge implementation of the Water Framework Directive (Stubbington et al., 2018; Acuña et al., 2020). Following recognition of their global prevalence, their considerable physical and biological diversity, and their key contributions to wider ecosystem functioning, now is the time for scientists to unite with environmental managers and policy makers to integrate IRES into updated legislation that grants these dynamic ecosystems the protection they deserve.

Biodiversity Conservation of Aquatic Ecosystems

Simon Linke[a] **and Virgilio Hermoso**[b], [a]CSIRO Land & Water, Brisbane, QLD, Australia; [b]Centre de Ciència i Tecnologia Forestal de Catalunya, Lleida, Spain

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Area-based conservation strategies These cover management or governance approaches that are applied to specific geographic areas and have objectives and/or outcomes relevant to conservation and sustainable use.
Conservation feature Biophysical attributes that can be mapped to a planning unit. Examples are a class in a classification, a certain vegetation type or a single fish species.
Cost In conservation planning terminology, cost is a summary term used to describe constraints in the optimisation. A typical example is planning unit area; however, cost can also include measures of ecological condition, vulnerability or pre-determined priorities. Multiple constraints can be combined to a single cost.
Drivers of biodiversity loss The main causes of biodiversity loss are demand for food, energy, water, as well as increased urbanization, international trade, climate change.
Integrated catchment management Management of freshwater ecosystems requires strategic decision-making to integrate multiple and often conflicting objectives, such as exploitation of freshwater resources and biodiversity conservation.
IUCN Redlist The world's most comprehensive inventory of the global conservation status of biological species. Species are assigned a rating from "Extinct," through various threat categories to "Least Concern."
Pressures Mechanisms by which the drivers act in biodiversity loss, for example water abstraction, river regulation, species exploitation, pollution, land-use transformation.
Restoration The assisted recovery of the biophysical processes that support river self-sustainability.
Systematic Conservation Planning A structured, step-wise and iterative approach to identify priority areas for conservation management actions to best represent and sustain the biodiversity of areas in the most cost-effective way (often used synonymously with spatial conservation prioritization, etc.). Most modern systematic planning approaches are based on the CARE principles: comprehensiveness, adequacy, representativeness and efficiency. Efficiency is usually provided by a complementarity-based strategy.
Wetland Is used analogously to the Ramsar definition, including all lakes and rivers, underground aquifers, swamps and marshes, wet grasslands, floodplains and peatlands.

Introduction and status of global protection

Freshwater systems are among the most endangered biomes globally (Dudgeon et al., 2006; Dudgeon, 2019). This is partly due to the connected nature of rivers, streams, lakes and wetlands. Threats to freshwater systems are often non-localized and can be propagated both longitudinally—along the river, usually from up- to downstream—but also laterally from the river to the associated floodplains (Linke et al., 2019a). Often, human populations reside close to freshwater systems, for the services provided by rivers, lakes and wetlands. These services include clean water for drinking and sanitation, carbon sequestration, erosion

prevention and local climate regulation. Another key service is food production, both instream through harvesting fish populations, crustacea and aquatic plants but also using irrigated agriculture (Green et al., 2015; Boulton et al., 2016).

A recent review identified key drivers and pressures to freshwater ecosystems and biodiversity (Acreman et al., 2020; Fig. 1). The drivers and pressures include

- Increased demand for food, energy and water: Abstraction for drinking water and irrigated agriculture will lead to river regulation and changed flow regimes. Demand for hydropower—often falsely seen as "clean green energy" can change flow regimes greatly. Overharvesting of aquatic populations, especially fish by a growing population is another pressure.
- Expansion of urban area leads to changes in hydrology and water chemistry, with flows becoming flasher and pollution washing into waterways.
- Climate change is an overarching threat, changing not only flow, but also thermal regimes and through increased flooding also exchange between the river and the surrounding floodplain. In some areas of the world, river habitat can disappear completely through greatly reduced inflow.

This leads to habitat loss and degradation, a decrease in native biodiversity and a change in species movements between habitats, driving a decline in species populations and ultimately species extinctions.

While protected areas are not the only strategy to conserve freshwater ecosystems and biodiversity, national parks and other areas designed to conserve nature represent an important contribution to conservation. Most protected areas were designed with terrestrial biodiversity in mind. They thus lack "integrated protection"—a term recently coined for adequate protection of upstream areas (Abell et al., 2017). A few rivers still have high rates of integrated protection, for example in the Amazon basin where 42.5% of river kilometers are assessed as adequately protected. That said, the lower reaches of the Amazon where flow exceeds 10,000 m^3/s are only 17% protected. Other large rivers yield lower protection, for example the Mekong (15.8%), the Yangtze (12.6%) and the Danube (9.2%). Among the lowest protection rates are the Volga (3.5%), the Rio Grande (3.3%) and the Mississippi at only 1.9%. The case of the Murray-Darling—the largest river in Australia—demonstrates that configuration of protection matters. While a total of 8.1% are protected, only 3.5% have adequate upstream protection (Fig. 2).

A global tally of wetland protection painted a similar picture of underrepresentation (Reis et al., 2017). While South America protected 17% of their wetlands, only 7% are covered in the highest IUCN categories with the remainder mainly in the frequently unenforced IUCN Category VI. Oceania and Central America yielded similar number, while North America and Europe showed similar protection percentages. Asia—where a large percentage of the population relies on freshwater services, has the lowest percentage of protection, with only 5% in the strictest category.

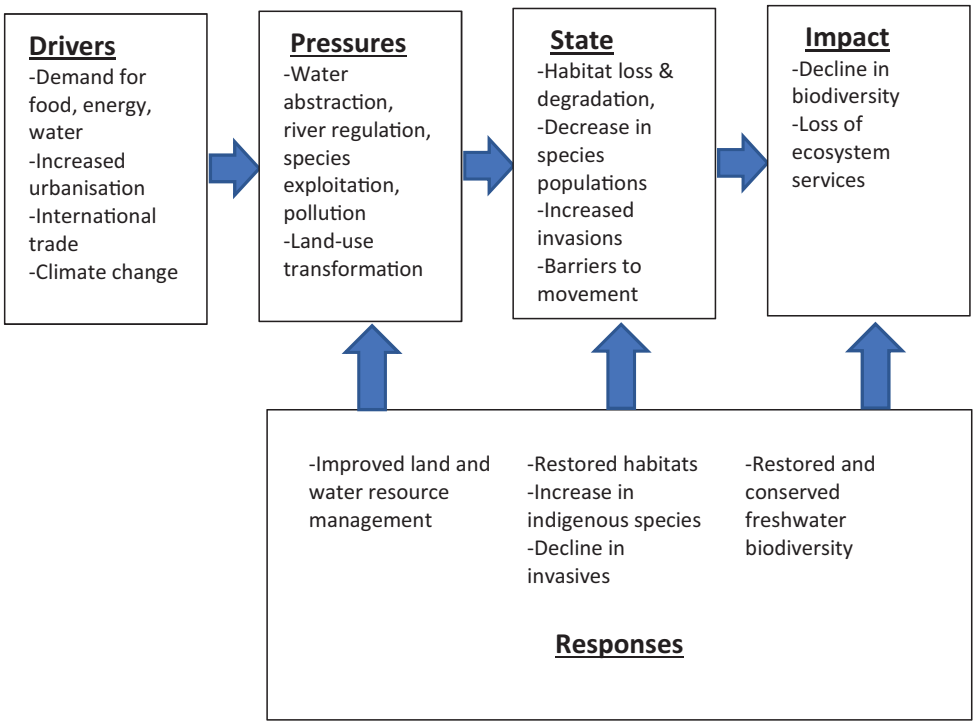

Fig. 1 Drivers, pressures, state, impact and responses to freshwater ecosystems. After Acreman M, et al. (2020) Protected areas and freshwater biodiversity: A novel systematic review distils eight lessons for effective conservation, Conservation Letters 13 (1), e12684.

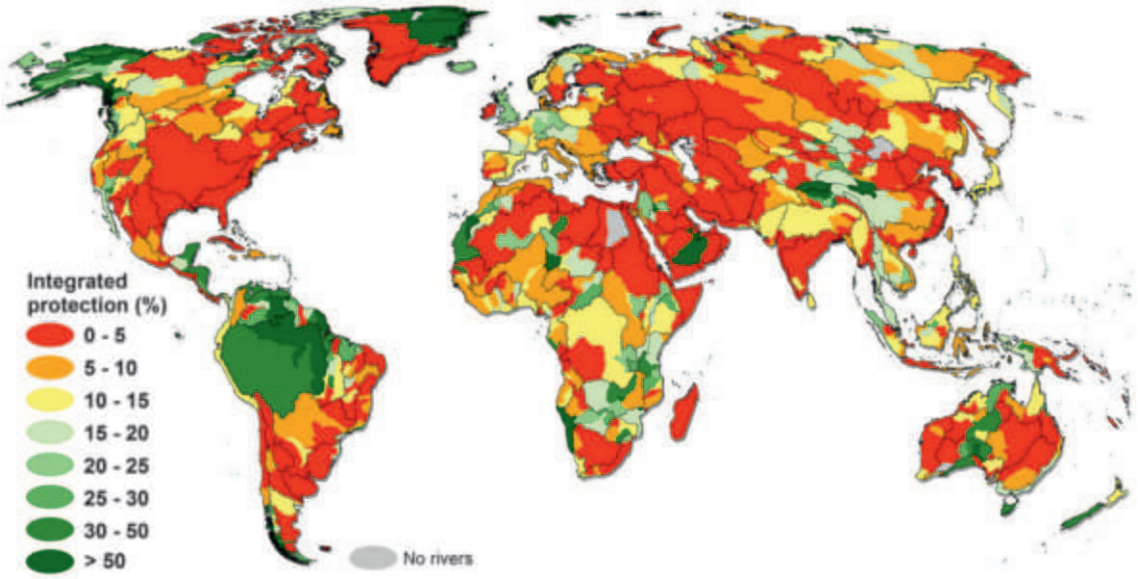

Fig. 2 Global protection status of rivers. From Abell R, Lehner B, Thieme M and Linke S (2017) "Looking beyond the fenceline: Assessing protection gaps for the world's rivers. *Conservation Letters* 10(4): 384–394.

In this chapter, we will detail the significance of these threats for the conservation of freshwater biodiversity, discussing the conservation status of freshwater biodiversity, key threats to freshwater systems and biota and strategies to conserve freshwater systems.

Status of freshwater biodiversity

While data about both the status and the distribution of freshwater biodiversity have been lagging behind their terrestrial and marine counterparts, the last 10 years saw high activity in assessments for the IUCN Redlist (Bland et al., 2019). Some taxonomic groups—freshwater shrimps and crabs for example—have complete global assessments. Other groups are slightly lagging behind, but have complete continental assessments. Fish, for example now have complete assessments for North America, Africa, Europe and Oceania (bar Papua New Guinea). Assessments of South American and most parts of Asia are underway, bar smaller areas in the Levant and Central Asia. In total, in late 2021, out of a total of ~18,000 fish species globally, 11,022 species have their assessments completed.

The IUCN Redlist is a homogenized rating system that classifies the relative risk of extinction. Categories range from "least concern" (LC), to vulnerable (V), to endangered (E) and critically endangered (CE). Note that the statistics we are reporting on will be based on all freshwater dependent taxa from the IUCN website, including the "freshwater & marine" and "freshwater & terrestrial" categories. In contrast to previous studies, which included the near threatened category, such as the "Bending the Curve of Global Freshwater Biodiversity Loss" opinion piece (Tickner et al., 2020), we will only include taxa that are vulnerable, endangered or critically endangered.

In 2021, out of a total of 35,000 species, 7529 were classed as threatened. This by itself is a staggering—and worrying—statistic, as 21.5% of all freshwater species are threatened. The number is likely higher than this as 7000 additional species are data deficient, some of which are certainly also endangered. While there is certainly bias in the coverage of the assessments, threat assessments differ both by regions and by between taxa.

Unsurprisingly—given the density of development and human population—Europe has an above average percentage of threatened species, with 27% of taxa in the V, E or CE category. Europe also has the highest assessment rates with only 9% classed as data deficient, lending high confidence to the percentage. North America—with a lesser population density—has an even higher assessment coverage (5%) and classes 15.5% of freshwater taxa as threatened. That said, North America has the highest extinction rates with a total 108 species extinct, amounting to 2.5% of total taxa. Nineteen of these extinct species are fish taxa, for example Silver Trout (*Salvelinus agassizi*) and the recently extinct Blackfin Cisco (*Coregonus nigripinnis*; Fig. 3), which was last sighted in 2006.

South America, South-East Asia and Oceania all have around 16% of endangered freshwater dependent taxa. Coverage for these areas is highly variable however. While in Oceania only 9% of the taxa are data deficient—indicating a higher certainty in the estimate, a total of 21% and 26% are data deficient in South America and South-East Asia, respectively. This indicates that the number of threatened species in South-East Asia could still increase once more fish are assessed. According to a 2016 analysis of change in human influence on ecosystem—measured by the change in "Human Footprint"—South America and South-East Asia are still in a trajectory of degradation (Fig. 4; see Venter et al., 2016; Linke et al., 2019b). We therefore expect a further degradation of

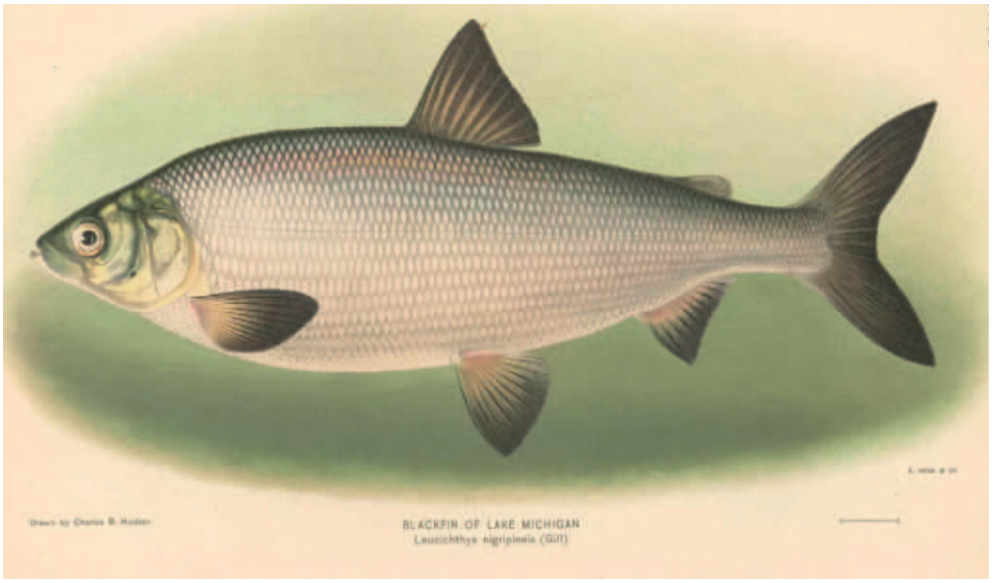

Fig. 3 The recently extinct blackfin cisco (*Coregonus nigripinnis* Painting by C.B. Hudson (1911) courtesy of the Freshwater and Marine Image Bank, University of Washington), last seen in 2006.

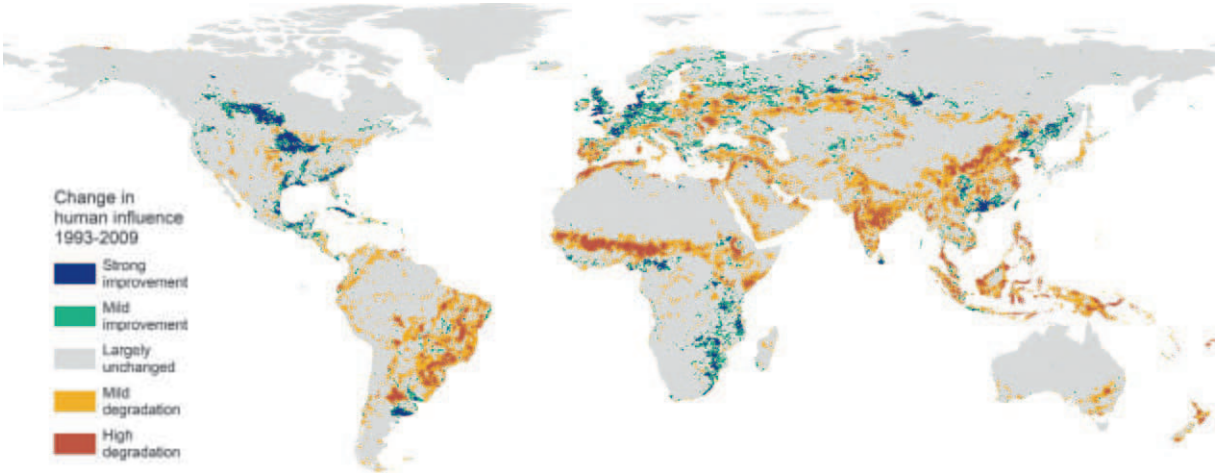

Fig. 4 Change in Human Footprint 1993 to 2009 by Level 8 Hydrobasins. Data from Venter O, Sanderson EW, Magrach A, Allan JR, Beher J, Jones KR, Possingham HP, Laurance WF, Wood P, and Fekete BM (2016) Sixteen years of change in the global terrestrial human footprint and implications for biodiversity conservation. *Nature Communications* 7: 12558; Linke S, Lehner B, Ouellet Dallaire C, Ariwi J, Grill G, Anand M, Beames P, Burchard-Levine V, Maxwell S, Moidu H, Tan F, and Thieme M (2019b) Global hydro-environmental sub-basin and river reach characteristics at high spatial resolution. *Scientific Data* 6(1): 283.

habitat and hence an increase of taxa classed as endangered in these areas, as opposed to many regions in Europe and North America that are either in a stable condition or have either succeeded in mitigating threats.

Taxonomic groups also display differing trends. Aquatic molluscs are heavily endangered with 25% of Gastropods and 31% of Mussels and other bivalves being classed as endangered. The real number could be even higher as these benthic organisms are harder to survey and are 20% and 31% data deficient, respectively. Aquatic mammals are also often highly endangered (37.5%) but have a high assessment rate, with only 10% being data deficient. Fish, which that are 80% assessed, have a slightly lower rate with 23% classed as endangered. Waterbirds and insects have lower rates, with 12% and 11%, respectively.

A second indicator is the Living Planet Index—an index of published population surveys of marine, terrestrial and freshwater organisms (Almond et al., 2020). The index is constructed by using the year 1970 as a baseline (=100%) and then tracking increases or declines in population. The last release in 2020 tallied populations until 2016 and showed a decline by around 62%, to a value of 38% of populations remaining. The plight of freshwater systems is especially clear in the index: When only counting freshwater-dependent species, the index is reduced to 22.5%, indicating that 77.5% of freshwater populations have been lost (Fig. 5).

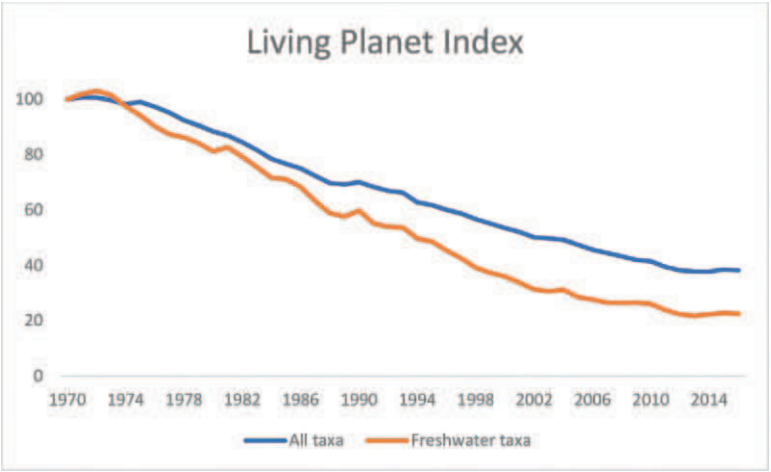

Fig. 5 Trajectory of the Living Planet Index 1970–2016. Data from Almond R, Grooten M, and Peterson T (2020) *Living Planet Report 2020-Bending the Curve of Biodiversity Loss*, World Wildlife Fund.

Major threats

Threats to aquatic ecosystems can stem from a diverse array of human activities. Some threats are direct and localized impacts of human activities on freshwater biota. An example of this is overfishing, a threat in which the impact is mainly local and occurs at the site where fish are extracted. Similarly, invasive species are a threat that is primarily a local threat, although of course invasives can spread across catchments. Other localized threats are, for example, habitat loss triggered by either changes to the river channel or the surrounding catchment, including the riparian zone. Similarly, point source pollution has its greatest impact in the local reach; however, like habitat loss, pollutants can have non-localized negative impacts. Flow regulation is a threat that can act on river health and biodiversity for thousands of kilometers. All of the above can be exacerbated by the overarching non-local threat—climate change, which can act as a driver detrimental to both thermal and hydrological regimes (Dudgeon, 2019; Reid et al., 2019).

Overexploitation of freshwater systems is mainly related to fishing impacts. Inland fisheries are an important source of nutrition globally (Funge-Smith and Bennett, 2019). The most recent estimate by the FAO was a catch of 11.9 million metric tonnes per annum. While this is only 12.9% of the overall catch—the remaining being marine fisheries—it still represents a sizeable amount of the total biomass. Often, the total impact of inland fisheries can be severely underreported. A recent study tallied 42 low and middle income countries in Asia, South America and Africa and found a net underreporting rate of 64.8%. Although the actual number harvested matters, the fishing techniques used are also important (Fluet-Chouinard et al., 2018). While no doubt a lot of the catch adheres to regulatory frameworks, a small number of extractions using illegal fishing practices (e.g., fishing with explosives) will cause additional damage. In addition to fish, amphibians, turtles or crocodiles are caught for food or traditional medicine, and these are poorly reported.

Invasive species are one of the hardest threats to control (Gallardo et al., 2016). Unlike most other endangering processes, invasive species are self-perpetuating. Single invasion events can lead to infestations of waterways that are extremely hard to control in the future. Impacts of invasive species can influence aquatic ecosystems in multiple avenues. Invasive species can change habitat, including water chemistry, and they often invade waters that display increased water temperature, nitrogen or organic matter concentrations. This of course depends on the context, as well as the species. For example the zebra mussel infestation in the Great Lakes led to major shifts in the Lakes' foodwebs. As the mussels filtered most of the primary producers from the water column, zooplankton populations declined, as did fish populations. In turn, submerged macrophytes increased as light penetration improved due to increased clarity. Invasive species can also directly act on other biota by predation, competition or increased grazing. Thus, the impact on the guild of natives depends on the trophic state of the invader. Invasive filter feeders have more of a grazing impact on plankton, whereas predators can decimate fish and benthic invertebrates. Apart from ecological losses, invasive species also have a major detrimental impact on the economy. A 2021 study estimated the global costs of invasions to aquatic systems to be at least $23 billion, 99% of which is in the freshwater realm (Cuthbert et al., 2021).

Land use change is one of the most complex proximate drivers of decline, as it can act through multiple avenues (Di Marco et al., 2019; Dudgeon, 2019). Habitat loss in freshwater systems can be caused by land-use changes around the river channel, for example by clearing riparian vegetation. Riparian corridors can filter nutrients and other pollutants, preventing them from reaching the river channel. Removing riparian vegetation will not only hinder this retention capacity but also reduce the input of terrestrial organic matter. Leaf litter is an important source of external energy inputs to river ecosystems, as are fallen branches and other woody debris that can act as nursing habitat for fish. Run-off from agricultural land often contains fertilizer that leads to excess nutrients being washed into the river, hence increasing primary production and often leading to algal blooms. Agricultural inputs can also increase fine sediment which can clog important habitat, an effect also observed by poor forestry landuses.

Unlike broader land-use effects, *point source pollution* stems from input contained in a defined area. This can be organic input—for example untreated sewage, which can lead to eutrophication, similar to land-use runoff. As point source pollution is localized, concentrations can often be higher. This can increase the direct impact at the local runoff point before dilution can attenuate concentration and lead to major damage. This is often not just restricted to organic inputs, but also includes chemicals from industrial runoff, as well as pathogens. Some of the most concerning chemicals are persistent organic compounds that do not degrade or cannot be metabolized in the food chain. An example for long-term exposure is the dioxin legacy in Sydney Harbour in Australia—an estuarine system in which fish harvest is forever banned due to high contamination.

The hydrological regime is a key influence on health, function and biodiversity of inland waters. Modifications to stream hydrology by *flow regulation* can influence the ecosystems thousands of kilometers downstream, and it can also present barriers to migratory species upstream of dams and weirs. A recent global study found that 67% of rivers had their flow intercepted to a significant level and only 23% of rivers flow uninterrupted to the ocean (Pittock et al., 2018; Grill et al., 2019). Hydrological change by either abstraction or seasonal reversal of flow can affect all types of organisms. Fish for example, need flows as spawning triggers but then often require overbank flow events to connect to nursery habitats. Floodplain vegetation requires regular watering events and overbank flows. Thermal regimes are often disturbed by regulation so spawning cues are missed. Invertebrates can also be affected by flow regulation as flushing flows that clean out sediment from interstitial spaces can be reduced.

Climate change will affect aquatic ecosystems through a combination of direct and indirect pathways (Knouft and Ficklin, 2017; Pittock et al., 2018). Primary drivers such as changes in rainfall and snow patterns lead to decreased flows and increased frequency and extent of drying. Air and water temperatures can have a direct effect on the ecology and life cycles of biota, but also on biogeochemical cycling, altering carbon and nutrient dynamics in aquatic system, which in turn affects aquatic systems. Water quality issues, such as increased frequency of algal blooms is a consequence of extended periods of increased temperature and reduced flows. The intensity of weather events (flooding and erosion) leads to direct physical effects on aquatic systems through elevated turbidity. Increasing salinity can also affect some freshwater systems as a secondary consequence of decreased dilution flows, but more directly in freshwater coastal systems that are under threat from sea-level rise.

The interaction between different threats can greatly exacerbate single detrimental effects (Dudgeon, 2019). Climate change, for example, can foster the establishment of invasive species by extending their range. Flow modification can be exacerbated by climate change when inflows are reduced. Flow modification can also increase effects of point source pollution when dilution is not present. Land-use change can add to a changing hydrograph and climate change can drive land-use change—when for example more land is needed for the agricultural production under climate change. These interactions call for a holistic approach to remediating actions, both in the nature of the remediation, but also the type of action taken (Fig. 6).

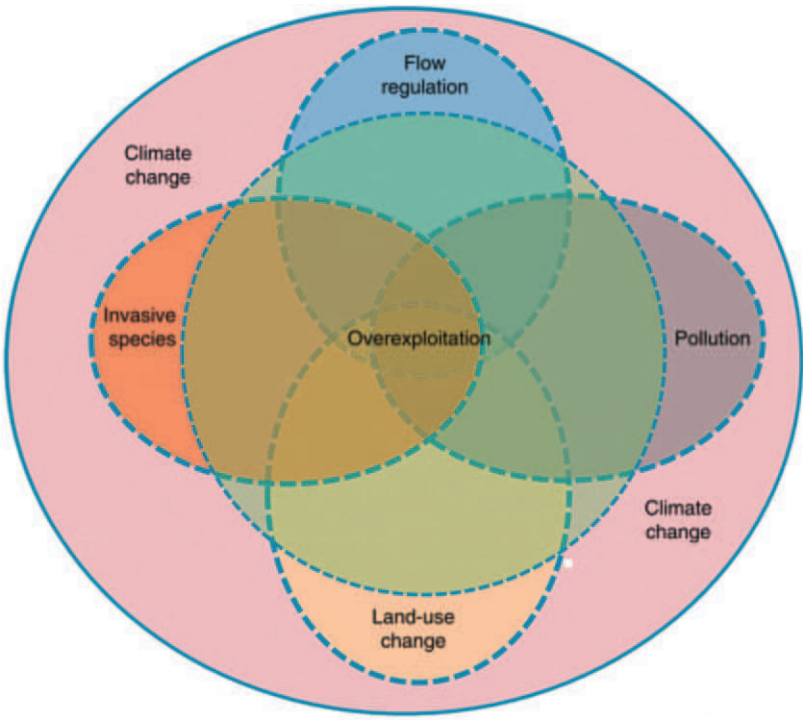

Fig. 6 A conceptual diagram of global threats to freshwater ecosystems. From Dudgeon D (2019) Multiple threats imperil freshwater biodiversity in the Anthropocene. *Current Biology* 29(19): R960–R967.

Conservation challenges

Freshwater conservation needs to be rooted in effective and efficient management. This is especially important in the face of rising pressures due to increasing demand for freshwater resources (e.g., clean water, construction material) and availability due to the impact of climate or land use change. Improving effectiveness and efficiency of conservation action in freshwater ecosystems faces important challenges that must become a priority to reverse the steep decline that freshwater ecosystems and biodiversity are now experiencing.

Some of these challenges are related to the special nature of freshwater ecosystems: they are systems that drain and accumulate impacts along full hydrological catchments. For example, the development of infrastructure to exploit freshwater resources might compromise the effectiveness of conservation action in lower regions in the catchment because of altered hydrological regimes and water quality. It is for this reason, that full catchment management plans are necessary. Moreover, in many cases freshwater ecosystems cross administrative boundaries, which makes the management of environmental problems and biodiversity conservation even more complex (Allan et al., 2019). Catchment management plans need to harmonize multiple (often conflicting) objectives that converge in freshwater ecosystems, for example water extraction of agriculture, hydropower production and biodiversity conservation. Management plans must identify the most suitable areas in the catchment to achieve these different objectives, while trying to minimize impacts of each objective on the others. Developing management plans requires the use of analytical tools and data to help make better informed decisions, negotiation and broad agreements across a multiplicity of stakeholders. There have been advances on the former, so tools and data are currently available to carry out prospective analyzes that help prioritize the allocation of different uses across full catchments to maximize the achievement of all objectives collectively while minimizing potential trade-offs between them (Hermoso et al., 2018). However, there is no single solution to facilitate negotiations and agreements across stakeholders. Multi-jurisdictional catchment-wide coordination exists, for example the Mekong River Commission that coordinates the development of catchment-wide management plans across Cambodia, Lao PDR, Thailand and Vietnam.

More effective conservation of freshwater biodiversity also needs full recognition of freshwater ecosystems as a unique realm in international and national agreements and policy as a step forward to setting meaningful targets and adequate management (van Rees et al., 2021). Freshwater ecosystems have been traditionally included as part of terrestrial systems (for example in the United Nation's SDGs), overlooking the particularities mentioned above. This has led to poor designs of freshwater protected areas and, therefore, important gaps in representation of freshwater habitats and species within protected areas There are initiatives, such as the Post-2020 Global Biodiversity Framework or the EU Biodiversity Strategy for 2030 (EC, 2020), that specifically set recovery targets for freshwater ecosystems and that are currently leading the path towards a better recognition for freshwater conservation needs.

Effective conservation must be supported by adequate and sufficient knowledge on the status of freshwater biodiversity, drivers of its decline and the effectiveness of different management options to address the impacts of those drivers. There are currently large gaps in all these different pieces that need to be addressed to enhance the effectiveness of conservation action in the future. For example, a large proportion of the described freshwater species lack adequate assessment of their conservation status following IUCN standards (see above), and there are many species, including vertebrates, that still to be described. These knowledge gaps are especially important in the regions that harbor the highest richness of freshwater biodiversity, such as large river systems in the tropics (e.g., Congo, Amazon or Mekong). There is also is insufficient knowledge of how different management strategies help abate the drivers of biodiversity loss. This lack of adequate information constrains our capacity to fully grasp the magnitude of the problem faced by freshwater ecosystems. It also hinders our capacity to raise awareness and plan action to reverse the decline of biodiversity in these systems. Monitoring programs are critical to fill some of these knowledge gaps. There are international initiatives, such as the Biodiversity Observation Networks (BON), as well as the development of indicators to track changes in ecosystem health or trend in populations of species, such as the Essential Biodiversity Variables; however, there is still support needed for systematically collecting and sharing data (Turak et al., 2017). An opportunity to address the challenge of better monitoring nature comes from emerging technology, such as e-DNA and bioacoustics, and citizen science. The development of these technologies is making them more accessible and cheaper, which will facilitate their use in the near future.

Freshwater ecosystems and biodiversity have also traditionally received less attention by the public, which has translated to less support to conservation action (Kochalski et al., 2019). A large proportion of freshwater biodiversity is out of sight under the water, and there are fewer examples of charismatic species commonly used to raise awareness of conservation problems and attract attention and funds. It is, therefore, a challenge of future conservation in these systems to improve public knowledge of the value of freshwater ecosystems and biodiversity and understanding of the specific problems that affect them through education and dissemination programs. In this sense, initiatives like the Alliance for Freshwater Life are needed to outreach society and educate on values and problems of freshwater biodiversity (Darwall et al., 2018).

Finally, although more knowledge is desirable, action is urgently needed. Given the complexities of managing freshwater ecosystems depicted above, this action needs to be supported by adequate planning at catchment scale and agreed among stakeholders: think globally to act locally.

Conservation strategies

Protected areas

Protected areas, as defined by the International Union for the Conservation of Nature (IUCN), are "clearly defined geographical spaces, recognized, dedicated, and managed, through legal or other effective means, to achieve the long-term conservation of nature with associated ecosystem services and cultural values." These are the most commonly used conservation tool worldwide and, consequently, the number and extent of protected areas has been growing constantly over the last decades.

The effectiveness of existing protected areas for freshwater biodiversity is often uncertain, given that there has been little emphasis on declaring or managing protected areas for the primary purpose of conserving freshwater ecosystems and biodiversity. A few exceptions to this place-based conservation approach do exist such as RAMSAR sites that are specifically designated to protect wetlands (not only freshwater). These sites have also experienced an important growth in area, but insufficient to halt the decline of natural wetlands (Gardner and Finlayson, 2018).

Although the majority of the world's protected areas are managed by governments at all levels, the importance of privately protected areas and mixed models is becoming increasingly recognized. Alternatives to conventional place-based approaches are quickly rising in freshwater systems. Some of these alternatives arise from recognition of the strategic value of freshwater resources for human wellbeing and development and to make the most of the opportunity of new markets that arise from the payment for ecosystem services. These alternatives go beyond designing place-based conservation efforts for biodiversity values alone and incorporate key ecosystem services provided by freshwater systems, for example water provision through different initiatives such as Water Funds and Water Reserves (Goldman-Benner et al., 2012).

To provide effective freshwater conservation, protected areas must consider some particularities of freshwater ecosystems which pose unique challenges to the implementation of effective conservation. For example, spatial-temporal connectivity plays a key role in maintaining important ecological processes, such as periodic migrations or dispersal from refuge areas, gene flow, or transport of energy and matter essential for the persistence of populations and species. To ensure conservation efforts in freshwater systems are effective, these connectivity components need to be considered when designing and managing freshwater protected areas. Freshwater ecosystems are extremely dependent on the surrounding terrestrial landscape, and the same connectivity that defines functional ecosystems also facilitates the propagation of impacts along river networks. For this reason, adequate management for conservation of freshwater biodiversity needs to go beyond the limits of the freshwater ecosystem and extend to the terrestrial realm, and sometimes even far distant areas. Finally, a key aspect to conservation in freshwater ecosystems is the need for water, often flowing but also standing water in lakes and connections to underground sources. However, as for connectivity, natural flows have been deeply transformed by human intervention: modification of the quantity, timing and variability of flows due to river regulation by dams, water abstraction and overexploitation of aquifers.

The designation of protected areas alone is therefore insufficient to halt freshwater biodiversity loss and must be accompanied by measures to ensure adequate habitat quality and connectivity at appropriate spatial scales. Additional management options are needed to expand management beyond the boundaries of protected areas and ensure effective conservation. These include maintaining and restoring free-flowing rivers key to ensure the maintenance of key ecological processes or environmental flows important to allow the transport of energy and material along the river network (Grill et al., 2019).

Integrated water resources management and integrated river basin management

Management of freshwater ecosystems requires strategic decision-making to integrate multiple and often conflicting objectives, such as exploitation of freshwater resources and biodiversity conservation. Integrated management needs to be sustained by strong objective setting and adequate planning. Objectives should be agreed on by all relevant stakeholders to reflect the diversity of interests and needs that converge in a particular freshwater ecosystem (Cañedo-Argüelles et al., 2019). As mentioned above, reaching agreements across stakeholders is still the most common challenge that hinders effective management of freshwater ecosystems and that deserves further attention and innovative solutions. Decision-making, to achieve those objectives, should be rooted in adequate planning, not only to help minimize potential trade-offs between conflictive objectives (e.g., construction of dams for the exploitation of freshwater resources and cultural/recreational ecosystem services), but also to promote co-benefits across objectives whenever possible (e.g., conservation of riparian forests for regulation ecosystem services such as carbon storage of flood retention and biodiversity conservation). There are multiple approaches to addressing this complex task of deciding what to do, where to do it and when to do it that span from expert elicitation to multicriteria and optimisation methods. Each approach, with its own pros and cons, can contribute to disentangling those complex questions and, therefore, help achieve conservation goals.

Integrated management for multiple objectives at catchment scale is challenging to implement, not only because of potential conflicts and trade-offs between objectives, but also because of the transboundary and cross-sectoral nature of freshwater ecosystems (Allan et al., 2019). Rivers often drain through different administrative boundaries, from regions to countries, which makes coordination across them essential to ensure effective management. Coordination of different sectoral administrations with different competencies and responsibilities within the same administrative unit can include catchment management authorities, National administrations (such as Ministries for the Environment) or even supra-national institutions (e.g., European Commission in the European Union) with competences and legislative capacity in biodiversity conservation issues. Catchment coordination agents, like the Mekong River Commission, can help disentangle the management conundrum by promoting both discussions on objectives and planning at catchment scale across jurisdictions and administrations.

Retaining wild or free-flowing rivers

Given the key role of connectivity in maintaining functional freshwater ecosystems, effective conservation of freshwater biodiversity needs to focus attention on maintaining (and restoring) free-flowing rivers (Grill et al., 2019). These are "rivers where ecosystem functions and services are largely unaffected by changes to fluvial connectivity." They are essential for maintaining populations of freshwater migratory species and megafauna, such as the European eel (*Anguilla anguilla*), the Chinese paddlefish (*Psephurus gladius*) or the Amazon dourada (*Brachyplatystoma rousseauxii*), that in many cases need to migrate over large distances (>1000 km) between spawning and adult foraging grounds. The cumulative impact of thousands of small infrastructures, such as small dams and weirs, can cause even larger impacts than a single large dam on freshwater ecosystems and their biodiversity (Lange et al., 2019). It is therefore crucial to adequately plan future development of infrastructure that impacts longitudinal connectivity of rivers, ideally following the mitigation hierarchy: whenever further impact cannot be avoided (prevent development) or minimized (corrective measures), restoration of connectivity in similar rivers (off-setting) must be warranted to ensure no net loss of free-flowing rivers. Under offsetting schemes, loses derived from new project developments that cannot be avoided need to be counterbalanced by generating an equivalent biodiversity benefit somewhere else. More importantly, restoration needs to focus on similar habitats to avoid net loss.

The protection of the free-flowing rivers can be operationalized through different policy tools, beyond formal designation of protected areas. For example, in the United States, the designation of Wild and Scenic Rivers provides protection for wild rivers with outstanding scenic, recreational, geologic, fish and wildlife, historic, cultural, or other conservation values, including the prohibition of dam construction. Protection of free-flowing rivers materialize through other means like granting rivers legal status similar to persons or adequate catchment management plans. For example, the Whanganui River in New Zealand was first in the world to be considered a legal person, providing traditional owners with legal instruments to protect the river's integrity (Charpleix, 2018). Catchment management plans are, on the other hand, a widely implemented instrument that can aim to harmonize contrasting objectives such as exploitation of freshwater resources and conservation of biodiversity and maintenance of free-flowing rivers. For example, the Strategic Environmental Assessment for hydropower in Myanmar recognizes the value of some mainstem rivers for maintaining critical basin processes and, therefore, proposed to be specially managed for their connectivity value. This recognition implies that no future dam development projects that impact longitudinal connectivity are allowed.

Dams: Operation, design, removal

The widespread impact of barriers makes them a focal point for effective freshwater conservation point of view. Preserving free-flowing rivers, as mentioned above, is key to freshwater biodiversity conservation but could not be sufficient to warrant the long-term persistence of freshwater biodiversity, as most rivers are already impacted by these infrastructures (see introduction). Dams can act as water storages and generate and store power, and they can also act to mitigate floods. Numbers on dams globally vary: global datasets like GOODD or GRanD contain 35,000–55,000 dams. These of course leave out many smaller impoundments like farm dams on agricultural properties. The AMBER barrier atlas currently contains 63,0000 dams and other artificial barriers globally—an exact number will be almost impossible to find.

As stated in the previous sections these structures can impede fish migration, for example upstream movement of anadromous fish to spawning grounds. Barriers can be mitigated by fish ladders—structures that can be used to bypass dams and move upstream. Fish ladders unfortunately are not a perfect solution as often only a limited pool of species can use them and they incur ongoing maintenance costs (Zarfl et al., 2019).

Thermal pollution is a key problem with dams globally. When lakes stratify in summer, the lower layer can be 5–15 °C colder than the surface layers. Upon release of the colder water river sections downstream of the dam will be unseasonably cold in summer (Miara et al., 2018). This can not only interfere with spawning behavior, but also stunt growth in fish larvae, as well as change aquatic food webs. Multiple mitigation strategies can temper the impact. Instead of releasing water from dams at the—usually cold—bottom of the late, multi-level offtakes near the dam wall can mitigate thermal pollution by drawing water from one of the top layers near the thermocline. Also, destratification measures are often used to mix the colder water from the lake bottom with surface water. This can be achieved using mixer structures to blend the water layers. Cheaper approaches include bubble plume destratification in which air flow from a bubbler hose can break the stratification (Helfer et al., 2011).

Altered flow regimes downstream of a dam can gravely affect ecosystems by changing many aspects of the flow regime and river ecology in general (Arthington et al., 2006; Arthington, 2012). Depending on the location and nature of the river, the natural flow regime shapes a river's ecology in multiple ways. In tropical rivers for example, large flood pulses shape the wet season hydrograph. This is similar in snow-fed rivers, where spring melts result in high volumes. Dams can change seasonality, volume but also the magnitude of high- and low-flow periods. Changes to seasonality, for example, can change trophic status of rivers, and also reverse spawning cues. Tempering of high flood pulses may protect downstream low-lying habitable areas, but it may also impact and reduce important flushing flows that clean sediment deposits out of in-stream habitat and reduce connections to the floodplain. This can impede movement to safe spawning habitats for biota and can also reduce nutrient fluxes between the floodplain and the rivers. Dam releases and other man-made interventions to restore these regimes are termed "environmental flows" (Poff and Zimmerman, 2010).

Despite optimal operational design and best management practises, dam impacts can sometimes not be sufficiently minimized and dam removal becomes the only option for biodiversity conservation. Dam removal has gained momentum over the last decades, with over 1000 dams been removed in the United States (O'Connor et al., 2015), see Duda and Bellmore this volume) or

the commitment made by the European Union of reconnecting at least 2500 km of rivers by 2030 in its recently adopted Biodiversity Strategy. Barrier removal projects can be expensive and can involve significant opportunity costs associated with the socio-economic benefits of dams and reservoirs. Restoration of natural connectivity needs to be carefully planned to maximize the recovery benefit while minimizing socio-economic trade-offs, ideally at the whole catchment scale. Although opportunistic decision-making at reduced scales can leverage local interests, it is only at large scales that the cumulative impact of barriers can be tackled in an efficient way.

Restoration

Given the poor conservation status of freshwater ecosystems worldwide (see "Major threats" section) restoration often needs to complement conservation efforts. River and wetland restoration projects have gained momentum in the last decades, not only to restore intrinsic biodiversity values, but also because of the importance of these systems as providers of services to humans (e.g., clean water, flood control, food or recreational opportunities). More than US$ 1 billion is spent annually on rehabilitation projects in the United State alone, and the number of projects has increased exponentially in the last decades (Allan et al., 2013). Despite these efforts, freshwater biodiversity continues to decline alarmingly. Compounding factors are behind this insufficient improvement, although the failure to address the true driving causes at a scale adequate to capture the ecological processes involved in the degradation could be some of the leading factors—along with failure to include socio-economic considerations.

Traditionally, decisions on where and what to restore were implemented following ad-hoc approaches, mainly making the most of opportunities (e.g., removal of obsolete barriers) that do not necessarily address the roots of the problem (the key drivers) at the adequate spatial scale. This results in resources invested in restoration poorly effective and, in some cases, redundant. For example, the removal of a barrier that impedes the movement of migratory species might be insufficient if habitat quality in the areas where the species need to migrate to is in poor condition and not restored simultaneously. It could even cause more harm than good if the infrastructure removed was an effective barrier containing the spread of invasive species. To overcome these issues and enhance efficiency of restoration investment in freshwater ecosystems, adequate planning is needed, to identify priority areas where restoration can help tackle the drivers of degradation at the adequate scale. Catchment scale planning of restoration seems the more adequate approach to overcome these problems (Hermoso et al., 2012).

International conventions on conservation

Since the last edition of the Encyclopedia of Inland Waters a number of international conventions have been ratified at a global level. Historically, the key conventions were the Ramsar Convention and early drafts of the Convention on Biological Diversity. The Ramsar Convention, ratified in 1971, aimed to halt worldwide loss of wetlands by conserving representative, rare or unique wetlands. Ramsar wetlands are not designed for exclusive use as national parks, but as a mixed-use conservation feature for which the imperative is to maintain its ecological character. A global wetland analysis in 2017 demonstrated that the Ramsar convention is reasonably effective—human pressures to wetlands protected under the convention Wetlands was higher compared to strict protection regimes (IUCN I-IV), but on par or even less than IUCN V-VI (Reis et al., 2017).

Since then, two major conventions were ratified—the Aichi Targets in the Convention on Biological Diversity (CBD), as well as the targets set by the UN's Sustainable Development Goals (SDGs). The Aichi Targets cover recommendations on habitat loss (Target 5), fisheries management (6), pollution reduction (8), invasive species (9), protected areas (11) and ecosystem services (14) (Juffe-Bignoli et al., 2016). The protected areas target for example recommends 17% of freshwater systems to be protected. As discussed above this is often not does include enough as upstream areas, and surrounding wetlands may need to be protected. The "Emergency Recovery Plan" outlined by a broad coalition of NGOs and academic partners (Tickner et al., 2020) also encourages extension of the Aichi targets by explicitly emphasizing freshwater systems and their connectivity requirements in Target 5, explicitly setting targets for inland fisheries (6), focusing on pollutants to freshwater systems (9) and considering the full range of freshwater ecosystem services (Juffe-Bignoli et al., 2016).

The same recovery plan discusses the SDG targets 6, 14 and 15. SDG target 6.3 mandates an improvement of water quality by reducing all sources of pollution including chemical pollution. This target, as well as target 6.4 (water use efficiency and sustainable withdrawals) align with the recovery plan. Target 6.6 (protection of water related ecosystems) as well as Target 15 (protection, restoration and sustainable use of ecosystems) suffer from a similar shortfall as Aichi 11: the spatial context in these targets is not explicitly dealt with, so pollution or water withdrawal upstream can adversely affect downstream ecosystems (Green et al., 2015; Harrison et al., 2016; Harper et al., 2021). Currently intergovernmental bodies, NGOs and the research community are working on longer term strategies to address these shortcomings, including re-framing quantitative targets.

Conclusions and further directions

Over the last 20 years, conservation of freshwater ecosystems has faced both renewed challenges (e.g., increasing population growth and consumption) and a drive towards systems science to conserve freshwater biomes at the landscape scale. Both governments and intergovernmental organizations have started to adopt large-scale conservation frameworks that are underpinned by science. That said, the biophysical realm is only one aspect of the conservation puzzle. A recent review that highlighted

25 essential research questions for freshwater conservation found that implementation of the science, as well as embedding conservation science in a broader social context, is essential for bending the curve on biodiversity loss (Harper et al., 2021).

Key areas this chapter highlighted include lessons from successful efforts of translating conservation research into policy. Communication of the importance of pollution reduction to industry, as well as incentives to embrace nature-based solutions, were highlighted as important to remediation efforts. Trade-offs in balancing resource needs between food production both on land and via aquaculture with freshwater biodiversity need to be identified and acted on. Policy and investment need to be made aware of the economic consequences of biodiversity loss and long-term funding stability for conservation management needs to be addressed. Integration with social scientists and the general public is needed to translate scientific findings into action, especially in areas that are underrepresented in standard scientific circles. Finally, acceptance that conservation science is not a one-way street needs to be fostered as indigenous and multicultural perspectives can contribute greatly to conservation.

Knowledge gaps

- *Distribution and threat status for biodiversity*: As species are less visible than their terrestrial counterparts, often distributions are not known. It is also harder to estimate threat status to trigger statutory protection.
- *Adequate monitoring*: Freshwater monitoring has been a key scientific discipline for decades, however with technological advances such as eDNA or autonomous sensor technology, higher spatial and temporal resolutions can be achieved.
- *Interaction of existing threats and climate change*: Climate change can exacerbate other threats, such as water extraction or invasive species. Factors that cannot be mitigated need to be included in proactive planning to minimize the effects on threatened species.
- *Effectiveness of protected areas*: Few studies have examined overall effect of protected areas on rare and threatened species. This is partially due to a relative lack of properly designed aquatic protected areas that integrate longitudinal and lateral protection.
- *Coordination across administrative boundaries*: Rivers often divide countries. There is a clear need for proper policy instruments that can help coordinate freshwater conservation between states or countries.
- *Trading off multiple objectives of conservation and human demand*: Both modeling approaches and policy processes need to develop better integrated workflows that trade off multiple objectives of biodiversity and human demand and human benefit.
- *Inclusion of socio-economic processes*: While not covered in this article, socio-economic processes, such as knowledge transfer between agents and general stakeholder engagement need to be included. Both processes, but also research insights are currently lacking.
- *Translating conservation into policy*: Clear avenues need to be developed that translate conservation knowledge and research into policy. These are currently lacking, with intergovernmental organizations acting as mediators, but often resolutions are not binding.

Climate Change and Extreme Events in Shaping River Ecosystems

Jonathan D Tonkin, School of Biological Sciences, University of Canterbury, Christchurch, New Zealand

This is an update of B. Finlayson, M. Peel, T. McMahon, Climate and Rivers, in Encyclopedia of Inland Waters, edited by Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00042-9.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Beta diversity Differences in ecological communities among multiple locations. More specifically, variability in species composition among locations within a region.
Ecological trap A situation where rapid environmental change leaves organisms in poor-quality habitats. Whether the habitat quality or the environmental cue changes rapidly to the point that one no longer reliably indicates the other, organisms mistakenly prefer habitats where their fitness is lower than in other habitats.
Extreme event "A rare or unusual weather or climatic occurrence (e.g., extreme of precipitation, temperature or wind) and/or the resultant extreme physical phenomena in river catchments (e.g., fluvial floods, hydrologic droughts, storm surges, fire or cryosphere-related effects)"; taken from Ledger and Milner (2015). See "Extreme events defined" section for full explanation.
Flow regime The long-term sequence of high (floods) and low (droughts) flows, characterized by five key components: magnitude, frequency, duration, timing, and rate of change.
Nonstationarity Generally, where a system no longer fluctuates within a range of variability that persists through time (no longer fixed underlying probability distribution). More specifically, differences in statistical characteristics, such as mean or variance, or in statistical relationships, through time.
Press disturbance Disturbances that arise rapidly and then maintain a constant level, such as the building of a dam to alter a flow regime or river connectivity.
Pulse disturbance Short-term and sharply delineated disturbances, such as flood events.
Ramp disturbance A disturbance where the strength of disturbance steadily increases over time, such as gradual land-use change, the spread of an invasive species, or long-term drought.
Resilience The capacity of a population or community to recover following a disturbance event.
Resistance The ability of a population or community to withstand a disturbance event.
Species range shift Changes in the distribution limits of a species, generally along altitudinal or latitudinal gradients.

Introduction

In June 2021, a large low-pressure mass built up over the Tasman Sea to the west of New Zealand before proceeding to pick up moisture-rich air from the Pacific Ocean to the north and slamming into the east coast of New Zealand's South Island. This event caused widespread destruction across the Canterbury region of New Zealand, with many of the large rivers draining the eastern slopes of the Southern Alps flooding, damaging critical infrastructure and putting lives at risk. Although this was described as a

one-in-two-hundred-year event, the reality of climate change means these kinds of events will recur at much higher frequencies than in the past (IPCC, 2021). In the weeks that followed this event, we witnessed catastrophic floods unfolding elsewhere in New Zealand, as well as across Europe and China. This is a recurring trend: over recent years, we have seen increasing frequencies of various extreme climatic events, including high profile drought and wildfire events across western North America and eastern Australia, causing tens of billions of dollars of economic losses, severe losses of biodiversity, and loss of human life (WMO, 2020).

Such events serve as a reminder that the main way in which humans will feel climate change is via increasing frequencies of what we currently consider extreme events. Climate change-driven disturbances are predicted to continue to intensify by more than an order of magnitude over the next 100 years (IPCC, 2021). We continue to see records being broken in terms of heat across the globe (WMO, 2020), with July 2021 being the hottest month ever recorded on Earth (NOAA, 2021). The threats to human infrastructure are clear. More nuanced, however, are the threats to freshwater biodiversity and to the ecosystem goods and services provided by rivers.

Rivers and streams are highly dynamic environments, with natural cycles of floods and droughts (Poff et al., 1997). Organisms that inhabit these ecosystems have evolved life histories to cope with, and indeed capitalize on, these natural disturbance regimes (Lytle and Poff, 2004). However, these regimes are rapidly changing in terms of their magnitude, frequency, timing, and duration (Blöschl et al., 2017, 2019; Stewart et al., 2005).

Climate change and extreme events are dynamically entwined in river ecosystems. In addition to magnifying and increasing the frequency of extreme events, climate change has the potential to alter many other aspects of river ecosystems, such as modifying temperatures and inducing species range shifts, or interacting with various other anthropogenic stressors, including invasive species, land-use change and flow alteration (Dudgeon et al., 2006). The physical basis of climate change has never been clearer: with an increasingly high level of confidence, science indicates that climate change will continue to intensify in coming decades (IPCC, 2021). The need to understand the effects of climate change on riverine ecosystems has, therefore, never been more pressing. In this chapter, I review the broad ways in which climate change will influence river ecosystems, and the role of climate-driven extreme events in shaping river ecosystems, including their structure and function.

The physical basis of climate change and extreme events

Extreme events defined

Climate change research has often focused on shifting mean conditions, but one of the key ways in which climate change will impact freshwater ecosystems is via increasing variation around increasing means; i.e., by amplifying the magnitudes and frequencies of extreme events. There is no consistent definition for what constitutes an extreme event in running waters. This lack of coherent definition is an issue that has transcended disciplines, which may have hampered our ability to understand and manage extreme events (McPhillips et al., 2018). Extreme events in rivers are typically considered statistically rare or unusual events (often climatically-driven) that translate into extreme physical effects, such as through floods or droughts, which may or may not have extreme consequences on the ecosystem. Extreme climatic events include prolonged droughts, heatwaves, or rainfall events associated with unusually large and infrequent storms.

Many have used probability-based definitions, such as extreme floods being those with a 100-year return interval or 1% excedence probability; or threshold-based, such as temperature crossing certain thresholds (Ledger and Milner, 2015). However, what is considered an extreme event in the present day based on certain thresholds or magnitudes will likely be revised as the climate continues to warm (McPhillips et al., 2018).

For the purpose of this chapter, I will focus mostly on climate-related extreme events, which largely reflect flood and drought regimes (flow regimes). My definition of an extreme event is deliberately broad, with no particular threshold or probability. Thus, I will loosely define an extreme event following the definition used by Ledger and Milner (2015): "a rare or unusual weather or climatic occurrence (e.g., extreme of precipitation, temperature or wind) and/or the resultant extreme physical phenomena in river catchments (e.g., fluvial floods, hydrologic droughts, storm surges, fire or cryosphere-related effects)." It is important to note that this definition also considers more than just the magnitude of events. For instance, if a major event falls well outside the typical timing of such events historically, it may have just as detrimental an effect as an extreme event defined by magnitude alone.

From historical range of variability to novel future regimes

Research has now demonstrated considerable change has already occurred to flow regimes across the world in recent decades (Blöschl et al., 2017, 2019; Stewart et al., 2005). Extreme flood events have increased substantially in frequency over the 20th century (Milly et al., 2002). These changes play out differently across the globe and within regions. Existing water stressed regions (Fig. 1) are set to become more challenged by water shortages. For instance, floods are arriving earlier in northeastern Europe due to warmer temperatures driving earlier snowmelt, later around the North Sea and parts of the Mediterranean coast due to delayed winter storms, and earlier in western Europe due to earlier soil moisture maxima (Blöschl et al., 2017). Similarly, flood magnitudes are increasing in northwestern Europe due to increasing autumn and winter rainfall, and decreasing in both southern and eastern Europe due to decreasing precipitation and increasing evaporation in southern regions, and decreasing snow cover and melt in eastern regions (Blöschl et al., 2019). In western North America, the onset of spring snowmelt and associated increases in river discharge is occurring earlier across the region (Stewart et al., 2005). Similarly, increases have been found in river temperatures over a 30-year period in northwestern United States (Isaak et al., 2012), a trend that is set to continue with increased climate change, not

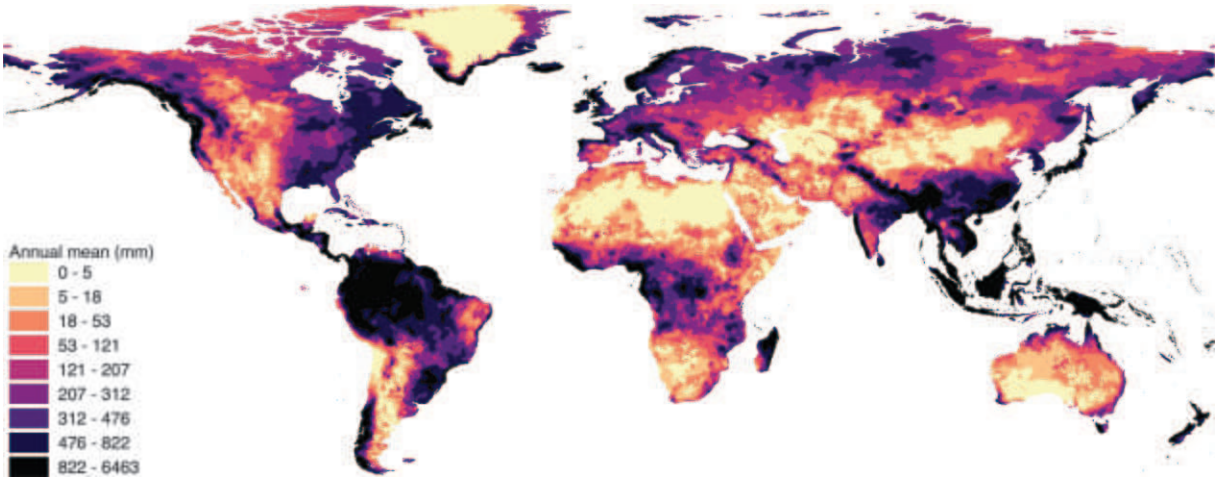

Fig. 1 Global map of land surface runoff (mm year^{-1}), based on long-term (1971–2000) averages, highlighting existing water stressed regions at risk of further climate change. Data were sourced from the HydroATLAS database (Linke et al., 2019).

just in North America, but across the globe (van Vliet et al., 2013). This shifting physical template of rivers presents critical challenges for the species that inhabit them, let alone the management of river flows for human wellbeing.

Effects on river ecosystems

The mechanisms by which extreme events influence biodiversity are varied depending on their nature, and effects can be direct or indirect. Extreme floods can significantly alter the physical template of rivers (Death et al., 2015), or cause direct mortality on individuals, but may also enable previously isolated populations to disperse and reconnect, particularly in arid landscapes where stream drying isolates permanently flowing channels (Datry et al., 2016; Tonkin et al., 2018a). By contrast, extreme droughts can fragment freshwater habitats or push temperatures and pollutant concentrations beyond tolerable limits for organisms (Palmer and Ruhi, 2019). Thus, ecological responses to extreme events, like everything in ecology, are context dependent. However, testing the effects of extreme climatic events on riverine biodiversity is challenging given the rarity of extreme events and the general associated lack of pre-event data (Poff et al., 2018). Thus, case studies on the effects of extreme events on riverine ecosystems are not common.

Nonetheless, evidence of the effects of these climate change-induced extreme events is beginning to accumulate. For instance, unprecedented droughts such as Australia's Millennium Drought or California's recent drought, can completely alter river and riparian ecosystems, shifting ecological communities over new thresholds (Aspin et al., 2019; Bogan and Lytle, 2011; Thomson et al., 2012). Further, the intensity and duration of drying can regulate rates of gross primary productivity (Colls et al., 2019) and litter decomposition (Mora-Gómez et al., 2020). At the other extreme, intensified floods can also have major impacts on the functioning of rivers (Palmer and Ruhi, 2019), including leading to population genetic changes as a result of mass mortality events (Poff et al., 2018).

Coupled geomorphological-ecological responses

Extreme floods resulting from climate change also have the potential to significantly change the geomorphological template of rivers (Death et al., 2015). Beyond the negative direct effects of large floods on organisms, such channel-altering floods, can provide significant benefits for resident biota by resetting physical conditions, opening up habitat for flood-adapted species, and removing nuisance accumulations of primary producers and exotic weeds. However, channel-altering floods can also multiply the effects of other stressors on aquatic life such as by redistributing toxic chemicals, in addition to their direct effects on human infrastructure (Death et al., 2015).

The geomorphological and ecological context can also influence the ecological response of stream ecosystems to extreme events. Robertson et al. (2015) examined the response of meiofauna, macroinvertebrates and fish to an extreme flooding event in southeast Alaska across four recently deglaciated catchments. The ecological responses to this event differed across the four catchments, which reflected both the local intensity of rainfall and factors related to the age of each stream (38–180 years), including channel morphology, and catchment vegetation type and cover. However, many questions remain unanswered regarding the effects of extreme floods on river geomorphology and ecology (Death et al., 2015).

Resistance vs. resilience

Given the inherent dynamism of rivers, riverine species are often relatively resistant and/or resilient to extreme flood events (Blondel et al., 2021; Lytle and Poff, 2004), as a result of the evolution of behavioral, morphological or life-history adaptations (Lytle and Poff, 2004). However, there is often a tradeoff between resistance and resilience to flood disturbances (McMullen et al., 2017). For instance, Poff et al. (2018) examined population genomic responses of aquatic insects to a one-in-500-year rainfall event in

Colorado streams. Local species responses depended on traits related to resistance and resilience, but persistence was lowest at locations with highest disturbance. Persistence was lowest for immobile taxa, with a greater chance of persistence for species with mobile larvae or terrestrial adult stages present during the flood event. Despite a clear role of resistance and resilience traits in determining species persistence, genomic changes were much less predictable for the six species examined. Resistance and resilience to extreme floods can also differ within populations depending on what aspects of the population are considered. For example, Blondel et al. (2021) found genetic diversity and population structure of native riverine guppies to be resistant, and phenotypic diversity, represented by body size and male coloration, to be resilient to extreme flood events. More specifically, minimal changes were observed in genetic diversity and population structure compared to preflood patterns whereas phenotypic diversity was more heavily impacted by the flood events, but these larger impacts were short-lived.

Altered flow regimes

Of the many changes that will occur to flow regimes as a result of ongoing climate change, one of the more concerning for native riverine organisms is changes to the timing of flow events. Flow timing is a critical component of the natural flow regime (Poff et al., 1997), and one for which species have evolved various strategies to capitalize on (Lytle and Poff, 2004). The predictability of flow regimes is a critical structuring agent of riverine biodiversity, with more predictably seasonal flow regimes able to harbor greater biodiversity (Tonkin et al., 2017). Riverine species have adapted to capitalize on these seasonal rhythms. This is not surprising given the predictability of flow regimes in many parts of the world (Fig. 2). For instance, in western North America, cottonwood (*Populus* spp.) release their seeds after the annual peak river flows that come with spring snowmelt, which facilitates dispersal and establishment into the floodplain (Mahoney and Rood, 1998). Shifting the timing of these peak flows may help non-native *Tamarix* to outcompete cottonwoods through time (Lytle et al., 2017), as has been seen below dams that have altered timing and magnitudes of peak flows (Merritt and Poff, 2010).

Fish are also fundamentally attuned to the natural timing of flow events in rivers. For instance, the timing of winter events is often critical for the reproductive strategies of coldwater fish species (Shuter et al., 2012). Given the existing evidence that the timing of flood events has already changed (Blöschl et al., 2017), it is not surprising that phenologies of riverine fish have already shifted (Shuter et al., 2012). Mismatched phenologies are a critical threat to freshwater fish as river flows continue to change, ranging from

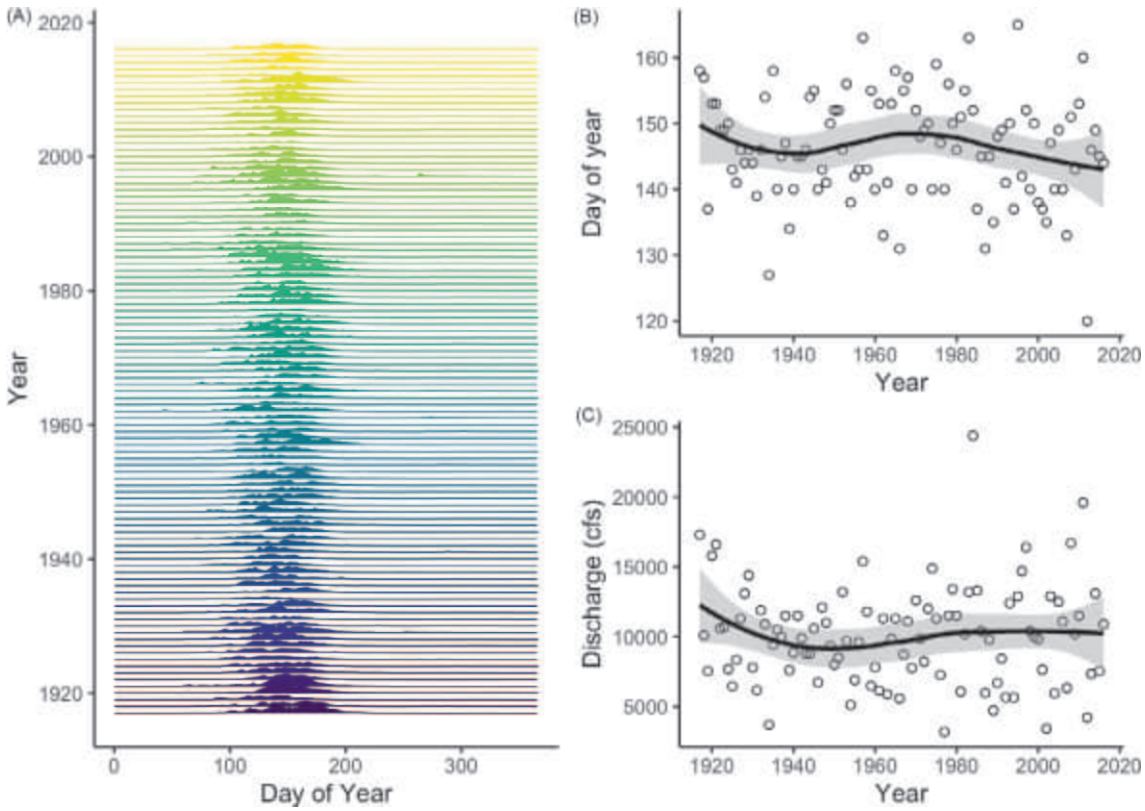

Fig. 2 (A) Ridgeline plot of flows in the unregulated Yampa River, a tributary of the Colorado River at Maybell, Colorado over a 100-year period. Each line is an annual hydrograph demonstrating the consistency of the spring snowmelt flood pulse from 1916 to 2016. Species such as riparian cottonwoods have evolved intricate relationships with these predictable pulses. Although difficult to discern here, climate change is already altering the natural phenology of river flows globally, and bringing spring snowmelt earlier across most of western North America (Stewart et al., 2005). (B) The day at which 50% of annual flow has passed the gage. (C) Annual peak in daily discharge over the 100 years. Trendlines in both B and C represent locally weighted smoothing (loess) curves.

increased larval mortality due to premature hatching to mismatched feeding phenologies between different stage classes shifting interactions between predation and competition (Shuter et al., 2012).

Human-altered flow regimes can be extreme in and of themselves. For instance, hydropeaking, where dams release different volumes of water throughout the day in response to energy demand imparts a novel pattern of flow variability into a river (Ruhi et al., 2018). These flows have been shown to reduce functional diversity of invertebrate communities downstream of a large dam on the Chattahoochee River in Georgia, United States (Ruhi et al., 2018), and lead to the near complete extirpation of mayflies, stoneflies and caddisflies in sections of the Colorado River subject to high levels of hydropeaking (Abernethy et al., 2021). Such alterations are analogous to the effects of urbanization, which can severely alter flow regimes and lead to exacerbation of flow extremes and their effects on riverine biodiversity (Palmer and Ruhi, 2019). Streams draining urban catchments are subject to regular, intense flow events due to their increased impervious surface and more concentrated runoff. In certain cases, this can lead to a cycling between flow extremes and extreme anoxia events (Blaszczak et al., 2019).

Complex and nonlinear responses to change

Biodiversity change in response to changing river conditions is complex and varied. For instance, Larsen et al. (2018) found no change in metrics typically used to detect biodiversity change but uncovered more nuanced underlying changes. Using a 30-year time-series dataset of benthic macroinvertebrates from southern Wales, they found no change in taxonomic or functional alpha diversity or spatial beta diversity. However, underlying this apparent stasis in widely-used metrics of biodiversity change was a temporal change in mean species composition. These changes reflected a systematic decline in mean community specialization, which was associated with a lower rate of recolonization of specialists as opposed to an increased local extinction rate.

Other studies have found clear evidence of change at multiple levels over recent decades attributable to climate change, but trends are often nonlinear. Using a comprehensive 42-year long dataset (1969–2010) of weekly species-level insect abundances from the Breitenbach Stream in central Germany, Baranov et al. (2020) uncovered major shifts in insect community structure, including an 82% decline in overall abundance and a 9% increase in richness. These changes occurred in the absence of any other ongoing stressors beyond a climate change-induced 1.9 °C water temperature increase and an altered flow regime, characterized by the change in four annual discharge patterns: dry years, wet years, aseasonal spate years and extreme spring spate years. Their research, again, uncovered often-missed mechanisms of change: peak insect emergence arrived 13 days earlier over the study period and the duration of emergence increased by 15 days. Understanding these mechanistic changes can enable a more comprehensive picture of how species may or may not adapt to ongoing warming. Although evidence suggests the responses of biodiversity to extreme climatic events is highly idiosyncratic and unpredictable (van de Pol et al., 2017), taking a more mechanistic approach to understand responses will likely uncover generalities that can transcend species, ecosystems and locations.

Understanding ecological responses to environmental regimes is often carried out by focusing on mean environmental conditions as the key drivers of ecological dynamics. However, in reality, one-off or extreme events may play an equal or larger role in shaping biodiversity in running waters than long-term trends through a legacy effect. Jourdan et al. (2018) compared the role of long-term climatic change and antecedent climatic conditions in predicting European stream invertebrate communities across a set of long-term ecological research network (LTER) sites sampled for between 10 and 24 years. They found that antecedent climatic conditions, measured as the mean temperature and daily precipitation, and the number of extreme hot, cold and high precipitation days over the preceding 12 months, were better predictors of community metrics than background long-term change. This highlights the need to both understand the mechanistic responses to individual flow events, including both ecosystem states and rates (Tonkin et al., 2019), and continue investment into long-term monitoring programs to help detect longer-term trends.

Species range shifts, community reorganization and invasion

One of the most apparent responses of biodiversity to ongoing climate change is caused by species moving their range to track shifting isotherms. In Europe, climate change projections have indicated a decline in climatically suitable habitat for more than 50% of invertebrate species and losses could be as great as 40% by late this century (Domisch et al., 2013). These models have indicated that species facing the largest decline in climatically suitable areas were cold-adapted species, whereas warm-adapted species were expected to gain suitable habitat (Domisch et al., 2013). Haase et al. (2019) analyzed changes in stream invertebrate community composition over 25 years across central Europe and found clear evidence of community reorganization, and in particular, evidence of a decline in cold-adapted species, with warm-adapted species appearing to replace them. The biggest distribution shifts were apparent with elevation rather than latitude, and these changes were apparent despite the temperature only having changed by 0.5 °C over this period. Systematic shifts have been found for riverine fish upstream and in elevation across France at rates faster than many terrestrial organisms but not rapid enough to track changing climate (Comte and Grenouillet, 2013).

Flow alteration and temperature change combine to threaten riverine species. Across western United States, projected climate-induced flow alteration has been shown to be equally as important as warming in its risk for stream invertebrate communities (Pyne and Poff, 2017). However, the vulnerability to projected gradients of temperature and hydrologic change varies widely across the ecoregions of the western United States—from the wet forests of the northwest to the desert of Arizona: communities in some ecoregions are more sensitive to warming and others to reduced flow (Pyne and Poff, 2017). Similarly, both increased water temperature and discharge reduction have played a key role in the disappearance of invertebrate species from the Middle Loire River in France over a 30-year period (Floury et al., 2013). During this period, species that specialize in slow flowing or standing waters, including invasive species, increased in number. Similar patterns have been uncovered for riverine fish with species

that prefer warm- and slow-water habitats increasing in dominance across the globe (Comte et al., 2021), changes that are exaggerated in human-modified regions (Comte et al., 2021).

Climate change-induced reorganization is already widespread across the globe. For example, stream invertebrate communities appear to be homogenizing through time in New Zealand (Mouton et al., 2020). Homogenization often accompanies invasion by non-native species, and many have found climate change to help facilitate the invasion of non-native fish species (Radinger and García-Berthou, 2020; Rogosch et al., 2019; Ruhí et al., 2016). Using a community-wide modeling approach, Rogosch et al. (2019) revealed non-native fish species in the southwest United States replaced native species as river flow regimes became increasingly affected by drought. These replacements reflected differences in mortality to the major flow events, including spring and summer floods, and droughts. Ruhí et al. (2016), using time-series techniques on multi-decadal ecohydrological data, uncovered high quasi-extinction risks of native species, and asserted that continuing current stream flow trends would further increase these risks for native species but decrease the risks to non-native species.

Dispersal becomes a critical tool in a species' toolbox for its response to ongoing change. Poor dispersers will be less capable of tracking shifting climatic conditions, and species that are restricted to dispersing along the river network will be more vulnerable to extinction than those that can also disperse overland (Tonkin et al., 2018a). Furthermore, species moving upwards in elevation along the river network are threatened by the "summit trap" effect, whereby further dispersal up hillsides is capped at mountain peaks (Sauer et al., 2011). Thus, the extent to which communities will reorganize will depend on a host of factors, including river network structure, dispersal ability and mode, and barriers to invasion.

Interactions with other stressors

There are very few rivers left in the world that have not been impacted by human activities. Understanding the true effects of climate change on riverine ecosystems requires a much broader understanding of species vulnerabilities beyond thermal tolerances to incorporate flow regimes and various other anthropogenic stressors including land use change (Comte et al., 2021). Human-altered systems are potentially more at risk both ecologically and economically from increased extreme events, such as dam failures that may occur with extreme future floods (Palmer et al., 2008). Dams, by altering the natural temperature regime of downstream flows, can also alter the natural responses of biodiversity to shifting climatic conditions. For example, Bruno et al. (2019) found contrasting changes between cold- and warm-adapted species from the 1970s to the 2010s between free-flowing and dam-altered rivers in alpine catchments of south-eastern France. Cold-adapted taxa decreased in both river types, but there tended to be a replacement of cold-adapted taxa by warm-adapted taxa in the free-flowing catchment over time. Such replacement was less pronounced in the regulated catchment, which led to a decline in taxonomic diversity, potentially due to the direct effect of flow regulation on habitat suitability and heterogeneity (Bruno et al., 2019). Dams or other instream barriers can also fragment rivers, which can exacerbate the effects of climate change on fishes (Marshall et al., 2021; Radinger and García-Berthou, 2020). For instance, instream barriers can limit the potential recovery of stream fishes following prolonged drought due to blocking colonists (Marshall et al., 2021). However, there is also a tradeoff associated with increasing connectivity, whereby the spread of non-native species may be worsened under climate change (Radinger and García-Berthou, 2020).

The relative vulnerability of human-altered ecosystems to species loss or diminished ecosystem function when faced with further environmental change or extremes is well illustrated when various stressors combine, leading to catastrophic ecological effects. Between December 2018 and January 2019, millions of fish died across three separate events near the town of Menindee in the Darling River, Australia. Ultimately, these events occurred as a result of human alteration of the river's water through a series of weirs, including substantial harvesting of water upstream, combined with an extremely hot and dry climate during 2018 (Vertessy et al., 2019). Specifically, the fish die-offs resulted from a series of events, including large fish biomass accrual, algal bloom development and thermal stratification of weir pools leading to hypoxic bottom-water conditions. These events culminated in rapid oxygen deprivation resulting from weir pool destratification following sudden cool weather changes (Vertessy et al., 2019). The result of this is likely to be ongoing impacts on fish populations both locally and potentially in the wider Darling catchment for some time to come. The key take home here is that ongoing (or press) disturbances related to climate change are likely to make a system more vulnerable to combined anthropogenic stressors such as the over-allocation of water that can further increase water temperatures and lead to a cascading series of events similar to those at Menindee.

The effects of large transient (or pulse) disturbances (e.g., extreme floods) on top of existing ramp or press disturbances (ongoing climate change shifting mean conditions over decadal scales) is an area in need of further attention. For instance, heat waves can result in fire regimes that can increase flood intensity due to combustion of forest vegetation. When extreme events of different forms combine, the results can be particularly detrimental. Dahm et al. (2015) found flash floods that followed a catastrophic forest fire led to major reductions in water quality that persisted for 50 km downstream. Indeed, combining events that may not be extreme in isolation can make them extreme via their combination (McPhillips et al., 2018). Vieira et al. (2004) studied the response of stream invertebrate communities to repeated flood disturbances after a wildfire in New Mexico, United States, and found that total insect density and taxonomic richness declined to near zero following the first 100-year flood after the wildfire. However, density returned to pre-fire levels rapidly due to the colonization of aquatic insects including simuliids, chironomids and baetid mayflies; taxa with resilience traits (including high dispersal ability) that are often associated with disturbance regimes (McMullen et al., 2017). By contrast, taxonomic richness and community composition were much slower to return to pre-fire levels as less resilient species slowly recolonized (Vieira et al., 2004).

The interaction between ongoing land-use alteration and climate change presents a key challenge for river ecosystem resilience as rates of change continue to intensify (Van Looy et al., 2019). For instance, catchment-scale land use can mediate the local-scale responses to extreme events (Woodward et al., 2016). Collier and Quinn (2003) found that invertebrate communities in streams draining pastoral catchments (representing an underlying press disturbance) can be more influenced by flooding than those draining forested catchments. Similarly, climate change-driven changes to water temperature and flow alteration are interacting with land-use change to reorganize riverine fish communities around the world (Comte et al., 2021).

Land use alteration and climate change, representing ongoing press or ramp disturbances, can combine to interact both synergistically (amplifying effects) and antagonistically (buffering effects) to affect river ecosystems, and the nature of these interactions is context dependent. For instance, both synergistic and antagonistic interactive effects of climate change and land use change are predicted to influence the future distributions of fish diversity in the Elbe basin in Spain, resulting in a predicted increase in average species richness of 0.7–2.9 species by 2050 across the entire river network (Radinger et al., 2016). Antagonistic effects of land use and climate change were predicted for up to 75% of the network, and synergistic and additive effects up to 20% and 16% of the network, respectively (Radinger et al., 2016). Further, improvement in water quality from historical degradation has been found to mask the long-term effects of changing climate on stream invertebrate communities (Vaughan and Ormerod, 2014), potentially via the arrival of pollution-sensitive taxa (Floury et al., 2013). Such improvements can make detecting climate change impacts challenging for freshwaters. These examples demonstrate that the multi-pronged effects of long-term environmental change must be studied together to get a clear picture of the true effects of climate change on freshwater biodiversity.

Thresholds and regime shifts

Ongoing changes in the environment, such as unprecedented drought, can potentially push communities and ecosystems into novel states. Bogan and Lytle (2011) examined aquatic insect community changes in two stream pools in French Joe Canyon, Arizona between 2003 and 2009 in response to multi-year drought. They found an abrupt shift between community states during this prolonged drought, which reflected a transition from a perennial to intermittent flow regime (Fig. 3). While richness of communities may recover following, or remain stable during, multi-year drought in streams, there is often an underlying reorganization of communities, such as a replacement of long-lived, weaker dispersers with short-lived, strong dispersers (Bogan and Lytle, 2011). Aspin et al. (2019) used experimental mesocosms to examine trait-based responses to drought intensification and found that intensifying stream drying events can push stream invertebrate communities over functional thresholds, a point whereby statistical changes in traits were more rapid than changes in drought intensity. They found that the specific traits responding depended on the intensity of drought: moderate drought levels resulted in shifts in morphological traits, whereas extreme drought, where surface water was lost, saw shifts in morphological and physiological traits including body size, respiration mode and thermal tolerance (Aspin et al., 2019). Riparian ecosystems are similarly at threat from climate-induced changes to flow regimes. Using a mechanistic modeling approach, Tonkin et al. (2018b) found that an increasingly dry future would lead to the collapse of networks of interacting riparian plant species and a loss of keystone species in the southwest of the United States. Unraveling interaction networks could have negative consequences for community stability and resistance to invasion, whereas losing keystone species could lead to the loss of important ecosystem services including habitat provision, flood mitigation and nutrient cycling.

Extreme drought associated with climate change can also lead to previously suitable habitat becoming an ecological trap for native species. Vander Vorste et al. (2020) found that endangered juvenile Coho salmon survival in intermittent Californian stream pools differed markedly depending on the duration of disconnection between upstream and downstream habitats. Approximately half of the pools studied that were previously able to sustain juvenile salmon in non-drought years appeared to transition into ecological traps—defined by survival being markedly reduced—during drought.

Geographic differences

The threats of climate change will likely play out differently around the globe. Scenario projections have predicted up to 75% of local fish biodiversity will be threatened by extinction by 2070 as a result of the combined effects of climate change and human water demand, but these differ geographically due to baseline differences in climatic conditions (Xenopoulos et al., 2005). Based on physiological estimates of thermal sensitivity, more recent research suggests that freshwater fish faunas will be most at risk of climate change in Northern Hemisphere regions, particularly at high latitudes (Comte and Olden, 2017). This disproportionate threat to high latitude biodiversity in rivers is not limited to fishes (Nilsson et al., 2015). Threats include greater temperatures, increased rainfall and altered timing of stream flow events as a result of altered snowmelt dynamics, many of which will translate into extreme forms, such as unusually large floods (Nilsson et al., 2015). Northern regions will also likely see the arrival of many new species as the climate warms. Emergent aquatic macrophytes have already expanded their distributions northwards in boreal regions over the past several decades, and models suggest this will continue over the next century due to increasing growing degree days (Alahuhta et al., 2011).

No region is spared from the ongoing effects of climate change, however. For example, increased drying associated with climate change in dryland regions will further threaten endemic fishes, particularly through hydrologic fragmentation (Jaeger et al., 2014). Reductions in network-wide hydrologic connectivity through drying is expected to be as severe as 6–9% over the space of the year and up to 12–18% during spring spawning season by the mid- to late-century in the Verde River Basin, United States (Jaeger et al., 2014). Tropical regions are particularly threatened by the considerable ongoing habitat loss and agricultural expansion that will

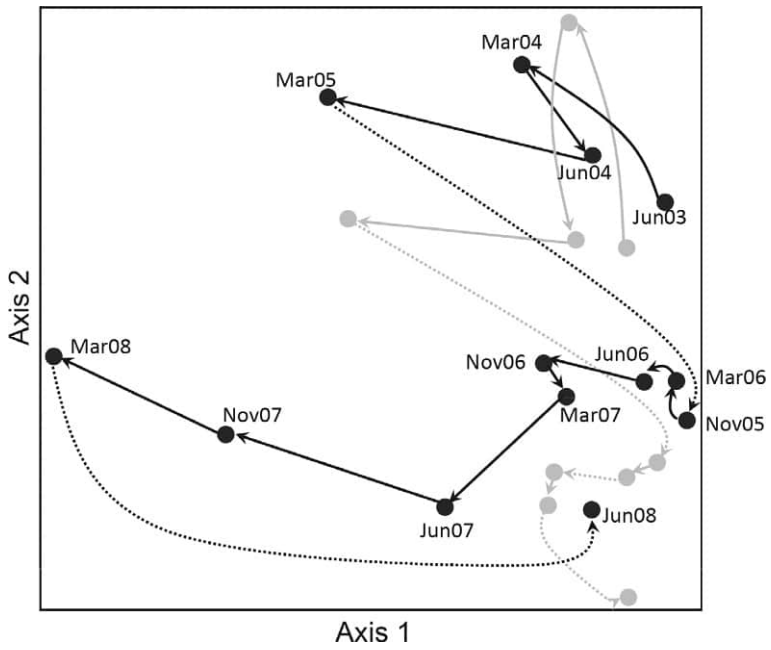

Fig. 3 Ordination plot of aquatic insect community changes in two pools (black vs. gray) in French Joe Canyon, Arizona between 2003 and 2009 in response to prolonged drought. Each point represents a community at one time-point, with those closer together reflecting more similar community composition. Trajectories of change through time are shown by the arrows (dates are labeled only on the black pool). Solid lines reflect times when continuous surface flow was available between both sampling dates. Dotted lines indicate the stream dried in between samples. March 2005 represents a transition from a perennial to intermittent flow regime. Reprinted with permission from Bogan MT and Lytle DA (2011) Severe drought drives novel community trajectories in desert stream pools: Drought causes community regime shifts. *Freshwater Biology* 56: 2070–2081. doi: 10.1111/j.1365-2427.2011.02638.x.

exacerbate the effects of climate change on river ecosystems (Sundar et al., 2020). However, considerable changes have already been observed in tropical Hong Kong stream invertebrate communities over recent decades in the absence of non-climate change drivers (Dudgeon et al., 2020).

Solutions

Many solutions are available for protecting riverine biodiversity, and indeed humans, from the growing threat of climate change and extreme events in river ecosystems. It is clear that the tools are here—the challenge is in the impetus and implementation—and I list a small selection of these tools below. First, in order to be able to better protect freshwater biodiversity from ongoing climate change, we need to go beyond observational data and correlational approaches, and understand mechanistic responses to individual events and whole regimes (Tonkin et al., 2019). This is particularly important for extreme events (van de Pol et al., 2017), and a mechanistic approach will enable a shift towards more robust forecasts and projections of future scenarios. Nevertheless, greater investment into coordinated monitoring programs is required to detect trends across broad regions.

The cost of anticipatory or proactive action will be cheaper than mitigation at a later date (Palmer et al., 2008). By focusing on employing adaptive or anticipatory management policies, much needed flexibility will be promoted to cope with the rapid rate at which systems are changing. Anticipatory or adaptive management aligns particularly well with ecological forecasting. Adaptive management and ecological forecasting can be coupled in an adaptive iterative cycle of model development, prediction and testing (Dietze et al., 2018). Moreover, frameworks such as eco-engineering decision scaling (EEDS) enable a quantitative assessment of trade-offs among potentially conflicting engineering and ecological targets across a variety of possible management regimes under uncertain hydroclimatic settings (Poff et al., 2016).

One key target to build resilience into rivers to rapidly changing futures is to embrace natural riverscape variability. This can be at both local and regional scales. For instance, giving rivers more room to move will enable a greater capacity to self-organize in response to extreme events. Even without the pending threat of climate change altering the frequency of large floods, rivers often naturally overtop their banks at regular frequencies. However, given the likelihood of large-scale river floods becoming more frequent and the fact that human infrastructure is often built on river floodplains, strategic decisions are required about where to give rivers the room they need to move and where to continue to lock in protective structures.

At more regional scales, there is a need to consider streams as metasystems from a dynamic perspective as flow regimes continue to change (Datry et al., 2016; Van Looy et al., 2019). Managing for variability and spatial connectivity across the landscape will

accommodate uncertainty and promote the resilience of river networks to change. Spatial environmental heterogeneity enables broad ecological responses (response diversity) to changing conditions, thereby imparting resilience by enhancing adaptive capacity at the landscape scale.

Designing and implementing spatial ecological networks that enable multiple species to persist, disperse and migrate, and that are robust to multiple climatic and environmental futures is possible using multi-criteria decision making (Albert et al., 2017). Without facilitating unhindered movement of organisms in this manner, managed relocation or assisted migration of species (Olden et al., 2011) or whole communities (Jourdan et al., 2019) will be required in many instances. Balancing local-scale optimal conservation goals while maintaining and promoting the variability that is inherent in natural systems remains key, but it presents major challenges for prioritization in the broader geographic context given the inherent tradeoffs and complexity in decision making required.

Often, the focus of management efforts is too local. Instead, effort should be put into strategic spatial prioritization of management actions for maximizing targets regionally while maintaining resilience at the landscape scale (Poff, 2018). Dammed river catchments may be more at risk from climate change than free flowing rivers via a reduced capacity to reorganize and absorb additional disturbances (Palmer et al., 2008). On the flip side, however, water-control infrastructure, such as dams, provides opportunities for managers to build both resilience and precision into human-altered systems (Tonkin et al., 2021). Although most research on designing environmental flows for human-altered rivers has so far focused on single dams, there is potential to apply this notion to portfolios of hydrologic infrastructure to minimize shortfall risk (in hydropower, water yields) while maximizing regional ecological outcomes. It is, nonetheless, a major societal challenge to achieve an appropriate balance between ecosystem conservation and water resource development.

Conclusions

Humans have extensively exploited river systems for their services, such as food and water supply, power, transport, and recreation, but at the cost of severe ecological degradation (Dudgeon et al., 2006). Climate change is now pushing river ecosystems into new domains of variation by altering regional precipitation and temperature regimes and extremes. The excursion of natural hydrologic variability outside the range of the historical undercuts assumptions of water resources management (Milly et al., 2008) and threatens ecosystems (Tonkin et al., 2019).

The alarming signals we are seeing from Siberian wildfires, extreme floods around the world, to deadly western United States heatwaves each represent the no-analog futures that atmospheric scientists have been predicting for some time. Only time will tell just how devastating these events will be for freshwater biodiversity. But the evidence provided in this chapter highlight that the effects will be wide ranging, from local species extirpations, range shifts, food web collapses, and homogenization. Riverine biodiversity is naturally resilient to dynamic fluctuations in the environment, but we need to be prepared to help increase this resilience through any means possible.

Klement Tockner is director general of the Senckenberg Society for Nature Research and professor for ecosystem sciences at Goethe University, Frankfurt am Main. He was president of the Austrian Science Fund—FWF (2016–20), full professor for aquatic ecology at the Free University Berlin (2007–20), and director of the Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin (2007–16). He received a Ph.D. from the University of Vienna (1993) and a Titulary Professorship at ETH Zürich (2005).

Klement Tockner is an internationally leading freshwater scientist, in particular in the research domains biodiversity, ecosystem science, and environmental management. He has published about 250 scientific papers including 180 ISI papers. He was editor-in-chief of the journal *Aquatic Sciences* (2005–2014) and is subject editor of the journal *Ecosystems*. He has published about 250 scientific papers including 180 ISI papers. In 2009, he edited a comprehensive book on European Rivers (Rivers of Europe, Elsevier; 2nd Edition in 2021). He is elected member of the Austrian Academy of Sciences and the German Academy of Sciences, Leopoldina.

Thomas Mehner is vice director and senior researcher at the Leibniz Institute of Freshwater Ecology and Inland Fisheries in Berlin, Germany. He is limnologist and fisheries biologist by training, and has got his Diploma and Ph.D. at the University of Rostock (formerly East Germany) in 1992. In 1999, he had received his habilitation and venia legendi in limnology, which allowed him to start teaching as Privatdozent at universities. Since 1997, he has been working at IGB in several positions. He has published about 170 ISI papers, with primary focus on fish communities, lake food webs, and species interactions. However, his topical interests are broader, and he has authored and co-authored several publications on freshwater fisheries management, fish population genetics and evolutionary and behavioral ecology of aquatic organisms. He has been Handling Editor of the journals "*Aquatic Ecology*" and "*Freshwater Biology*" for several years, and he is currently member of the Editorial Boards of "Global Change Biology" and "Limnologica." Since spring 2018, he has been the president of the International Society of Limnology (SIL), the oldest and most international scientific society devoted to the study of inland waters. Thomas Mehner has taught M.Sc. courses at universities on limnology, fish ecology, fisheries management, and behavior and evolution. His one-week course on "Scientific Writing" for Ph.D. students has been run at 3 universities and in total 18 times, with >120 international students participating. He has trained many M.Sc. and Ph.D. students and supervised their theses, and he is actively mentoring undergraduates, graduates, and post-doc researchers.

EDITORIAL BOARD

Editorial Board Names and affiliations

SECTION EDITORS

Damien Bouffard is leader of the aquatic physics lab at Eawag (Switzerland). He holds a Ph.D. from EPFL (with Ulrich Lemmin). After his Ph.D. he worked in Canada with Leon Boegman (Queen's U.), Ram Yerubandi (Environment Canada), and Joe Ackerman (Guelph U.) before returning to Switzerland as first assistant at EPFL with Alfred (Johny) Wüest. He has published over 70 peer-reviewed papers in aquatic physics and serves as associate editor for JGLR, AS, and HESS. His program research is focused on two axes: (i) linking the small-scale turbulence to the large-scale forcing with today a special interest in convective processes in lakes and (ii) aquatic physics as a tool to understand lake ecosystems. The later includes the use of 1D and 3D operational hydrodynamic models such as simstrat.eawag.ch or meteolakes.ch. Bouffard is also involved in promoting multidisciplinary and high-tech research on lakes, notably as member of the steering committee of the LéXPLORE floating research platform in Lake Geneva and in promoting open science in limnology with the web platform Datalakes-eawag.ch.

Debbie Chapman as a graduate of the University of London, Deborah Chapman started her research career as limnologist at the Freshwater Biological Association in the English Lake District. She subsequently became interested in monitoring the impacts of disposal of sewage sludge on aquatic organism and the potential for human health impacts from aquatic pollution. In 1986 she joined the United Nations Environment Programme's (UNEP) Monitoring and Assessment Research Centre (MARC) in London, participating in the international monitoring and assessment activities of UNEP and the World Health Organization (WHO), and assisting in global environment assessment programs. In 1988 she became the deputy director of MARC and took responsibility for the developing country workshops and training program, and global environment data review and compilation. After moving to Ireland in 1990, she worked as a freelance Environmental Consultant engaged mostly on international and developing country projects for WHO, UNEP, and other international organizations. She has assisted with the compilation of State of the Environment reports and has contributed to, edited, and produced more than 20 books on water resources and environmental management, including the internationally successful *Water Quality Assessments: A guide to the use of biota, sediments and water in environmental monitoring.*

In 1998 she joined UCC becoming the first lecturer in Environmental Science and then Head of Environmental Science in 2013. In recent decades her research interests have focused on water resources management, especially recreational and amenity lakes and reservoirs, developments and current practice in design and implementation of water quality monitoring programs, and human health risk assessment in relation to the use of freshwater resources and wastewater disposal. Drawing on 30 years of international experience, in 2015 she established the UNEP Global Environment Monitoring System for Water (GEMS/Water) Capacity Development Centre at UCC. This center delivers capacity development activities in water quality monitoring and

assessment worldwide for UNEP, including support for the Sustainable Development Goal indicator for good ambient water quality. She retired as director of the center in June 2021 and now acts in an advisory role and as an independent consultant.

Kendra Spence Cheruvelil is professor of limnology and co-director of the Data-intensive Landscape Limnology Laboratory at Michigan State University (MSU) in the Department of Fisheries and Wildlife (https://www.canr.msu.edu/fw/). She is also serving as Interim Dean of the Lyman Briggs College, which is MSU's residential college for studying the sciences and maths within their societal and global contexts (www.lbc.msu.edu). Kendra co-established the discipline of landscape limnology (https://bigdatalimno.org/research-themes/landscape-limnology/) and co-leads the LAGOS research program that is creating the research infrastructure to conduct big-data research on U.S. lakes (https://lagoslakes.org/). This large, collaborative, and interdisciplinary research program has been funded by the U.S. National Science Foundation and seeks to understand how global changes such as climate change and land use intensification affect lakes across regions and continents and through time. Dr. Cheruvelil also pushes the boundaries of how to conduct limnology research by using data-intensive science, science of team science, and open science approaches, tools, and perspectives to answer complex scientific questions. She also has an active research program to advance diversity and inclusion in the sciences (https://ee-stem.weebly.com/) and serves as an associate editor for the journals *Limnology & Oceanography Letters* and *Frontiers in Ecology & the Environment*. Prior to joining MSU, Dr. Cheruvelil was a faculty member in the Purdue University system. She has a dual Ph.D. from MSU in Fisheries & Wildlife and Ecology, Evolution, & Behavior (2004).

Catherine Febria is a Tier 2 Canada Research Chair in Freshwater Restoration Ecology and assistant professor at the Great Lakes Institute for Environmental Research (GLIER) & Dept. of Integrative Biology at the University of Windsor. Her research focuses on the ecology and restoration of small streams and wetlands in human-impacted landscapes, and the role of small waterways in supporting good ecosystem health in the Laurentian Great Lakes. She launched her lab—the Healthy Headwaters Lab—in 2019 and also wears multiple hats as co-director of the GLIER Organic Analysis & Nutrients Laboratory (a central research facility), associate director of FishCAST (an NSERC CREATE graduate student training program in Canada), co-chair of the International Science Advisory Panel for New Zealand's Biological Heritage National Science Challenge, coordinating editor with the journal *Restoration Ecology* and alumni fellow and contributing author with the Intergovernmental science-policy Platform on Biodiversity and Ecosystem Services (IPBES). She previously held a postdoctoral role at the University of Maryland's Chesapeake Biological Laboratory (USA), the University of Canterbury (Aotearoa New Zealand). Her research has been published in the *Science*, *Nature Geoscience*, *Canadian Journal of Fisheries and Aquatic Sciences*, *Environmental Science & Technology*, and *Frontiers in Microbiology*, *Restoration Ecology*, *Proceedings of the Royal Society*, to name a few. She is co-founder of the Kindness in Science global initiative, and contributes actively to actions, scholarship and mentorship to advance justice, equity, diversity, and inclusion in academia.

Christian Griebler is full professor and head of the Limnology unit at the University of Vienna, Austria. He is a dedicated groundwater ecologist with core expertise in microbial ecology and biogeochemistry.

Kenneth Irvine has a broad range of multidisciplinary experience working on aquatic ecology, ecological assessment of surface waters, especially lakes and wetlands, and policy and related policies and management. After gaining a Ph. D. in 1987 at the University of East Anglia (U.K.) for a study on trophic ecology of shallow lakes, he worked for the U.K. Nature Conservancy Council, before moving to study ecosystem structure of Lake Malawi in Africa. He moved to Trinity College Dublin in 1994 Ireland. There, he continued work on the African Great Lakes, as well as building a research group working on ecological assessment in support of the EU Water Framework Directive. In 2011 he moved to IHE Delft Institute of Water Education, the Netherlands, as chair of Aquatic Ecosystems. Current work focusses on wetlands and capacity development in Sub-Sahara Africa. Recent work also includes a review of hydromorphology and links to policy. He currently sits on the Board of the Board of the *African Center for Aquatic Research and Education* (ACARE) and on the Scientific Advisory Board of the *Leibniz Institute of Freshwater Ecology and Inland Fisheries* (IGB), Berlin.

Wolfgang Junk was scientist of the Max-Planck-Institute for Limnology, Dep. Tropical Ecology, Plön during 1970–75.He was scientist of National Amazonian Research Institute, leader of the Dep. of Hydrobiology and Inland Fishery at Manaus, Brazil during 1976–79. and leader of the Working Group "Tropical Ecology" at the Max Planck Institute for Limnology in Ploen, Germany during 1980–2007.He is expertise in ecology and sustainable management of floodplains, land-water interactions, wetland classification. His main research areas arestudies on biomass, primary production, and decomposition of wetland plant communities; nutrient fluxes between land and water; adaptations of plant and animals to periodical drought and flooding; ecology of aquatic macrophytes and fish communities; biodiversity; conceptional considerations on river-floodplain systems, sustainable management of wetland resources and wetland protection with emphasis on the Amazon River floodplain and the Pantanal of Mato Grosso, Brazil. He supervised numerous M.Sc. and Ph.D. students and published more than 300 peer-reviewed publications, including several books and book chapters on Amazonian wetlands and the Pantanal of Mato Grosso. He received many honors, among them the Award of the Grande Cruz (the highest distinction of Brazil) for exceptional scientific performance, and the Cross of Merit First Class of the Federal Republic of Germany. He is corresponding member of the Academy of Sciences of Brazil.

Krantzberg is professor and lead for the engineering and public policy in the School of Engineering Practice and Technology at McMaster University offering Canada's first master's degree in engineering and public policy. Gail completed her M.Sc. and Ph.D. at the University of Toronto in environmental science and freshwaters. She worked for the Ontario Ministry of Environment from 1988 to 2001, as coordinator of Great Lakes Programs, and senior policy advisor on Great Lakes. Dr. Krantzberg was the director of the Great Lakes Regional Office of the International Joint Commission from 2001 to 2005. In 2007 she was appointed as an adjunct faculty member of the United Nations University Institute for Water and Environmental Health and participated in the twinning of the Laurentian and African Great Lakes (principally Lake Victoria). She has co-authored and edited 9 books and more than 200 scientific and policy articles on issues pertaining to ecosystem quality and sustainability and is a frequent speaker to media and the public. Her research interests include investigating Great Lakes governance capacity, analyzing interjurisdictional co-management arrangements internationally for application to the Great Lakes regime, and methods to better integrate science and engineering in policy formulation and decision-making.

Marie-Elodie Perga is associate professor of limnology at the University of Lausanne in Switzerland. Since receiving her Ph.D. from the University of Savoie-Mont Blanc (France), she has worked at the University of Victoria in Canada, and the French National Institute for Agronomy and Environment (France), before moving UNIL.

Because she is a Lindeman's groupie, her research lies at the interface of community ecology and biogeochemistry, through lake food webs and carbon processes. More recently, she added a pint of hydrodynamics with the intent to bridge physical and biogeochemical mechanisms, especially in alpine and high-altitude lakes. Her work covers centennial up to minute timescales through the combination of high-resolution paleo-records and high-frequency data from autonomous sensors.

She is also involved in promoting high-tech research on lakes, notably as a member of the steering committee of the LéXPLORE floating research platform in Lake Geneva, and in connecting science and management through a transdisciplinary network involving National Parks in France. She has published over 75 peer-reviewed papers and serves as associate editor for WIRES Water.

N. LeRoy Poff is professor of biology at Colorado State University and holds a partial appointment as distinguished professor at the University of Canberra, Australia. Since receiving his Ph.D. in 1989, his research has focused on understanding how natural and human-caused hydrologic variability regulates the interactions among species and the structure and function of riverine ecosystems. By developing techniques to quantify streamflow variability in ecologically meaningful terms and using species (functional) traits as generalized, mechanistic response variables, he has been a leader in advancing the field of hydroecology. Through his interdisciplinary and collaborative work, he has contributed fundamentally to the development of the field of "environmental flows," which aims to support sustainable management of streams and rivers at local to regional to global scales in the face of growing human water demands. His current interests are on developing better conceptual frameworks and decision support tools for science-based management of streams and rivers in our current period of rapid climate and ecological change.

Lars Rudstam is professor of fisheries and aquatic sciences in the Department of Natural Resources and the Environment, Cornell University (USA) and the director of the Cornell Biological Field Station. He has a master's degree from the Center for Limnology, University of Wisconsin-Madison and a Ph.D. from Stockholm University, Sweden. Rudstam has published over 250 papers ranging from lake physics to phytoplankton, zooplankton, mussels, mysids, fish, birds, and anglers, mostly about processes associated with food web interactions and ecosystem dynamics. He has worked in lakes in North America, Europe, and Asia as well as the Baltic Sea.

Stuart Warner works with the United Nations Environment Programme with a focus on helping countries to monitor and assess their freshwaters. He was born in England, he moved to Ireland in 2001 to work at University College Cork. Stuart has published in the areas of water quality monitoring and assessment and citizen science approaches to data collection. He has written reports on the capacity of countries to understand their freshwaters which highlight the challenges faced in different world regions. Recent efforts have focused on the development and implementation of a global water quality indicator, and the delivery of capacity development targeted at improving freshwater management. His professional interests include using both traditional and innovative approaches to understand and protect freshwater ecosystems.

Florian Wittmann is professor for physical geography and head of the Department of Wetland Ecology at the Karlsruhe Institute for Technology, Germany. He studied geography, geology, and botany at the Universities of Mannheim and Heidelberg, got his Ph.D. in physical geography at the University of Mannheim, and his lecturer qualification at the University of Bayreuth, Germany. He held post-doc positions at the Max Planck Institutes for Limnology and Chemistry, Germany, where he was working at the bilateral project between the Max Planck Society and the National Institute for Amazonian Research in Manaus, Brazil, for more than 15 years.

His research focuses on neotropical wetlands, with special interest in biogeography, plant species distribution, species diversity, forestry and sustainable management, remote sensing, biomass and primary productivity, and botany and vegetation ecology. Actually, he teaches at the Institute for Geography and Geoecology of the Karlsruhe Institute for Technology, Germany, and in the post-graduate program of Tropical Ecology—Botany at the National Institute for Amazon Research—INPA, Manaus, Brazil. He supervised numerous M.Sc. and Ph.D. students and published more than 150 peer-reviewed publications, including several books and book chapters on Amazonian wetlands.

CONTENTS OF VOLUME 3

Structures and functions of Inland Waters - Wetlands

This page intentionally left blank

Section Introduction: Wetland Ecology

CM Finlayson, School of Biological, Earth and Environmental Sciences, Faculty of Science, University of New South Wales, Sydney, NSW, Australia; IHE Delft, Institute for Water Education, Delft, Netherlands

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Wolfgang Junk and Florian Wittmann.

Glossary

Biogeochemical cycling Is largely mediated by the microbiota, in particular bacteria and fungi, that are responsible for the degradation of organic matter and the cycling of nutrients, including nitrogen and phosphorus.
Decomposition Is the conversion of plant material at the end of the growing season to detritus and then to carbon dioxide, which can be released to the atmosphere, or remains as recalcitrant compounds (such as hemicelluloses and lignin) in the wetland.
Primary production A measure of the amount of carbon fixed through photosynthesis and released through respiration by the plants and algae (photosynthetic organisms) in a wetland.
Vegetation Succession The consequence of disturbances in the wetlands causing changes in the species composition of the vegetation, with species acting independently of one another.

Introduction

This article provides an overview of key aspects of the ecology of inland wetlands, including their extent and distribution, species diversity, and ecological processes. The range of inland wetland types varies greatly in terms of their size (area and volume), water quality (conductivity, nutrients and trace metals), hydrological patterns (permanency, flows, connectivity), and biodiversity (composition, richness, or abundance). They have also been defined in many ways with many terms used to describe them (Finlayson et al., 2018) and with much discussion over formal classifications (Gerbeaux et al., 2018).

Their ecological condition and management status also varies, with recent global analyses, based on information collated through the Ramsar Convention on Wetlands' Global Wetland Outlook, showing that many are in decline or have been destroyed, their species populations threatened, and their ecosystem services diminished (Ramsar Convention on Wetlands, 2018).

Following the acceptance of the Global Wetland Outlook by the parties to the Ramsar Convention a list of policy suggestions to improve wetland management (Finlayson and Gardner, 2020) was provided. This was based around the concept of maintaining the ecological character of a wetland (Fig. 1) which has been defined by the Convention to include the ecological components (biological, chemical, and physical), ecological processes, and ecosystem services (Pritchard, 2021). Key aspects of the ecological character of inland wetlands are presented with a description of the extent and distribution of wetlands, their species diversity, and vegetation succession, and ecological processes including primary production, decomposition, and nutrient cycling. Ecosystem services are not considered further given that they are derived from the interactions between the ecological components and processes in a wetland and from the associated social interactions and values. The importance of ecosystem services for human

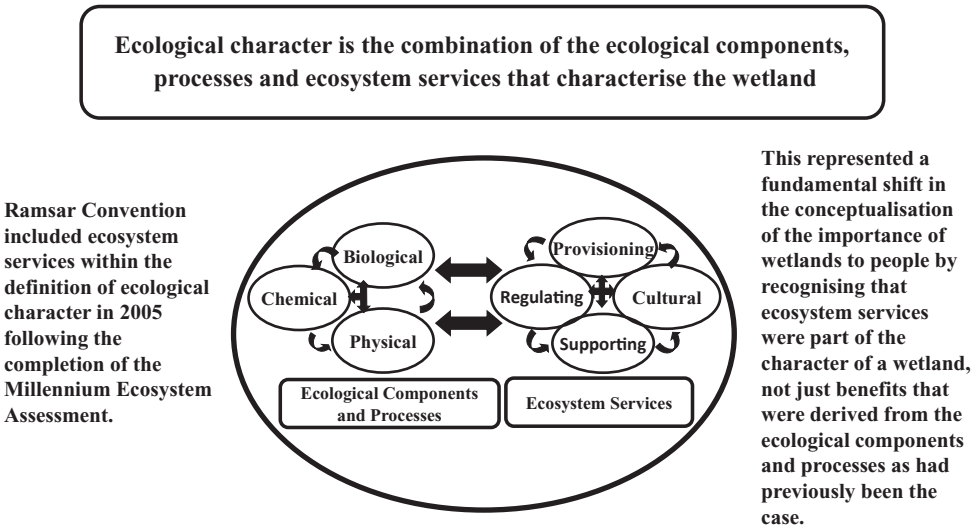

Fig. 1 Pictorial representation of the Ramsar Convention on Wetlands concept of ecological character whereby a wetland is comprised of ecological components, ecological processes, and ecosystem services.

wellbeing and livelihoods is shown by the estimate from Davidson et al. (2019) that the economic worth of inland wetland ecosystem services was US$27 trillion per year at 2011 values, or 25% of the total global value of all ecosystem services.

The ecological processes considered here include the hydrology or water regime, primary production and biogeochemical cycling (nitrogen, and phosphorus). The hydrology of a particular wetland is one of its fundamental features and underpins the occurrence and dynamics of the biodiversity and biogeochemical cycles. Primary production is the balance between the fixation of carbon through photosynthesis and release through respiration by the plants and algae. The text addresses primary production by vascular plants, and not that by the highly diverse phytoplankton population that occur in inland wetlands. Similarly, secondary production is not described. Biogeochemical cycling is associated with the primary production in and wetlands and is largely mediated by the microbiota, in particular bacteria and fungi, that are responsible for the degradation of organic matter and the cycling of nutrients, including nitrogen and phosphorus (Baldwin, 2018).

Wetland extent and distribution

Estimates of the area of wetlands need to be considered in terms of the types of wetlands included, and the method and scale of the analyses (Davidson and Finlayson, 2019). The latter reflects advances in data collection, increasingly from Earth Observation using data obtained from satellite-based remote sensing (Rebelo et al., 2018), while the former can be greatly influenced by the method of data analysis and the types of wetlands that are included. Both are affected by the way in which changes in inundation are considered, whether these occur seasonally, or annually, or stretching to decadal time periods. Davidson and Finlayson (2019) further noted that global estimates based on data collated from multiple sources tended to be greater than those from satellite-based remote sensing data.

A recent collation of data from multiple sources by Davidson et al. (2020) provided an estimate of the area of inland wetlands of approximately12.38 million km^2 including lakes (>10 ha in size), lakes and ponds (<10 ha in size), non-forested and forested peatlands, mixed marshes and swamps on alluvial soils, and forested wetlands on alluvial sources. There is a further estimated 1.90–1.94 million km^2 of human constructed wetlands, including rice paddy, reservoirs, small ponds, aquaculture ponds and wastewater treatment ponds. Based on these sources of inventory information the area of inland wetlands is dominated by peatlands (4.23 million km^2), natural lakes (3.23–4.20 million km^2), and marshes and swamps on alluvial soils (2.53 million km^2) which together comprise 80% of the total. Recent analyses of the area of Arctic wetlands suggest that the area of peatland may be an underestimate, as discussed by Davidson et al. (2020), including consideration of the extent of permafrost wetlands.

It is likely that information on the extent of particular wetland types or in specific areas may not have been included in such collations given limits to literature searching and access to large amounts of information, and discrepancies between definitions of wetland types.

Calls for greater attention to the collation of such information and the creation of reliable global estimates have not resulted in the creation of a reliable inventory repository for wetland inventory data at a global scale. As an example, in a data base proposed by the UNEP as a resource for individual countries, the area of inland wetlands in South America is given as 0.4 million km^2 (Kingsford et al., 2021) compared to higher estimates of 1.96 million km^2 in Davidson et al. (2020) and 2.338 million km^2 from Junk et al. (2018). Junk et al. (2014) report that wetland area in South America could extend to 20% of the area of the continent, namely, about 3.56 million km^2. There are further inconsistencies as to whether floodplains, that are complex systems (Tiner, 2016), are considered as wetlands in all parts of the world, and uncertainties around the area of ephemeral wetlands that may be dry for years or even decades (Parra et al., 2021).

Given that many countries in reporting to the Ramsar Convention on Wetlands (2018) noted the absence of a national wetland inventory there is a need to continue to improve the data resource (Davidson et al., 2020). In addition, greater consistency in the use of wetland definitions would assist with the mapping of wetland areas at continental and global scales.

Recent analyses have highlighted the continuing loss and degradation of wetlands globally with Darrah et al. (2019) reporting a loss of 35% since 1970, where data is available. The latter is an important phrase as there are still gaps in the analysis of wetland extent as well as loss. On this basis the areal estimate is likely to be an underestimate, and extrapolation of the rates of loss to continental or global statements needs to be done with caution. Further data are needed before these values can be considered as definitive. This is particularly so for historical wetland loss where definitive data may be lacking about the extent of wetlands and losses in many parts of the world. Biases could also be introduced by the algorithms used in these analyses, such as recently considered for the use of similar indices for species changes (Leung et al., 2020).

Descriptions of individual wetland types are provided in many publications including continental and global overviews, national and sub-national inventories, and site descriptions. Finlayson et al. (2018) provide a summary of major sources of information, including continental-scale wetland directories and inventories, collations and overviews of wetland types, and national overviews. Milton et al. (2018) similarly provide a summary of information sources for regional compilations of individual or wetland complexes and introduce detailed overview articles that inter alia describe the diversity within the wetland, its distribution and extent. The Ramsar Convention on Wetlands provides a data base of 1977 inland wetlands of international importance (accessed 14 October 2021, https://rsis.ramsar.org/ris-search/?f%5B0%5D=wetlandTypes_en_ss%3AInland%20wetlands) with information on their ecological character and management arrangements. Fig. 2 shows a range of inland wetland types.

Species diversity

The species diversity in many, but not all inland wetlands, is high, with many being populous and dynamic, with wetlands in higher altitudes and latitudes generally less biodiverse. A snapshot of vertebrate diversity in wetlands is given in Fig. 3. Turak and Pittock (2018) used several key sources to provide an estimate of the number of freshwater species in various taxa (Table 1). They used a general definition to include the diversity of species that occur in inland waters, including those that occur in saline wetlands (such as salt lakes and marshes), and which accomplished all or part of their life cycle in these wetlands. This was in line with the Freshwater Animal Diversity Assessment (Balian et al., 2008) which provided a global overview of the diversity of selected animal groups and wetland plants (macrophytes). Gopal and Junk (2001) provide a similar definition of wetland species, namely "all those plants, animals and microorganisms that live in a wetland permanently or periodically, (including migrants from adjacent or distant habitats), or depend directly or indirectly on the wetland habitat or on another organism living in the wetland." The groups covered by Turak and Pittock (2018) are shown in Table 1 and comprised more than 131,000 species with others, such as freshwater fungi and plankton that could be added, as well as an unknown number of microbial species. Estimates of species also vary, with for example, Piedade et al. (2021) conservatively reporting 3457 macrophyte species.

Despite a paucity of information about the ecology of many of these populations their importance is underpinned by their role in the ecological processes that are outlined below.

The population sizes of many species are unknown with estimates constrained by difficulties in measuring them as well as fluctuations due to environmental changes and, increasingly, due to the negative impact of human activities. Population estimates are notoriously difficult to obtain for many species, regardless of whether they are sedentary or migratory, due to difficulties in observing individuals, and for migratory species accounting for both short and long-distance movements and, for some species, rapid changes in numbers in response to environmental stimuli, such as the onset of flooding in seasonal and even more so, in ephemeral wetlands. Difficulties in obtaining estimates of species populations are reflected in the limited application of the criteria used by the Ramsar Convention for listing wetlands as internationally important based on species populations sizes (Stroud and Davidson, 2021). This is well shown for waterbird populations that have been investigated for decades, using extensive networks of observers, but which still lack current population estimates for many species.

Given the range of inland wetland types and the variety of climate and water regimes that influence these it may be fallacious to make generalized statements about the biodiversity in inland wetland types. This is shown by the differences in species diversity recorded in five large wetlands, as recorded in Junk et al. (2006) and shown in Table 2. In these examples it was possible to make reasonable comparisons between vertebrate species, for example, but the data for invertebrate species were inadequate for a meaningful comparison. Meaningful and more detailed comparisons, if required, could be based on wetland types within biogeographic zones, particularly if the biogeographical zonation reflects wetland distribution and is not based on terrestrial features. In this respect the Freshwater Ecoregions of the World (FEOW) proposed by Abell et al. (2008) provide a relevant base for considering the biogeographical distribution of wetlands, as done by Milton et al. (2021) for wetlands of international importance (Ramsar sites). A mapping of inland wetland types across these ecoregions is not available.

Vegetation succession in wetlands

Wetland vegetation comprises a wide range of plant types, including woody and non-woody species that accomplish all or part of their life cycle in the wetlands. As inland wetlands can vary from having permanent water to ephemeral systems that can be dry for years or even decades, a large range of plants can be found in wetlands with Cronk and Fennessy (2001) characterizing them as

Fig. 2 A variety of inland wetlands occur globally with many being freshwater, but some also brackish to saline, others permanently or intermittently filled, and of different sizes and depths. Photographs © C.M. Finlayson.

being able to grow in water or a waterlogged substrate generally deficient in oxygen. They further characterize them as: (i) emergent (herbaceous and woody species) with leaves, stems and reproductive parts above the surface of the water, or the waterlogged substrate; (ii) submerged plants with leaves and stems generally below the water, with flowers that may be above or below the water;

Derived from Junk WJ, Brown M, Campbell IC, Finlayson CM, Gopal B, Ramberg L and Warner BG (2006) The comparative biodiversity of seven globally important wetlands: A synthesis. *Aquatic Sciences* **68**: 400–414.

(iii) floating-leaved plants that are anchored in the substrate and may have leaves below the surface as well as floating; and (iv) floating plants that are not attached to the substrate. The range of species and their dominance is greatly influenced by the climate and the water cycle in any particular wetland, and also by the substrate type and chemical composition, and the water quality, including nutrients and salinity (Piedade et al., 2021). Changes in the composition of the plants over time, referred to as ecological succession, occur as a consequence of competition between species, the accumulation of organic matter and sediments, as well as changes to the water regime (water depth, flow rate, period of inundation) and the water quality.

An overview of succession in wetlands is provided by Middleton (2018) who saw succession as the consequence of disturbances in the wetlands causing changes in the composition of the vegetation, with species acting independently of one another. An alternative view that there was a successional progression towards a climax state in wetlands with interlocked species associations is largely disregarded nowadays (Niering, 1987; Anderson, 2018). Rather, disturbances including changes in the water and salinity regimes, as well as the impact of herbivores and fires, climatic events, and earthquakes, are considered as driving succession in wetlands.

Using these concepts and considering the life history traits of dominant plant species, Van der Valk (1981) developed a model for vegetation succession in wetlands based on initial investigations in prairie pothole wetlands in North America and further specifically applied in monsoonal wetlands in Australia (Finlayson, 1991) and in India (Middleton, 1999). The model represents wetland succession as a cycle that maintains wetlands over varying periods of time in response to the abovementioned ecological factors. In tropical wetlands subject to pronounced wet and dry seasons, such as in the monsoonal wetlands of south and east Asia, the drying-flooding cycle occurs across annual time periods whereas in many temperate zone wetlands the cycle may operate over many years. The regrowth or re-establishment of many species following changes in the water regime is dependent on the survival of reproductive propagules in the sediments, in what is simply called a seed bank although it can contain vegetative propagules as well as seeds, and how they respond to the conditions that exist in a wetland at a particular time, or to them being carried into wetlands by water flow, by prevailing winds, or by animals.

Van der Valk (2018) discusses the application of plant attributes to determine successional changes in wetlands whereby the environmental conditions act as a sieve which determines which species can become established and which will persist under specific conditions.

The accuracy and usefulness of such approaches are dependent on understanding the life-history attributes of the species involved and how they respond to changing environmental conditions, and to new species becoming established in a wetland.

The dynamics and growth patterns of wetlands associated with large rivers have been intensively investigated in South America especially those in Amazonia and the Pantanal of Mato Grosso. As described by Junk et al. (2000) and Piedade et al. (2010) wetlands along the Amazon river support forests that contain more than 1000 plant species growing in areas that are flooded annually for up to 8 months in a year, and at depths that reach 10 m. The trees have a wide range of anatomical, morphological and physiological adaptations to the oscillating flood pulses that they experience annually and are highly productive with large amounts of biomass when the nutrient levels in the water and soils are sufficiently high. The importance of pulse flows to the dynamism and ecological changes that occur annually in these wetlands is mentioned further below in this chapter.

As climate change may lead to more species "moving" and becoming established in various wetlands the currently recognized successional paths may be altered. The establishment of the submerged plant *Egeria densa* in the Rio Cruces wetlands in Chile following an earthquake in 1960, and subsequent decline illustrates both the type of changes that can occur as well as the lack of understanding of the drivers of these changes (Marín et al., 2018). The advent of global climate change is expected to drive further change in successional patterns in wetlands.

Hydrology

The importance of hydrology for wetlands is encapsulated in the following statement from Tiner (2018, p. 217) "Hydrology—the frequency, duration, and timing of inundation and/or soil saturation—is the lifeblood of wetlands. The presence of water strongly influences the physical and chemical environment, biota, productivity, and connectivity between wetlands and waterbodies and among habitats within wetland complexes."

A general overview of the hydrology of inland wetlands is provided by Rasmussen et al. (2018). The hydrological pattern or water regime of a wetland shapes its biogeochemical features, from the occurrence and dynamics of the biodiversity and successional patterns to the ecological processes that sustain the biodiversity and cycling of nutrients and other materials. As wetlands are often seen as occupying a transitional zone between permanently saturated aquatic and terrestrial environments, the presence of water in the substrate or sediment can lead to anaerobic conditions that creates specific growing conditions for aquatic plants and the biogeochemical processes such as nutrient cycling and availability.

Inland wetlands tend to occur in low-energy environments and generally experience slower water flows than in adjacent or inflowing rivers, although under high rainfall events this can change quickly with much faster flows and increasing depths. Flood flows can to some extent be stored in wetlands with water being released slowly during subsequent dry periods. The storage and release of water is largely dependent on the morphology of individual wetlands, in particular their size, depth and shape, and to some extent the vegetation that they contain, and the water balance upstream and downstream of the wetland, and in the underlying aquifers. This illustrates the connectivity that occurs between many wetlands, including with floodplains and groundwater systems.

Wetlands tend to form where surface water and groundwater accumulate within topographic depressions, such as those along floodplains, and behind dunes or levees, or in groundwater seepage, and near the shore of streams and lakes. Fringing wetlands can form along the shoreline of lakes, with periodic inundation occurring as water levels rise and fall. Perched wetlands form above substrates with low permeability.

The water regime (or hydropattern) of a wetland is a function of the topography and the difference between the inflows from atmospheric, surface and sub-surface sources, and the outflows. It is characterized by the timing, frequency and duration, depth and spatial extent of the flows. The water regime in some wetlands fluctuate over short time periods, whereas others fluctuate more slowly. Water levels tend to rise following storms with heavy precipitation and subsequent flows, and then decline slowly. The water budget of a wetland is derived from the balance of inflows from precipitation, surface flows, groundwater flows, and seepage, and outflows from evapotranspiration, and surface and groundwater flows. When the inflows exceed the outflows the wetland stores water.

The way in which a wetland fills, or the water is replenished, and retained is an important driver of its ecological features, with many wetlands responding to pulse flows on an annual basis, while others can be dry for long periods, even decades, and then undergo rapid filling with an explosion of biological activity as the hydrological and water quality conditions allow.

The concept of pulse flows, or flood pulses, in wetlands has extended since being ascribed as an important factor driving seasonal changes in Amazonian floodplains, including the inter-relationships between water levels, functional dynamics and species diversity (Junk, 1982). This is particularly the case in tropical wetlands rather than in temperate zone swamps or peatlands that experience more stable or permanent inundation. Flood pulses are important for wetlands in between the contributary channels of large rivers (interfluvial wetlands) as well as for the extensive savanna wetlands in highly seasonal semi-arid environments, which may connect with coastal lagoons and mangrove wetlands. Junk et al. (2018) summarize the variation of flood pulses based on their duration, amplitude, frequency and regularity as monomodal, bimodal, polymodal, of low or high amplitude, predictable or irregular.

- Predictable, monomodal pulse with low amplitude (in large, interfluvial wetlands and coastal lagoons) and high amplitude (along large rivers); or polymodal pulses with variable amplitude (in tidal wetlands);
- Unpredictable, polymodal pulses with variable amplitude (along streams and small rivers, in depressions, or in coastal lagoons); or multi-annual pulses with low amplitude (wetlands in semi-arid zones); or
- Variable anthropogenic predictability, with variable pulses and amplitude (in reservoirs and paddy fields).

Large rivers such as those in the Amazon, the Orinoco River, and the Mekong, have monomodal flood pulses with high amplitudes of up to 8–15 m. In contrast, large savanna wetlands have monomodal pulses with amplitudes of a few meters, and some Andean rivers and the Congo River have a bimodal flood-pulse (Piedade et al., 2021). Middleton (2002) has compiled cases where steps have been taken towards restoring pulse flows in previously degraded wetlands to help with the re-establishment of ecological processes and biodiversity with varying levels of success. The variability in water regimes, including in the features that characterize pulse flows, in individual wetlands is reflected in the primary production and successional patterns that occur over time and across the variety of inland wetland types.

Primary production

As outlined in Fennessy and Cronk (2018), primary production in wetlands is a measure of the amount of carbon fixed through photosynthesis and released through respiration by the plants and algae (photosynthetic organisms) in the wetland. Photosynthesis is a complex physiological process for the conversion of solar energy into chemical energy in plant cells containing chlorophyll, as expressed in the following equation:

$$6CO_2 + 12H_2O \rightarrow C_6H_{12}O_6 + 6O_2 + 6H_2O$$

Photosynthesis is carried out by primary producers, or autotrophs and include a variety of plants (including a variety trees, shrubs, macrophytes, as well as macro-algae and phytoplankton species). Many have specific adaptations to enable them to function in aquatic or semi-aquatic conditions, with fresh or saline water, and in ephemeral wetlands, with periodic drying and wetting.

Photosynthetic organisms (or autotrophs) have vital roles in wetland ecosystems, including influencing the trophic dynamics and the cycling and retention of plant nutrients (Cronk and Fennessy, 2001). Net Primary Production (NPP) is often reported and is the difference between Gross Primary Production (GPP), or the total amount of carbon captured and stored through photosynthesis, and respiration which is the conversion of chemical energy contained in organic compounds to Adenosine Triphosphate (ATP) which maintains cellular activity (Fennessy and Cronk, 2018). The balance represents the net carbon fixed and which can be used to build the biomass of primary producers.

The amount of carbon fixed by global wetlands is estimated to be 137 Tg $year^{-1}$ (Mitra et al., 2005), although as the types of wetlands and autotrophs in them are extremely diverse, their primary production is also highly variable (Kang and Jang, 2018). The rate of primary production varies in response to the wide variation of conditions and climates and in any specific wetland is influenced by the species composition as well as by nutrient availability (e.g., nitrogen and phosphorus), wetting and drying, light intensity, and temperature ranges (Kang and Jang, 2018).

In boreal wetlands and peat bogs, primary productivity typically ranges from 100 to 300 g (dry weight) m^{-2} $year^{-1}$ (Cronk and Fennessy, 2001; Cook et al., 2009), far less than in temperate areas with rates of 1500–4000 g m^{-2} $year^{-1}$, and reaching 5000 to 10,000 g m^{-2} $year^{-1}$ in tropical wetlands (Piedade et al., 1997, 2021). Marshes, both freshwater and saline, dominated by emergent herbaceous vegetation are generally highly productive, with above ground primary productivity of marshes in temperate zones reaching 2000 g m^{-2} $year^{-1}$ and freshwater swamps 1800 g m^{-2} $year^{-1}$ (Kang and Jang, 2018). Given difficulties with sampling, below ground production may not be recorded, but it can represent a substantial amount of the production of a particular species or wetland. Measurements of the total primary production of a wetland require a combination of measures covering *inter alia* algae, submerged and emergent plants as well as trees and shrubs, possibly using different methods with the results converted to the same units and combined in order to reflect whole system productivity (Fennessy and Cronk, 2018; Pezeshki, 2018a, 2018b).

The biomass of plants in wetlands varies greatly with higher values in forested and tropical wetlands than in herbaceous and temperate wetlands. In the United States Cronk and Fennessy (2001) reported biomass from multiple studies being <1300 g m^{-2} across a range of temperate to sub-tropical wetlands for above ground materials.

Vegetation decomposition

The decomposition of vegetative organic matter in wetlands is an important process as it determines whether and how fast inorganic nutrients are cycled and made available for further plant growth, or whether gases (such as carbon dioxide or methane) are released (Whigham, 2018). The high primary production in wetlands can lead to the accumulation of a large amount of organic matter that is decomposed by a variety of invertebrates or microorganisms (such as fungi, bacteria, and prokaryotic microbes). This material, as described by Verhoeven (2009) can comprise: (a) easily degraded materials which decompose over a few weeks or months; (b) cellulose and hemicellulose in plant cell walls which decomposes over a few months to a year; (c) lignins and waxes which can take several years to decompose; and (d) antibiotic polyphenolics which affect the decomposition of the above mentioned.

As described by Whigham (2018) in an overview of ecological processes in wetlands the rate of decomposition is determined by a combination of factors, including the chemical properties of the organic matter, the temperature, nutrient and oxygen supply, microbial properties, and the wetting and drying cycles. Following senescence of the plant material at the end of the growing period, much of the organic material, including the carbon, is converted to detritus which is then decomposed and converted to carbon dioxide, and released to the atmosphere, or to recalcitrant compounds (such as hemicelluloses and lignin). In the drying phase of the hydrological cycle in many wetlands much of the carbon may also be consumed by fire. Hot fires can burn much of the vegetative material stored in organic substrates, including in peatlands and in seasonally dry floodplains.

The fate of the senesced material in a wetland depends on many factors including the absence or presence of oxygen in the substrate, the nutrient and oxygen content of inflowing water, the air and water temperature, and the nutrient content of the plant material. The nutrient content of the plant material varies and is in part related to the type of plants that are included in inflows, including that from rural, urban or industrial landscapes. Decomposition is generally faster in wetlands dominated by herbaceous species compared to wetland dominated by woody trees and shrubs, and also in more nutrient enriched environments.

A general understanding of decomposition is presented by Whigham (2018). The easily degraded materials are decomposed soon after senescence with soluble labile materials retained in the substrate, available for uptake by plants and microbes, or exported to other systems. The more recalcitrant cellulose and hemicellulose, and lignins and waxes decompose slowly and are likely retained in the wetland. Decomposition can also lead to the production of methane (CH_4) through methanogenesis, although under aerobic conditions most is used by methane oxidizing bacteria and very little reaches the atmosphere. Under anaerobic conditions a wetland can be a source of methane to the atmosphere.

Nitrogen cycling

The nitrogen contained within a wetland can undergo a number of transformations, predominately mediated by microbial processes (Baldwin, 2018). Key processes within the nitrogen cycle in a wetland include the following: atmospheric deposition,

fixation of atmospheric nitrogen by microbes and some plants, leaching from biotic sources, ammonification, nitrification, denitrification, and immobilization (Whigham, 2018).

The cycling of nitrogen in a wetland is complex and in part dependent on the particular hydrological features along with the physico-chemical conditions in the water and sediments, and the microbial populations that are present (Deemy et al., 2021). Nitrogen can enter a wetland from a number of sources, including from the atmosphere into the water column of a wetland where it can be taken up by nitrogen-fixing bacteria or by some plants. Surface and groundwater inflows can contain organic nitrogen, dissolved ammonia, nitrate and nitrite, while large numbers of migratory animals, such as the large numbers of waterbirds that are known to annually migrate or move in a more nomadic manner in response to climate triggers, can add pulses of nitrogen. Litterfall from plants adjacent to a wetland can contribute nitrogen, while plants within a wetland can cycle nitrogen through absorption and then litterfall and subsequent decomposition. Nitrogen export from wetlands can occur through the water flows from the wetlands, and by volatilization of ammonia after denitrification, although some of the nitrogen produced by denitrification can be cycled within a wetland by nitrogen-fixing bacteria. Within a wetland organic nitrogen can be deposited and stored in the sediment, with some also being released and exported by outflowing water, or to the atmosphere during drying and burning of the plant material.

As described by Whigham (2018) the conversion from one form of nitrogen to another is tied to the physiochemical characteristics of the sediment or substrate in a wetland, in particular the presence of aerobic or anaerobic conditions and associated microbial populations.

Under aerobic conditions the presence of oxygen enables bacteria and fungi to mineralize carbon-containing compounds to produce carbon dioxide and ammonium-nitrogen which can be assimilated by plants under alkaline conditions. In the presence of oxygen ammonium is converted to nitrate, or to nitrite and then to nitrate. This process can be reversed, and nitrate also converted to nitrogen gas through denitrification which leads to the loss of nitrogen to the atmosphere. Under anaerobic conditions denitrification can also occur in the oxygenated microzones (often referred to as a rhizosphere) around plant roots and rhizomes. Denitrification also releases nitrous oxide that contributes to global warming, although in the presence of water the residence time in the soil is increased.

Phosphorus cycling

The phosphorus cycle in wetlands is described by Baldwin (2018) and Whigham (2018). The main source of phosphorus for wetlands is from the water that enters as surface flow from streams, or as runoff from adjacent landscapes, either associated with organic or mineral particles, or in a dissolved form. Within a wetland the biologically available phosphorus, as orthophosphate (PO_4), can be taken up by plants, algae and microbes, while the rest is adsorbed on inorganic and organic particles. It has a strong affinity for metals such as aluminum, iron, and calcium, and will preferentially bind to suspended particulate matter containing these. About 10–15% of the biologically available phosphorus is taken up by the biota with the rest being sequestered in the sediment or in the litter or detrital material.

The ability of wetland to store phosphorus is largely dependent on the amount of aluminum and iron that is present with a high absorptive capacity for phosphorus when in high concentrations. Alkaline soils with a high calcium content also provide long-term storage. While sediments may represent the largest sink in aquatic systems, they may also represent a major source of phosphorus remobilization. This involves the release of phosphorus from sediment particles to the interstitial water and then to the overlying water column. This process is mediated by iron reducing bacteria that convert ferric (oxidized) iron to ferric (reduced) iron that releases the phosphorus. Additionally, sulfate- reducing bacteria that reduce sulfur to sulfide which reacts with iron minerals can release the phosphorus. The phosphorus enters the water column following disturbance of the interstitial water, such as scouring by high flow events, or by bottom-feeding fish or invertebrates. The phosphorus can also be taken up through the roots of aquatic plants.

Conclusion/synthesis

There is increasing knowledge and understanding about the ecology of the biodiversity in inland wetlands and the ecological processes that support the biodiversity. Global estimates of the area of inland wetlands are in the vicinity of 12.4×10^6 km^2 with a further estimated 1.90×10^6 km^2 of human constructed wetlands. Best available estimates are that 35% of the wetland area has been lost since 1970, although further analyses are needed to confirm this value. Species diversity in individual inland wetlands can be high, but not uniformly across the range of wetland types.

The basics of the key ecological processes of vegetation succession and decomposition, and biogeochemical cycling of nitrogen and phosphorus in wetlands are well known, although the specific details for individual wetland types may need further elaboration. This is particularly so given the major role that the microbial populations in wetlands play in these processes. It is expected that further application of genomic analyses and more sophisticated models will assist in understanding the dynamics of these processes in different wetlands, and how these may respond under changing climatic conditions.

Knowledge gaps

- The extent and distribution of all inland wetland types is unevenly known, described or mapped.
- The populations sizes and dynamics of major species in inland wetlands is poorly known, including sedentary and migratory species.
- The successional patterns of vegetation in inland wetlands in response to changing environmental drivers requires further elaboration and development of descriptive models
- The extent of gaseous emissions to the atmosphere following microbially-mediated decomposition of wetland vegetation and cycling of nutrients is of increasing importance under global change scenarios.

Structure and Function of Inland Waters-Wetlands: Classification Systems of Wetlands

Wolfgang J Junk, Former Working Group Tropical Ecology of the Max-Planck-Institute for Limnology, Plön, Germany; National Institute of Science and Technology in Wetlands (INCT-INAU), Federal University of Mato Grosso, Cuiabá, Brazil

This is an update of R.W. Tiner, Ecology of Wetlands: Classification Systems, in Encyclopedia of Inland Waters, Edited by: Gene E. Likens, Elsevier Inc.,2009, https://doi.org/10.1016/B978-012370626-3.00057-0.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Editor Thomas Mehner.

Introduction

Wetlands occur in all continents and are represented by a large variety of types, ranging from simple habitats of a few hectares in size up to complex wetland landscapes with many interacting different habitats extending over thousands of square kilometers. According to general estimates, between 4% and 6% of the Earth's surface is covered by wetlands (Mitsch and Gosselink, 2015), but this may be an underestimate because there is still no clear definition of what constitutes a wetland. Traditional definitions restrict wetlands to those common in temperate regions, such as bogs, fens and mires. By contrast, scant attention has been paid to periodically drying wetlands, which account for the majority of wetlands in tropical and subtropical regions. In South America, they account for roughly 20% of the continent's surface. In addition, while permafrost soils in North America and Asia fulfill the environmental requirements established for wetlands, such as waterlogged soils during the growth season of vegetation and the occurrence of wetland plants, they have not been considered as such in calculations of worldwide wetland area.

In ancient times, wetlands drove the development of high cultures, such as those along the Euphrates and Tigris Rivers, the Nile River, the Mekong River, the Indus and Brahmaputra Rivers and the Huanghe River. In some tropical countries, wetlands are still home for local human populations with distinctive cultural traits. Other important functions of wetlands are water storage, supply and purification. Moreover, wetlands provide favorable habitats for many plants and animals and are thus important to the maintenance of biodiversity (Gopal et al., 2000-2001). Nonetheless, they are among the most threatened ecosystems of the world, and the loss of wetlands is a major concern of the governments in many countries.

A first step in protecting wetlands is their definition, delimitation and classification (summarized in National Research Council (NRC), 1995; Tiner, 1999; Maltby and Barker, 2009; Mitsch and Gosselink, 2015; Finlayson, 2018; Gerbeaux et al., 2018; and others). The authors of those studies used different parameters according to the ecological, geographic and socio-economic peculiarities of the respective country or region, but the different approaches also reflect the preferences of the involved scientists. The development of a classification system that allows comparisons of available scientific data across fields of research would stimulate advances in wetland science, management and protection (Scott and Jones, 1995; Finlayson and van der Valk, 1995). The need for a better wetland classification was also recognized by Ramsar's Scientific and Technical Review Panel, which called for the "development and testing of a hydro-geomorphically-based system of wetland classification" (Davidson and Finlayson, 2007). This chapter provides a summary of the state of the art of wetland classification and a proposal for a unified classification.

Wetlands in ecological theory

The position of wetlands at the interface of terrestrial and aquatic ecosystems

Wetlands are situated at the interface between terrestrial and aquatic ecosystems. They interact with the permanent terrestrial environment and, in those with further connections, with deep-water inland (rivers and lakes) and marine ecosystems.

This intermediary position of wetlands led many scientists to consider them as ecotones. While there are many definitions of ecotones, all of them stress the transitional character between two or more ecosystems. For example, Holland (1988) defined ecotones as "a zone of transition between adjacent ecological systems heaving a set of characteristics uniquely defined by space and timescales and by the strength of the interactions between adjacent ecological systems." This definition certainly holds true for smaller, linear wetlands situated between, for instance, the upland and a lake, referred to as "littoral ecotones" by Hillbricht-Ilkowska (1993). Many wetlands, however, are surrounded by uplands and are not connected with permanent deep-water ecosystems, such as peat bogs and swamps in depressions. Also, the complex geomorphological structures, soil properties and hydrological conditions found in the inner portions of many large wetlands, exemplified by those of the Pantanal and the Amazonian várzeas in Brazil, the Everglades in United States, the Okavango Delta in Botswana and the Sundarbans in India/Bangladesh, result in unique ecological characteristics that distinguish these wetlands from adjacent terrestrial and aquatic ecosystems. As such, they can be considered as specific wetland ecosystems (Odum, 1959). Large wetlands encompass ecotones that bridge major landscape units, which are called macrohabitats in large Brazilian wetlands, for instance in Amazonian large river floodplains (várzeas and igapós), the Pantanal (Junk et al., 2014, 2018), and the Paraná River floodplain (Junk et al., 2021).

Independent of the discussion of the ecotonal character of wetlands, the contributions of the different scientific disciplines have to be considered in wetland studies. Freshwater ecosystems are the focus of limnologists, who very early on developed concepts to explain their structures and functions (Illies, 1961; Naumann, 1932; Thienemann, 1915; Vannote et al., 1980). These differ from the concepts used to describe marine ecosystems but both have to be considered in discussing coastal wetlands (Junk, 1997; Fig. 1).

In flood-pulsing wetlands, large areas are periodically covered by shallow water bodies, which behave ecologically like shallow lakes. Water distribution inside the floodplain and between parent rivers and their floodplains occurs by temporary or permanent channels, thus periodically resembling streams and small rivers. In both subsystems, the processes taking place during the aquatic phase are best explained from a limnological perspective. During the low-water period, formerly inundated areas become dry, in which case terrestrial concepts well explain the ecological conditions, such as the switch from anoxic wetland to oxic dryland conditions.

Organisms in large flood-pulsing wetlands can be similarly subdivided into terrestrial species, deep-water aquatic species and specific wetland species (Gopal and Junk, 2000). The large species diversity in these wetlands is the result of the mosaic of permanent terrestrial, aquatic and flood-pulsing environments. The switch between aquatic and terrestrial conditions in the areas affected by the flood pulse allows the colonization of the same area by terrestrial, aquatic and wetland plants and animals. Consequently, the migration behavior of fishes between deep water habitats and the floodplains in South America can be understood by applying limnological theories, and that of large herds of ungulates between the Okavango Delta and the surrounding upland savannas by the application of both terrestrial and wetland concepts.

Wetland specific concepts

The most common wetland types in temperate regions are oligotrophic peat bogs, eutrophic swamps and different types of coastal wetlands. Their genesis and ecology are well-studied and the conceptional framework is well established but will not be treated here.

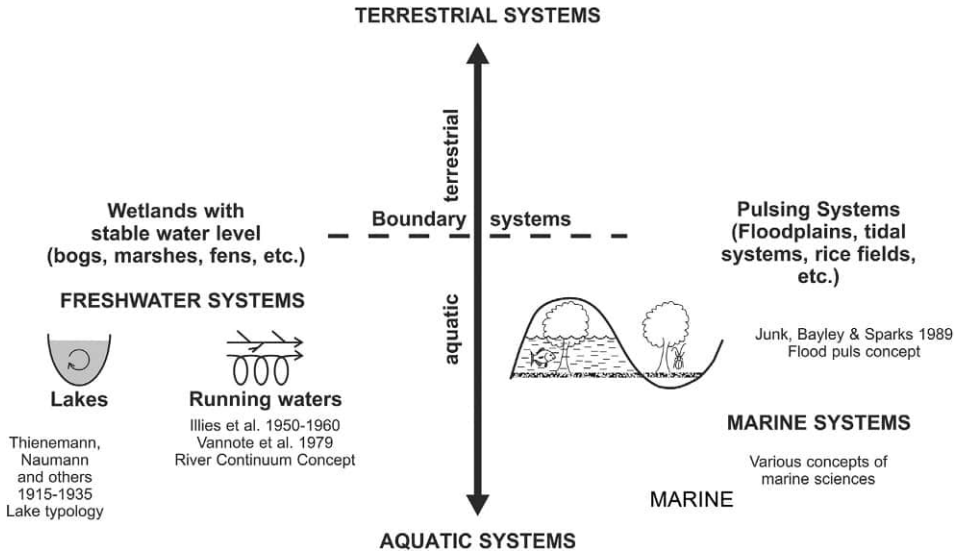

Fig. 1 The position of wetlands in relation to other aquatic and terrestrial ecosystems. From Junk WJ (1997) General aspects of floodplain ecology with special reference to Amazonian floodplains. In Junk WJ (ed.), *The Central Amazon Floodplain: Ecology of a Pulsing System*. vol. 126, Ecological Studies, pp. 3–22, Springer Verlag: Berlin Heidelberg\New York.

By contrast, large river floodplains are of interest to terrestrial ecologists, who focus on the terrestrial phase of these wetlands, and to limnologists, who focus on their aquatic phases, but an integrated approach is for the most part lacking.

The lateral dimension of the river-floodplain system and its ecological implications were first described by fish ecologists and fishery biologists. Lowe-McConnel (1964) showed that the fish communities of rivers and streams were related to the periodically flooded savannas of the Rupununi District in Surinam. Holcik and Bastl (1977) described the impact of floods on fish populations in the Danube River floodplain. Welcomme (1979) analyzed environmental factors in river floodplains and described the importance of floodplains for fisheries in tropical river systems.

Junk and Welcomme (1990) analyzed the data on floodplain systems and identified floodplains as *areas of low-lying land that are subject to inundation by the lateral overflow of water from river and lakes with which they are associated. The floods further bring about such changes in the physico-chemical environment that biota react by morphological, anatomical, physiological or ethological adaptations or by change in community structure. In some cases flooding may directly result from rainfall or snow and ice melt whereby water periodically accumulates in shallow depressions (sheet flooding). While such areas are not true floodplains in that they are not associated with any permanent water body, they do merit consideration as seasonally flooded wetlands*.

Junk et al. (1989) formalized this approach in the flood pulse concept (FPC), in work that was later complemented by Junk and Wantzen (2004) and Junk (2005) and extended to lakes by Wantzen et al. (2008). The FPC treats the river channel and its floodplain as one unit, called the river-floodplain system. Periodic inundation by high river stages or rainfall events is referred to as the flood pulse. The resulting aquatic conditions in the affected wetland area, called the aquatic terrestrial transition zone (ATTZ), links the area with the parent river or permanent lakes by a moving littoral. Aquatic and terrestrial phases influence each other and are thus considered as alternating ecological stages of the same ecosystem. The ATTZ is colonized by plants and animals adapted to the specific conditions. It is also frequented by visitors from the surrounding upland and connected lakes and rivers, which temporarily use the wetland's many resources. Processes switch from terrestrial to aquatic depending on the dry or wet status of the system. The transfer of organic matter and nutrients between terrestrial and aquatic phases complicates the differentiation between allochthonous and autochthonous material. Additions of the FPC were formulated by Ward et al. (1999), Ward and Stanford (1995), Ward et al. (1999), Puckridge et al. (1998), Humphries et al. (1999), Tockner et al. (2000), and others.

Wetland indicators

Wetland hydrology

Hydrology is probably the single most important determinant of the establishment and maintenance of specific types of wetlands and wetland processes. This is reflected in the many wetland definitions discussed in Section "Wetland definition, identification and delimitation" of this chapter, all of which refer to permanent or periodically shallow flooding or water logging. However, the parameters that define wetland hydrology vary in different regions and climatic zones. Classification schemes in the northern hemisphere must consider the impact of hydrology during the growing season of the vegetation and thus the overlap of periodic flooding (flood pulse) with another important ecological driver: the light/temperature or summer/winter pulse. At high latitudes the light/temperature pulse determines the biological activities in wetlands, but its strength diminishes towards the equator. In the subtropics and tropics, the seasonal variations in light and temperature have little or no impact on the biota, but water availability, often driven by heavy rainfall events or by rainy and dry seasons, are the decisive determinants.

The definition of a wetland depends on ecological parameters but also on political/economic requirements. This is well-demonstrated by the definition of the wetland status of areas in the United States. The National Food Security Act Manual (in National Research Council (NRC), 1995) concluded that flooding for 14 consecutive days is sufficient to create wetland conditions. If an area is covered with water or there is saturation to the surface in most years (>50%) for more than 12.5% of the growing season, then the area is defined as a wetland based on its hydrology. If water is present for 5–12.5% of the growing season then it may or may not be a wetland, depending upon other parameters (hydrophytic vegetation and hydric soils). Areas with standing water or water saturation to the surface for <5% of the growing season do not meet the definition of a wetland. The definition of the growing season relies on cultivated crops and varies among regions. Notably, however, ecological aspects are not considered in this definition (Tiner, 1999).

Considering the large importance of hydrology, the minor role of hydrological parameters in wetland classification systems and the larger reliance on other parameters, such as geomorphology, climate, soils, water chemistry, and vegetation, is perplexing. In a recent attempt to counter this discrepancy, Brazilian scientists proposed a hierarchical classification that at higher levels is primarily based on hydrological parameters (Table 1) and only at lower levels on chemistry and vegetation (see Section "Wetland classification"). The classification considers the fact that in large subtropical and tropical wetlands a monomodal flood pulse imposes an annual hydrological seasonality on the biota, which contrasts with the climatic unseasonal rain forest areas around the equator. This approach has been adopted also by Columbian scientists for Columbian wetlands.

Wetland soils

In the first wetland classification system originating from the United States, hydromorphic, halomorphic and alluvial soils were associated with wetlands (Shaw and Fredine, 1956). The National Technical Committee for Hydric Soils (NTCHS) defined a hydric soil as *a soil that formed under conditions of saturation, flooding, or ponding long enough during the growing season to develop anaerobic*

Table 1 Flooding regime and affected wetlands in the Brazilian classification system.

Wetlands with rather stable water levels			
Wetlands with fluctuating water levels			
Flood pulse variables			
Predictability	*Frequency*	*Amplitude*	*Wetland type*
Predictable	Monomodal	High	Large river floodplains
		Low	Large interfluvial wetlands
Predictable	Polymodal	Variable	Tidal wetlands
Unpredictable	Polymodal	Variable	Wetlands along low order rivers
			Wetlands in small depressions
Unpredictable	Multi-annual	Low	Wetlands in arid regions
Variable (human-made)	Variable	Variable	Reservoirs, paddy fields

conditions in the upper part (Federal Register, 1994). This definition emphasizes climate, because it considers the growing season, which is determined by the summer/winter (light/temperature) pulse. While this pulse has a large impact at high latitudes it has none on the growing season in the tropics and subtropics.

Soils are classified into organic soils characterized by an accumulation of organic material at the surface, and mineral soils composed of a mixture of sand, silt and clay. Soil texture has an important influence on the water retention capacity (Vasilas et al., 2018). Soil color is used in classification systems, but it depends on many factors. In the United States, a standardized procedure for measuring and describing soil color using the Munsell Color System has considerably improved the precision of the method (Schulze et al., 1993). However, soil color changes with soil wetness and is thus more relevant in the tropics and subtropics, where many wetland soils are dry during the dry season. All countries provide soil maps with general information on hydric soils. In Brazil, 36 types of hydric soils are distinguished (Dos Santos et al., 2018).

Flooding and water logging lead to anoxic soil conditions that reduce the decomposition of organic material. In temperate regions, the oligotrophic acidic conditions and prolonged waterlogging lead to the formation of extended peat layers, often associated with the growth of moss (*Sphagnum* spp.) and resulting in the formation of large peat bogs with characteristic acidophilic vegetation. Peat accumulation is a slow process, with a rate of only about 1 mm $year^{-1}$. However, after the last glacial period, peat layers of up to 10 m depth accumulated. Under eutrophic conditions, organic matter is produced by highly productive emergent herbaceous plants, such as *Typha* spp. and *Phragmites* spp. In an advanced stage of terrestrialization a swamp forest develops. Peat bogs and swamps are considered long-term sinks for organic carbon. By contrast, in flood-pulsing wetlands the accumulation of organic matter is hindered because during the dry period soil aeration favors decomposition. This is the case for most tropical and sub-tropical wetlands, which therefore cannot be considered as long-term sinks for organic carbon (Junk, 1985).

Water logging affects microbial communities in the soil and thus gives rise to biochemical processes referred to as oxidation-reduction (redox) reactions. Under anoxic conditions, manganous manganese, ferrous iron, methane, ammonia, and hydrogen sulfide, among others, are produced. The reduced compounds are often soluble and available for plants, but some of them, such as aluminum, are toxic at higher concentrations.

Wetland organisms

Wetland plants

Definition of hydrophytes

The morphological and physiological adaptations of aquatic macrophytes to waterlogging of the substrate and flooding, the classification of these plants and their role in wetlands are treated in a separate chapter. Here, only aspects directly related to wetland classification are discussed.

Plants have been and continue to be used as indicators to identify and delineate wetlands. There are innumerous definitions of wetland plants. Scientists working in wetlands recognized early on the problem of separating wetland plants from terrestrial plants. Warming (1909) stated *. . .there is no sharp limit between marsh plants and terrestrial plants. . .the boundary zone represents a gradual transition from terrestrial to aquatic conditions and it is impossible to establish any sharp distinction between swamp-forests and forests on dry land*.

That study distinguished between two major types of wetland plant communities: saline swamps with halophytic vegetation and freshwater swamps with three sub-groups: reed swamps dominated by emergent herbaceous plants, bush swamps characterized by the growth of alders (*Alnus* spp.), willows (*Salix* spp.), birches (*Betula* spp.) and others, and forest swamps (Juniper swamps characterized by the Atlantic white cedar *Chamaecyparis thyoides*, black gum swamps with *Nyssa sylvatica* and bald cypress swamps with *Taxodium distichum*).

Weaver and Clements (1938) stated that . . .*amphibious plants have a wide range of adjustment and may grow for a time as mesophytes or partially submerged....(they are) the least specialized of water plants.*

The definition of hydrophytes varies among countries and authors and has considerably changed since the beginning of modern science. Limnologists and many botanists describe only aquatic herbaceous plants as aquatic macrophytes or hydrophytes (e.g., Sculthorpe, 1967; Cook et al., 1974). Other terms include "aquatic cormophytes" (aquatic plants with roots, shoots and leaves), "aquatic vascular plants, aquatic tracheophytes" (all aquatic herbaceous plants with specialized vascular tissue, excluding algae and bryophytes), "helophytes" (perennial marsh plants whose buds overwinter under water) and "mesophytes" (plants growing in moist soils).

According to the definition of Raunkiaer (1934): *Hydrophytes are plants which have vegetative parts submerged or floating at the water surface, but not emerging into the air, and which survive unfavorable seasons as submerged buds attached to the parent plant or lying free on the substrate.* Thus, it excludes emergent herbaceous plants and woody species.

Dobenmire (1968) introduced oxygen deficiency into the definition: *A hydrophyte is any plant growing in a soil that is at least periodically deficient in oxygen as a result of excessive water content.*

The simplest and most comprehensive definition is that of Weaver and Clements (1938): Aquatic macrophytes are *plants that grow in water, in soil covered by water, or in soil that is usually saturated.*

The definition of Lichvar et al. (2012) includes herbaceous and woody species: *Obligate Wetland Plants almost always occur in wetlands. With few exceptions, these plants (herbaceous or woody) are found in standing water or seasonally saturated soils (14 or more consecutive days) near the surface.*

Animals

The importance of wetlands as habitats for animals is well-documented and the diversity and abundance of these species are one of the strongest arguments for wetland protection. Indeed, the Ramsar Convention for the protection of wetlands of international importance was established for the protection of migrating waterfowl.

According to Gopal and Junk (2000), wetland animals can be classified into six main categories: First, are residents in the wetlands proper. This group covers a wide range of taxa. Vertebrates have been the focus of many studies but very few studies have considered invertebrates. The role of Amazonian river floodplains as important generators of species richness was demonstrated by Erwin and Adis (1982) and Adis and Junk (2002) and many other authors. The second category comprises regular migrants from deep-water habitats and thus mostly fishes. Juveniles of many fish species use the floodplains during the high-water period for hiding and feeding. In Amazonia, however, some turtle species and the manatee (*Trichechus inunguis*) also migrate from deep-water habitats into the floodplains for feeding. In the third group are regular migrants from terrestrial habitats. This group also covers a wide range of species and includes the well-known large migrations of ungulates between the African floodplains and adjacent savanna. Less obvious are the nocturnal visits of bats from the surrounding uplands into the Pantanal floodplain for feeding. In the fourth group are regular migrants from other wetlands, such as the extended migrations of waterfowl between South American wetlands depending on the water level of the respective areas. Some species from northern and southern high latitudes spend the winter in tropical and subtropical South American wetlands, but terrestrial birds may also use the floodplains as stopping points during their migrations (Junk et al., 2006). The fifth group comprises occasional visitors and in the sixth are animals that indirectly depend on wetland biota. The last group, which includes canopy invertebrates and also pathogens and parasites of wetland species, has hardly been studied but it contributes significantly to the overall species diversity of wetlands.

For wetland classification purposes, however, the mobility of animals limits their use as indicators, although the presence of some species can serve as an indicator of the ecological integrity of wetlands or parts of them. In the Brazilian Pantanal, for instance, the presence of top predators such as the jaguar and the giant otter indicates a high level of ecological integrity of the respective region.

Wetland definition, identification and delimitation

The ecological diversity of wetlands is demonstrated by the many definitions put forward by nearly every country. This reflects the fact that: (1) scientists from different disciplines emphasize different parameters; (2) local politicians prefer national or even regional definitions and (3) the local population is more likely to understand and support environmental protection when it is related to landscape units described with local names and thus in familiar terms.

Definitions of wetlands can be divided into two groups. One exclusively considers scientific aspects and is important for scientific work, environmental protection and sustainable management. The other also takes political and socio-economic conditions into consideration. However, these regional approaches often omit scientific definitions, are frequently in conflict with the requirements of environmental protection by favoring economic demands and their use in comparative international studies is difficult.

At the international level, the Ramsar Convention, with 169 signatory countries, plays a leading role with respect to the conservation and wise use of wetlands. The Ramsar definition of wetlands states: *Wetlands are areas of marsh, fen, peatland or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish or salt, including areas of marine water the depth of which at low tide does not exceed six meters.*

Semeniuk and Semeniuk (1995) defined wetlands as *areas of seasonally, intermittently or permanently waterlogged soils or inundated land, whether natural or otherwise, fresh or saline.* The authors called attention to Western Australia, where only the permanently

inundated part of the wetland was traditionally considered as wetland area, and thus correctly extended the definition of the peripheral wetland boundary to periodic *dampness, or hydric soils or vegetation indicative of wet conditions*. In arid regions all over the globe, there are depressions that become filled with water only every couple of years (playa, barlkarra of Semeniuk and Semeniuk, 1995), but during that period they fulfill important wetland functions, by providing breeding and feeding grounds for aquatic animals and waterfowl. During the multiannual dry periods, the wetland boundary may be indicated by changes in the salt content of the soil.

At the national level, Cowardin et al. (1979) defined wetlands in the United States as . . . *lands transitional between terrestrial and aquatic systems, where the water table is usually at or near the surface or the land is covered by shallow water. Wetlands must have one or more of the following three attributes: (1) at least periodically, the land supports predominantly hydrophytes; (2) the substrate is predominantly undrained, hydric soil; and (3) the substrate is nonsoil and is saturated or covered by shallow water at some time during the growing season of each year*.

In this definition, the inclusion of the growing season is a concession to management interests, because under ecological aspects many wetland processes are not restricted to the growing season but are ongoing during the entire year. Indeed, for management purposes, state regulatory programs in the United States use specific wetland definitions that differ in nearly every state (Tiner, 1999).

For Brazilian wetlands, a consortium of scientists provided the following definition: *Wetlands are ecosystems at the interface between aquatic and terrestrial environments; they may be continental or coastal, natural or artificial, permanently or periodically inundated by shallow water or consist of waterlogged soils. Their waters may be fresh or highly or mildly saline. Wetlands are home to specific plant and animal communities adapted to their hydrological dynamics* (Junk et al., 2014).

Determining the borders of a wetland would seem to be a simple task, assuming that its water level was relatively stable. Hydric soils with an accumulation of organic material and the presence of hydrophytes are good indicators of wetlands, and the transition zone to the upland is normally narrow. In wetlands with an oscillating water level, however, delimitation is very difficult and scientific definitions often contradict political and economic priorities.

Brazilian ecologists proposed the following definition for wetland delimitation: *The extent of a wetland can be determined by the border of the permanently flooded or waterlogged area, or in the case of fluctuating water levels, by the limit of the area influenced during the mean maximum flood. The outer borders of wetlands are indicated by the absence of hydromorphic soils and/or hydrophytes and/or specific woody species tolerant to grow in periodically or permanently flooded or waterlogged soils. The definition of a wetland area should include, if present, internal permanently dry areas as these habitats are of fundamental importance to the maintenance of the functional integrity and biodiversity of the respective wetland* (Junk et al., 2014).

With its citation of the mean maximum flood level, this definition recognizes hydrology as the main determinant in wetlands while also considering the importance of permanently dry areas inside large wetlands as both a periodic refuge for animals during high floods and the source of the large plant and animal biodiversity. However, this wetland definition proposed by Brazilian scientists has been rejected by Brazilian politicians and representatives of agrobusiness, who favor a definition of the wetland border at the low-water level that strongly reduces the size of the wetland area.

Wetland classification

Wetland classification systems rely on different parameters, especially hydrology geomorphology, soils, water chemistry and vegetation. As noted above, many countries, and often many regions, have their own classification systems. In Argentina, the classification system of Neiff (2001) differentiates between nine wetland types, using 12 parameters to describe wetlands according to their geomorphology, soils, fire stress, vegetation, fauna, water origin, and several hydrological factors. Brinson and Malvárez (2002) differentiate between nine types of Argentinian wetlands, but use climate, hydrology, soils and the regional vegetation as criteria.

The current U.S. Fish and Wildlife Service classification hierarchy for wetlands and deep-water habitats distinguishes five major systems, 10 subsystems and 56 classes (Cowardin et al., 1979). Major systems are marine (subtidal, intertidal subsystems), estuarine (subtidal, intertidal subsystems), riverine (tidal, lower perennial, upper perennial, intermittent subsystems), lacustrine (limnetic and littoral subsystems) and palustrine. Classes are described based on different attributes, such as rock bottom, emergent wetland, forested wetland, aquatic bed and unconsolidated shore. The hydrogeomorphic classification of Brinson (1993) relies on geomorphic, physical and chemical parameters to provide a better understanding of the relationship between organisms and their environment.

The classification system used in the Directory of Neotropical Wetlands (Scott and Carbonell, 1986) lists 19 wetland types while that of the Directory of Asian Wetlands includes 22 types (Scott, 1989), using geographic, geomorphological, hydrological and vegetation parameters in a non-hierarchical approach.

The European CORINE Biotopes database (Co-ORdinated INformation on the Environment), established in 1985, lists the following biotopes, including wetlands, in Mediterranean countries: coastal and halophytic communities (10 habitats), non-marine waters (4 habitats), scrub and grassland (2 habitats), forests (1 habitat), bogs and marshes (3 habitats), inland rocks, screes and sands (4 habitats), agricultural land and artificial landscapes (5 habitats) (European Communities - Commission, 1991). The Natura 2000 inventory specifies the CORINE Biotopes database and for 12 EU member states lists 71 habitat types, under the EU Birds Directive or Habitat Directive. The database differentiates between marine and inland habitats, which are characterized mostly by trophic status and communities of higher plants (European Commission, 2014).

Semeniuk and Semeniuk (1995) proposed a geomorphic approach to the global classification of inland wetlands that combines landform types with hydroperiod and distinguishes 13 primary types of common wetlands: permanently inundated basin (lakes), seasonally inundated basin (sumpland), intermittently inundated basin (playa), seasonally waterlogged basin (dampland), permanently inundated channel (river), seasonally inundated channel (creek), intermittently inundated channel (wadi), seasonally waterlogged channel (trough), seasonally inundated flat (floodplain), intermittently inundated flat (barlkarra), seasonally waterlogged flat (palusplain), seasonally waterlogged slope (paluslope) and seasonally waterlogged highlands (palusmont).

The frequently cited Ramsar classification claims to classify wetlands at the worldwide scale but it has been interpreted differently by different authors. Scott and Jones (1995) recognize six major wetland systems: (1) marine (coastal wetlands including coastal lagoons, rocky shores, seagrass beds and coral reefs); (2) estuarine (including deltas, tidal marshes and mudflats, and mangrove swamps); (3) lacustrine (wetlands associated with lakes); (4) riverine (wetlands along rivers and streams); (5) palustrine (i.e., "marshy," including marshes, swamps and bogs) and (6) human-made wetlands (fish and shrimp ponds, farm ponds, irrigated agricultural land including rice paddies, salt pans, dams, reservoirs, gravel pits, wastewater treatment ponds and canals). These systems are subdivided for hydrological characterization using the terms subtidal, intertidal, perennial, intermittent, permanent and seasonal. Subunits are characterized by geomorphological, hydrological and/or botanical parameters.

Matthews (1993) examined the history and development of the Ramsar Convention on Wetlands. The Ramsar classification repeats the differentiation between marine and coastal wetlands (with 12 habitat types), inland wetlands (with 14 habitat types) and human-made wetlands (with 9 habitat types). It uses the same non-hierarchical mixture of criteria for the characterization of habitat types, including hydrological criteria (permanent, seasonal, intermittent), vegetation parameters (shrub-dominated, tree-dominated, marshes, peatlands, mangroves, etc.), geographical parameters (tundra/alpine wetlands, deltas, etc.) and limnological parameters (rivers, streams, lakes, springs, etc.) and others. The attributes for characterization used by Finlayson (2018) were similar to those used by other authors and differentiate between 42 wetland types: marine and coastal wetlands (12 types), inland wetlands (20 types) and human-made wetlands (10 types).

The recent classifications devised for Brazilian and Colombian wetlands (Junk et al., 2014; Ricaurte et al., 2019) are much more detailed than these other approaches but they also differentiate at the system level among coastal, inland and artificial wetlands. Higher categories, consisting of subsystems, orders, suborders and classes, are determined according to hydrological parameters, such as the predictability, frequency and height of the flood pulse (see Table 1). Hydrological, hydrochemical and vegetation parameters are used to differentiate within lower categories (functional units, subclasses and macrohabitats) (Junk et al., 2014; Nunes da Cunha and Junk, 2017), Fig. 2.

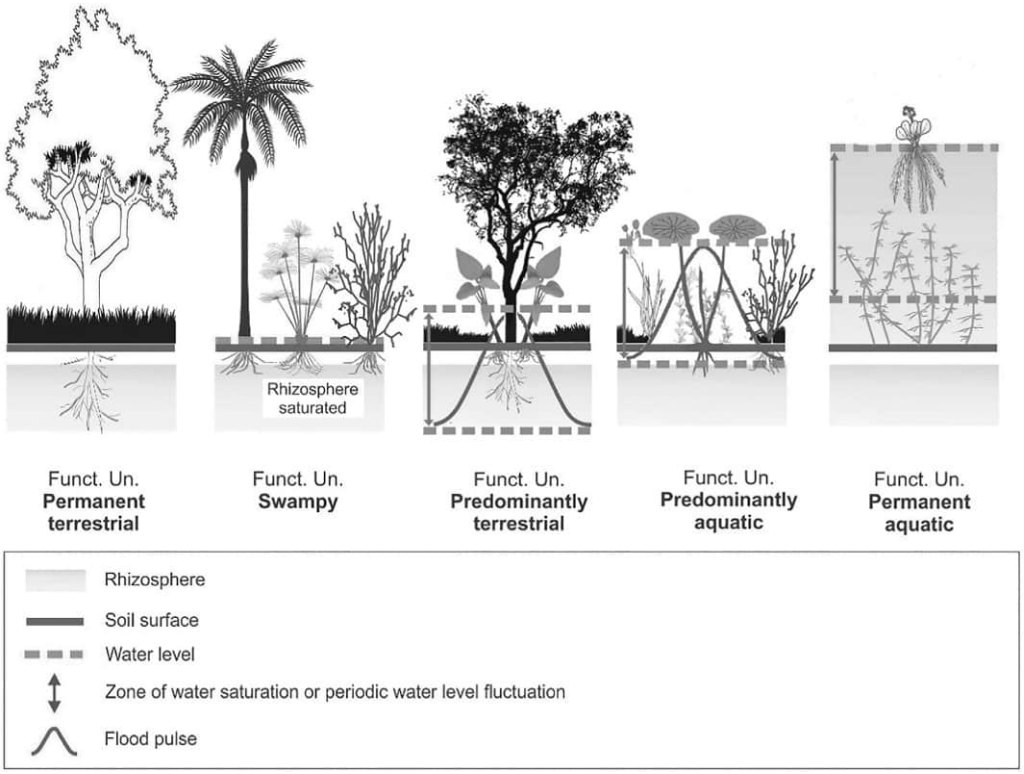

Fig. 2 Functional units in large floodplains according to their hydrological status. adapted from Nunes da Cunha C and Junk WJ (2017) Classificação dos macrohabitats do Pantanal mato-grossense para fins de gestão. In Nunes da Cunha C, Arruda EC, Junk WJ (Orgs). *Marcos referenciais para a Lei Federal do Pantanal e gestão de outras áreas úmidas*. pp. 73–79, Cuiabá-MT: Carlini & Caniato Editorial, EdUFMT. p. 156. ISBN 978-85-8009-177-9 (Carlini & Caniato); ISBN 978-85-327-0604-1 (EdUFMT).

Wetland distribution and contribution in ecosystem coverage

The data in the literature on wetland coverage vary considerably. The UNEP-World Conservation Monitoring Centre has estimated ~570 million hectares (5.7 million km^2), roughly 6% of the Earth's land surface; Mitsch and Gosselink (2015), estimated 4–6% of the Earth's land surface. Mangroves cover some 240,000 km^2 of coastal area, and an estimated 600,000 km^2 of coral reefs remain worldwide. Nevertheless, a global review of wetland resources prepared for Ramsar COP7 in 1999, while affirming that *it is not possible to provide an acceptable figure of the areal extent of wetlands at a global scale*, indicated a "best" minimum global estimate of 748–778 million hectares. The same report indicated that this "minimum" could be increased to 999–4462 million hectares when other sources of information are taken into account.

These figures certainly underestimate total wetland area, because conventional approaches consider only "classic" wetlands (peat bogs, marshes, fens, etc.). New approaches emphasize periodically flooded areas, which includes most wetlands in South America. In Brazil, wetlands account for ~20% of the national territory (Junk et al., 2012), in Argentina 23% (Kandus et al., 2008), and in Columbia 27% (Ricaurte et al., 2019). We estimate similar values for other South American countries, which means that about 20% of South America can be considered as wetland. For the northern hemisphere, estimates of wetland area are restricted to "classic" recognized wetlands. However, if the three criteria for wetland definition are applied, i.e., periodic saturation with water during the growing season and the presence of hydric soils and plants adapted to them, then many areas of permafrost soils have to be considered as wetlands. This approach will greatly increase the current total wetland area estimate of 4–6% provided by Mitsch and Gosselink (2015).

Discussion and conclusions

Scott and Jones (1995) provided a global overview of the many approaches to the classification and inventory of wetlands. They also called for international standards to strengthen international agreements among partner countries regarding wetland protection. Finlayson and van der Valk (1995) noted the difficulties in determining general parameters for wetlands that can be used on a worldwide scale to define and delimit wetland areas, and the need to resolve differences between regional wetland definitions and regional typologies. They also recommended a standardization of data collection and the dissemination of new technologies in order to establish ample international inventories. The Ramsar's Scientific and Technical Review Panel likewise called for the *development and testing of a hydro-geomorphically-based system of wetland classification* (Davidson and Finlayson, 2007).

Indeed, the many wetland definitions and classification systems formulated decades ago for specific purposes do not meet current scientific and regulatory requirements. However, there are two major problems in compiling a general wetland classification. The first is that any classification system must encompass wetlands of different size and complexity. Classification systems that differentiate between specific wetland types, such as shallow lakes, swamps, grasslands, and forests, are not applicable to the large, complex wetland systems that often cover tens of thousands of square kilometers. In *Wetland Indicators*, Tiner (1999) treated floodplain wetlands as hydrologically problematic, briefly considered floodplain forests and called for additional studies. In the Ramsar Convention's typology of wetlands published by Finlayson (2018), floodplains are not considered as a specific category because they are complex and include several wetland types. This shows the limits of most typologies.

Large floodplains, but also other large wetland complexes, are made up of different subunits that interact with each other. Examples are the Everglades in North America (Brown et al., 2006), the Sundarbans Mangrove Ecosystem at the Indian subcontinent (Gopal and Chauhan, 2006), the Okavango Delta in Africa (Ramberg et al., 2006; Ellery et al., 2000), Tonle Sap and connected wetlands in Southeast Asia (Campbell et al., 2006), the wetlands of the Kakadu National Park in Australia (Finlayson et al., 2006), the Pantanal (Nunes da Cunha and Junk, 2014) and the Amazonian várzeas and igapós (Junk et al., 2012, 2015) in South America, the mires of the former Soviet Union (Masing et al., 2010) and the northern peatlands of Canada (Warner and Asada, 2006). These wetlands must therefore be treated holistically, including considerations of the political, social, cultural and ecological aspects of the entire wetland complex.

The second problem is that most classification systems do not organize the hydrological, geomorphological, botanical or soil and water chemical parameters of wetlands hierarchically. While the large majority of scientists agree that hydrology is the main driver in wetlands worldwide, this is rarely reflected in classification systems and comparisons between the different systems are accordingly difficult. These and other challenges, discussed herein, have hindered the development of a wetland classification system that is acceptable worldwide.

Certainly, wetlands in boreal regions differ from those in the tropics, wetlands in arid zones from those in humid regions and wetlands in high mountains from those in the lowlands. Furthermore, at the national level, politicians may require a differentiation of wetlands that takes into account economic aspects, such that a geographic delimitation of major climatic, geomorphological and perhaps also politically defined areas may be necessary. This can be achieved at supra-national and national levels depending on the technical and political requirements, as demonstrated by the Colombian classification. It differentiates between four macro regions: the Amazonia and Orinoco region, inter-Andean lowlands, the Andean range and coastal systems, but uses in all regions the same hydrological criteria for major classification units (Ricaurte et al., 2019).

A serious problem for all wetlands, influenced by strong water level fluctuations, is the delimitation of their areas. In most countries, the wetland area is subjected to specific legal protection measures. This situation creates conflicts of interests between different stake holders. Ecologists extend the wetland borders, pointing to the importance of occasionally flooded areas for the

maintenance of biodiversity, whereas ranchers and planners reduce the borders to permanently wet core areas, accepting the risk of losses in biodiversity but also of crops, domestic animals and even human life during high floods. This problem will increase in future because of the increase of extreme flood and drought events predicted by the Intergovernmental Panel on Climate Change (Intergovernmental Panel on Climate Change (IPCC), 2014).

Many classification systems include permanent aquatic habitats, and even deep lakes as wetlands, but not the permanent "terrestrial islands" within large wetland landscapes. Studies in the Brazilian Pantanal however have shown that permanent terrestrial macrohabitats, such as paleo-fluvial levees and terraces, are of fundamental importance for biodiversity. Yet, they are also the most threatened areas, because ranchers use them for pasture plantation and they are often designated for infrastructure development, typically with the argument that these areas are not wetlands. A modern wetland definition and classification approach should incorporate these areas, as does the Brazilian system (Junk et al., 2014). It defines the wetland area as the area influenced during the mean maximum flood and includes permanent dry areas inside the wetlands as of vital importance for the maintenance of wetland integrity. This definition, however is heavily contested by the Brazilian agroindustry.

An international wetland classification system should, in its higher rankings, be based on hydrological aspects, because hydrology is the only factor of general, worldwide importance, and it can easily be classified, as shown in this review. Lower rankings should refer not only to the regional hydrology but also to other classification parameters of regional importance, such as vegetation and hydrochemical peculiarities. At this level, also economic and management aspects such as the use by agriculture, forestry, cattle ranching and fishery can be established. This approach is simple, user-friendly and satisfies the requirements of scientists, environmentalists, politicians, and local populations.

Glossary

Angiosperms Vascular seed plants that bear flowers and have seeds encased in an additional layer of tissue called a carpel. Includes two major subgroups: monocots (e.g., grasses, palms, lilies) and eudicots (most broad-leaved trees, shrubs and herbs). Early-diverging lines belonging to neither subgroup include magnolias and water-lilies.
Bog A type of wetland in which peat accumulates under waterlogged, low-oxygen, acidic, nutrient-poor conditions, with water from precipitation, sometimes building up above the topography.
Bryophytes Nonvascular, herbaceous land plants. Includes modern liverworts, hornworts, and mosses.
Chert Sedimentary rock composed of microcrystalline to cryptocrystalline silica (quartz, chalcedony).
Cladoxylopsids Extinct vascular plants that are ancestors of ferns and horsetails.
Coal A combustible rock containing more than 50% organic matter (carbon) by weight, and 70% carbonaceous material by volume including inherent moisture, formed from the compaction and alteration of peat.
Cordaitales Extinct vascular woody plants ancestral to conifers.
Facies Characteristic combinations of grain size, bedding, fossil assemblages, etc., in sedimentary strata representing a specific depositional environment.
Fen A type of wetland in which peat accumulates under waterlogged, low-oxygen, nutrient-rich conditions, generally sourced by groundwater in topographic depressions.
Glossopteridales A group of extinct, vascular gymnosperms, named for their most common genus, the shrubby to arborescent genus *Glossopteris*.
Gymnosperms Vascular plants in which seeds are not surrounded by specialized tissue ("naked seeds"). Includes modern conifers, ginkgophytes, gnetophytes, and cycads.
Histosol An organic soil order formed from peat or organic-rich muck in bogs and fens.

Lycopsids Vascular, spore-producing herbaceous to arborescent plants. Includes modern club mosses, quillworts, and spike mosses, and also the extinct scale trees (lepidodendrids and sigillarians).
Maceral The microscopic framework constituents of coal, which are the byproducts of the original plant material from which the coal formed. Macerals are analogous to sediment grains and cements in sedimentary rocks.
Marsh Wetlands with emergent, herbaceous, nonwoody plant cover established on a mineral substrate.
Peat An organic deposit or layer formed predominantly from partly decomposed plant material under acidic, low-oxygen, waterlogged conditions in wetlands like bogs and fens.
Progymnosperms Vascular, woody, spore-bearing plants, which are ancestors to gymnosperms.
Pteridosperms Extinct vascular, seed-bearing, herbaceous to arborescent (tree ferns) gymnospermous plants.
Sphenopsids Extinct vascular, reed-like plants, which are a sister group of equisetales (horsetails).
Swamp Wetlands with trees (>6-8 m in height).

Introduction

Wetlands have a long geologic history. Land plants first colonized, evolved, and diversified in wetlands, changing and altering those environments over geologic history (Hotton et al., 2001). Land plants evolved from freshwater green algae (charophytes) in aquatic wetlands in the early Paleozoic, first as groundcover plants, then herbaceous plants, then shrubs and trees. As plant stature and rooting systems evolved, so did wetlands: from groundcover wetlands, to marshes, to forest swamps on mineral substrates, and then to fens and swamps on peat. The plants and animals that inhabited ancient wetlands were different from those of today, but as different types of wetlands evolved, so did their many critical functions and links to Earth's geochemical cycles (Greb et al., 2006).

Data and methods for interpreting ancient wetlands

Ancient wetlands are interpreted from coals, paleosols and rooting horizons, fossils, and other geologic data.

Coals

Coal is formed from peat, and most banded coals formed from peat accumulated in situ (Fig. 1A and B). Coals of all but the highest ranks contain microscopic spores and pollen (Fig. 1C and D), which can be analyzed through palynology. Similar to modern palynological studies of peat and wetland soils, coal palynology reveals the plants that grew in the original peatland and allows for interpretations of lateral (spatial) and vertical (temporal) variability in plant types in coal beds (Dai et al., 2020). Petrographic analysis of coal macerals provides data on the relative contribution of original botanical tissue components in the peat (Fig. 1E and F), and ratios of degraded and nondegraded macerals can be used to interpret paleowater tables in the original peat (Diessel, 1992). Combinations of petrographic, palynologic, and geochemical data are also used for a variety of depositional interpretations, including interpretations of rheotropic (groundwater-fed) vs. ombrotrophic (rainwater-fed) wetland origins (Eble and Grady, 1993).

Paleosols and rooted horizons

Paleosols are fossil soils (Fig. 1G and H). Many of the physical and geochemical features found in modern soils are preserved in them. Hydric soils, characterized by high water tables, are anaerobic in their upper horizons at least for part of the year. Anaerobic conditions lead to preservation of organic material in paleosols, accompanied by gleying and root halos (Retallack, 1990).

Fossils

Plant fossils (macroscopic and microscopic remains) provide direct evidence of vegetation throughout Earth's history. In some cases, plant fossils are found in growth position. In-place (autochthonous) fossils in wetland facies include buried stumps of wetland trees (Fig. 1I), and coal balls (permineralized peat) in coal beds (Fig. 1J and K). Coal balls can preserve cellular details of the peat-forming flora. In many cases, plant fossils represent transported (allochthonous) elements (Fig. 2A–C). Some fossil plants (megascopic and macroscopic) have extant members that are hydrophytic; hence, interpretation of wetland habitats or ecologies for these taxa is straightforward. Interpretations for other taxa are based on comparisons to related extant plants, on their own morphological features, or on their associations with wetland facies.

Animal fossils are also found in association with wetland strata (Fig. 2D). Most common are invertebrates (bivalves, gastropods, etc.) and invertebrate traces (burrows, tracks, trails), but many famous vertebrate fossils are also associated with ancient wetlands (Greb et al., 2006; Greb, 2013).

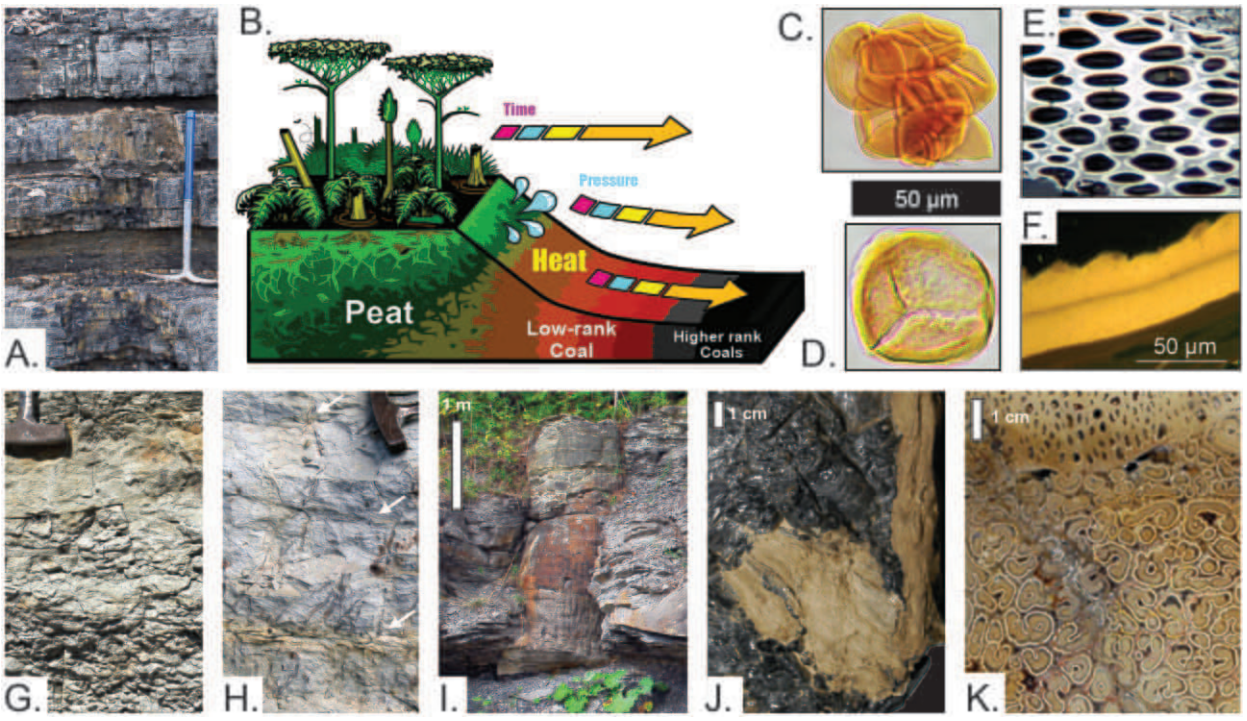

Fig. 1 Some of the types of geologic data collected to interpret ancient wetlands. Examples are from Pennsylvanian coals in Kentucky. (A) Coal interbedded with shale representing alternating peat accumulation and overbank flood deposits. (B) Coal is formed from peat. (C) Microscopic image of tree fern spore, *Punctatisporites minutus*, and (D) *Lepidodendron* lycopod tree spore, *Lycospora pusilla*, from coal samples. (E) Microscopic images of inertinite maceral (charcoal) and (F) sporinite (spores) from coal samples. (G) Gleyed wetland paleosol (soil) with orange root halos. (H) Lycopod forest roots *(Stigmaria)* in a sandstone. (I) In situ lycopod tree stump buried by sandstone splay deposits. (J) Coal ball (calcareous cementation) preserving plant debris in coal. (K) Detail of tree fern internal structure from a coal ball.

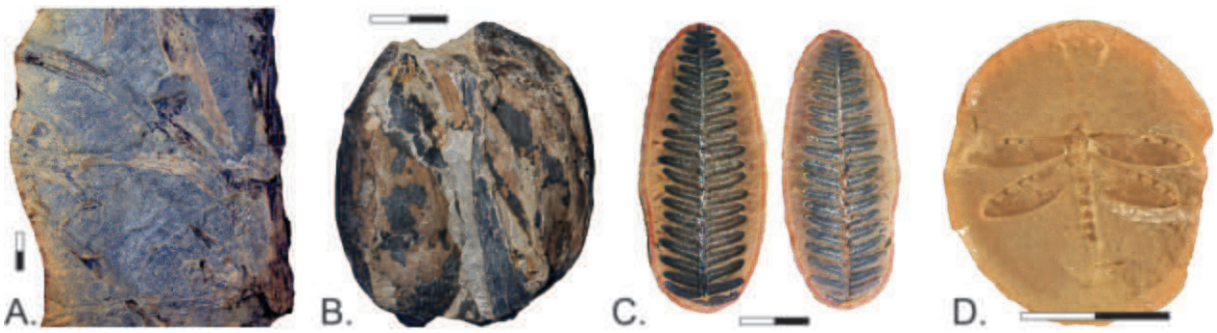

Fig. 2 Examples of transported plant and animal fossils from prehistoric wetlands. Compression fossil of (A) Devonian marsh plant, *Pertica quadrafaria*, Maine, and (B) Paleocene *Nypa* sp. mangrove fruit, Columbia. (C) Pennsylvanian fern, Indiana, and (D) insect, *Eubleptus danielsi* Illinois in siderite nodules. Insect fossil, no. PE40223, with permission Field Museum of Natural History.

Other geologic data

Some rock types, including coals and some organic-rich terrestrial shales, formed only in wetlands. Palustrine limestones and some marls are characteristic of more seasonally wet conditions, including seasonal wetlands (Wright and Platt, 1995). Recognition of facies containing or surrounding coals, organic-rich shales, and palustrine strata allows comparison to original depositional settings (e.g., fluvial, levee, floodplain, etc.). In addition, facies associations are used to infer broader paleogeographic features, including ancient deltas and coastlines, which are important characteristics for many wetland classifications.

Geologic history of wetlands

Pre-Ordovician wet areas

Stromatolite (cyanobacteria) mounds are the oldest fossil life on Earth. Most stromatolites are marine, but some forms from Proterozoic strata more than 2 ½ billion years old are interpreted as inhabiting intertidal areas (Noffke et al., 2006) and freshwater ponds and lakes (Bolhar and van Kranendonk, 2007). Although interpretations of freshwater stromatolites are equivocal (Martín-Closas, 2003), if intertidal or freshwater stromatolites existed in Proterozoic times, and aquatic wetlands are defined to include cyanobacteria mounds in shallow ponds, then the origins of wetlands may extend back into truly deep geologic time.

Ordovician–Early Devonian: Groundcover wetlands

Land plants (embryophytes) are interpreted to have evolved from freshwater charophytes (green algae) in the Late Ordovician to Early Silurian (Graham, 1993; Delwiche and Cooper, 2015) in ponds and aquatic wetlands (Fig. 3). The earliest confirmed, nonspore fossil embrophyte consists of bryophyte-like mats from the Early Silurian (Llandoverian; 443 Ma) of Virginia (Tomescu and Rothwell, 2006). All early embryophytes required moist substrates. The habitats of these low-lying flora come closest to modern moss-lichen wetlands, or wet meadows that lack standing water but have seasonally high water tables, with substantial differences. "Moss-like" wetlands (based on stature) or "groundcover" wetland might describe these primitive wetlands better (Fig. 4).

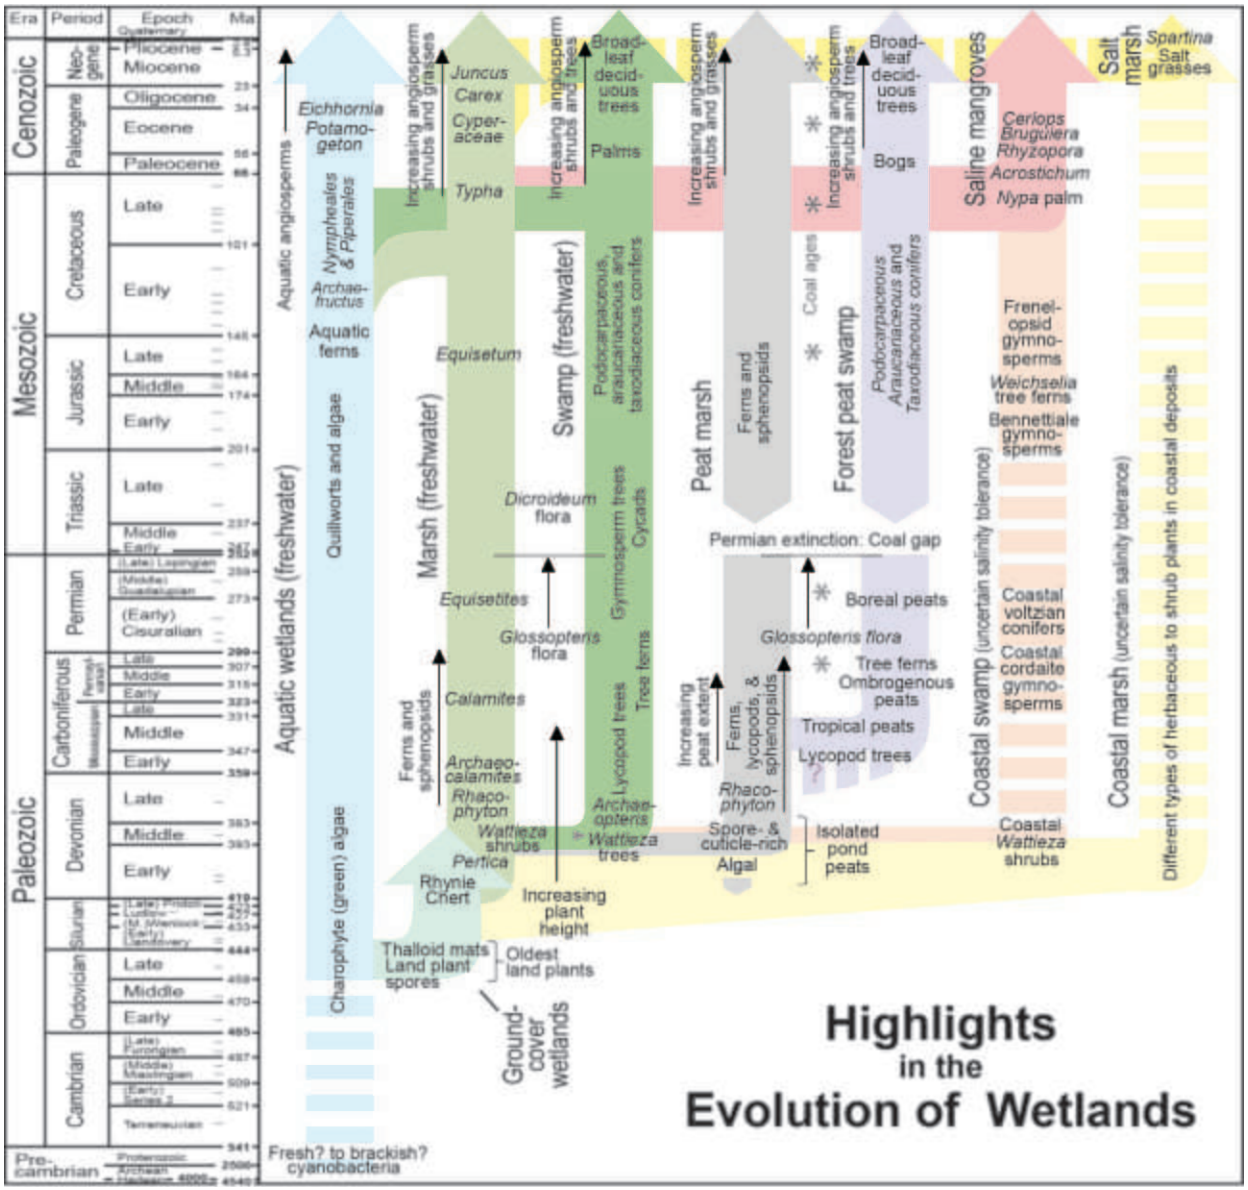

Fig. 3 Wetlands through time. Data are based on flora and fauna discussed in Greb et al. (2006). Ma = Millions of years ago.

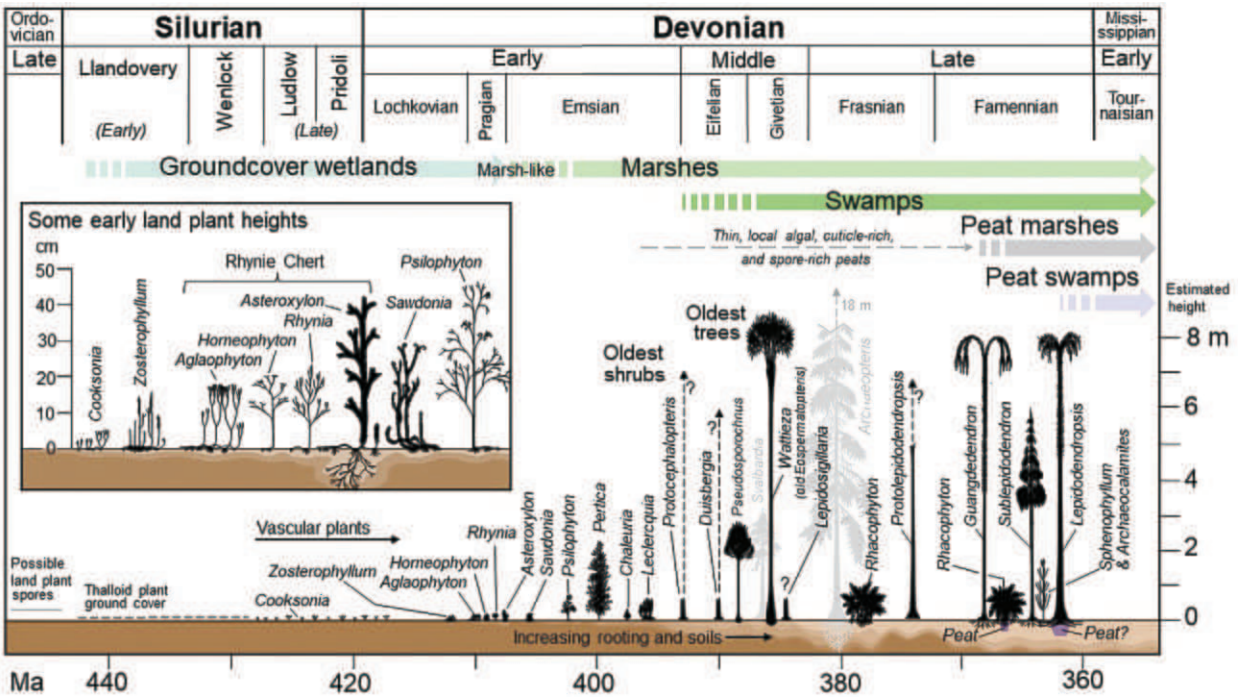

Fig. 4 The early diversification of flora and the wetlands they formed. See vegetation references in text. Modified from Greb et al., 2006, Fig. 1.

By the Early Devonian, a variety of slightly taller plants (mostly <20 cm) occupied wetlands along channel margins, floodplains, coastal areas, and bays (Hotton et al., 2001; Kennedy et al., 2013). The most famous example of Early Devonian (Pragian; 407 Ma) wetlands is the Rhynie Chert of Scotland (Kerp, 2018). The chert preserves fossils of freshwater plants, charophytes, fungi, and tiny invertebrates (Rice et al., 1995). Plants such as *Aglaophyton*, *Horneophyton*, and *Rhynia* were <20 cm tall, but *Asteroxylon* grew to 40 cm (Fig. 4). The Rhynie habitat could be described as a groundcover wetland to wet meadow, or perhaps marsh-like wetland. The association of tiny arthropods with the Rhynie flora shows that even from their origins, wetlands were providing critical habitats for animal life. By the mid-Devonian, the first land vertebrates would emerge from ponds and lakes in wetlands (Clack, 2002). In the Early Pennsylvanian, the earliest reptiles *(Hylonomus)* lived in lycopsid swamp forests (Calder, 2012).

Early–Middle Devonian: Evolution of freshwater marshes

As wetland plant height increased, the first marshes formed and expanded. Early Devonian (Emsian; 407 Ma) plants such as *Pertica* and *Leclercqia* may have grown to heights in excess of 1 m (Fig. 4) and occupied lacustrine-fringing-, floodplain-, and coastal/estuarine-margin marsh habitats (Fig. 4; Allen and Gastaldo, 2006). Wetland marshes with shrubby (<6–8 m) plant taxa evolved by the Middle Devonian (Fig. 4). The cladoxylopsid *Wattieza* (generally <5 m tall) grew in Middle Devonian (Givetian; 385 Ma) marshes on the margins of oxbow lakes (Retallack and Huang, 2011). By the Late Devonian (Famennian; 360 Ma), the pre-fern *Rhacophyton* was widespread in riparian river-margin and lake-margin marshes (Scheckler, 1986). In addition, sphenopsids (horsetails and relatives) such as *Sphenophyllum* and *Archaeocalamites* (Fig. 4) were established with reed-like morphologies and rhizome stems in disturbance-prone riparian and lake-margin marshes (Wang et al., 2005)—habitats their distant ancestors still inhabit.

Mid-Late Devonian: Evolution of forest swamps

The oldest trees evolved in the Middle to Late Devonian and quickly occupied both wetland (Figs. 3 and 4) and non-wetland habitats. Those early trees rooted in wetland paleosols represent the oldest forest "swamps." An example is the Mid-Devonian (Givetian; 385 Ma) tree-fern-like *Wattieza* (previously *Eospermatopteris*), from Gilboa, New York (Driese et al., 1997; Stein et al., 2012). Based on fossil stump diameters, *Wattieza* varied from tall shrubs to trees nearly 9 m tall (Retallack and Huang, 2011). One of the first large trees (18+ m in height), the deciduous progymnosperm *Archaeopteris*, evolved in the Middle Devonian and became common in Late Devonian floodplain and lake margin settings (Scheckler, 1986) marginal to wetlands (Retallack and Huang, 2011). A variety of lycopsid trees also evolved in the Devonian, including *Protolepidodendropsis* (mid-Devonian, Frasnian; 380 Ma) in North America and Europe (Berry and Marshall, 2015) and *Guangdedendron* (Late Devonian, Famennian; 372 Ma) in China (Wang et al., 2019). Lycopsid trees evolved specialized root systems (*Stigmaria*), which allowed them to thrive in flooded substrates.

Expanding marshes and forest swamps in the Devonian and Carboniferous established several wetland functions. River banks were stabilized by vegetation, which changed Devonian stream patterns (Davies and Gibling, 2010). The evolution and expansion of roots likely altered the global nitrogen and phosphorous cycles (Greb et al., 2006). Rooting changed rates of chemical weathering (Algeo et al., 1995). Increased weathering and the deposition of organic carbon from spreading land plants dramatically changed the carbon cycle (Algeo et al., 1995; Berner, 1998; Boyce and Lee 2017).

Mid–Late Devonian: Evolution of peat marshes

The oldest coals are from the Devonian. Thin, laterally isolated, "boghead" coal beds from the Early to Middle Devonian of Siberia and China (Kennedy et al., 2013) represent local freshwater algal peats. Some Middle Devonian non-banded coals represent accumulations of peat from mostly monotypic spores or cuticles from land plants in ponds and lakes (Dai et al., 2020). Organic contributions in these early coals may have been from marsh plants growing along the margins of ponds, and not necessarily growing in the ponds on a peat substrate. By the Late Devonian (Famenian; 360 Ma), thin-banded coals dominated by the pre-fern *Rhacophyton* are recorded (Scheckler, 1986), and may represent plant growth on peat (histosol) substrates. Because *Rhacophyton* had shrub stature, these thin coals may represent the oldest peat marshes, a habitat that became more common into the Carboniferous (Figs. 3 and 4). These early peat marshes could be termed "fens," although they lacked significant contributions from mosses and, of course, the angiosperm reed, rush, and sedges that typify modern fens.

Late Devonian–Carboniferous: Evolution of peat swamps

The oldest peat-accumulating forests or swamps probably spanned the Late Devonian–Mississippian transition (Figs. 3 and 4). Lycopsid swamp trees evolved in the Late Devonian paleotropics and became widespread in the Mississippian on both mineral and peat substrates (Scheckler, 1986). Russian coals from the Middle Mississippian (Visean; 345 Ma) are dominated by lycopsid trees, with some contributions from gymnosperms and sphenopsids (Mosseichik and Ruban, 2010). Although Carboniferous coals are sometimes interpreted as "bogs," that term sometimes implies significant bryophyte contributions, which is not the case for Late Devonian and Carboniferous swamps.

Paleozoic coastal marshes

Many of the Silurian and Early Devonian plants described from early freshwater marshes have been found in coastal and estuarine facies (Fig. 3) or are capped by marine facies, and interpreted as inhabiting possibly brackish- or saltwater coastal marshes (Allen and Gastaldo, 2006; Wang et al., 2019). In coastal and estuarine settings, however, it is not uncommon for wetland plants to occupy local freshwater lenses and ponds, yet be rooted in coastal sediments and subsequently buried in coastal or marine sediments. Hence, it is difficult to definitively interpret the salinity tolerance of fossil plants based solely on characteristics of the strata that encase the fossil assemblage.

Paleozoic coastal mangroves?

Numerous shrub and small-tree taxa are also known from Devonian coastal tropical deposits (Fig. 3). The Devonian cladoxylopsid *Wattieza* has been found in intertidal facies and interpreted as a possible estuarine mangrove (Retallack and Huang, 2011), although it also occupies a variety of freshwater habitats. In the Carboniferous, some Cordaitales are interpreted as possible mangroves (Raymond and Phillips, 1983), although they may have tolerated only occasional brackish incursions, rather than forming true mangrove wetlands (Falcon-Lang, 2005). Voltzian conifers (woody gymnosperms) in coastal deposits from the Permian (Asselian; 295 Ma) are also possible mangroves and have physiological adaptations to drought tolerance, which might have provided salinity tolerance (Falcon-Lang et al., 2015).

Carboniferous: The oldest widespread peatlands

Coals became thicker and more widespread throughout the paleotropics and subtropics during the Late Mississippian and Pennsylvanian (Gastaldo et al., 2020), which demonstrates continued evolution of peatlands. Early to Middle Pennsylvanian coals tend to be dominated by lycopsid trees (e.g., *Lepidodendron*), with subordinate pteridosperms, tree ferns, woody sphenopsids, and small ferns, and variable amounts of Cordaitales (Phillips and Peppers, 1984; DiMichele and Phillips, 1994; Montañez, 2016). Niche partitioning of wetland communities increased through the Mississippian and expanded in Pennsylvanian wetlands among many plant clades (DiMichele et al., 2001). Vertical successions in some coals indicate upward drying and leaching, and floral changes suggest the oldest ombrogenous (domed peats fed by rainwater) peat development (Eble and Grady, 1993) and the oldest hydroseral successions in peat bogs.

Some Middle Pennsylvanian (Desmoinesian; 310 Ma) coals were the oldest to have very large geographic extent. These coals record broad blanket peatlands, approaching the scale of some of the largest modern blanket peatlands (Greb et al., 2003). Because of the many widespread coals in eastern North America and Europe during the Pennsylvanian, it is sometimes called the "Coal Age." The extent of coals has varied through time, however, and coal ages have occurred in different parts of the world at different times (Fig. 3); at other times, there were few coals, and therefore few peatlands (Cross and Phillips, 1990; Thomas, 2002).

Permian: The rise of wetland gymnosperms and high-latitude peatlands

Today, widespread peatlands occur at both high latitudes and in the tropics. In the Permian (299–252 Ma), tropical peats are found in what is now southeast Asia (Wang et al., 2012). Mid- to high-latitude peats are recorded in coal beds from Australia, Brazil, India, South Africa, and Antarctica, which formed part of the Gondwana supercontinent. Gondwana coal beds are dominated by gymnosperms, including glossopterids (like *Glossopteris*), cordaitales, conifers, and cycads but also subordinate horsetails (*Equisitales*), ferns (Filicopsids), herbaceous lycopsids, and bryophytes (Archangelsky, 1986; Cúneo, 1996). Gymnosperms would remain the dominant trees in forest swamps and peatlands in the Permian, and through much of the following Mesozoic (Cross and Phillips, 1990; Wing and Sues, 1992; Graham, 1999).

Some Permian high-latitude deposits represent the oldest conifer-dominated boreal wetland forests. In addition, mid-Permian coals from Antarctica contain clastic dikes, comparable to polygonal soil wedges in modern palsa peats with permafrost cores (Krull, 1999), attesting to cold climates for some high-latitude Permian peatlands. High-latitude peatlands in the Southern and Northern Hemispheres have come and gone since the Permian as landscapes and climates changed through geologic history.

Mesozoic: Aquatic plants, angiosperms, and lacustrine wetlands

Lacustrine wetlands coexisted with the earliest coastal and floodplain wetlands, but a component of modern lacustrine wetlands—truly aquatic vascular plants in open water—did not evolve until much later (Fig. 3). Aquatic quillworts such as *Isoetes* are known from the Triassic (Retallack, 1997) and possibly Permian (Hetherington et al., 2019). These fossils may represent the oldest submerged aquatic vascular plants, and may have contributed to the oldest shallow-water wetlands not dominated by submerged algal macrophytes. Aquatic ferns of the Marsileaceae family evolved in the Late Jurassic to Early Cretaceous, approximately 145 Ma (Yamada and Kato, 2002), and Salviniaceae (floating aquatic ferns) in the early Late Cretaceous (Cenomanian; 94 Ma; Hall, 1974). Angiosperms did not evolve until the Early Cretaceous (Barremian stage; 125 Ma). Floating and emergent aquatic angiosperms are common in two early-diverging orders—Nymphaeales (water lilies and allies) and Piperales (Friis et al., 2003)—as well as among the basal lineages of monocots and eudicots, which constitute the vast majority of extant crown-group angiosperms. The evolution of aquatic (submerged, emergent, and floating) angiosperms through the Cretaceous Period and early Cenozoic Era dramatically altered aquatic (littoral, limnetic) wetlands, which became essentially the same as modern forms by the Eocene Epoch of the Paleogene (Graham, 2011).

Mesozoic–Cenozoic coastal mangrove wetlands

Several small, woody Mesozoic gymnosperms with drought-tolerant (possibly salt-tolerant) adaptations are interpreted as possible mangroves (Fig. 3). Some Bennettitales (extinct cycad-like plants) and conifers of the Late Jurassic (Barbacka et al., 2006), and Early Cretaceous (e.g., *Frenelopsis*; Upchurch and Doyle, 1981) were facultative saline-tolerant plants, but equivocal mangroves (Sucerquia et al., 2015). Some species of the Middle Jurassic (Bathonian; 166 Ma) to mid-Cretaceous (Cenomanian; 94 Ma) tree-fern *Weichselia*, have also been interpreted as mangroves (Retallack and Dilcher, 1981).

The oldest extant mangrove lineage is that of *Nypa* (palm family) known from the Maastrichtian (Late Cretaceous) (Fig. 3, Harley, 2006). Fossils of the mangrove fern *Acrostichum* have also been reported from Maastrichtian (Bonde and Kumaran, 2002), but the assignment to the extant genus has been questioned (Schneider et al., 2004). Most other extant mangrove taxa originated in the Cenozoic Era (Plaziat, 1995; Ellison et al., 1999).

Cenozoic: Saltwater marshes

Continued angiosperm radiation in the Cenozoic involved the evolution of many plants commonly associated with freshwater and saltwater marshes (Fig. 3). Extant saltwater-marsh plants such as cordgrass (*Spartina* sp.), rushes (*Juncus* sp.), and sedges (*Carex* sp.) are angiosperm grasses (Poales), and all have very poor fossil records. Ancestral grasses can be traced back to the Cretaceous, but the crown groups of modern Poales date to the Paleogene (66 Ma) at the beginning of the Cenozoic Era (Bouchenak-Khelladi, et al., 2014). These groups originated in damp, freshwater, infertile substrates (Givnish et al., 2010) prior to expansion into saline habitats. *Carex* spores can be traced back to the mid-Cenozoic (Eocene–Miocene; 56–23 Ma); *Juncus* has a poor fossil record and can only be traced back to the Miocene (23–5 Ma); and *Spartina* also has a poor fossil record, but may postdate the Miocene (Daghlian, 1981). Hence, extant saline marshes dominated by these taxa are geologically relatively recent types of wetlands.

Cenozoic: Return of the bryophytes at high latitudes

Modern high-latitude peatlands are dominated by *Sphagnum* moss. Although bryophytes were among the first inhabitants of wetlands, they remained only very minor components of wetlands until the Cenozoic Era. *Sphagnum* evolved by the Early Jurassic (206–144 Ma), and increased in abundance in the Late Cretaceous and Cenozoic (Cross and Phillips, 1990). Spores and biomarkers (C^{23}/C^{31} *n*-alkane ratio) of *Sphagnum* from a German lignite (Inglis et al., 2015) indicate that ombrogenous sphagnum-dominated bogs existed in the Paleocene (55 Ma), but most species of *Sphagnum* evolved after late mid-Miocene (17 Ma) global cooling (Shaw et al., 2010) and are also relatively recent additions to mid- and high-latitude peatlands.

Cenozoic: Climate and tectonic changes and wetlands

Many of the changes to wetland (and other) biomes through time are influenced by global climate and tectonic changes. During the Cenozoic, separation of South America, India, and Australia from the southern Gondwana supercontinent, and mountain building in South America and the Himalayas led to physical barriers and climate change, which greatly influenced wetland and rainforest distribution in the world (Wing and Sues, 1992; Graham, 1999; Hoorn et al., 2010; Morley, 2018).

Modern-style, closed-canopy, angiosperm-dominated vegetation was present in tropical wetlands of South America by the Paleocene (Wing et al., 2009; Graham et al., 2019). During early Cenozoic "hothouse" climates, wetland floras at middle and high latitudes were dominated by taxodioid conifers (Cupressaceae) and deciduous broad-leaved eudicots, but palms extended to both the Arctic and Antarctic (Williams et al. 2003; Reichgelt et al., 2018). Freshwater marsh habitats became essentially modern in the Middle Eocene to Early Miocene (Graham, 2011). Through the mid-Miocene warm period (17–15 Ma) northern mid-latitude floras continued to include what are today more tropical as well as temperate lineages, but the latter came to dominate during the cooler late Neogene (Tiffney and Manchester, 2001). In North America, cool-temperate forests (and wetlands) at mid and high latitudes changed to boreal forests similar to their modern counterparts by the mid-Miocene (6 Ma) (Graham, 2011; Pound et al., 2012). Northern Hemisphere continental glaciation (waxing and waning) from the Pliocene (5 Ma) through the Quaternary was accompanied by dramatic changes in the distribution and extent of temperate and northern latitude wetlands as great ice sheets advanced and retreated across the continents.

Conclusions/Summary

The history of wetlands is ancient and intricately tied to the evolution of the terrestrial flora. As wetland plants evolved, so did different types of wetlands; from groundcover wetlands, to marshes, to swamps. Increasing morphological adaptations to the physical and chemical requirements of living in wetlands led to increased niche partitioning of flora, and a wide array of wetland habitats through time. Because lowland wetlands have provided habitat for fauna since their earliest beginnings, and have high preservation potential, prehistoric wetlands have been a major source of the fossil flora and fauna geologists use to interpret the geologic past from the Late Silurian to the present. The evolution of different types of wetlands has influenced sedimentation along rivers, lakes, and shorelines, and dramatically influenced several global biogeochemical cycles, including the carbon cycle. Through geologic time, wetlands have fostered evolutionary innovation, but have also been habitats where some species have remained in refugia past their demise in other habitats. Wetlands have expanded and contracted across the globe through history in response to changes in climate, sea level, and tectonics; because of this, prehistoric wetlands are important sources of data for modeling the potential impacts of future climate, sea level, and landscape changes at a variety of scales.

Knowledge gaps

- *Preservational bias*. Much of what we know about the ancient history of terrestrial ecology comes from coastal-deltaic areas in subsiding basins, which have a higher chance of being buried by sediment. Hence, the geologic record of wetlands is biased toward coastal and paludal settings. Wetlands in upland settings and in areas where tectonic subsidence is uncommon have lower preservational potential.
- *Nonpeat wetlands*. Ancient wetland history is biased toward studies of coal because it is fossil peat. Nonpeat wetlands are less commonly studied.
- *Discovery bias*. In many parts of the geologic record, terrestrial fossils are found in association with industrial activities, such as coal mining. This has acted to multiply the biases already described—paleontologists are more likely to find and collect the wetland fossils associated with the artificial exposures created by these activities. The plants and animals living in the less frequently preserved, seasonally dry habitats are also less likely to be searched for and found.
- *Wetland diversity*. The plant macrofossil record only preserves a small proportion of the original systematic diversity of these sites. Fossil pollen and spores recovered from wetland deposits may contain information not only about the plants that grew in wetlands, but also of the regional contribution from communities growing on other substrates. Knowing exactly which plants may have grown under high-watertable conditions and those outside of wetlands is sometimes difficult.

The Geomorphology of River Wetlands

Edgardo M Latrubesse and Taina M Suizu, Environmental Sciences Graduate Program-CIAMB, Federal University of Goiás, Goiânia, GO, Brazil

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Wolfgang Junk and Florian Wittmann.

Glossary

Anabranching Alluvial multi- channel patterns. The channels are separated even at bankfull discharge stage by vegetated semipermanent alluvial islands excised from existing floodplains or formed by within-channel accretions. Anabranching patterns are dominant among the largest rivers in water discharge and also present in a wide range of environments and smaller rivers worldwide.

Avulsion Natural process by which flow diverts out of an established river channel to a new relocated course.

Avulsive rivers Unstable rivers that experience avulsion of long fluvial belts at a variety of time scales, but without the typical conical shape of channels radiating from an apex that characterize the megafans.

Braided Braided rivers are bedload-dominated systems characterized by a network of braided ephemeral bars, unstable channels, and limited riparian vegetation.

Floodplain Depositional surfaces adjacent to the active channel subject to floods, constructed by river processes and built with alluvial sediments. A floodplain is a morphosedimentary unit related to the present-day dynamic. However, older related alluvial units at the same or similar elevation level can also be frequently flooded.

Meanders Sinuous fluvial morphology in a single channel. Meandering rivers wander across a floodplain forming a series of sinuous bends. The water flow patterns through meanders encourage erosion on the outer bank, while deposition and point bars form in the inner bank.

Megafan Megafans are large-scale avulsive alluvial systems formed by unstable rivers that exhibit multiple radial channel patterns (active or abandoned) diverging from an apex. Megafans are >100 km in length and their depositional area ranges from ~7000 to ~200,000 km^2.

Introduction

The global relevance of fluvial systems for inland wetlands is self-evident as wetlands are defined as permanently or seasonally water-saturated land areas, with flowing or stagnant water or saturated soils, and where plant and other biological activity adapted to wet conditions can develop (IUCN, 1971; Cowardin et al., 1979; Brinson, 1993; and many others). Rivers and their landforms/environmental mosaics sustain a significant proportion of inland-continental freshwater wetlands on Earth. Some early classifications of wetlands that incorporated hydrogeomorphology concepts are limited to including descriptions in topography, hydrological, and soil parameters (Brinson, 1993; Neiff et al., 1994; Semeniuk and Semeniuk, 1995; among others), but fluvial wetlands have been dominantly defined under a biological, ecological, and hydrological perspective (Lisenby et al., 2019). Since those pioneer efforts to incorporate hydrogeomorphology into fluvial wetlands research and freshwater conservation, scientists have perceived the relevance to incorporate hydrogeomorphologic concepts into the classification, delimitation, and environmental understanding of wetlands (e.g., Phillips, 1989; Tooth and McCarthy, 2007; Latrubesse, 2012; Sinha et al., 2017; Mu et al., 2021;

Kandus et al., 2017, 2018; Latrubesse et al., 2017, 2021). This chapter reviews and discusses the links between wetlands and hydrogeomorphology, classification systems of fluvial wetlands, the hydrogeomorphologic environmental role of fluvial wetlands, and the global environmental challenges they face. We concentrated on inland fluvial wetlands and did not include wetlands in transitional continental-marine environments, such as deltas and estuaries.

Rivers, fluvial wetlands, and floodplains

Fluvial systems are open physical systems where the primary inputs and outputs of the fluvial system are water, sediment particles, and solutes (solid load and dissolved load). These components are conveyed through the channels that contain water permanently, seasonally, or episodically. Channel development is controlled by the lithological substrate and water and sediment flows, resulting in various channel geometries. The fluvial channels can be shaped by (a) eroding the terrain surface in a self-building channels network; (b) self-formed by alluvial materials the own system transport and deposit, or (c) built by a combination of both processes.

They can be relatively stable or unstable features as erosional and aggradation processes can constantly modify them. Channels adjust and evolve, and a wide range of channels are found in nature. When water flow exceeds the channel capacity during flooding, flooding waters overtop the channel and spread onto the surrounding terrain. Part of the flooded area can be alluvial sediments deposited by the system or terrains formed by rocks and older sediments unrelated to the river's hydro-geomorphologic dynamics. Fluvial flooded areas can be defined from a hydrological or geomorphological point of view. The engineering hydrological definition for floodplains considers a flat surface delineated by the extension of a flood with some particular recurrence interval of flooding (e.g., 100 years). It is also defined as the Special Flood Hazard Area by agencies such as the Federal Emergency Management Agency of the United States (FEMA). Urban planning and insurance companies have thoroughly used the flood-recurrence criterion to delimit the areas of flood risk. However, the delimitation of that area is not necessarily a well-delimited natural unit as "$(x)_{years}$" floods can spread on different kinds of lithology and landscape components. The geomorphologic definition is based on the principle that floodplains are flat depositional surfaces adjacent to the active channel subject to floods, constructed by river processes and built with alluvial sediments. This means that a floodplain is a morphosedimentary unit related to the present-day dynamic. However, older related alluvial units at the same or similar elevation level can also be frequently flooded. It happens because a fluvial system is a natural system with a history, and floodplains are fluvial archives containing recent alluvial units of the Holocene age that can be frequently flooded but not necessarily deposited by the present hydro-geomorphologic regime.

Floodplains are an essential environmental component of the fluvial system and play different functions and services. They are the central fluvial wetlands, support a variety of environments and habitats, act as an erosional-depositional and hydrological buffer area during extreme events, act as aquifers, provide agricultural land and other multiple socio-economic services for humans, and can be a sink of sediments and pollutants.

River's typology

Rivers can be classified in a variety of ways. A simple approach uses the physiographic setting by considering the relief in categories and classifying rivers in mountains, highlands-plateaus, lowlands, and coastal rivers. We can add other factors if the systems reach the Ocean (exoreic basins), if the flows end inland (endorheic basins), and if the flow regime is perennial, seasonal, or intermittent. In some regions, such as in the Amazon, the physical-chemical characteristics of water (water types such as black, clear, and white) have been used to differentiate rivers (Sioli, 1984). In some cases, the kind of environment they drain can also be used to qualify them, as those draining peats and classified as "peat rivers."

Classifying rivers is still challenging, and not a single holistic classification covers all the necessary conceptual and classificatory aspects and their hydrogeomorphologic and environmental diversity. Considering major geotectonic domains of river basins across the planet, many basins spread on more than one geologic domain and climatic zone; therefore, Latrubesse (2015) and Latrubesse and Sinha (2021) proposed four main groups of geological and geomorphological settings of rivers. The main categories are (a) orogenic mountain belts, (b) cratonic areas, sedimentary and basaltic plateaus/platforms, (c) lowland plains in sedimentary basins, (d) and mixed terrains (Table 1). This highlights the complexity of geologic-geomorphic settings of the global rivers, which manifests in morphological diversity and, as a consequence, in the diversity of wetlands.

From the classification above, we can consider two major groups of physiographic settings and two main types of fluvial hydro-sedimentological conveyors. From the physiographic point of view, rivers draining mountain and highlands plateaus are mainly dominated by erosional v-valleys landforms and have considerable stream power and higher slopes than their lowland counterparts. Of course, it is a generalization as some high elevation's settings, such as high plateaus (Altiplano, Tibet), old planation Gondwana surfaces, basaltic plateaus, and a variety of tectonically controlled intra-mountain and inter-mountain basins can also hold rivers that, at a reach/regional scale, exhibit some similar characteristics to those of lowland rivers. Also, medium-size and large rivers can have headwaters in the highlands or mountains and flow downstream through the lowlands. It is relevant as the upper catchment can control the hydrology of the system, and, more relevantly, it usually controls the primary source of sediment load to the rivers. Therefore, generalizing, mountain rivers (or upper catchments of lowland rivers) are mainly flowing on erosional valleys and have relatively large energy with a dominant erosional-transport regime. Consequently, they do not hold a relevant proportion of fluvial wetlands.

Table 1 Geological, geomorphologic settings and fluvial wetlands for large axial rivers, megafans and avulsive rivers.

Category/Description	*Examples*	*Wetlands-floodplains*
1. Linear axial rivers: stable and avulsive fluvial belts		
A. Orogenic belts-linear fluvial belts: rivers with headwaters and long reaches in active orogenic belts, basins' shapes are commonly elongated.		
A.1 Encased in rocky terrain but poorly developed alluvial plain (better developed in the lower reach)	Ayeyarwady, Mekong	Narrow, developed in alluvial reaches, islands, bars and limited floodplain lateral extension Lager rocky-alluvial mixed islands (Mekong)
B. Platforms/Plateau: river draining dominantly platform areas and plateaus (basaltic or sedimentary) bedrock channels, with incised valleys and rapids, bed-load dominant	Upper Parana	Complex-wide wetlands, islands, swamps, paleochannels, paleoislands, lakes
C. Cratonic: headwaters and good part of the river length in low relief areas of stable Pre-Cambrian crystalline basement		
C.1 Confined rivers. Bedrock channels, with incised valleys and rapids, bed-load dominant, v. low suspended load, fragmented, narrow alluvial plain in lower reaches	Tocantins	Narrow, poorly developed with some islands and bars
C.2 Blocked rivers. Large flooded valleys, bed-load dominant, v. low suspended load, rapids in middle or upper courses	Tapajos, Xingú	Blocked valley, large ria-lakes, can have also mixed alluvial-rocky archipelagos.
C.3 Wide valleys with complex islands. Anabranching complex reaches alternating with narrow reaches with rapids or nodal points, bed-load dominant, low suspended load	Negro, Congo	Very wide floodplain, complex huge relict island, sandy fluvial bars.
D. Lowland plains: large aggradational plains- lowlands		
D.1 Meandering belts. Single channel, non-harmonic meanders, muddy banks, high suspended load	Jurua, Purus, Mississippi	Meanders, oxbows, swamps, scroll bars, crevasse splays
E. Mixed: Rivers draining mixed terrains		
E.1a Platforms + cratons. Mainly anabranching with braided tendency, alternating with incised valleys, abundant bed load	Middle Araguaia Middle Parana	Channel dominated anabranching floodplains, impeded floodplains, elongated abandoned-channel lakes, islands, fluvial bars, splays
E.1b Platform + lowlands + Mountains Mainly anabranching with braided tendency in the main multichannel conveyor, large islands, water saturated floodplain, floodplain deltas, meandering floodplain branches		Channel dominated anabranching floodplains, impeded floodplains, elongated abandoned-channel lakes, floodplain deltas, islands, fluvial bars, splays, scroll bars from meandering branches
E.2 Orogenic belts + (or) platforms + (or) cratons + (or) sedimentary lowlands. Complex systems, low to moderate anabranching with braided tendency in some cases, confined reaches and rocky reaches or rapids alternating with wide alluvial reaches, high sediment load (bed load + suspended load) when the orogenic belt is the dominant area, lower sediment load when the platform/cratonic zone is dominant	Orinoco, Madeira, Lena, Obi, Yangtze	Channel dominated dynamics floodplains Related periglacial processes in floodplain wetlands of high latitudes. Can alternate geologically controlled reaches of wide floodplains and narrow floodplains.
E.3 Orogenic belts + lowlands. Headwaters in mountains and well-developed fluvial belts in lowlands		
E.3.1 Stable fluvial belts. Anabranching or meandering systems with stable well defined fluvial belt and terraces	Japura, Içа	Channel dominated anabranching with islands, abandoned channel and swamps. Oxbows and swamps can be present in sinuous reaches
E.3.2 Unstable-avulsive fluvial belts in the forelands		
E.3.2.1 *Avulsive anabranching, high vertical aggradation systems in floodbasins*	Lower Magdalena	Flood basin anabranching system, paleochannels, splays, lakes, swamps, floodplain deltas
E.3.2.1 *Avulsive rivers, lateral migration by avulsion dominant, unstable channels, normally meandering or anabranching with some sinuosity, high in suspended load*	Beni, Ucayali, Pastaza	Paleochannels, lakes, swamps and splays
2. Megafans		
A. Foreland: the whole fan lying in foreland (proximal wedge top-foredeep zone)	Kosi	Shifting fluvial belts and splays
B. Cratonic: Source areas lying in cratonic settings, depositional zone dominantly linked to intra-plate basins	Okavango	Flooded basins and avulsion
C. Complex: Source area in mountains, fan spreading into different settings such as foreland and lowland plains, platforms-cratonic zones	Pilcomayo, Bermejo	Paleochannels, swamps, splays

On the contrary, lowland rivers (rivers with their alluvial tract on lowlands, although the headwaters can or not be in highlands and mountains) are usually characterized by lower valley slopes and less specific energy, well-developed floodplains, and, in many cases, they have bigger rates of lateral migration than the valley-incised mountain rivers. For those reasons, lowland rivers hold the most extensive fluvial wetlands on the planet. Two main groups can be individualized for lowland rivers: (a) axial rivers, (b) avulsive rivers and megafans (Table 1).

Axial lowland rivers flow confined through a valley, their length is typically multiple times (hundreds or thousands of times) larger than their width, and they characteristically exhibit well-developed floodplains. The second group encloses avulsive rivers and megafans. Avulsion is the natural process by which flow diverts out of an established river channel to a new relocated course. Megafans are depositional landforms radiating from an apex. They form when a river debouches from an elevated relief into a plain (apex), depositing the sedimentary load in a radiate conical shape because of the lateral instability and shifting of the channel through time. Other avulsive rivers that are not classified as megafans are those where rivers can suffer avulsion along many significantly long reaches and at a variety of time scales, but without the system presenting the typical conical shape of channels radiating from an apex as in the megafans.

Axial, megafans, and avulsive rivers exhibit in nature a variety of channel patterns. Alluvial channels can be classified in braided, meandering, and anabranching. Straight patterns can be considered, but they are the exception and restricted to short reaches.

Channel patterns in axial rivers and wetlands

Therefore, considering that floodplains are the biggest fluvial wetlands and that there is a link between a channel pattern's style and the floodplain hydro-morphological mosaic, the relationships between channel patterns, floodplains, and fluvial wetlands is analyzed. Though the three patterns can also be found in megafans and avulsive rivers, we discuss braided, meandering, and anabranching patterns specifically for axial rivers. In contrast, megafans and avulsive rivers are presented separately. Thus, questions raise on what is, in the present time, the relative abundance of each type of channel patterns on Earth, what is the size of the rivers (in water discharge and floodplain development) that relates to each channel typology, and how they correlate with the occurrence and extension of fluvial wetlands.

Braided rivers

Braided rivers occur where the flow divides the channel into a series of braided bars by accumulating sediment. Braided rivers are bedload-dominated systems characterized by a network of unstable channels, ephemeral bars, and limited riparian vegetation (Ashmore, 2013). They possess a relatively high slope for the available discharge and a large proportion of bedload concerning the total load. Mid-channel bars are covered by water during the bankfull discharge stage, acting as a single channel system.

Many modern active high bed-loaded axial braided systems are related to mountain-alpine conditions and proglacial systems or semiarid regions. However, some braided systems can be found in mountain zones and foot slopes of tropical areas, India's monsoonal wet-dry seasonal climate, and other climatic zones. But most of the braided rivers in the geomorphologic and sedimentological literature come from rivers with moderate water discharge. Thus, as Latrubesse (2015) claimed, quintessential braided rivers with large water discharges are not found anywhere on the planet. Braided systems are characterized by a high width to depth (w/d) channel ratio, but their channel-floodplain is no more than a few kilometers in width as the fluvial processes are self-contained in the channel-dominated braiding corridor (Figs. 1 and 2). Despite the lack of large braided rivers in present times, it seems that the size and importance of braided rivers have been different during some glacial periods, so larger braided paleochannels and coarse Pleistocene deposits are found across the globe (Latrubesse, 2015).

Meandering rivers

Meandering alluvial rivers wander across a floodplain forming a series of sinuous bends. The water flow patterns through meanders encourage erosion on the outer bank, while deposition and point bars form in the inner bank. It creates asymmetric cross-sections and longitudinal sequences of pools and riffles. As the channel shifts, meander bends tend to expand by lateral migration until chute cut-off and neck cut-off happen, leaving oxbow lakes and scroll bars on the floodplain. Meandering rivers are globally found in any kind of non-glaciated environment.

Meanders are the most studied fluvial channel pattern. Although meandering rivers are not the largest on the planet, several are large rivers and developed big fluvial belts. Even many smaller rivers have formed large meandering floodplains, several kilometers in width. That is possible because of the capacity of meandering rivers to shift laterally through time. Therefore, large meandering rivers develop wider floodplains belts than the largest braided rivers (Figs. 1 and 2). Typical hydrogeomorphic environments and landforms in meandering rivers are point bars, scrollbars, oxbow lakes, levees, back swamps, and crevasse splays.

In some meandering rivers, lateral shifting can be coetaneous with local avulsion of the meander belts, increasing the coverage of the fluvial mosaic of wetlands through large areas. Floodplains characterize several of the largest meandering rivers and recent episodically flooded lower terraces that can reach more than 10 km in width. In water discharge, the largest meandering river is the Mississippi River, but islands are common in some channels' reaches. The most emblematic and most significant wetlands in a meandering system are those of the middle Mississippi River. In western Europe, wetlands in meandering rivers and floodplains are also present locally (oxbows and swamps). Some remarkable examples of wetlands in meandering reaches are those of the upper Loire, the upper Rhine at the German-French border, and the trilateral floodplains of the Morava-Dyje-Danube Ramsar site.

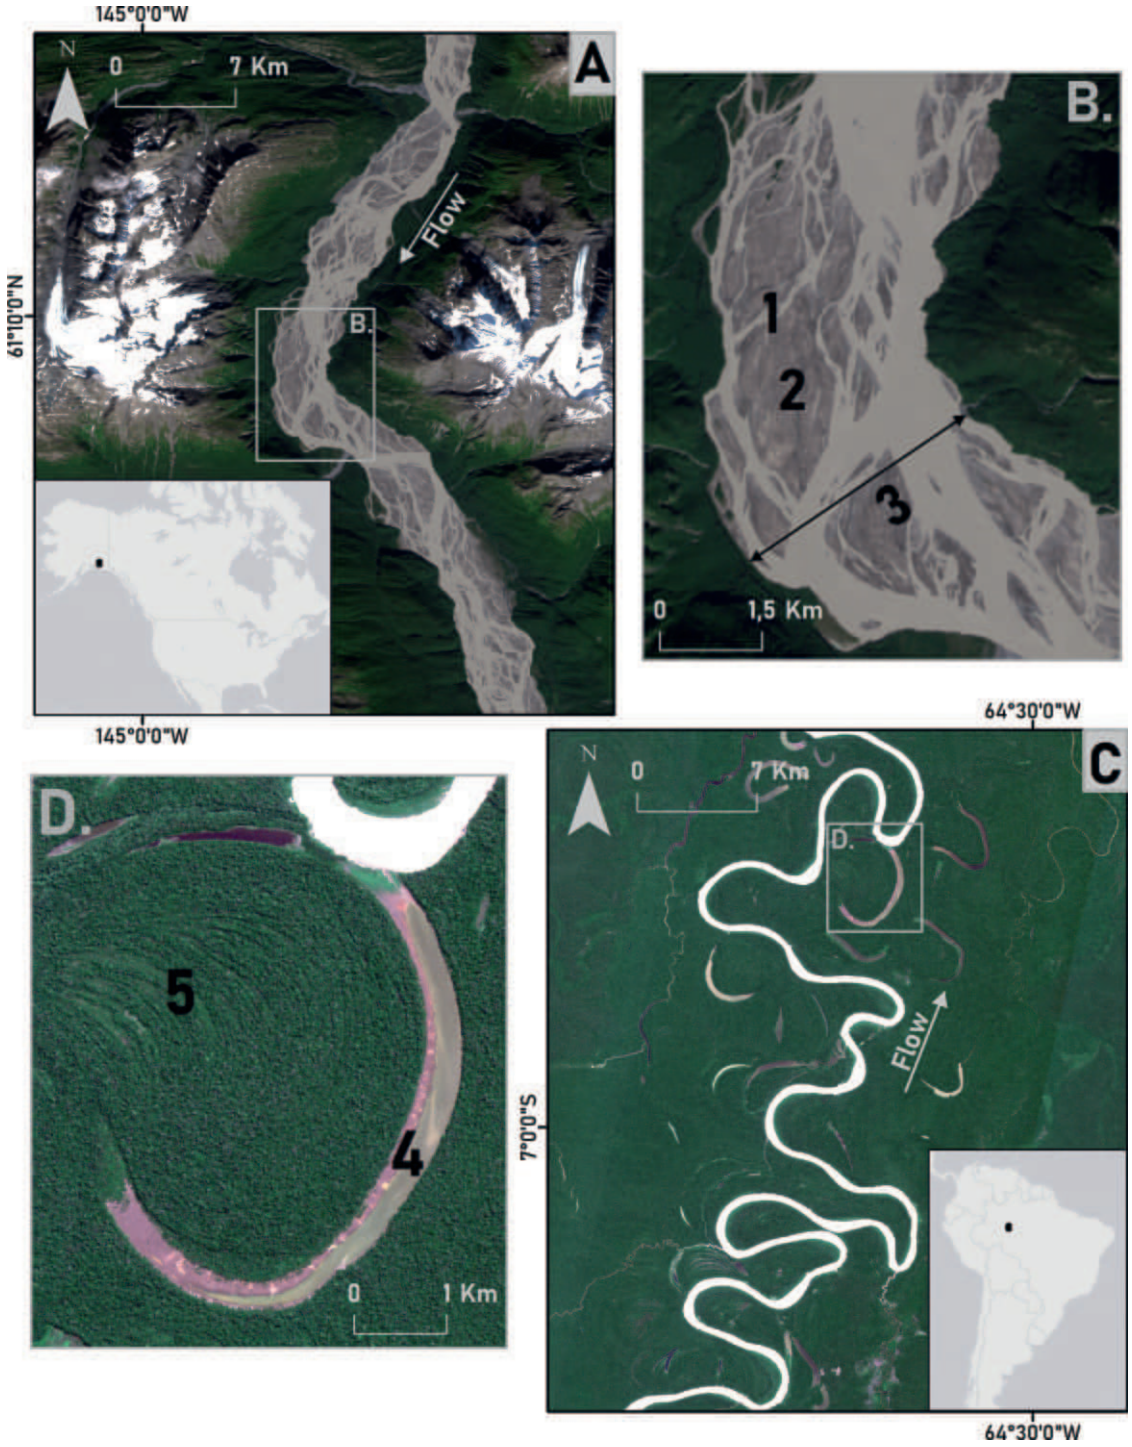

Fig. 1 (A and B) Channel-dominated braiding corridor of the Copper River, Alaska (B1,secondary channel; B2 and B3, fluvial bars), taken on 21 August 2021. (C and D) Meandering floodplain of the Purus River,Amazon basin, over 2nd July 2021. Background Sentinel-2 image downloaded from Google Earth Engine (GEE) platform. D, Oxbow lake (4 abandoned channel; 5 scroll bars).

However, river engineering and land-use changes have affected all those systems in Europe and North America, big or small. We can consider that the most extensive, natural flow, non-engineered single-channel meandering river of the planet in water discharge is the Purus River, a tributary of the Amazon.

Anabranching rivers

Anabranching rivers consist of multiple channels separated even at the bankfull discharge stage by vegetated, semi-permanent alluvial islands that are excised from existing floodplains or formed by within-channel accretions. The islands effectively divide flows into branches, even at bankfull discharges. These rivers are also present in a wide range of environments, from the subarctic to

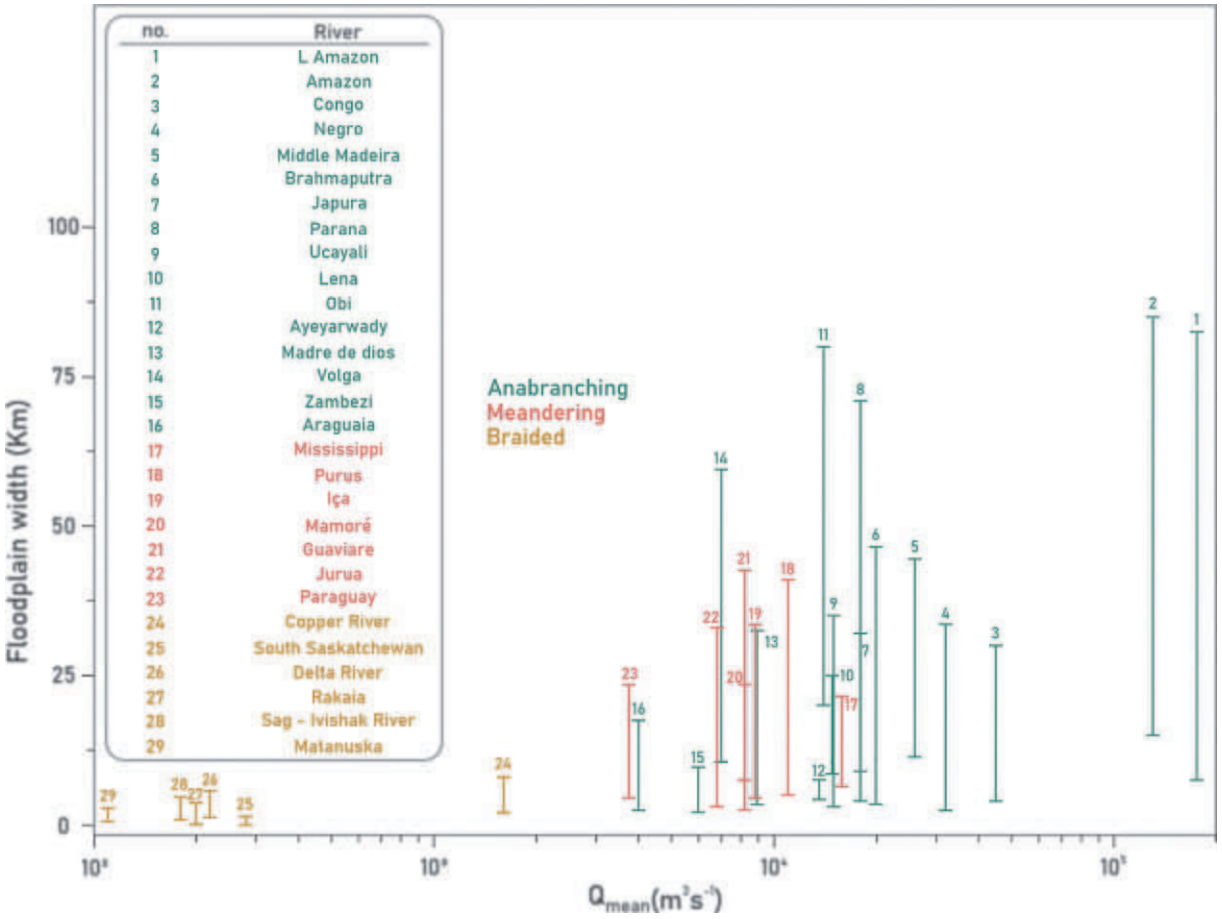

Fig. 2 Representative floodplain width (approximated minimum and maximum widths) of present braided, meandering, and anabranching rivers and the related mean annual discharges (Qmean). Chanel patterns are highlighted with different colors. Figure adapted and expanded from Latrubesse E (2015) Quaternary megafans, large rivers and other avulsive fluvial systems: A potential "who is who" in the geological record. *Earth Science Reviews* **146**: 1–30.

the tropics and temperate regions to the drylands of Africa and Australia. Anabranching rivers consist of multiple semi-permanent channels that concentrate streamflow and maximize bedload transport by constantly adjusting the optimum channel width-to-depth ratio under conditions with little or no opportunity to increase gradient (Nanson, 2013). Branches of the anabranching rivers can show different geomorphic styles and even tend to meander or braid. Islands in large rivers can persist for more than a century, and anabranching floodplains are in many cases a palimpsest of units of different Holocene ages that were generated by a variety of morphological processes (e.g., Santos and Stevaux, 2000; Ramonell et al., 2002; Latrubesse and Franzinelli, 2002, 2005; Sarma, 2005; Lahiri and Sinha, 2012; among others). Vegetated islands are distinctive morphosedimentary components in anabranching rivers, from densely vegetated with alluvial forest in tropical rivers to scarce lines of trees in arid systems of Australia.

The vegetation produces an arial anchoring effect on the floodplain/channel landforms where sediment trapping by vegetation helps stabilization and vertical accretion, and contributes to the floodplain mosaic's variable roughness. Although vegetation is not a prerequisite to developing an anabranching pattern, it could significantly contribute to sustaining and triggering a diversity of anabranching patterns and landforms in multichannel-floodplain systems and play a relevant role in the development and stabilization of islands (Latrubesse, 2015).

Islands and parts of the floodplain can hold swamp lakes, scroll bars, levees, paleochannels, diverse types of elongated straight and sinuous lakes formed on paleochannels, floodplain channels, and internal deltas that generate from the connection between the main channels and big lakes in the floodplain.

The nine largest rivers on Earth in water discharge have anabranching channel patterns (Latrubesse, 2008) and anabranching patterns are also dominant among the world's 15 largest rivers (Latrubesse, 2015). Thus, they have the most extensive floodplains, and consequently, their wetlands are the largest and hydro-geomorphologically diverse among axial fluvial rivers (Fig. 2).

The Amazon and its main anabranching tributaries contain the largest and most diverse belt of continuous floodplain wetlands of the planet (Figs. 2 and 3) (Latrubesse, 2012). The Amazon floodplain "várzea" forests are the most species-rich wetland forests globally (Wittmann et al., 2006). Other iconic wetlands in anabranching systems found in the literature are the Columbia River floodplains, the Saskatchewan River delta-Cumberland marshes in Canada, the upper Brahmaputra floodplain, the Rio Negro and its flooded forest (igapó), the vast middle-lower Paraná River floodplain, the Lena River floodplain, among many others.

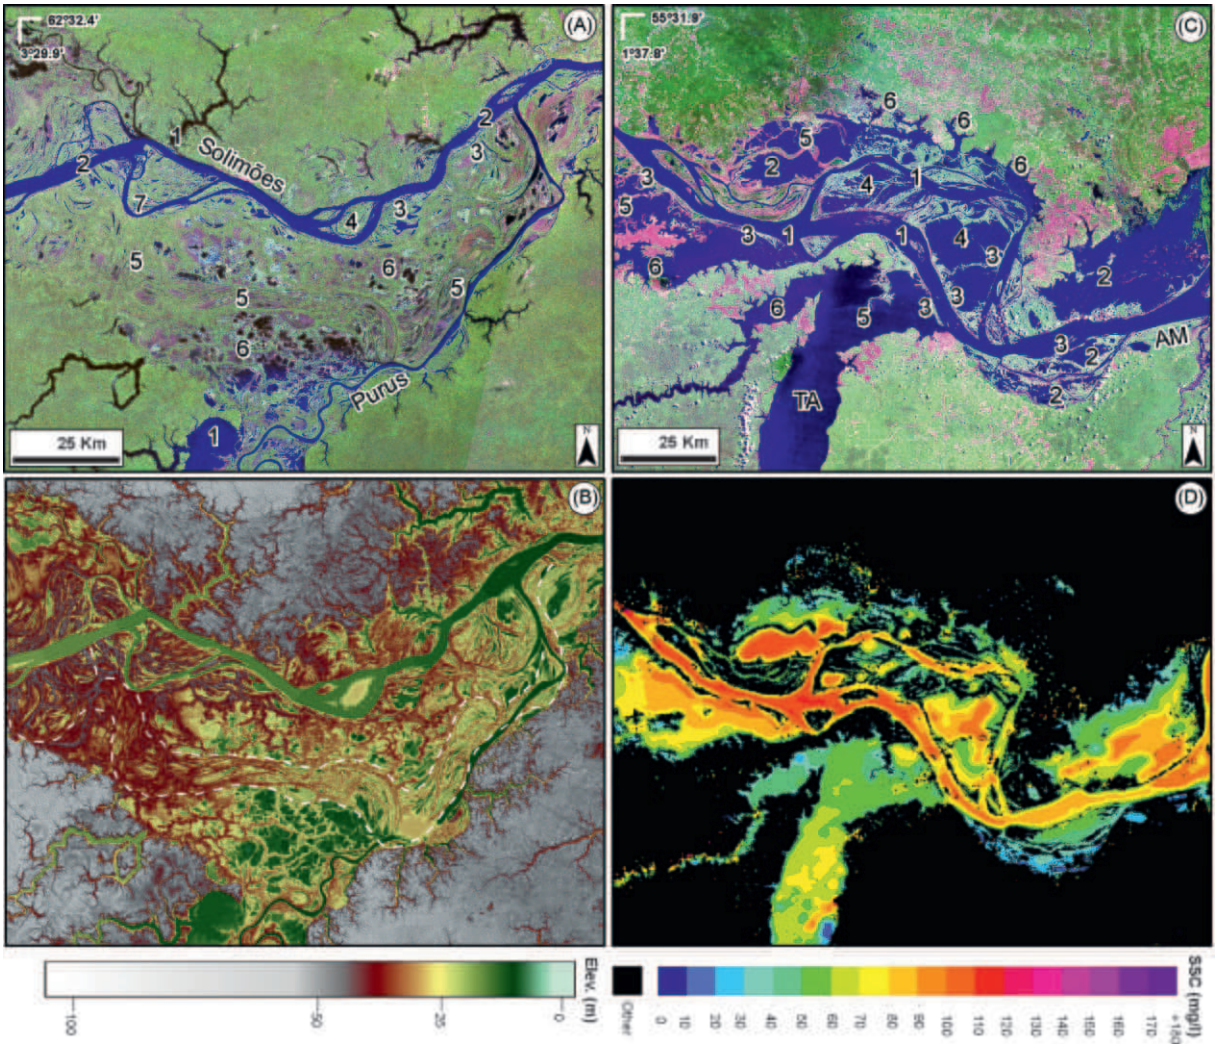

Fig. 3 The Solimões (upper Amazon) River (A and B) complete floodplain with an abandoned belt by avulsion in a tectonic sunken block upstream of the confluence with the Purus River. (A) The sedimentation of the floodplain dammed several tributaries generating blocked valley lakes (1). The Solimões River channel is anabranching (2) with levees (3) and large islands (4). A large alluvial belt of the Solimões River was abandoned by avulsion (5). Numerous small rounded lakes form the impeded floodplain unit (6) while secondary sinuous branches scrolled topography (7) (Geocover image). (B) Digital elevation model (SRTM) of the same area than (A). The dashed line indicates the original position of the Solimões River before avulsion. (C and D) The lower Amazon River at the confluence with the Tapajos River. The Amazon at this reach is an example of incomplete floodplain that is still storing more than 140 Mt. y^{-1} of muddy sediment load (Park and Latrubesse, 2019). (C) The Amazon River is anabranching with large islands (1). The floodplain is characterized by rounded lakes in an impeded drainage floodplain (2). Long and well-developed levees confine the river flow along a surrounding water saturated floodplain (3). Large islands and island lakes characterize the anabranching pattern (4), and floodplain deltas sourced by the main channel system splay into the floodplain lakes (5). The sediments of the Amazon block the lower valley of tributaries (6) which behave as lake systems (Geocover image). (D) Surface sediment concentration maps during rising water stages (April, 15, 2006) around and downstream Obidos, showing the channel–floodplain interactions and the impact of sediment inputs from the main channel toward the floodplain. Values of suspended sediments were calculated with the suspended sediment concentration model by Park and Latrubesse (2014). Although the anabranching pattern is the ultimate planform adjustment of large rivers, small to mid-sized anabranching rivers are found extensively in different climatic and geological regions around the world and exhibit a diversity of peculiar patterns (Nanson, 2013). It points that far from an oddity, as previously assumed by fluvial specialists, a variety of anabranching patterns are, perhaps, the most dominant in our planet.

Megafans and avulsive rivers

Megafans and plains formed by large avulsive rivers are fluvial aggradational mega-landforms that can be found in many climatic settings, but they reach maximum extent in the tropical-subtropical systems (Latrubesse et al., 2005; Leier et al., 2005; Sinha et al., 2012; Latrubesse, 2015) and develop in a variety of tectonic, sedimentary basins, such as foreland and internal continental basins.

Some use a standard >100 km length to define megafans (Gohain and Prakash, 1990; Wilkinson et al., 2006; Chakraborty and Ghosh, 2010; among others), and a depositional area that ranges from ~7000 to ~200,000 km^2 (Wilkinson et al., 2006).

Both, megafans and large-scale avulsive systems are formed by unstable rivers. Megafans exhibit alluvial radial channel patterns (active or abandoned) diverging from an apex, while large alluvial avulsive systems are characterized by long belts of avulsion but their paleochannels do not exhibit a radiating pattern from an apex.

Channel patterns on megafans frequently change downstream from braided at the apexes to transitional wandering, meandering patterns, and anabranching patterns. The avulsive rivers are usually slightly confined or unconfined, and, in some cases, the pattern can also be distributive, meaning with ramifications downstream, although it is not the norm. The change of channel patterns is not abrupt. It can coincide with a progressive but not exacerbated reduction of channel width as channel planform adjusts to changes in bed load caliber, total load, decreasing slope, and even, in some cases, discharge reduction, mainly when distributive patterns are present. As aggradational landforms, the slope surface of megafans and plains of large avulsive systems are very smooth, and local smooth relief created by the fluvial landforms plays an essential local role in concentrating or impeding surface flow. The megafan's alluvial plain surface is imprinted by paleochannels of different ages and local depressions formed by flooded paleochannels, lakes, swamps on the hyper-flat area, creating a mosaic of permanent, seasonal, or episodic wetlands.

Because megafans and avulsive rivers are megaforms widespread in large areas, they hold many of the most extensive wetlands on Earth. Some of the largest megafans are in the Chaco plain, the Pantanal of Mato Grosso, the Indo- Gangetic Plain, and in Africa, like the Okavango.

For far, the largest area of the world with megafans in the Chaco is also one of the most important wetland regions in South America. The major Chaco fluvial basins have their headwaters in the Andean mountains of Bolivia and Argentina, and several rivers debouch into the Chaco plain generating gigantic megafans. They are from north to south (from Bolivia to Argentina) the Grande, Parapeti, Pilcomayo, Bermejo, Salado-Juramento, and Dulce megafans, covering an area of approximately 520,000 km^2 (Iriondo, 1993; Latrubesse, 2015). The whole Chaco plain is a mosaic of permanent and seasonal wetlands related to relict fluvial landforms, widespread swamps and water bodies on the plain's flat surfaces, and areas that suffer the direct influence of river floods and water table saturation. At total, ~306,000 km^2 or 48% of the total surface of the megafans are seasonally flooded. When comparing megafans, the largest wet areas belong to the Pilcomayo and Juramento-Salado. However, when analyzing the ratio between wetland and total megafan area, Dulce has the most significant ratio (~64%) while the Bermejo has the smallest one (~32%). Several extensive Chaco wetlands are currently declared Ramsar sites or protected as Biosphere Reserves, Natural, Provincial Reserves, and National and Provincial Parks.

With a depositional area of ~200,000 km^2, the Pilcomayo is the largest megafan on Earth (Fig. 4). Two main mechanisms control the flood dynamics and shifting of the Pilcomayo River. The first one is the sequence of paleochannels that compose the old Quaternary megafan and the recent lobe. Downstream the river lacks entrenchment in the megafan surface, and becomes perched a couple of meters above the megafan surface. During floods, the water flows toward paleobelts 1.7–3 km in width on the megafan's surface. The fan slopes can be one magnitude bigger than the channel slope. In addition, lateral migration can capture and reactivate old morphologies, revitalizing the inactive landforms during floods. Both situations favor the development of splays, concentrated runoff on the paleofan surface, and potential avulsions. The second central mechanism triggering avulsion is the high accumulation in the channel of fine sediments and woody debris, which blocks the water flow, starts water spills over the megafan surface feeds with sediments extensive marshes and wetlands (esteros and bañados) and paleochannels on the plain become occupied by underfit streams.

The Mato Grosso's Pantanal in Brazil is the second-largest area with fluvial megafans. This tectonic subsidence basin holds a ~150,000 km^2 wetland formed by 11 megafans, sourced by fluvial basins draining the surrounding tablelands and lowlands catchments (Assine et al., 2015). The most extensive and unstable system is the Taquari River megafan, with an area of ~50,000 km^2 that accounts for about 37% of the Pantanal Basin area (Zani et al., 2012).

Although of smaller dimensions, megafans in other regions of the world are also relevant wetlands. In the Indo-Gangetic plain is the very active Kosi River megafan, which has repeatedly shifted in historical times (Sinha, 2014). Although the area is hazardous for floods, the intense land use and occupation prevent the presence of widespread natural wetlands on its surface. Different from other megafans in the Indo-Gangetic plain, the largest wetlands concentrate on interfan regions, such as the Buri Gandak-Ganga rivers interfluve and the Kaabar Tal wetlands in the Baghmati-Kosi interfan area (Sinha et al., 2017).

The large cratonic megafans store a slight amount of sediment but sustain huge wetlands. In Okavango, the flooded area seasonally ranges from ~2450 km^2 to ~11,400km^2 (McCarthy et al., 2003). In the Pantanal, the long-term inundation area is ~34,880km^2, but it can be ~130,000 km^2 during large floods (Hamilton et al., 2002).

Avulsive rivers with related remarkable wetlands are recorded in every continent, but also the most impressive are located in South America.

An almost unknown area, the Bananal, is the largest intracratonic Quaternary South American sedimentary basin. It is located at the Cerrado-Amazon ecotone in Central Brazil and is part of the Araguaia River basin. The Bananal sedimentary basin was filled-up by avulsive belts of the Araguaia river during the Pleistocene and Holocene (Valente and Latrubesse, 2012). Currently, this flat area is a large tropical plain with paleochannels and underfit river systems, swampy areas, and lakes, covering ~106,000 km^2. The plain is flooded by rainfall and water table saturation, and it can be classified as a seasonal wetland (Valente et al., 2013). The area includes a gigantic island called Bananal Island, and the inundation area can reach 58,550 km^2, although the long-term estimated coverage is 13,110 km^2 (Hamilton et al., 2002; Valente et al., 2013).

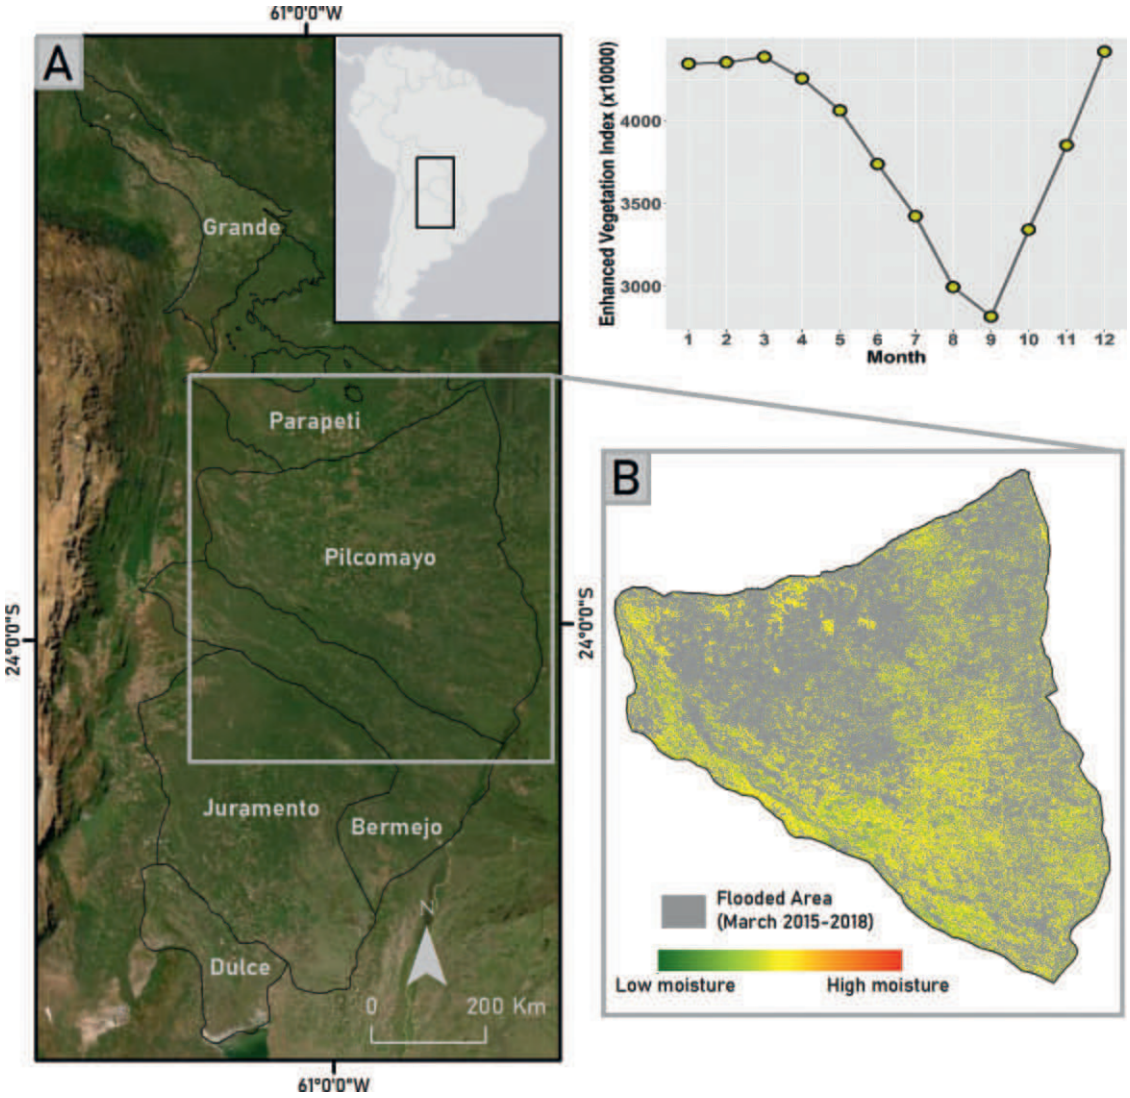

Fig. 4 (A) Chaco megafans (Image source: ESRI Basemaps). (B) Average flooded area (grey pixel) of the Pilcomayo megafans in March between 2015 and 2018, assessed by MODIS EVI. EVI is used to map both the open water (<0.36) and flooded vegetation (>0.47). Inset graph shows the inter-annual average (2015–2018) monthly EVI values for the three largest fans of the Chaco: Pilcomayo, Bermejo, and Juramento-Salado. The highest EVI is attained during March for the three fans, which is the month shown on the map. MODIS-Terra MOD13Q1 product (version 6) supplied from the Land Processes Distributed Active Archive Centre (LPDAAC).

The Yangtze River, one of the top 10 largest rivers in water discharge, also forms extensive wetlands by avulsion of meandering-anabranching belts when it crosses a tectonically active basin from Chijiang to Ouchi (Wang et al., 2011). The river gains some sinuosity and generates a complex set of secondary anabranching avulsive channels, transferring water flows and sediment toward Dongting Lake. This vast area covered by channels and paleochannels exceeds 20,000 km^2.

Another extensive area of wetlands formed by avulsive rivers is the subsiding Ucamara depression in the Peruvian Andean forelands, which is located immediately upstream of the confluence of the Marañon and Ucayali rivers. Very rich in biodiversity, the area is protected by the Pacaya-Samiria National Reserve. The wetlands were formed by multiple avulsion of the rivers Marañon and Ucayali during the Holocene. A complex network of paleochannels covers the very flat tectonic subsiding area of 33,0000 km^2, with floodplain channels, underfit channels, and permanent and semi-permanent swamps and lakes.

The unstable Beni River in Bolivia, which debouches from the Andes into the Moxos-Beni plain sequence of successive avulsed meandering belts in the Holocene now occupied by underfit rivers (Yakuma, Tapado, Bata, and Negro rivers) (Dumont, 1996). The whole plains are flooded by river water, rainwater, and water table saturation. It was estimated that the maximum flooded area is ~92,000 km^2 (Hamilton et al., 2002).

The anabranching Magdalena River in Colombia forms ~25,000 km^2 large wetlands in the Momposina depression tectonic basins where ~21 Mt. y^{-1} of sediment is trapped (Restrepo et al., 2006). The wetland is a geomorphic palimpsest of swamps, lakes, splays, and paleochannels abandoned by avulsion.

River inflows maintain moderate to extensive wetlands in drylands in combination with other factors that serve to impede drainage or reduce infiltration, including faulting, rock outcrops, swelling soils, and ponding by tributary or aeolian sediments (Tooth and McCarthy, 2007). In Asia, the Brahmaputra and the Indus (both dominantly anabranching systems) are rivers known for rapid migration and avulsions recorded since the XVIII century (Sinha and Tandon, 2014; Best et al., 2007). However, wetlands in those systems are relatively small because of the regulation by barrages and dams, the floodplain's land use, the highly seasonal monsoonal regime, and their fluvial geomorphic style.

Smaller but regionally relevant wetlands in avulsive rivers are the Murray-Darling basin in Australia and meandering rivers in southern Africa (Lisenby et al., 2019).

Fluvial wetlands like hydrosedimentary sinks

Wetlands are natural areas that act as sinks, storing water, sediment, and nutrients (Phillips, 1989). In the case of river wetlands, storage happens in both axial rivers, floodplains, and megafans-avulsive systems. A review of the most oversized active fluvial sediment sinks is provided by Latrubesse (2015). Both large axial rivers, as well as megafans and avulsive rivers, can store massive amounts of sediments. Although megafans and wetlands in axial rivers are found in every continent, South America is a land of superlatives because it is the home to both the most extensive axial fluvial wetlands and the largest megafans on Earth.

Sediment and water storage can be found at any spatial scale in axial rivers, from small to large rivers. Still, in large axial rivers, Holocene floodplains can be composed of huge complex areas of impounded water that spread over thousands of kilometers in length and tens of kilometers in width. The floodplains of some of the largest large rivers that transport abundant sedimentary loads, such as the Amazon and Paraná, are still acting as sediment sinks (incomplete floodplains). The 1200 km long stretch of the lower Amazon River wetland is a huge sediment sink that annually stores at least 140 Mt. y^{-1} of muddy sediments through channel-floodplain interactions (Park and Latrubesse, 2019) (Fig. 3), while the Middle Paraná in Argentina stores 17–60 Mt. y^{-1} of suspended sediments in the floodplain (Amsler, 2006; Latrubesse, 2015) through migration of meandering branches, floodplain deltas, and overbank deposits (Fig. 5). In the Colombian forelands, the anabranching Magdalena River stores in the Momposina depression tectonic basins ~21 Mt. y^{-1} of sediment (Restrepo et al., 2006).

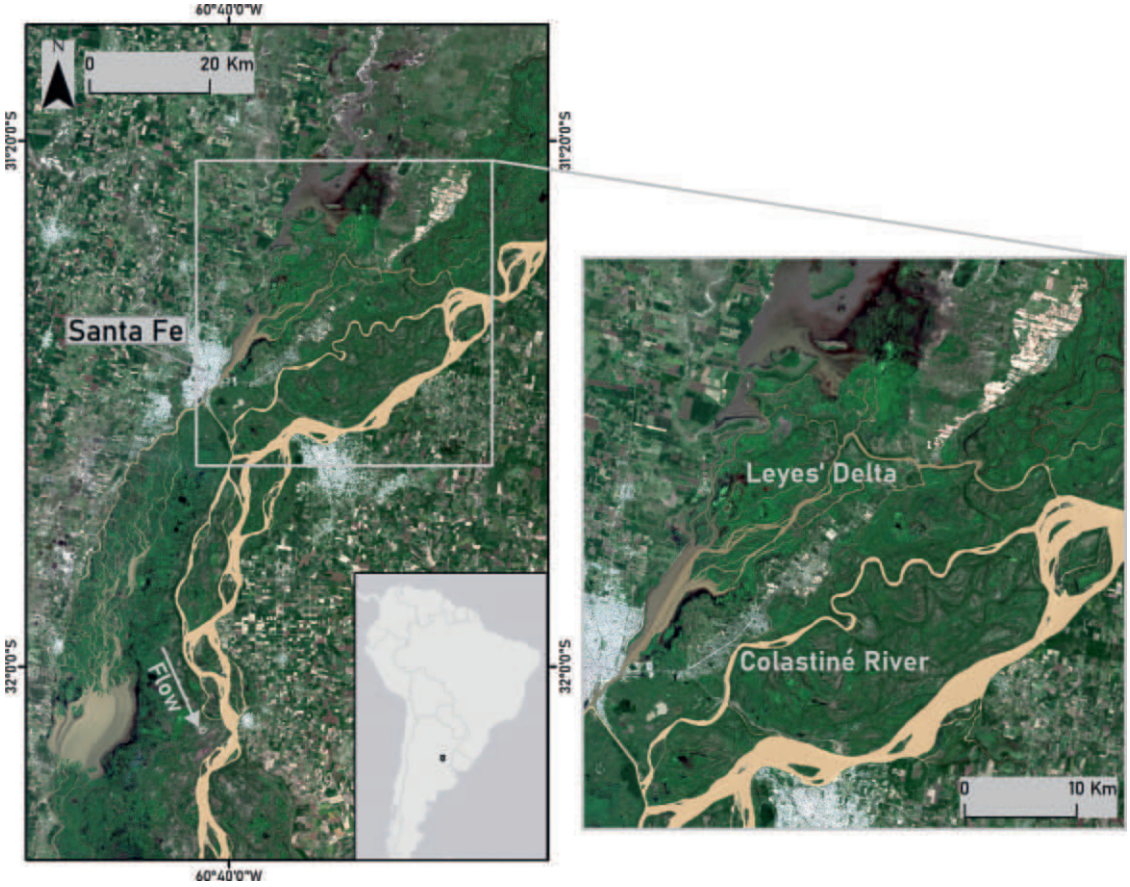

Fig. 5 The complex morphology of the middle Parana River wetlands at Santa Fe, Argentina. The main channel is anabranching with well-developed and large vegetated islands. The meandering Colastiné River branch shifts across the floodplain forming scrolled-plain morphologies. A connection from the main channel with the floodplain through the Leyes floodplain creek, creates the impressive fluvial-lacustrine Leye's Delta, which prograde on the Setubal floodplain lake. Background Sentinel-2 image (07 March 2021) downloaded from GEE platform.

Other rivers with headwaters in the mountains experienced high rates of sedimentation in the Holocene, such as the Brahmaputra and Ganges, or even the upper Amazon (Solimões), while its large Andean tributaries, have "complete floodplains" in the lowlands. Consequently, they have small to null space accommodation to sink sediments and export their sediment load downstream toward the Ocean. Those "complete floodplain" rivers are dynamic and shift laterally or can even suffer avulsion in historical times, such as the lower Brahmaputra. Still, the rates of erosion-depositions are in equilibrium or much closer to equilibrium regarding sediment fluxes than rivers with incomplete floodplains. An example of a fluvial wetland in a complete floodplain is the middle-upper Brahmaputra, one of the world's largest water and sediment discharge rivers. Despite its high discharge, the anabranching Brahmaputra River does not exhibit extensive alluvial wetlands compared to other large anabranching counterparts in South America and Siberia. Other significant rivers with complete floodplains, such as the Mekong, flow mainly into narrow geologically controlled valleys, so their floodplains are constrained to the lowermost reaches and delta.

Rivers draining cratonic old terrains of crystalline and metamorphic rocks have low sediment yields and suspended sediment load. In the Amazon basin, flooded areas of rivers draining the Paleozoic and Precambrian shields of Guyana and Central Brazil cover an area of approximately 200,000 km^2. The largest clear water rivers are the Xingu, Tapajós, and Trombetas, whose floodplains cover approximately 67,000 km^2 (Wittmann et al., 2010). With a mean annual discharge of about 32,000 $m^3\ s^{-1}$ and a drainage area of 600,000 km^2, the Negro River is the second largest tributary in water discharge of the Amazon. The Negro River is the typical black-water river of the Amazon basin, with olive-brown to coffee-brown colored water and transparencies from 1.3 to 2.3 m because of dissolved humic substances (Sioli, 1984). The Negro River transports 8 Mt. $year^{-1}$ of suspended sediment to the Amazon (Filizola, 1999), an insignificant quantity of suspended load in relation to the huge water discharge. Its basin's wetlands cover 118,000 km^2 (Melack and Hess, 2010), and the Negro holds the biggest fluvial archipelagos in a fluvial system that support the largest black-water inundation forest in the world, regionally called "igapó" (Montero, 2011; Montero and Latrubesse, 2013).

All these cratonic rivers described above are characterized by incomplete floodplains in the middle-lower reaches and their enormous valleys act as water reservoirs with low velocity flows because they are partially (Negro) or strongly blocked (Tapajós, Xingu) by the trunk-collector system, the Amazon.

Because these large cratonic anabranching rivers transport a minimum amount of suspended load, the wetlands on the large islands and other floodplain units that they exhibit are relict landforms in disequilibrium with the present morpho-dynamic conditions of the river. The most extreme case on the planet is the Negro River where the largest and most complex fluvial archipelagos developed and the islands are covered by tropical flooded forest (Latrubesse and Franzinelli, 2005; Latrubesse and Stevaux, 2015).

Located in active sedimentary basins (foreland and intracratonic basins), megafans are among the most effective sediment traps of the planet. The Chaco catchments draining the central Andes in the subtropical belt (~15°–30° S), have small discharges (>360 $m^3\ s^{-1}$), high discharge variability (Latrubesse et al., 2005), high sediment yields, and relatively low values of specific runoff. The sediment production of the central Andean rivers in the Chaco is one of the highest in the world, up to two orders of magnitude greater than high runoff rivers draining the northern Caribbean and Pacific Andes, and many times bigger than other orogenic mountain belts of the world, such as the Alps, while comparable or even higher than several fluvial basins in the Himalayas (Latrubesse and Restrepo, 2014). The sedimentary load is unproportioned when compared to the relatively small discharge of these rivers. From a total amount of ~475 Mt. y^{-1} sediments exported to the Andean piedmont through the main fluvial Chaco systems, ~68% (~327 Mt. y^{-1}) is trapped and stored in the Chaco plain by the six megafans, instead of being transferred to the Ocean through the Paraná or the Amazon basins. Thus, the Chaco plain and its megafans are one of the (and perhaps the most) largest active continental sedimentary basins of the planet.

Another area with high sediment load rivers and megafans is the Indo-Gangetic plain, in the Himalayan foreland. However, the Indo-Gangetic megafans have limited capacity of sediment trapping in the depositional area, exporting a significant part of their sediment load to the collector Ganga River (Sinha and Friend, 1994).

In cratonic basins, large megafans such as the Pantanal and Okavango sustain large wetlands but although they are important inland sediment sinks at a regional scale, the formative rivers have low sediment yields and suspended sediment loads, and the amount of trapped sediments is low when compared to the highly loaded megafans draining orogenic belts.

Fluvial connectivity-flood pulse and others

Several important concepts highlight the relevance of hydrogeomorphologic processes to identify, delimitate, classify and study fluvial wetland's functioning.

The concepts of river continuum (RCC) (Vannote et al., 1980), hydrological connectivity, and the flood pulse concept (Junk et al., 1989) have been paramount paradigms in the ecological studies of wetlands.

Hydrological connectivity for ecologists focuses on the relationship between flood pulses (as a dominant explanatory variable) and the ecological variables, as it has been conceptualized in terms of water volume and the rate of water transfer from the mainstream (and branches if present) to the floodplain. It has been extensively utilized as a central idea in ecohydrology, especially following the development of the flood pulse concept (Junk et al., 1989; Neiff, 1996; Neiff et al., 2003; Pringle, 2003; Tockner et al., 2000). Therefore, for floodplain ecologists, lateral connectivity and distance from the channel/s and the wet-flooded areas of the floodplain have been considered an essential factor in characterizing river-floodplain hydrological connectivity (Amoros and Bornette, 2002; Heiler et al., 1995).

But riparian and wetland landscapes are shaped, and genetically and functionally dependent on hydrological and geomorphic processes. Thus, wetlands are not just hydrological systems but also geomorphologic systems (Phillips, 1989). The plants that form vegetation types and the animals that use those spaces as habitat are influenced in their persistence and abundances by disturbance processes associated with a set of hydro-geomorphologic phenomena, such as channel morphodynamics, erosional-depositional landforms and processes, channel-floodplain interactions, floods, and many other processes and mechanisms that create and sustain complex environmental patterns and spatial geomorphic mosaics.

Consequently, understanding the connectivity between the channel and the floodplains is fundamental for incorporating morphodynamics and a broader time scale that allows assessing changes of functionality and connection through specific periods. Therefore, considering hydro-geomorphic changes under a particular time scale is crucial because rivers are dynamic systems, and both hydrogeomorphic and biogeochemical functioning and alterations in floodplain wetlands occur through these interactions.

Since the 1980s, multiple models strongly based on stage-discharge relationships and the statistic of hydrological series have been developed to assess connectivity (Junk et al., 1989; Poff and Ward, 1989). However, they only partially explain the diverse mechanisms of hydro-sedimentary transferences from the river toward the floodplain (and into the floodplain). The denominated Aquatic Terrestrial Transition Zone (ATTZ) (Junk et al., 1989; Junk and Wantzen, 2006) is far from a single terrestrial-flooded terrain relation but a complex response that depends on the spatiotemporal interrelations of hydroecological and hydrosedimentological connectivity among the different geomorphic units. Even more, connectivity processes over different geomorphic units are not necessarily correlated with their minimum distance (shortest lines) from the river. Distance has to be considered simply as another factor in analyzing hydrological channel-floodplain connectivity processes.

Beyond water stage variability as a primary factor, connectivity processes are affected by the complexity of the floodplain geomorphic mosaic, local hydrological inputs, and intricate paths and mechanisms of flow transferences that depends not only on the hydrological regime but on the channels pattern's types and the complex morphology and evolutive history of the floodplains mosaic. Some specific cases are discussed as follows.

As observed in floodplains of meandering rivers (Drago et al., 2008; Hudson et al., 2012; Phillips, 2013), each unit's geographic location (proximity to the River) does not necessarily directly relate to the sequential flooding. River-recharge connections and floodplain water residence time did not simply correlate with the ordinary distance (shortest straight line) from the river.

In the case of large anabranching rivers, there is no direct simple correlation between the floodplain flooding and the proximity to the main channel (Mertes, 1997; Neiff et al., 2003; Latrubesse, 2012; Dunne and Aalto, 2013; Marchetti et al., 2013; Stevaux et al., 2013; Lininger and Latrubesse, 2016; Park and Latrubesse, 2017, 2019). For example, Park and Latrubesse (2017) demonstrated that the connectivity processes in a reach of the middle Amazon are related to 12 geomorphic sub-units of the floodplain that are interconnected at different stage thresholds through channelized and overbank flow paths, while lakes act as reservoirs for flood waters, local rainfall, and water table saturation-seepage (Fig. 3). A large proportion of the middle Amazon River floodplain lakes are fully connected, reach their maximum areal development, and the floodplain is spatially water-saturated when the river reaches lower stages than bankfull, before overbank diffusive processes start to happen. Thus, a major recommendation to understand connectivity in certain detail is to develop specific studies at reach scales, calibrating individual thresholds of hydrological connection-disconnection levels and flood routing paths as they are dependent on the internal geomorphic variability of the floodplain. The heterogeneous flood thresholds and flood duration times for different floodplain units, as assessed by Park and Latrubesse (2017), are central for floodplain ecology because suspended sediments (mostly silt and clay) and colloidal particles source nutrients that sustain a broad range of floodplain ecological communities (Tockner et al., 2000), and hydrological stress (duration of drought or floods) is a main ecological factor (Junk and Piedade, 1997). As highlighted by some ecologists, the role of low water levels in the hydrological connectivity is also important for floodplain ecology because during the dry season, the plants suffer stress, ceasing the rowing and absorption of the leaves (Neiff and Poi de Neiff, 1990), and there is more limited space and lower habitat quality for the fauna of the floodplain (Neiff and Malvarez, 2004).

Another important concept on riverine wetlands is that of vegetation successions and the vegetational mosaics of the floodplain. Vegetation and water bodies are the main environmental components that easily reflect to the observer the environmental internal diversity and complexity of the fluvial wetlands. Linking the hydrogeomorphologic mosaic, the hydrology of the system, the morphodynamic processes, and the physiognomy of the vegetation offers a more holistic perspective about the functionality and evolutionary landscape stages of the wetland mosaic. Vegetation areas that occupy a specific location in a geomorphologic unit represent a particular environmental mosaic that in some order differs floristically, pedologically and topographically from neighboring morphosedimentary units. Thus, integrating geomorphology with vegetation maps produces functional geospatial morpho-vegetational units, and other relevant factors such as intensity and duration of floods, types of soils/catenas, and other parameters can be easily integrated into wetland qualificatives.

Early studies on fluvial dynamics and vegetation successions have concentrated on shifting meandering rivers in the Northern Hemisphere (e.g., Everitt, 1968; Nanson and Beach, 1977; among others). In the tropics, studies on meandering rivers from Peruvian Amazon related primary vegetation succession, large-scale forest disturbance, and forest regeneration as produced by the migration of meandering rivers (Salo et al., 1986; Puhakka et al., 1992).

However, the understanding of vegetation successions in anabranching rivers is still incipient, largely because of the different geomorphic styles and floodplain hydro-geodiversity they exhibit worldwide. Vegetation successions were documented in the Solimões and Japurá rivers by using recent channel migration rates, a simplified description of floodplain and terraces units (low and high várzea), and some physical variables such as local sedimentation rates and soils texture (Wittmann et al., 2004, 2010; Peixoto et al., 2009).

The relationships between morphosedimentary units, multitemporal geomorphic mapping of river changes, and vegetation successions, were also studied in the middle Araguaia River, a very dynamic anabranching sandy-loaded river of Central Brazil (Morais et al., 2008). Three floodplain geomorphic units of the floodplain named hindered floodplain, paleomeanders and present meanders, and accreted bars and islands correlated to five physiognomic vegetation units (pioneer herbaceous, shrub-arboreal, arboreal, anthropized areas), and lakes. The connectivity with the paleomeanders units is established before the river reaches bankfull stage. At the overbank stage, the floodplain becomes in average covered by floods only ~5% of the time (~18 days). During the last four decades, the river has been destroying older and more stable vegetation successions of the paleomeanders units and hindered floodplain units, while generating younger and more herbaceous successions on the accreted bars and islands unit. While in meandering rivers the continued vegetation renovation response to erosion is in equilibrium by creating similar repetitive successions on the accretion zones, in the Araguaia, the current anabraching morphodynamics is not balanced. The geomorphic processes are triggering the partial replacement of more diverse (in species and habitats) vegetation by removing arboreal and shrub-arboreal communities of the paleomeanders-meanders and hindered floodpain units, which are replaced by less complex and biodiverse herbaceous and pioneer shrub-arboreal vegetation along the channel dominated floodplain (islands and accreted bars).

The dynamic of the vegetational mosaic and vegetation successions of the riverine forest was also studied in the Paraná River in Argentina, on islands, floodplain deltas, scroll morphologies, swamps, and levees (e.g., Neiff et al., 2014; Marchetti et al., 2013; Marchetti et al., 2020) (Fig. 5). The hydro-sedimentological dynamics of the Paraná River floodplain are regulated by its geomorphological architecture. Hence, the annual dynamics of vegetation activity are influenced by the geomorphologic unit's level, rather than by the short duration modelling processes (i.e., hydrological cycles or drought-flood pulses) (Marchetti et al., 2013) (Fig. 5).

Thus, the development and distribution of the vegetation and aquatic environments follow the variability imposed by the geomorphologic environments of the floodplain and are subject to hydrogeomorphologic perturbations (state and transformation variables) by the channel style and dynamics. The hydrological, erosional, and depositional processes modulate the generation and renovation of vegetation successions and the time evolution/response of the fluvial mosaic.

Fluvial wetlands and their relationships with other geomorphic systems

Fluvial systems interact with other geomorphic systems where processes and landforms can coexist, creating a mixed hydro-geomorphologic mosaic. Both geomorphic systems can be simultaneously functional and interactive, but relict aeolian landforms on the landscape can also impose controls on the hydrogeomorphology dynamics of the river wetlands.

Among extensive fluvial-aeolian wetlands with a dominant presence of non-active dunes (paleodunes) are the Niger inner wetlands and the Orinoco Llanos of Venezuela. The Orinoco Llanos are a large and very flat plain covered by avulsed paleochannels of the Apure-Meta-Arauca-Capanaparo rivers. Widespread aeolian-fluvial interactions occurred in the Llanos during the late Pleistocene, and large fields of parabolic dunes developed from deflation of the alluvial deposits (Latrubesse, 2003; Carr et al., 2016). The rivers have been flowing and shifting across the aeolian fields, and the fluvial-aeolian plain behaves as a wetland seasonally flooded by rivers, rainwaters, and water table saturation. The total area covered by floods (excluding temporary lakes and rivers) can reach more than 105,000 km^2 (Hamilton et al., 2004). The Inner Niger Delta, a Ramsar site since 2004, is a large inland wetland of 41,195 km^2 located in Mali, between the Markala dam (near Se'gou) and Timbuktu. Downstream of the wetland depression, the massive east-west non-active linear dunes of the Erg of Bara, 5–10 m high and transversely oriented to the regional river flow, represent an obstacle that imposes conditions on the hydrogeomorphological dynamic of the Niger River (Fig. 6). The available interdune space controls the flood processes. The anabranching pattern becomes ramified in multiple sinuous to low sinuosity channels, flowing through the interdunes and struggling to connect downstream. However, the system can recover and integrate into a more constrained and narrower multichannel pattern downstream near Timbuktu.

Permanent fluvial wetlands in drylands are rare, but episodic floods triggered by episodic extreme rainfall events can activate both, permanent and ephemeral wetlands. For example, in Australia, ephemeral wetlands and permanent waterholes can be found on extensive floodplains and floodouts and among aeolian dune fields (e.g., Knighton and Nanson, 1994, 2000; Tooth and McCarthy, 2007).

Wetlands in fluvial basins can also be related to large inland depressions with very gentle slopes, characterized by impeded water flow and even peat. For example, the Cuvette Centrale in the Congo basin is a massive inland tropical peatland-flooded forest wetland, spreading over 145,500 km^2, that could store 30.6 Pg of carbon (Dargie et al., 2017). The wetland is characterized by diffusive drainage and low suspended sediment concentrations in the fluvial systems, sediment trapping that influences the hydrology, the biogeochemistry of the Congo River due to diluting the suspended matter (SM), as well as the total dissolved solids (TDS), while increasing organic matter concentrations and lowering the pH of the water (N'Kaya et al., 2020). But perhaps the most extensive peat wetlands are those of the Amazonian interfluvial region, which could contain the largest tropical wetland area (800,720 km^2) (Gumbricht et al., 2017).

At higher latitude, several of the largest rivers in Siberia and North America drain toward the Arctic throughout periglacial environments with continuous permafrost. Alluvial and periglacial processes can interact in the tundra and part of the taiga. Fluvial styles in periglacial zones are not of a particular style (braided, meandering, or anabranching). Still, climate imposes conditions on

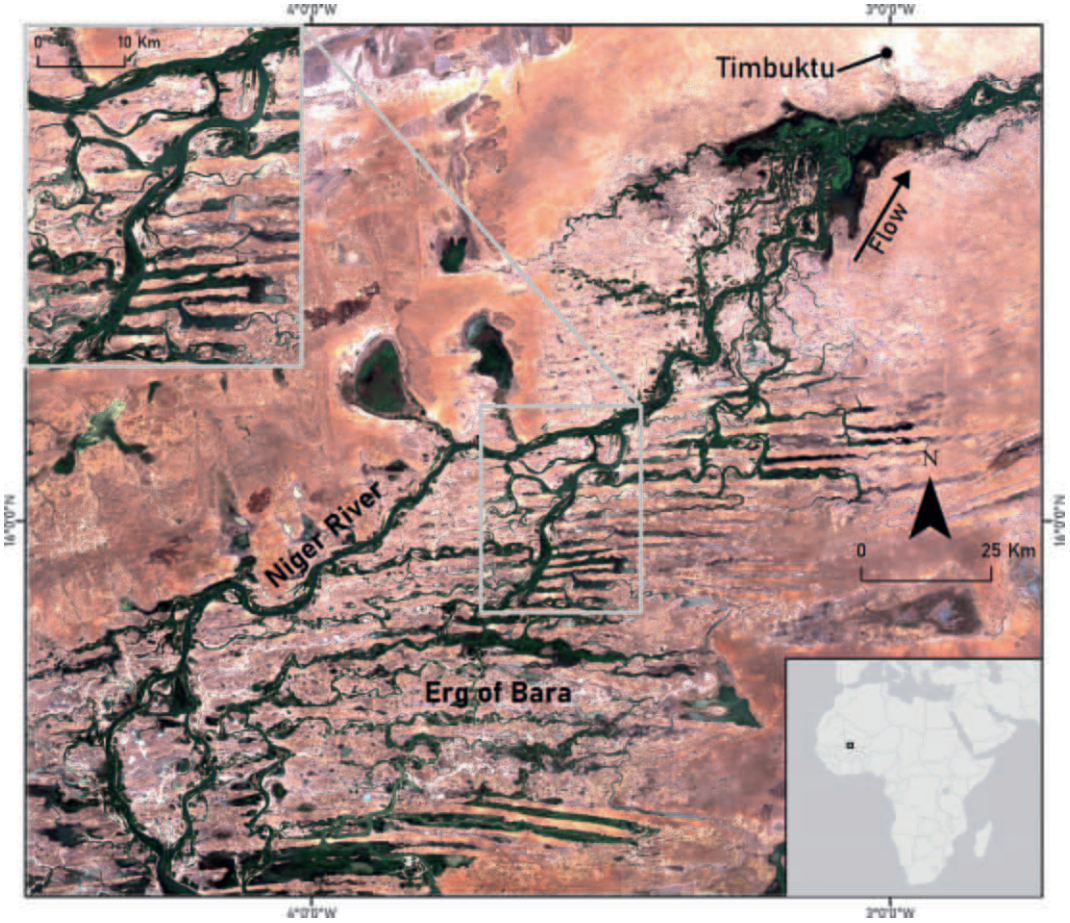

Fig. 6 The anabranching Niger River downstream the Inner Niger Delta. The linear paleodunes system of the Erg of Bara impose control over the river planform and the extensive wetlands. Background Sentinel-2 image (26–31 October 2020) downloaded from GEE platform.

the fluvial systems. It modulates the hydrology, the periglacial processes on the alluvial materials of the floodplain, and the channel becomes frozen in winter. The runoff concentrates in a few days or weeks during the melt period (30–90%) and ice jams can cause flooding (Vandenberghe and Woo, 2002).

The Lena River, one of the largest rivers of the world in terms of water discharge (~16,500 m^3 s^{-1}), has a relatively low suspended sediment load (20–49 Mt. y^{-1}) but still contributes ~15% of the total sediment input to the Arctic (Costard et al., 2007). Like the majority of the large rivers, the alluvial reaches of the Lena are anabranching (Fig. 7). The vast floodplains hold a variety of wetlands that are also dynamically related to the thermokarst process and river water recharge from the surrounding plains (Fig. 7). The combined thermal and mechanical erosion triggers thermo-erosive niches on the banks (Gautier et al., 2021). Before 1987 the river ice thickness near Yakutsk exceeded 1.5 m every 2 years, but since 1987, the river ice only exceeded that value four times (Costard et al., 2007). The permafrost causes low underground water input and rapid floods during breakups (Gautier et al., 2021). Permafrost also modifies the mechanical properties of frozen banks. During the break up periods (summer), the combined effect of the rising water and the stream temperature triggers thermal and mechanical erosion and high recession of the river banks (Costard et al., 2007; Gautier et al., 2003). Climate change consequences is resulting in an unprecedented increasing frequency of high floods and the disappearance of small floods (Gautier et al., 2018).

The alluvial islands of the anabranching reaches are dynamic. The island's area increased during the last 50 years, and the islands have high rates of migration (1967–2002). But since 2003, accretion has decreased, small young islands with seasonal permafrost are developing, and older islands with permanent permafrost are suffering erosion as the consequence of global warming and the floodplain permafrost degradation (Gautier et al., 2021).

The environmental struggle of fluvial wetlands

Most rivers are anthropogenically modified by land-use changes, river engineering, and river regulation that significantly impact and modify the river systems' hydrogeomorphology, sedimentology, connectivity, and fluxes. Anthropogenic stress results in long-lasting river morphology changes, reduction in water flows, altered sediment fluxes, loss of channel-floodplain connectivity,

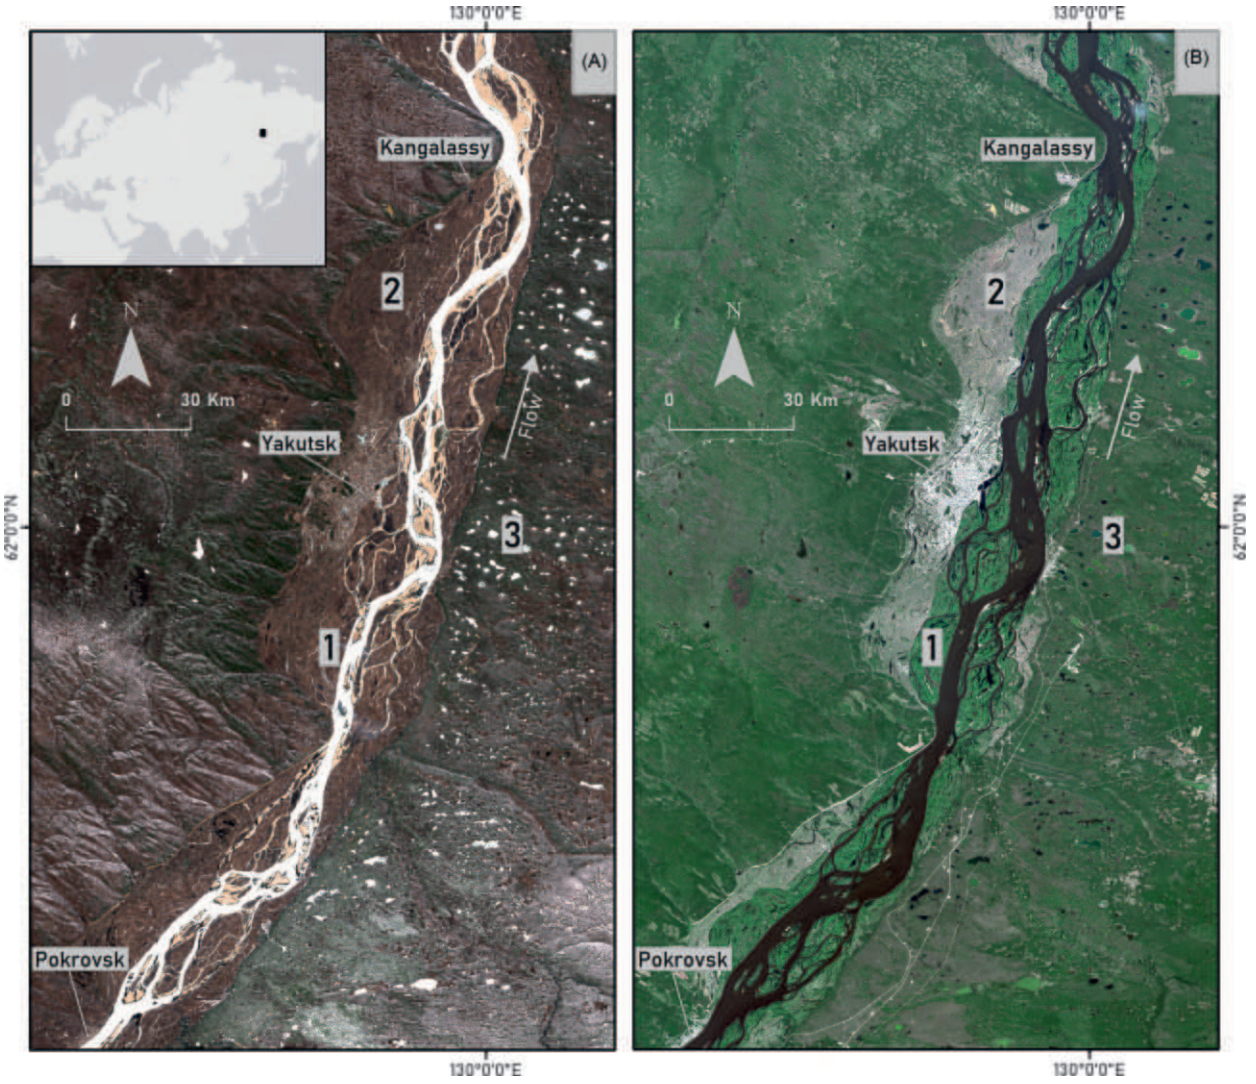

Fig. 7 Geomorphic diversity of wetlands on the anabranching Lena River and its valley. Background Sentinel-2 images from (A) 04 May 2020 and (B) 23 July 2020 A. 1. (A and B) differ in color due to the different spectral response of the Taiga forest in the transition between seasons. GEE platform.

damage and loss of floodplain wetlands, and alterations of the nutrient dynamics, among other factors. A substantial environmental impact is produced by dams that modify and regulate water flows and trap sediments in the reservoirs upstream of the barrages. It was estimated that dams reduced the global sediment yield to the world oceans by ~15% in the 20th century (Syvitski and Kettner, 2011). In some axial rives of east and southeast Asia, ~70% reduction in sediment flux from the major rivers to the Ocean has been documented in the last 1000 years (Wang et al., 2011), while in many large tropical African and South American rivers, water and sediment fluxes decreased because of recent human interventions (Latrubesse et al., 2021). In a few cases, sediment fluxes increased as a response to land-use changes (Latrubesse et al., 2021; Latrubesse and Sinha, 2021).

All these impacts are translated into loss and deterioration of fluvial wetlands worldwide. For example, in Central Europe, up to 95% of the floodplains have been restructured or destroyed (Werther et al., 2021). The situation is particularly critical in the tropics because tropical countries concentrated, during the last decades, the largest rates of deforestation and the maximum number of proposed dams to be constructed (Latrubesse et al., 2017; Latrubesse and Sinha, 2021).

Megafan wetlands are also being rapidly impacted and threatened. The Pantanal megafans and Okavango are natural world heritages and wildlife-protected sanctuaries, and the Chaco megafans also embrace multiple important wetlands, conservation areas, and Ramsar sites. However, all are under significant anthropogenic pressure, threatened by human settlements, cattle ranching, and agricultural activities that encroach and expand into the source basins and the megafans bodies, in addition to being impacted by waterways, channelization, and the multiplication of constructed and planned dams in their upper catchments. The upper catchments of the Pantanal, which source waters and sediments, are highly impacted by extensive soybean agriculture, while the megafan's depositional area supports cattle ranching. In the Chaco, deforestation accelerated in the recent decades

(Latrubesse, 2009). The native vegetation was replaced dominantly by soybean crops on extensive portions of the megafans. It negatively impacted the fluvial wetlands by artificial drainage, lack of connectivity, and desiccation.

But there is some hope, as society's perception on the relevance of fluvial wetlands for nature and environmental services is slightly changing across the world, and conservation and wetlands restoration are being promoted.

Final remarks

Fluvial wetlands enclose a variety of hydro-systems related to the geological and climatic settings of the rivers, their type of hydro-sedimentological conveyor (axial or megafans), channel patterns, and floodplains.

Braided rivers are restricted to medium-sized and small water discharge systems and do not create and sustain extensive wetlands. Their constrained plan-shape (channel-dominated corridor) and hydrogeomorphological characteristics (bedload dominant, high energy) are restraining factors in developing fluvial wetlands.

Meandering rivers are common on Earth, but only a small number of rivers with meandering patterns or sinuous branches (meandering-tendency to divide into branches) are part of the largest rivers in water discharge. Meandering rivers sustain mosaics of floodplains and related wetlands ecosystems and are a common planform at any scale.

However, for axial rivers, the most extended, widest, complex, most geodiverse, and most biodiverse fluvial wetlands on Earth belong to large anabranching alluvial rivers.

Megafans exhibit a variety of geomorphic types. The forming fluvial systems drain orogenic or cratonic lands, and the depositional fan areas spread on sedimentary basins and lowlands, holding a significant proportion of the global fluvial wetlands.

Fluvial systems are the main geomorphologic engine shaping the Earth, and fluvial wetlands in axial rivers and megafans are the main sediment continental sediment sinks of the planet. Although wetlands can be considered geomorphic systems, hydrogeomorphology has been relegated in the study and classification of river wetlands. We echo here the claim that understanding the genesis, functioning, and evolution of fluvial wetlands, incorporating hydrophysical processes, geospatial analysis, and geomorphologic time scales in wetland research and classification is not just desirable but a need. Fluvial wetlands are rampantly destroyed globally, and geomorphology is a fundamental tool for defining conservation areas, assessing impacts, and designing management and restoration plans in wetlands.

Acknowledgments

We thank Edward Park for his assistance in the processing of Fig. 3, Pilcomayo River megafan, and Florian Wittmann and Thomas Mehner for the constructive review.

The Landscape Role of River Wetlands

Florian Wittmann, Department of Wetland Ecology, Institute for Geography and Geoecology, Karlsruhe Institute for Technology (KIT), Karlsruhe, Germany

Glossary

Alpha-diversity Species diversity at a local site.
Beta-diversity Or "absolute species turnover" (β), is the compositional differentiation among habitats.
Disjunct (species) distribution Two or more groups of related species that are considerably separated from each other geographically (i.e., through habitat fragmentation).
Gamma-diversity The total species diversity in a landscape.
Hypertrophied lenticels Loosely connected cells on the epidermis of different plant organs (stem, petiole, fruits) that always remain open and permit the exchange of gases (i.e., oxygen) between the environment and the internal tissue spaces of organs.
Invasive species Introduced organisms that become overpopulated, adversely affecting its new environment, causing ecological, environmental, or economic damage.
Pneumatophores Lateral (aerial) roots that extend out of the water surface and facilitate the exchange of oxygen and carbon dioxide with the atmosphere.
Trophic level The position an organism occupies in a food web.
Vicariance Fragmentation (splitting) of a landscape that divides a larger population into isolated subpopulations.

River wetland environments

Physically, riparian zones and river wetlands are distinguished environmentally from adjacent uplands in three important ways: (1) the episodic, seasonal or permanent presence of surface water and its interaction with ground water (2) the transport, deposition, and remobilization of alluvial substrate and nutrients and (3) the provision of special microclimates. Ecologically, linear watercourses are considered "open ecosystems," where any point along a water course is influenced by the environmental and biotic settings of upstream river sections, while these, in turn, influence rivers downstream. This longitudinal ecological connectivity and dependency over large geographic areas (i.e., river continuum concept, Vannote et al., 1980), combined with the transversal interactions with adjacent uplands (i.e., flood-pulse concept, Junk et al., 1989) result in a highly complex system where wetland organisms are influenced by multiple ecological gradients. Combined, the physical and ecological settings in river wetlands have strong controls on how biological communities are organized in time and space. In the following, the environmental settings of riparian areas and river wetlands are outlined, and examples on how they influence the landscape and biota are subsequently presented.

Water retention and hydrology

Wetlands cover approximately 12.1×10^6 km^2 of the global land surface (Davidson et al., 2018), emphasizing their importance for landscape ecology. As all life forms depend on water, it's presence on the land surface is an attracting force for many organisms, in particular where rainfall is permanently or seasonally limited. However, all surface waters undergo water-level fluctuations that can result in temporary flooding of larger areas, which results in considerable fine-scale wetland heterogeneity and consequently shapes the organization of biological communities.

River wetlands play an important role in regulating aquifers through groundwater-surface water exchange (Winter, 1999; Sophocleous, 2002; McLaughlin and Cohen, 2013). The groundwater recharges when surface waters are abundant and high, and river wetlands provide the base flow of streams and rivers in times of short rainfall. At low discharge, rivers flow in well-defined channels, while at high water levels, large floodplains maybe formed by lateral overflow and inundation. The ground water is important for a range of invertebrate communities inhabiting it (i.e., Boulton et al., 2008), but it is also a critical water source for many terrestrial plant species.

Water level fluctuations of rivers depend primarily on climate (mainly amount and variability in rainfall and temperature), geology and geomorphology (i.e., size of the catchment area, elevation, slope, permeability, pore volume of rocks and substrates), vegetation (transpiration, modification of infiltration), and anthropogenic alterations (water deviation, flow regulation, dams). Surface waters of streams maybe permanent, as in many temperate and tropical climates, or periodic, as in subtropical arid climates or in cold climates where the ice cover persists during parts of the year. Episodic inundation regimes prevail in desert and steppe climates with unpredictable rainfall events.

Stream order and basin size are important variables influencing water-level changes. Low order streams collect rainfall from small catchments and thus are mostly characterized by irregular food pattern. With increasing catchment area, local precipitation becomes less important in defining the hydrological regime (Junk et al., 1989). Rather, the regimes of lower courses of large rivers are determined by basin-wide climate that drives rainfall seasonality throughout its catchment. In tropical and subtropical latitudes (pluvial regimes), precipitation seasonality is often pronounced, and most tropical large rivers typically present a unimodal flood regime, with one high and one low water period during the year. Exceptions are rivers with catchment areas in the two hemispheres; these may present a bimodal flood pattern, such as the upper Negro, Magdalena and Zaire Rivers. In cold and temperate climates, stream and river hydrology is strongly influenced by the accumulation of water as snow or ice during winter and its melting during warm seasons (glacial or nival regimes), as well as by the timing of the vegetation period and evapotranspiration rates through the annual cycle. Flood regimes are mostly complex and polymodal, with several high and low water phases during the year, and, in regions that lack a clear climate seasonality, less predictable.

At the lower courses of large rivers, floodplains may extend to thousands of square kilometers. With increasing size of the floodplain, the rate of rising water levels is slow, but the period of inundation increases. The complex interaction of floods and terrestrial variables influencing the distribution of organisms and biological processes in large-river floodplains provide multiple environmental gradients that are difficult to disentangle. The timing of hydrological regimes with climate seasonality is crucial for the composition and productivity of plants and animals. For example, when local precipitation at low river water levels is comparatively high, floodplains are usually densely forested, such as in the tropical Amazon and Congo, and subtropical Mississippi. Conversely, when precipitation during low river water levels is low, floodplains are mostly dominated by herbaceous species while forests are restricted to the mesic environment of riparian areas and river wetlands, such as in many rivers in tropical and sub-tropical savanna climates (i.e., Paraguay, Paraná, Zambezi Rivers).

The ecotone of aquatic to terrestrial environments is named the aquatic-terrestrial transition zone (ATTZ, Junk et al., 1989). The ATTZ encompasses the transition from strictly aquatic to strictly terrestrial. The boundary between terrestrial and riparian ecosystems coincides with the lower elevation limit of terrestrial plants that do not tolerate inundation (Nilsson et al., 1993), while the boundary between riparian and aquatic ecosystems coincides with the upper elevation limit of strictly aquatic and semi-aquatic plant species (Nilsson et al., 1993; Naiman and Décamps, 1997). However, when water-level changes amount to several meters and seasonally inundate floodplains of hundreds of kilometers, such as in many tropical large-river floodplains, the aquatic-terrestrial ecotone might bridge entire landscape units or ecosystems (Junk et al., 2015).

As all surface waters undergo water-level fluctuations, the ATTZ is constantly subject to spatio-temporal movements across rivers, riparian areas and floodplains ("moving littoral" sensu Junk et al., 1989). Classical limnological or morphological features describing the typical habitats of shorelines become time-dependent, and this time-dependency is important because it affects the life-cycles and productivity of plants and animals. For example, increasing water levels expand the habitat for aquatic animals, but reduce habitat for terrestrial species intolerant to floods.

While terrestrial animals can move and therefore potentially avoid changing water levels, sessile plants cannot. The latter are therefore often better indicators of wetlands because they need to develop specific adaptations to changing hydrological environments. Numerous adaptations and functional life-history traits of plant species are specifically related to inundations and related disturbance. Adaptations to flooding include physiological, morphological and biochemical traits to avoid oxygen deficiency during the waterlogged period. Riparian and floodplain trees, for example, reduce their metabolism during flooded conditions, which results in decreased photosynthetic rates, and reduced wood and shoot growth (Worbes, 1986; Schöngart et al., 2002; Parolin et al., 2010). Further adaptations include partial or complete leaf shedding with the onset of flooding, the formation of adventitious roots and/or specialized roots such as pneumatophores, increased root biomass during flooding, the formation of hypertrophied lenticels on roots and stems, the formation of root aerenchyma, the induction of activity of fermentative enzymes under anaerobic conditions, as well as the production of elevated levels of anti-oxidant compounds (i.e., Wittmann and Parolin, 2005; Parolin, 2009; Kreuzwieser and Rennenberg, 2014). In addition, specific acclimations such as the timing of seed dispersal (Van Splunder et al., 1995), seed dispersal by river waters and aquatic dispersers, and enhanced germination rates of seeds in dependence of its contact with river waters are especially common in species subject to a regular flood pulse (i.e., Kubitzki and Ziburski, 1994; Oliveira Wittmann et al., 2007; Correa et al., 2015). Lastly, the degree of acclimations and adaptations in a riparian community defines the usually well-developed zonation of species along the gradient of flood frequency and duration, and thus directly influences on the composition and richness of communities (Wittmann et al., 2006, 2010).

Geomorphic disturbance

Geomorphic disturbance along streams and rivers is another phenomenon that importantly influences landscapes and vegetation communities mainly through alternating cycles of destruction, recolonization, vegetation succession, and floristic recombination. Slip-off and undercut slopes, swales and ridges, point bars and islands are important alluvial landscape patches of varying hydro-geomorphologic disturbance. Lateral river bed migration, in addition, creates abandoned secondary channels, lakes with varying connectivity to the main river channel, and fluvial terraces with varying connectivity to surface and ground waters. Locally varying hydraulic forces sort deposited grains by size and weight, influencing pore volumes, soil aeration, and the water retention potential of the substrate (i.e., Wittmann et al., 2010). The type and rate of geomorphic disturbance varies with a range of environmental factors, such as climate (mainly rainfall amount and seasonality), slope and hydraulic force, bedrock type, as well as sediment transport and cohesion, and importantly interacts with the vegetation cover and type along riparian areas and in floodplains. The notion of the integration of fluvial geomorphology and riparian plant ecology is the basis for important ecological concepts, where river ecological functioning is conceptualized in four dimensions: longitudinal, transverse, vertical, and temporal ("fluvial hydrosystem", Amoros et al., 1987; Ward, 1989). The "river continuum concept" (Vannote et al., 1980), the "flood-pulse concept" (Junk et al., 1989) and the concept of "aquatic-terrestrial ecotones" (Naiman and Décamps, 1997) also consider different aspects of interactions of hydro-geomorphic disturbance with longitudinal (i.e., from upper to lower river sections) and transversal (from rivers to floodplains) biotic processes.

When slopes are steep (i.e., mountain bedrock channels), hydraulic force combined with mass movements and very coarse substrates strongly limits plant establishment in the mostly small riparian zone. The geomorphic system is exclusively driven by interactions of flow regimes and sediment properties leading to the total destruction of previously established vegetation communities through fluvial landform remobilization (Corenblit et al., 2007). After catastrophic high water events, this "geomorphic phase" (Corenblit et al., 2007) in vegetative succession may lead to floristic recombination (Tabacchi, 1995). Notably, plants establishing in these dynamic riparian zones need to overcome several stressors, such as the complete absence of humus and soils, extreme shear stress through water flow and water-transported material (i.e., gravel), highly variable water levels, and, because of the lack of a close vegetation cover, full solar radiation (Fig. 1). In addition, low temperature and snow and ice cover at high elevations or high latitudes form additional stressors (i.e., Walker and Hudson, 2003).

Downstream, the riparian and floodplain vegetation increasingly influences stream and river geomorphology (i.e., Tabacchi et al., 2000; Wittmann and Parolin, 2005; Gurnell and Petts, 2006; Gurnell et al., 2012). Allogenic succession, which is solely controlled through abiotic factors, such as physical disturbance, increasingly shifts to autogenic pathways, where positive and negative interactions among plants prevail (Van Andel et al., 1993; Wittmann and Parolin, 2005). In this "biogeomorphic phase" (Corenblit et al., 2007), flexible (i.e., herbaceous species) and stiff vegetation (i.e., tree species) promote flow resistance and favor the deposition of transported material, organic matter, and nutrients. By modulating matter and energy fluxes, riparian plants

Fig. 1 Lech River, Austria. Braided gravel-bed rivers in mountain areas may undergo catastrophic river bed changes during a single high-water event and destroy previously established vegetation communities. Plants establishing in these dynamic riparian zones need to overcome several stressors, such as highly variable water levels, the absence of humus, extreme shear stress through water flow and water-transported material, full solar radiation, and seasonal snow and ice cover.

Fig. 2 Two examples of vegetative succession along river banks. Above: Amazon River, central Brazilian Amazon, with the macrophyte species *Paspalum fasciculatum* (front) and the tree species *Salix martiana* (back). Below: Danube Delta, Romania, with the macrophyte species *Phragmites australis* (front) and the tree species *Salix alba* (back). Following the differential influence of frequency, height, and duration of annual floods and associated geomorphic variables, such as fluvial erosion, sedimentation rate, and deposited grain sizes, sharply delimited successional pioneer stages establish. These trap further sediment, locally increase the accumulation of organic material and modify further environmental parameters, such as flood duration, solar irradiance, and water retention capacity of alluvial soils, facilitating the establishment of secondary species, which in turn are replaced through late-successional species.

impact fluvial landform dynamics (Gurnell et al., 2012; Gurnell, 2014). Riparian plants also modify physical and chemical substrate properties by means of roots, interaction with bacteria (i.e., Doty et al., 2005) and mycorrhizal fungi (i.e., Beauchamp et al., 2006), as well as nutrient uptake and the release of organic matter and exudates (Corenblit et al., 2015). In addition, they strongly influence local microclimates, including humidity, light regimes and temperature in the river-floodplain system (i.e., Tabacchi et al., 2000; Wittmann and Junk, 2003) (Fig. 2).

Adaptations to geomorphic disturbance are usually those that enable plants to withstand mechanical stress, excavation and burial (Gurnell, 2014). The first colonizers on bare substrates exhibit a range of traits related to reproduction, germination and growth. Seeds are usually small and light and dispersed by wind and water, and the time of dispersal is mostly attuned to river high flows (i.e., during winter and spring in temperate regions) and the presence of bare moist substrates for establishment after water-levels decrease (i.e., Guilloy et al., 2011). Many pioneers also combine sexual with asexual reproduction by means of resprouting from plant segments (i.e., branches, roots). Adaptations to flow regimes and shear stress are flexible stems, extensive below- and aboveground root systems, and the capacity to develop new secondary root layers close to the surface in areas prone to sediment burial (i.e., Wittmann and Parolin, 2005) (Fig. 3).

Sediment and nutrients

Because water courses transport bedload and suspended material over long distances, their riparian zones and floodplains often create "azonal" edaphic conditions that contrast soils developed in situ from local bedrock (Wittmann et al., 2017). Best examples are rivers that originate from tectonically uplifted regions, such as the mountain ranges of the Alps, Andes, Hindukush, Himalaya and Rocky Mountains. Rivers originating from relatively young orogeny may introduce fertile sediment with relatively un-weathered clay minerals of high ion exchange capacity into older geological formations where local weathering processes have decomposed and lixiviated underlying rocks. Even low-order rivers that develop on the same geological basement as surrounding terrestrial landscapes promote this azonal environment to a certain degree because the erosive material laterally introduced through denudation (wash load) derives from the entire catchment and thus concentrates a wider geographic range of sediment and nutrients in the linear discharge and transported alluvium.

Organic matter, either in its particulate form (POM), or dissolved (DOM) originating from the riparian zone is a further important nourishment for both, aquatic and semi-aquatic organisms (Vannote et al., 1980; Naiman and Décamps, 1997). While POM mainly derives from litter fall and—to a smaller degree—from lateral transport of litter to streams, DOM originates either from direct litter fall, lateral movements, groundwater base flow or seepage from fringing wetlands (McClain and Richey, 1996; Naiman and Décamps, 1997). Litter decomposition releases important nutrients to soils during the growing seasons. The sediment trapping through plants has an important effect on the accumulation of nutrients in riparian zones and floodplains. Plant uptake results in a short-term accumulation of nutrients in non-woody biomass and a long-term accumulation in woody biomass (Naiman and Décamps, 1997). Nutrient uptake may be enhanced in many wetland plants under low-oxygen conditions, and particularly N and P uptake might be several fold higher in wetland than in strictly terrestrial plant species (i.e., Hosner et al., 1965; Peterjohn and Correll, 1984; Cooper, 1990). Most riparian areas and wetlands, in particular those with organic soils, also show exceptional rates of either nitrification (i.e., Kern and Darwich, 1997; Kern et al., 2010) or denitrification (i.e., Alldred and Baines, 2016).

Fig. 3 Burial of trees by sediment is a common stressor in sediment-rich floodplains to which trees adapt through the formation of secondary root layers near the surface (i.e., Wittmann and Parolin, 2005). When the alluvium is composed of fine grains, topsoils crack during the low-water phases providing aditional stressors by the rupture of fine roots.

Elevated fertility in river floodplains may be one of the most important ecosystem services for humans, as it is widely held to be associated with the rise of human civilization along the Nile, Euphrates, Tigris, and Indus Rivers (Hammerton, 1972; Boulé, 1994), allowing for intense agriculture (Gopal, 2013) and the domestication of animals (Junk, 2002). High fertility also translates into fast plant growth and the comparatively high primary productivity of many nutrient-rich wetlands, which are among the most productive ecosystems on the globe. In Amazonian várzea floodplains, net primary productivity—the total amount of carbon (i.e., wood biomass increment + litter fall) fixed from the atmosphere for the biochemical construction of new aboveground organic matter per time unit (Chambers et al., 2001)—is extraordinarily high. In várzea forests, aboveground net primary productivity (ANPP, dry mass) ranges from 31.8 Mg ha^{-1} $year^{-1}$ in a 50-year-old secondary stage to 13.3 Mg ha^{-1} $year^{-1}$ in a 240-year-old late-successional stage (Schöngart et al., 2010), which is about 2–3 times higher than ANPP in surrounding upland forests and one of the highest reported ANPP on Earth. In herbaceous areas, however, primary productivity is even higher, measuring 70–100 Mg ha^{-1} $year^{-1}$ for the grasses *Paspalum fasciculatum* and *Echinochloa polystachya* (Piedade et al., 1991).

Microclimate

Wetlands importantly regulate local and regional temperatures because of the groundwater-surface water exchange, which buffers surface waters from high or low temperatures, and the effect of evapotranspiration and latent heat exchange from water and wetland plants. Mainly, the transformation of water from aqueous to gaseous phases resulting from evaporation of surface waters or transpiration from leaf surfaces releases energy, and cools the local surrounding. In any landscape, wetlands therefore provide a microclimate-regulation service (McLaughlin and Cohen, 2013) alleviating heat island effects through water availability, often linked to dense riparian or floodplain vegetation (Drexler et al., 2004) and the advection of sensible heat (Spronken-Smith et al., 2000). Besides being a significant factor in a wetland's water budget (i.e., Gilman et al., 1998; Gardner, 1991), high evapotranspiration rates of wetlands thus provide a cooling effect, which is especially pronounced in forested wetlands, where transpiration dominates evapotranspiration fluxes (Law et al., 2002).

Implications for landscape ecology

Corridor function

Rivers and their riparian zones and wetlands represent important ecological corridors for a wide range of organisms. Aquatic and wetland plants generally disperse both up and down riparian corridors (Naiman and Décamps, 1997) through the dispersal of diaspores or vegetative fragments. Because rivers flow from high to low elevation, and in addition connect different catchment areas, diaspore dispersal may cover large distances and different climate zones (Naiman et al., 1993) in relatively short time. Surface waters provide connectivity over large geographic ranges and many wetland plants make use of dispersal through water (hydrochory) or aquatic dispersers (i.e., ichthyochory). In Amazonian floodplains, the fruiting phenology of many tree species is timed to the annual flood cycle with many tree species maturing and shedding fruits at high water (Kubitzki and Ziburski, 1994). After dropping into the water, seeds may float during periods of up to 2 months. Seed buoyancy or submergence increase the distance of dispersal by river waters and enhance the probability of dispersal by fish and other aquatic organisms (Goulding, 1980). Moreover, seed dormancy is broken by exposure to river water (i.e., Oliveira Wittmann et al., 2007), thus seeds germinate as soon they land on substrates as water-levels recede.

The consumption of fruits and seeds by fish has been documented in approximately 200 freshwater fish species and more than 800 plant taxa (Correa et al., 2007), mostly occurring in—but not restricted to—tropical regions (i.e., Amazon, Congo, Mekong, Niger, Chad and Nile Rivers). Fish interactions with flowering plants are likely as old as 70 million years in some tropical regions, pre-dating most modern bird-fruit and mammal-fruit interactions, and contributing to long-distance seed dispersal and the radiation of early angiosperms (Correa et al., 2015).

Rivers that cross different climate zones are particularly important as migration corridors for many wetland and drought-sensitive terrestrial organisms and thus exert a fundamental role in landscape ecology and maintenance of biodiversity by sustaining biogeographic connections across humid biomes separated by otherwise inhospitable dry climates (i.e., Oliveira-Filho and Ratter, 1995; Wittmann et al., 2017). For example, many drought-sensitive tree species from Amazonian wetlands are able to track favorable wetland microclimates and expand their distribution ranges into tropical savannas (i.e., Cerrado and Caatinga), particularly along N-S oriented rivers, such as the Xingu and Araguaia (Wittmann et al., 2017). Similar biogeographic exchanges were reported for tree species of the Brazilian Atlantic rainforest that extend their distribution ranges towards the South American Cerrado, and the subtropical Pampas through riparian corridors (i.e., Oliveira-Filho et al., 2015).

Because many terrestrial animals depend on surface waters, the corridor function of rivers is not restricted to aquatic and wetland organisms. Many terrestrial vertebrate species strongly depend on habitat and resources from wetlands, which provide refuges from annual droughts, or seasonal low temperature at high latitudes and altitudes. For example, plant zonation along flood frequency and duration gradients across tropical Africa provide a temporal resource heterogeneity for herbivores, which graze on floodplain peripheries in the early dry season, but migrate to deeper floodplains and swamps during the late dry season and during droughts (Fynn et al., 2015). Many water and shore birds migrate annually between breeding grounds and wintering areas, and tropical/subtropical rivers that cross different climate zones are particularly important as corridors along which they are able to migrate (Sparks, 1995).

Species and habitat diversity

River wetlands host among the highest numbers of taxa in many animals, including planktonic and benthic communities, aquatic and terrestrial invertebrates, and aquatic and terrestrial vertebrates that live in or are highly dependent on rivers and wetlands. For benthic invertebrates, habitat diversity is especially high along the upper river courses, where river bed geomorphology is most diverse. Most invertebrates of river wetlands have relatively short life cycles, which allows their rapid occupation of the new sites provided by fluctuating water levels and river dynamics (Irmler, 1981). Many invertebrates also migrate or drift in the water to new sites (Junk and Robertson, 1997). In seasonal wetlands, life cycles of most invertebrates are tightly coupled to the hydrological cycle, with examples from Mediterranean climates (i.e., Cañedo-Argüelles and Rieradevall, 2011), semiarid climates of the United States (i.e., Hall et al., 2004), Amazon floodplains (Adis and Messner 1997; Adis and Junk, 2002) and the Brazilian Pantanal (Wantzen et al., 2016).

Globally, the freshwaters of rivers, floodplains and lakes harbor approximately one third of all vertebrates and nearly half of all fish species (Balian et al., 2007; Vega and Wiens, 2012). In addition, river wetlands also provide food and habitat for a range of terrestrial, deep water and bird species, including those that migrate to spawning and feeding areas (i.e., fishes), escape from seasonal drought (i.e., herbivores in savanna regions) or escape from low temperatures at high latitudes (i.e., migratory birds) (Welcomme, 1985; Sparks, 1995; Junk, 2007; Fynn et al., 2015). In all examples, water-level changes of wetlands are likely to influence the diversification of habitat specialists, either directly through the availability of water, or through the provision of habitat and high primary productivity of their vegetation cover.

Hydrological cycles in wetlands as well spur the evolution of plant species. Many wetland plants, for example, time their reproductive cycles to the flood pulse, and it is likely that over time this leads to speciation. In the Amazon basin, where flood pulses are high and prevalent since at least the Paleocene, many endemic tree species evolved in large-river floodplains (Wittmann et al., 2010, 2013). Endemic tree species in other wetlands are scarce, because climate changes during the past led to repeated drought or wet cycles that interrupted the formation of flood-specific adaptations and species. However, many wetlands of the globe host endemic herbaceous species, that are more likely to evolve over relatively shorter time scales because generation cycles are faster (Sculthorpe, 1985).

From riparian areas to large-river wetlands, the attraction of organisms to mesic environments increases with increasing drought (Wittmann et al., 2017). Therefore, river wetlands are the most species-rich environments in many arid climate zones, including tropical and subtropical savannas, but also continental boreal and subarctic steppes. In subtropical and tropical regions, riparian areas represent forest refuges within landscapes dominated by open savannas (Meave et al., 1991). Ground water availability in riparian areas contrasts the soil water deficiency that characterizes most of the savanna landscape. Impacts of seasonal drought and fire frequency are reduced (i.e., Felfili, 1995; Kellman and Meave, 1997) (Fig. 4). In per-humid, tropical forested landscapes, wetlands might be poorer in species than ecosystems of adjacent uplands. Here, variable periods of waterlogging and inundation act as an important environmental filter (i.e., Householder et al., 2021), selecting for species with specific adaptations to seasonal or permanent hypoxic conditions.

Fig. 4 Lower Miranda River, Brazilian Pantanal. Riparian areas contrast the soil water deficiency of the surrounding savanna landscape and are less affected by seasonal drought and fire activity—therefore, they often represent the most species-rich communities in tropical and sub-tropical savannas.

Independent of the climate zone, hydro-geomorphic activity provides a myriad of ecological niches along the flood-level and geomorphic disturbance gradients (i.e., Peixoto et al., 2009; Junk et al., 2012) (Fig. 5). Together with changing topographies, alluvial landforms may change at small geographic scales. High habitat diversity translates into high beta-diversity. According to the degree of adaptations developed by organisms to the disturbance provided by the interaction of hydro-geomorphic gradients, sharply developed zones of biotic communities (i.e., successional stages) develop. It is this patchwork of biotic communities that increases beta-diversity and frequently leads to exceptional species richness of riparian zones and floodplains compared to terrestrial landscapes. In their worldwide review on the comparative species richness of different taxonomic groups between terrestrial and riparian habitats, Sabo et al. (2005) reported that riparian zones increase regional species richness by harboring different, not necessarily more, species. The authors conclude that riparian habitats increase regional gamma-diversity across the globe by more than 50% on average, and thus suggest that conservation planners can easily increase the number of species protected in a regional portfolio by simply including a river within terrestrial biodiversity reserves.

The contrasting fertility of the alluvium compared to terrestrial landscapes represents a further attractive force to many organisms, and increases beta-diversity at the landscape scale. Nutrient-rich alluvial soils may represent vectors of range expansion in otherwise adverse landscapes of poor nutrient conditions. White-water river floodplains (várzeas) of the Amazon, for example, contain large populations of tree species that are nearly absent elsewhere in the Amazon, but dominant upon nutrient-rich soils of the tropical Andes and central America (Wittmann et al., 2010; Fig. 6). The disjunct distribution of these species are an important floral component in the Amazon contributing to elevated gamma-diversity.

The resetting of vegetation succession and the varying response of plants to differences in flooding, shear stress, sediment texture, and soil development and age has important biotic effects. Vegetation resetting constantly provides habitats for early-successional (i.e., pioneer) species, which are inhibited from competitive exclusion through dominant, late-successional species (i.e., Sedell et al., 1990). Moreover, most rivers provide a patchwork of environmentally differentiated habitats for both, early-successional species (i.e., at slip-off slopes) and late-successional species (i.e., on opposing undercut slopes) at relatively small spatial scales, enabling their coexistence within the same landscape. These functional groups contrast in resource allocation for growth (early successional stages) and survival (late-successional stages) (i.e., Grime, 1977; Pickett and Cadenasso, 2005) and therefore also profoundly affect landscape spatial patterns of resource availability for all organisms at higher trophic levels.

Lastly, while adaptations to environmental stressors such as flooding can lead to speciation of wetland organisms, large rivers may also represent physical distribution barriers for strictly terrestrial species and thus directly influence the beta-diversity of landscapes. In the Amazon, large rivers are thought to be the divisors for a range of terrestrial species, such as primates (Wallace, 1852; Boubli et al., 2015), lowland birds (Haffer and Prance, 2001; Ribas et al., 2012), lizards (Ávila Pires, 1995), butterflies (Hall and Harvey, 2002), and terrestrial woody plant species (Prance, 1982). In fact, the several recognized areas or "districts of endemism" in the Amazon basin are sharply divided by major rivers, which might have favored vicariance in numerous terrestrial species groups (Silva et al., 2005).

Fig. 5 Mamirauá Sustainable Development Reserve, between the confluence of the Solimões and Japurá Rivers, western Brazilian Amazon. Sediment-rich large-river floodplains (várzeas) often create a large number of ecological niches and increase the habitat diversity of landscapes by the creation of fluvial landforms such as ridges, swales, secondary channels, slip-off and undercut slopes and lakes of varying hydrological connectivity, which have differential influence of floods, hydraulic energy, geomorphic dynamics, topsoil grain size distribution, and ecological connectivity to both wetlands and uplands.

Fig. 6 Fluvial island in the Japurá River, central Brazilian Amazon, during the low-water season. Freshly deposited substrates incur environmental constraints for plant colonization, such as high solar radiation, high soil temperature, and low water retention capacity of alluvial soils, providing edaphic drought for colonizing plant species. Nevertheless, these conditions attract pioneer species, such as annual grasses, perennial herbaceous and also specialized woody species that are poorly competitive in the adjacent, strictly terrestrial environment, which in this landscape is nutrient-poor and vegetated by dense rainforest. The pioneer species in Amazonian floodplains are adapted to the higher fertility of alluvial substrates and therefore often display disjunct distribution in non-forested biomes of higher fertility, such as the higher elevations of the Andes, central America, and tropical savannas.

Refugia

Refugia are areas in which a population can survive through an extended period of unfavorable conditions. The relatively high water availability, habitat diversity, fertility and the provision of special microclimates is widely held to have provided important refugia for numerous plant and animal species throughout Earth's evolutionary history. For example, the cooling effect is interpreted as a principal driver for the persistence of disjunct distributions of boreal/alpine species in temperate wetlands, leading some ecologists to refer temperate wetlands as "interglacial climate refugia" (Frederick, 1974; Nekola, 1999). Refugia experience buffered climates and support species preferring cooler environments than surrounding regions (Barnosky, 2008; Ashcroft, 2010; Raney et al., 2014). In another example, Amazonian peat swamps were found to harbor taxonomic compositions appearing to be 1050 $\pm$ 391 m above their actual elevations due to a high abundance and number of families with high elevation optima (Householder et al., 2015). Similar findings originate from Amazonian várzea forests, where up to 20% of flood-tolerant tree species of lowland Amazonia were reported to occur at elevations >3.000 m along the Andean slopes (unpublished data F. Wittmann). While all these examples suggest temperature as determinant of wetland refugia, high relative water availability in river wetlands is likely the most important factor for the persistence of species in refugia, especially in landscapes subject to adverse climates with seasonal or permanent water scarcity (McLaughlin and Cohen, 2013). For example, in the Amazon basin, large-river wetlands are interpreted as one of the most prominent forest refuges for rainforest tree species diversity during drier climates of past glacial periods—the large Amazonian rivers were too large to dry out, preventing drought-sensitive rainforest tree species from regional extinction (i.e., Wittmann et al., 2013, 2017). Water availability in mesic riparian habitats and river wetlands may be loosely coupled to rainfall and therefore buffered from climate change (McLaughlin and Cohen, 2013). Limiting conditions, including elevated temperatures, increased drought, and soil nutrient deficiency, are all less pronounced in river wetlands, emphasizing their function in the provision of species refugia in terrestrial landscapes.

Consequences of habitat destruction and fragmentation

While any human influence on the hydrological cycle affects the ecological integrity of wetlands, the most dramatic effects of wetland degradation on catchments and terrestrial landscapes originate from deforestation, water deviation and flow regulation through channel rectification and damming. These activities directly influence fluvial processes that sustain their landscape functions, and also affect groundwater levels and as such the capacity of wetlands in their retention and release of water to landscapes. A disturbed water balance and buffering capacity of a wetland reduces its capacity to mitigate climatic extremes, which increases the probability of more frequent and more intense catastrophic drought and inundation events.

Globally, riparian zones and floodplains of an increasing number of rivers are affected by flow alteration through land drainage, water deviation, channel rectification, river impoundment, and the construction of reservoirs. Lehner et al. (2011) estimate that 7.6% of the world's rivers with average discharge >1 m^3 s^{-1} are affected by dams, while this number increases to more than 46% in large rivers (discharge >1000 m^3 s^{-1}). The highest degrees of river regulation were reported for North-America (38% of all rivers), followed by Europe (30%), Australia, Africa and Asia (16–19%), and South America (approximately 9%). Only for European rivers, Belletti et al. (2020) reported approximately 1.2 million instream barriers in the rivers of 36 European countries.

Channel rectification is one of the most prominent reasons for floodplain loss and degradation in European rivers, and also has far-reaching effects for catchment areas. Formerly multi-branched or braided rivers were linearly confined. As a consequence, river channels dispose of higher water energy and tend to incise their channels. Channel incisions lead to lowered ground water levels, affecting moist-dependent plants and invertebrates, which are more and more replaced by strictly terrestrial species. In addition, floodplains along rectified channels are flooded less frequently, because inundations are mostly restricted to extreme high-water events. While coarser sediment, such as gravel and sand, is transported by high water velocities of confined channels, the sediment deposited in rectified channel-floodplains is mostly fine (silt and clay). This leads to silting up and homogenization of sediment and alluvial soil types in floodplains. Many plant and animal species that inhabit coarser sediment of dynamic floodplain environments are replaced by generalist species, leading to species losses and even regional extinction in numerous examples. Rectified channel floodplains also show modified gradients of lateral connectivity, negatively affecting many macroinvertebrates (i.e., Paillex et al., 2007), and consequently aquatic and terrestrial food webs. Rectified channel-floodplains are especially prone to the colonization by invasive species, which reduce local biodiversity through habitat occupation, the introduction of pathogens and diseases, and lead to genetic erosion (i.e., Aguiar et al., 2001; Bunn and Arthington, 2002; Stromberg et al., 2007).

The impact of dams, barriers, and impoundments is particularly dramatic in lowland rivers. Modified flood regimes, sediment and nutrient trapping, and the loss of hydro-ecological connectivity significantly affect the flora and fauna of dammed rivers well beyond the limits of the artificial reservoir. Floodplains located downstream of barriers usually experience higher low water levels and lowered high water levels compared to pre-dam conditions, which leads to dramatic plant species losses at both the highest and lowest floodplain topographies ("sandwich-effect" sensu Wittmann et al., 2019). Species losses may occur along river stretches up to hundreds of kilometers downstream from a dam, as shown for central Amazonia (Assahira et al., 2017; Schöngart et al., 2021), and the Paraná River (Junk et al., 2021). The loss of wetland-specific plant species influences the provision of habitats and food sources of numerous animal species, cascading down to fish communities and thus also affecting the food chain of terrestrial vertebrates. Agostinho et al. (2008) have shown, that the several dams established at the Paraná River in south-western Brazil affected more than 80% of all native fish fauna, leading to a replacement of ecologically specialized species through generalist species. Sediment and nutrient trapping through river dams in addition lead to the transformation of the physico-chemical water properties (i.e., water temperature, pH, electrical conductivity), with often dramatic consequences for invertebrate and vertebrate communities. Ultimately, these changes also affect marine biogeochemical processes, salinity levels, food webs, and consequently biodiversity (i.e., Krumins et al., 2013), in particular in estuaries, deltas, and other terrestrial-marine transition zones.

Combined, the cumulative impacts of flow regulation, damming, and water deviation of river wetlands is exacerbated through climate change. The relatively dry summers and autumns in Central Europe in 2018–2020 resulted in exceptional low water levels of rivers such as the Rhine, Danube and Elbe and caused unprecedented lowered groundwater levels, causing a mass mortality of tree species in southern Poland, Czechoslovakia, Germany and France, particularly of the native genera *Picea*, *Pinus*, *Fagus*, and *Quercus* (Petit-Cailleux et al., 2021). Streamflow lows are increasing in magnitude and frequency in central and southern Europe especially during the spring and summer months (Stahl et al., 2012), and many organisms that depend on high ground water levels are increasingly threatened by hydrological droughts. In another example, the Pantanal wetland in Brazil was heavily affected by fires in 2021 (i.e., Leal Filho et al., 2021), when the meteorological drought was reinforced by the flow regulation and lowered ground water levels in the upper basins of important tributaries of the upper Paraguay River, as shown by the increasing number of hydropower facilities (Ely et al., 2020). In south-eastern Brazil, water volumes of most reservoirs are at 10–20% of their capacity, causing shortage of drinking water and hydropower generation. In this situation, the 88-year historical drought of the Paraná River in 2021, caused immense damage to biodiversity and agricultural economy (i.e., Abriel et al., 2021).

The reduced water retention capacity of flow-regulated river floodplains also reinforces catastrophic inundations, in particular where the active floodplains are limited through artificial dikes for flood protection. In many regions on Earth, climate change leads to an increase in the frequency and intensity of heavy rainfall events. While wetland degradation is not the single cause of high water events, those are strongly reinforced by the increased discharge of rectified and diked river channels, as painfully experienced recently in the Ahr river valley in western Germany in July 2021, causing the loss of 130 lives and an unprecedented damage of homes and infrastructure (i.e., Schlömer et al., 2021). Catastrophic events like this will affect many regions on Earth with increasing severity and frequency with climate change.

Deforestation, inadequate resource use, and pollution through mining activities, wastewaters, and agricultural activities are further environmental threats for most river wetlands on Earth. Whenever affecting wetland species populations and biogeochemical cycles, the impacts are not restricted to aquatic environments but mostly extend to the entire catchment, and vice versa. Worldwide, rivers annually transport 43 MT of nitrates and 8.6 MT of phosphates to the oceans, mainly originating from agricultural fertilizers and wastewaters, leading to the eutrophication of more than 80% of the World's marine ecosystems (Sutton et al., 2013). In another example, Peterson et al. (2021) reported on elevated mercury concentrations in raccoons and skunks in seasonally impounded brackish marshes in California and concluded that other wildlife of similar and higher trophic positions may also bioaccumulate methylmercury. Similar results are reported for bat species of the Peruvian Amazon, where mercury is used in the

mostly illegal gold mining activities along low order rivers. As shown by Kumar and Divoll (2014), higher trophic bat levels (i.e., piscivores and insectivores) bioaccumulated more mercury than lower trophic levels (i.e., frugivores), demonstrating the negative effects of water pollution that often has strong capacity to permeate through aquatic and terrestrial food chains.

Conclusions

Riparian zones and river wetlands influence the water balance of landscapes and are crucial ecosystems for landscape ecology and biogeography in how they influence species evolution, species exchange, biodiversity, trophic chains, biochemical processes, and the mitigation of hydrological extremes as caused through climate change. River wetlands are interdependent with surrounding terrestrial catchments, thus any fragmentation or ecological degradation of riparian zones and wetlands has direct impacts on terrestrial landscapes, and vice versa. The longitudinal ecological connectivity and dependency over large geographic ranges combined with the transversal connectivity of adjacent uplands results in highly complex ecological interactions where wetland organisms depend on multiple ecological gradients. This notion implies that organisms inhabiting riparian zones and river wetlands are particularly vulnerable to human activities and land-use change. Because riparian zones and river wetlands belong to the most biodiverse ecosystems in many climate zones, and provide vital ecosystem services for humans in terms of the provisioning of water, the regulation of biogeochemical cycles, and the mitigation of climatic changes, they should receive special attention in conservation efforts.

Future research

- Comparative phylogenetic studies on wetland plant and animal species with their terrestrial and marine congeners are needed in order to better understand the role of wetlands in species distributions, evolution, diversification, and refugia.
- Hydro-climatic models should be combined with experimental studies on species vulnerability and resilience to confidentially predict impacts of hydrological climate change on the wetland-dependent biota.
- Wetland conservation and restoration should focus on the integrative protection of freshwater systems including their terrestrial and marine interactions, using a landscape approach.

Mountain Rivers: A Global Overview of River Channel Forms, With a Focus on Braided Rivers

Felix L Maier[a], Stewart B Rood[b], Severin Hohensinner[c], Isabell Becker[a], Jerneja Harmel[d], Norbert Müller[e], and Gregory Egger[c,a], [a]Karlsruhe Institute of Technology, Institute of Geography and Geoecology, Karlsruhe, Germany; [b]Department of Biological Sciences, University of Lethbridge, Lethbridge, AB, Canada; [c]University of Natural Resources and Life Sciences Vienna, Institute of Hydrobiology and Aquatic Ecosystem Management, Vienna, Austria; [d]ZaVita Consulting, Ljubljana, Slovenia; [e]Department of Landscape Management & Restoration Ecology, University of Applied Sciences Erfurt, Erfurt, Germany

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Wolfgang Junk and Florian Wittmann.

Glossary

Alluvial river Self formed river in which the bed and banks are made up of mobile sediment.
Confined river River characterized by a straight channel and few bends.
Fluvial Processes and landforms created by the flowing water.
Geological age Describes the timing and relationships of events in geologic history.
Gravel-bed rivers Coarse-grained alluvial rivers which are particularly characterized by dynamic fluvial processes that constantly change and renew the surface and subsurface of the river's valley floor.
Last glacial maximum The LGM was the most recent time during the Last Glacial Period where the ice sheets were at their greatest extent.
Meandering river Strongly winding river course with a sinuosity greater than 1.5.
Morphodynamics Landscape changes due to erosion and sedimentation processes.
Multi-thread anabranching river River with braided to sinuous-meandering channels usually with vegetated islands.
Multi-thread bar-braided river Braided river with almost only unvegetated gravel bars within the active channel.
Multi-thread island-braided river Braided river with vegetated islands within the active channel.
Permafrost Soil, sediment or rock which has in varying thicknesses and depths below the earth's surface been continuously exposed to temperatures below freezing point for at least few years.
Pseudo-meandering river Straight or sinuous channel that display large, alternate bars at low flow.
Sinuosity Ratio of channel length to valley length.
Specific stream power Represents the amount of work that a river may do.
Transitional wandering river Transitional channel form between fully braided and oscillating/sinuous patterns.

Introduction

Globally, mountain ranges cover 22% of the overall land area and provide space to live for 915 million inhabitants (Romeo et al., 2015). Formed by ongoing or abandoned plate tectonics, they constitute impressive landscape regions, which occur in every continent. Closely associated with the orogeny, or mountain development, a multitude of smaller and larger fluvial systems originate from, or are entirely located within the mountainous terrain (Paixão and Kobiyama, 2019). The morphological variety of these mountain rivers reflects the diverse nature of the individual mountain ranges in terms of geological age, tectonic processes, lithology and climate (Wohl, 2010). Besides typical bedrock-confined or braided channels, the spectrum of alpine river channel types also includes sinuous, transitional or even meandering forms (Hohensinner et al., 2019).

As recognized by the FAO, mountain rivers are of great importance worldwide because half of the world's population obtains drinking water from mountain catchments (FAO, 2014; Huss et al., 2017). Additionally, they provide habitats for many specially adapted animal and plant species, thus providing important contributions to global biodiversity (Arscott et al., 2003; Gray and Harding, 2007). Mountain rivers support some of the most endangered ecosystems worldwide due to the human impacts to their hydrologic and sediment regimes by river dams and diversions for flood control, hydropower generation and water storage, and

river flow regulation for irrigation and other human demands (Bravard et al., 1986; Hauer et al., 2016; Hohensinner et al., 2021; Müller, 1995; Tockner and Stanford, 2002; Tockner et al., 2006). Another threat to the biodiversity is their vulnerability to invasion by alien, or non-native plant species because they provide barren sites for seedling colonization and the river flows serve as seed dispersal pathways (Liendo et al., 2015).

Against this background, this chapter reviews the worldwide distribution of common river channel types in mountain ranges and determines their characteristics on a global scale. Accompanying this overview, braided rivers are analyzed in more detail relative to the physical and habitat characteristics. Braided river channels occur primarily in mountains and their foothills, and thus represent distinctive aquatic ecosystems with a global distribution.

Braided rivers are characterized by mobile, multi-thread channels within gravel or sand-dominated fluvial corridors (Gray and Harding, 2007; Leopold and Wolman, 1957; Rinaldi et al., 2016). These braided channels are characterized by continuous change, in sharp contrast to the more stable surrounding landscapes. Mountainous braided rivers are determined by dynamic flow and sediment regimes, the hydrodynamics and morphodynamics, respectively. These especially occur with high, late spring and early summer flows caused by rapid snowmelt, when the melt coincides with periods of high rainfall, and rain-on-snow provides further runoff contributions (Bristow and Best, 1993; Bridge, 1993; Pomeroy et al., 2016; Tockner et al., 2006).

Another fundamental factor leading to the development of braided river channels is high sediment supply of coarse substrates which originate from the steep mountainous catchments with high erosion rates. This braided channel form often accompanies reduced sediment transport capacity due to a decline in the river gradient, often combined with valley widening (Ashworth et al., 2004; Hohensinner et al., 2021; Piégay et al., 2009). This leads to sediment deposition that chokes the channel, leading to relocation and often channel splitting, or bifurcation. With these repetitive processes, braided river channels are repeatedly reshaped by floods of annual or sub-annual frequency (Rinaldi et al., 2016). These dynamic processes and environmental parameters of braided rivers channels have been investigated for different spatial scales, from river sections to catchments and mountain regions, as well as for entire mountain ranges. The braided river channels are classified as wetlands in a broader sense in this chapter and their description includes characteristics of the aquatic zone as well as of the transition zone. The majority of research publications originate from northern temperate sites and the underlying processes may be similar in many other mountain regions (e.g. Hohensinner et al., 2021; Sambrook Smith et al., 2006; Surian and Fontana, 2017; Tockner et al., 2003, 2006).

Definition and classification of mountainous river channel types

The study area is based on map data of Natural Earth (2018) and ESRI (2016), and includes 204 major mountain ranges of the world. To provide global conclusions regarding the typical physical and habitat characteristics of different channel types, 120 representative reference catchments were selected based on stratified random sampling. Within these reference catchments, the morphological channel types were determined for all river reaches within the limits defined by the Natural Earth (2018) and ESRI (2016) data. These river reaches were analyzed with respect to their physical and habitat parameters and the properties refer to the entire categories.

The 204 mountain ranges of the world were classified in categories comprising two decisive aspects: geological age of mountain range and degree of glaciation of catchment area under current conditions or in the last glacial maximum (LGM; RGI Consortium, 2017; Ehlers et al., 2011) (Fig. 2). The age of mountain range is important because correlations were detected with elevation, stream gradient and soil erosion. Younger mountain ranges have higher erosive processes which increase sediment supply in river reaches, which subsequently favors the development of braided channel types (Hohensinner et al., 2021; Mueller and Pitlick, 2014; Piégay et al., 2009). In addition, the degree of glaciation also increases sediment supply by increasing soil erosion and seasonal floods (McKernen et al., 2018). This also lowers water temperature and provides cool air drainage, which impedes the establishment of plants, further fostering the evolution of braided channel patterns (Huss et al., 2017).

Bivariate categories were defined by the combination of four ice cover classes: (i) recent high (>10%); (ii) recent low (>0–10%); (iii) no current ice cover but in LGM; and (iv) never ice-covered. Three geological age classes were determined by literature research: (i) young, Cenozoic (<66 MYA, million years ago); (ii) medium, Mesozoic (66-252 MYA); and (iii) old, Paleozoic (>252 MYA). Categories were investigated according to the distribution of channel types and those with few results and lacking significant differences were combined, which lead to a classification of eight categories (see Fig. 2): (1) very high ice cover and young or medium age, (2) high ice cover and young age, (3) ice cover in the LGM and young age, (4) never ice-covered and young age, (5) high ice cover and moderate or old age, (6) ice cover and moderate or old age, (7) never ice-covered and moderate age, and (8) never ice-covered and old age.

Fifteen representative river catchments were randomly selected for each category, and these were globally distributed in 77 of the worldwide mountain ranges. The subsequent analyses were based on these 120 reference catchments (Fig. 2; Table 1).

Inside the catchments, all rivers which have been identified by Linke et al. (2019) were considered and calculations were based on river reaches with relatively homogeneous boundary conditions, consistent process-form interactions and with a new reach starting at the confluence of another water body (Gurnell et al., 2016). For the European Alps, historical river data were used due to the extensive human impacts on those rivers (Hohensinner et al., 2021).

Following Rinaldi et al. (2016) and Hohensinner et al. (2019), the classification of channel types was based on the number of river branches, sinuosity, and the proportion of vegetation versus open substrate within the active channel. Subsequently, channel types and their percentage per river reach were determined by interpretation in QGIS from Google maps, Bing maps and satellite

Table 1 Category number, continent, climate zone, age of mountain range (Age Mt.R.: Cenozoic (Cz), Mesozoic (Mz), Paleozoic (Pz)), ice coverage of catchment during last glacial maximum (IC LGM), ice coverage area under current conditions (IC C) and proportion (%) of the four common river types braided river (BR), transitional gravel-bed rivers (TR), single-thread confined rivers (CR) and meandering rivers (MR) for the 120 reference catchments.

images. Several channel types can occur for each river reach and were considered as subreaches when they exceeded 20% of the reach length. In that case, the proportional length of each channel type was calculated for each river reach.

In total, 11 different classes could be sequenced by form: confined, multi-thread bar-braided, multi-thread island-braided, multi-thread anabranching, transitional wandering, transitional pseudo-meandering, single-thread meandering, highly altered/modified reaches, glacier lakes and braided meltwater brooks, rivers in glacier areas, and unclassifiable river reaches due to incorrect positioning. The unclassifiable rivers represented 8.9% and were excluded, along with the sparse classes: rivers in glacial areas (4.9%), glacial lakes and brooks (3.0%) and the anabranching class that included anastomosed rivers (0.6%). There was subsequent grouping of related classes to provide four common, composite channel types, which represented 82.6% of the total river reaches. These predominant channel types were: (i) multi-thread braided rivers (BR), (ii) transitional gravel-bed rivers (TR) which include transitional wandering and pseudo-meandering rivers, (iii) single-thread confined rivers (CR), and (iv) meandering rivers (MR). Following this classification, in the 120 river catchments (total 511,839 km^2 catchment area) there are 13,537 river reaches with a mean length of 3.9 km (total length of 53,085 km). Within these reaches, a total of 18,279 subreaches of the four dominant channel types could be distinguished and were analyzed considering their geomorphological channel types, and physical and climate parameters (Global Drainage Basin of Masutomi et al., 2009; and HydroATLAS of Linke et al., 2019).

Channel type distribution and environmental factors

The most common channel types in the mountain areas are confined rivers with 49.3% and transitional gravel-bed rivers with 37.3%. Braided rivers account for 8.3%, whereas meandering rivers are less common, representing 5%.

Table 2 provides an overview of the key physical and habitat parameters of the analyzed channel types for the locations presented in Fig. 2. Braided rivers are characterized by high soil erosion and correspondingly high sediment supply. That exceeds the transport capacity of the river which leads to their characteristic sand and gravel bars between numerous, interwoven flow channels (Buffington and Tonina, 2009; Hohensinner et al., 2021; Montgomery et al., 1996; Piégay et al., 2009). Sediment supply is highest in catchments with glacier areas, while soil erosion is more pronounced than in areas that are not affected by glaciers. Thus, the study underlines the decisive role of sediment supply in determining the channel type (Mueller and Pitlick, 2013, 2014). Glacier cover and a climate of cold temperatures and low precipitation also inhibit the establishment of vegetation, which also contributes to increased soil erosion and high morphodynamics.

In the long term, the retreat of glaciers leads to reduced runoff and reduced erosion (Huss et al., 2017; Huss and Hock, 2018; O'Neel et al., 2014). There is subsequently a decrease in bedload and suspended sediment load (Fleming and Clarke, 2005; Milner et al., 2017; Singh et al., 2016), and decreasing sediment availability (Moore et al., 2009), transport capacity and stream power (McKernen et al., 2018; Raymond Pralong et al., 2015). Confined and transitional gravel-bed rivers differ substantially, and according to Cohen, 1992; see Table 2) the primary effect size is in the amount of bare areas relative to the braided rivers. Compared to braided rivers, transitional gravel-bed rivers have a slightly lower specific stream power, which provides a surrogate for transport capacity. However, they can transport the incoming bed load due to smaller volumes of sediment supply and the focussed single river arm. Alternately, confined rivers are primarily characterized by their high stream gradient, which prevents the deposition of sediments. Finally, meandering rivers occur in warmer and wetter regions that are characterized by less permafrost and smaller glaciers, which in turn lead to increasing proportions of artificial impacts and cultivated areas.

The reaches of the transitional gravel-bed rivers are characterized by reduced soil erosion and higher upland forest cover in the catchment, warmer temperatures, higher precipitation, and greater evaporation in the river reach, as compared to braided rivers. Glacier and snow cover and permafrost proportion are less extensive in the associated catchment areas for the transitional gravel-bed rivers. Also compared to braided rivers, the transitional gravel-bed rivers occur at lower altitudes and have shallower channel slopes, while the average runoff is comparable but less variable. The subsequent decline in morphodynamics facilitates the establishment of vegetation in the active riverbed and initiates the transition from multi-channel braided rivers to single-channel transitional gravel-bed rivers (Kondolf and Curry, 1984). This trend continues with further decrease in morphodynamics, so that succession occurs, and more floodplain forest can establish following the 'fluvial biogeomorphic succession concept' proposed by Corenblit et al. (2007).

Confined river reaches have comparatively less soil erosion and higher forest cover than braided river reaches. Precipitation, temperature and evaporation are also higher, and the catchment areas have limited snow cover and very low proportions of glaciers and permafrost. Confined rivers have the steepest gradient and the smallest catchment area above their river reaches. The reaches mainly occur in higher elevations but occasionally also in lower areas. Their discharge is generally low and less variable. They occur predominantly, but not always, in the upper reaches of river catchments.

Meandering rivers are characterized by lower stream gradients compared to other channel types. They show higher discharges than most of the other channel types, and with less variability. The reaches occur in warmer and more humid climates so that the vegetation can establish more easily.

The distribution of the channel types with respect to the three mountain age classes shows that the braided river proportion is higher in the young mountains from the Cenozoic era with 62%, intermediate in the medium old mountains from the Mesozoic era with 24%, and only 14% occur in the old mountains from the Paleozoic era. The meandering rivers also have a higher proportion in the younger mountains (young/medium/old: 48/31/21%). In contrast, the transitional gravel-bed rivers (35/33/33%) and the confined rivers (28/35/37%) have approximately equal distributions in all three mountain age classes.

Table 2 Physical and habitat parameters of all channel types (Md: median, M: arithmetic mean).

Percentage values are based on the dominant river type of the reach. Superscript numbers indicate significant differences of other channel types compared to braided rivers by Kruskal-Wallis-Test (Kruskal and Wallis, 1952) and Dunn's-Test (Dunn, 1961), with different effect sizes according to Cohen (1992).

[a]0.3–0.5, medium effect.

[b]0.1–0.3, weak effect.

[c]>0.5, strong effect.

On a global scale, braided rivers are mainly distributed in the young mountain ranges with high ice cover (see Fig. 3). In the Category 1 combination of young and moderate-aged ranges with very high ice cover, the braided rivers represent about 20%, followed by Category 2 with high ice cover with about 15%. Within Category 1 the reference catchment of Alaska mountains contains the highest percentage of braided rivers (92.1%), followed by Vatnjajökull, Iceland (79.8%). Categories 1 and 2 include parts of the Canadian and Alaskan mountain ranges on the west coast, parts of the Southern Andes and high proportions in the Central Asian mountain ranges such as the Himalayas and the Tian Shan (Central Asia), and there is a noticeable decline in the occurrence of braided rivers with declining ice cover. Even formerly glaciated young mountain ranges of Category 3 have rather low median river length of braided rivers, but the high upper quartile values of almost 20% show the considerable occurrence of braided rivers like the reference catchments of the Elias Range (Canada) at 44.8%, the European Alps (prior to the extensive river regulation in the mid 19th to early 20th century) at 42.0% and the Chukchi Range (Russia) at 34.1%. Young mountain ranges that were never glaciated (Category 4) had low proportions of braided rivers but with a few exceptions including the Arabian mountain range (reference catchment of Al Hajar Mountains at 22.1%). Older mountain ranges with elevated ice cover had some braided rivers (Category 5; reference catchment of Cherskiy Range (Russia) at 30.4% and of Mackenzie Mountains (Canada) at 23.6%). In the remaining categories 6 to 8 there are few braided rivers (see Table 1 for selected characteristics of all 120 reference catchments).

About two-thirds of the investigated braided rivers are located in cold and wetter climates (Fig. 4). One peak of occurrence lies in extremely cold and wet climates such as the North Saskatchewan River (Fig. 5), with another peak in extremely cold and mesic climate (White River and River Lech; Figs. 1 and 6). There are occurrences in cool and moist (Rio Petrohue; Fig. 7), warm and mesic (Vjosa; Fig. 8), and cool and dry climates (River Naryn; Fig. 9). Some occurrences are also found in hot to the extremely hot and xeric to arid climates like the wadis of the Arabian Peninsula (Rostam River; Fig. 10).

There were also other environmental influences on the distribution of braided rivers (Fig. 11). Water area at mean water discharge covers only small amounts of braided river reaches (1.6%, SD 7). On average almost 22% (SD 29) of the catchments of braided rivers are covered by bare bedrock, gravel and sand bars and even more by herbaceous vegetation (40%, SD 32). Later succession stages cover a lower percentage, with 6% (SD 14) for shrubs and 9% (SD 19) for trees. Since the main global distribution of braided rivers lies in cool climates, average snow and ice cover approximately 16%. Human impact is rather low for braided rivers and artificial and cultivated areas cover only approximately 3% of upstream catchment areas. These percentage values are based on the dominant river type of the reach but there is substantial variation within and across the watersheds for the braided rivers (Fig. 11).

The average temperature of braided rivers is just below freezing (0 °C; Table 2). This provides an important difference from the other river types that occur in substantially warmer regions. For the median minimum temperatures, even the upper quartile of braided rivers is below the freezing temperature (Fig. 11). Conversely, a few outliers are located in much warmer climates with average and minimum median temperatures of more than 20 °C. Climate is generally dry with three-quarters of catchments with less than 1000 mm of precipitation, but outliers extend up to about 4000 mm.

Fig. 1 The White River (Alaska) is one of the largest tributaries of the Yukon River. It is glacier-fed and characterized by enormous sediment loads, which form the valley-wide braided river channel. The climate zone is extremely cold (temperature class) and mesic (aridity class; see Fig. 4). Photo: G. Egger.

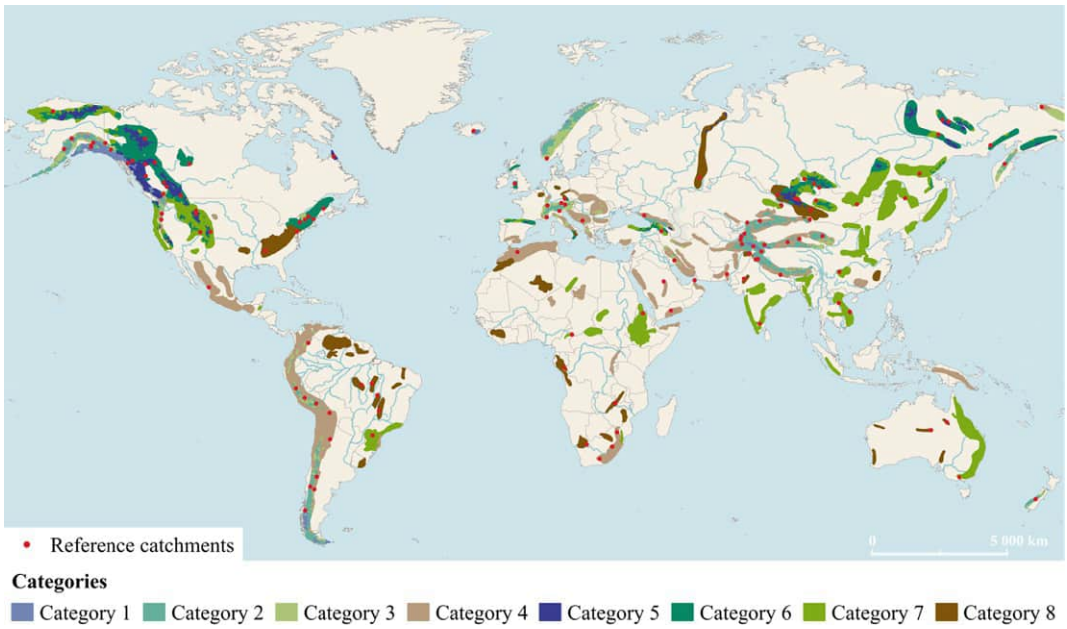

Fig. 2 Global distribution of the nine different bivariate categories of mountain ranges and locations of the 120 reference catchments (red dots - data sources: ESRI, 2010; ESRI, 2016; Natural Earth, 2018).

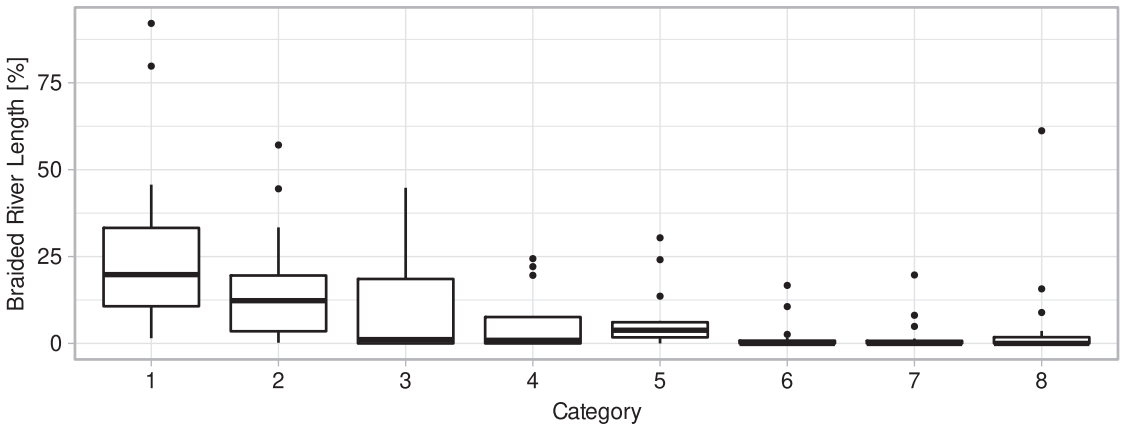

Fig. 3 Percentage of braided rivers by length of all rivers in the 15 reference catchments for each of the mountain categories (see Fig. 2).

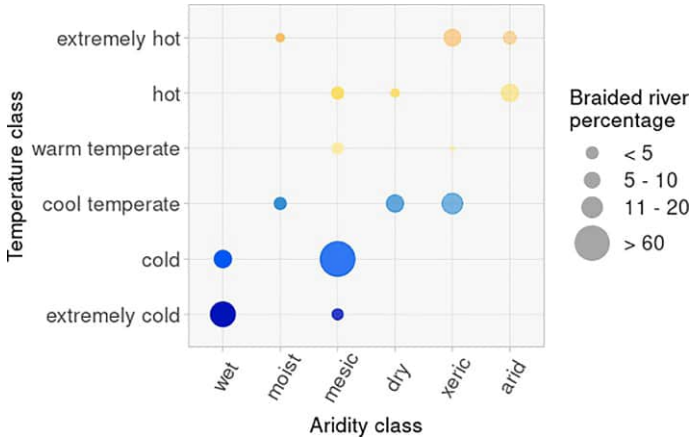

Fig. 4 Global occurrence of braided rivers in different climates categorized by temperature classes (growing degree-days on a 0 °C base (GDD), reflecting latitudinal and altitudinal temperature gradients; Metzger et al., 2013) and aridity classes (aridity index; Trabucco et al., 2008).

Fig. 5 The North Saskatchewan River in the Rocky Mountains in Banff, Canada, displaying the dynamic, braided channel form, with multiple shallow, interwoven channels and relatively barren islands. The climate zone is extremely cold and wet. Photo: S. Rood.

Fig. 6 The River Lech is one of the last near to natural braided rivers in the Eastern Alps (Austria). The climate zone is extremely cold and mesic. Photo: C. Damm.

Fig. 7 The Rio Petrohue nearby Chaiten is a typical island braided river of the Andes (Patagonia). It is characterized by largely natural forests in the catchment area, which have not become victims of the fire clearing. The climate zone is cool and moist. Photo: G. Egger.

Fig. 8 The Vjosa is the largest braided river in the Balkan region, which flows into the Adriatic Sea. It is characterized by natural morphodynamics. The riparian forests of the floodplain zone, on the other hand, have largely given way to farmland. The climate zone is warm and mesic. Photo: G. Egger.

The upstream river catchments of the braided rivers mainly have glacier extents below 10% of the area but some cases have with more ice cover. Snow cover is generally high, with half of the upstream areas ranging between 20% and 70%. Permafrost cover is substantial but variable in the braided rivers with a median of about 50% (Fig. 11).

For one quarter of the braided rivers, the catchment area is characterized by a higher proportion of unvegetated bare land. The amount of artificial/cultivated land as a surrogate of anthropogenic impact is rather low for braided rivers. Median forest extent is also very low with the upper quartiles reaching about 8% of upland areas. However, both indices have a broad distributions and outliers with values approaching 100% (Fig. 11).

Fig. 9 The Naryn is one of the biggest rivers in the Kyrgyz part of the Tian Shan Mountains and is overall the most water-rich river in the country. The climate zone is cool and dry. Photo: F. Betz.

Fig. 10 The Rostam River is located in the south of Iran and flows west of Bandar Abbas into the Persian Gulf. The climate is extremely hot and arid. Photo: G. Egger.

Conclusion and synthesis

Here, we present a global analysis of river channel types in mountain ranges. Globally, confined rivers and transitional gravel-bed rivers are the most common river types of mountain ranges, combining to represent 87% of rivers. A very small proportion of mountain rivers is represented by the meandering channel form (5%).

We emphasize the braided rivers that display a distinctive form with multiple, dynamic and interwoven channels, which is uncommon in other landscapes. The braided river form accounts for only a relatively small proportion of the total length within mountainous areas, with approximately 8%. However, there are large regional differences which reflect climate, historical and contemporary ice and snow cover and mountain age. The decisive parameters for the development of the geomorphological channel types are soil erosion, stream gradient, glacier cover and climate. Surprisingly, the local geology displayed limited influence on the expression of the channel types.

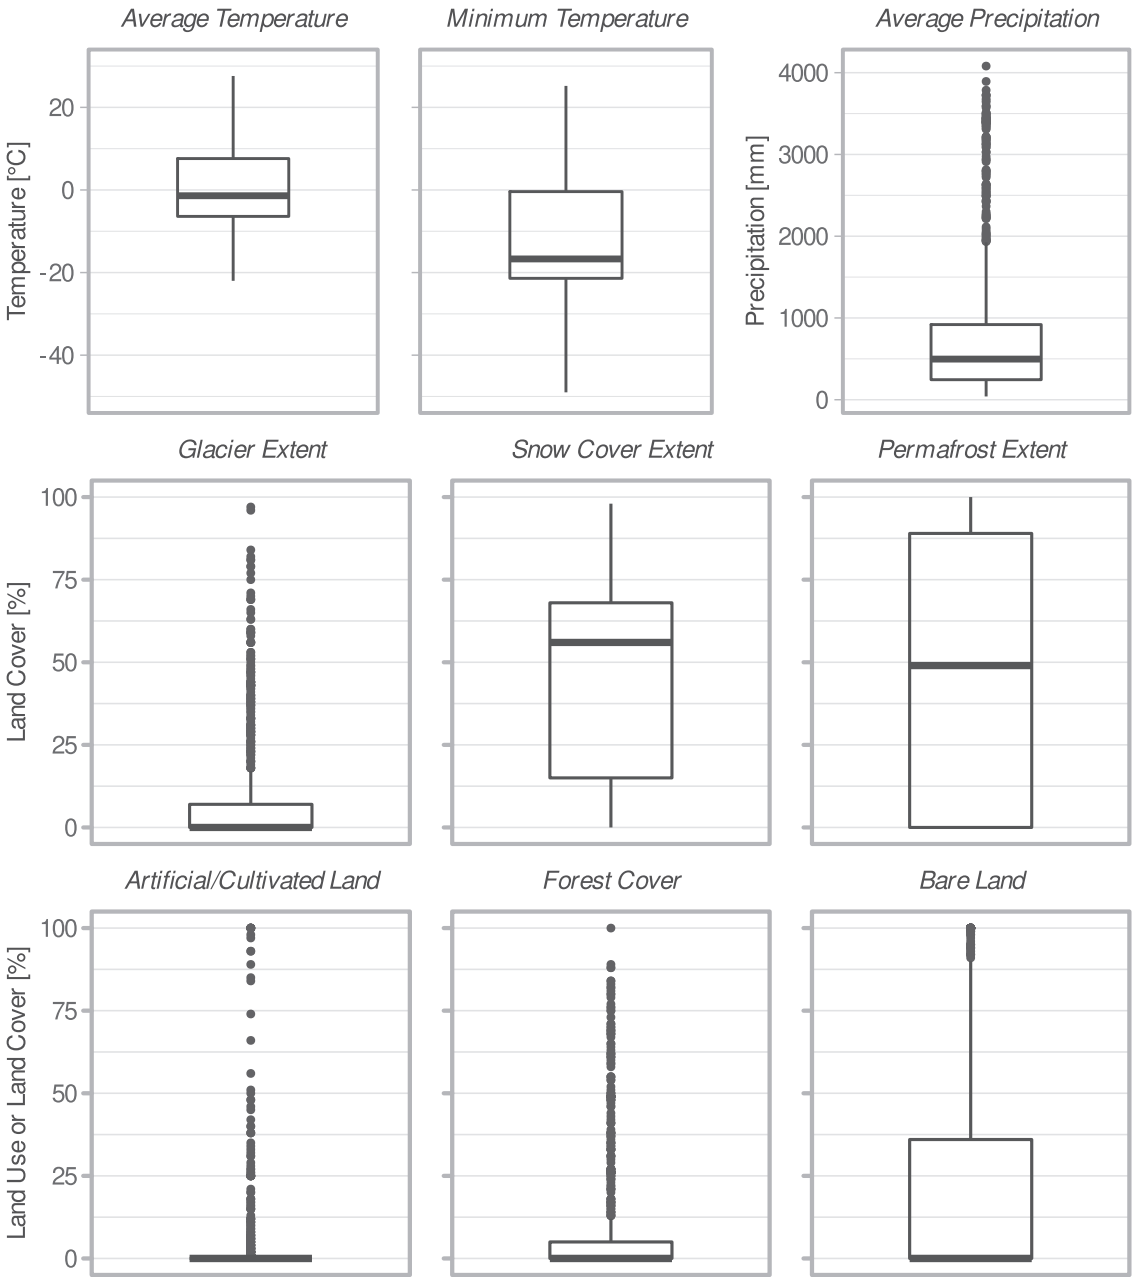

Fig. 11 Selected physical and habitat parameters of braided rivers.

Our study revealed that braided river reaches are characterized by extensive soil erosion, low temperatures, low precipitation and evaporation, and limited forest cover. The catchment areas are characterized by large snow and glacier cover extent and high permafrost percentage. The braided rivers generally occur in high altitudes and have comparatively steep stream gradients. Compared to other channel types, they commonly have lower but variable discharge regimes. The predominant proportion of braided rivers occurs in temperate to arctic boreal regions but a second, smaller distribution is in the dry-hot and vegetation-poor desert areas of the Middle East.

This study provides an initial overview of the physical and ecological relationships and effects of primary parameters on the characteristics of mountain river channel types on a global level.

Future research

However, there are still questions that need to be clarified. In particular, the effects of climate change in connection with the melting of glaciers, warmer temperatures and reduced runoff and sediment availability, must be examined and whether this could subsequently lead to a further decline of the proportion of the distinctive, braided river form.

Glossary

Eutrophic Nutrient-rich.
Geomorphology Study of Earth surface landforms and landform processes.
Hydrosere A typical sequence of organisms, particularly plants, that occur as water-bodies get shallower over time.
Hyporheic flow The flow of water through gravels normally in a river.
Limnophilic Fish that typically live in lakes.
Ombrotrophic mire Mire fed by only precipitation and usually domed above the local watertable.
Paludification Drowning by a rise in the water-table.
Rheotrophic Taking nutrients from flowing water.
Saproxylic Living on dead or decaying wood.

Introduction

River wetlands can be broadly defined as wetlands on river floodplains, and they can be classified in various ways; geomorphologically on their formation or genesis, hydrologically from their principal source(s) of water, and biologically on their ecology/hydroecology, particularly their vegetation. Together the geomorphology and hydrology form the abiotic template that conditions the biotic response, although other factors, most notably climate and land use change are clearly important. As can be seem from Fig. 1 these aspects are inter-related to a large degree, but any floodplain can have a mix partly dependent upon size, climate and history. The aims of this chapter are to summarize the past and present distribution of these systems and examine the interactions of the abiotic templates with ecological processes. This has relevance in conservation, management and restoration, and is a high priority because these ecosystems have been impacted, even before the Anthropocene, more than any other due to the high potential of floodplains for agriculture and human settlement (van Diggerlen et al., 2006). In a recent analysis of hydro-climatic changes of wetlands globally it was found that cold Temperate and Boreal wetlands had experienced the most warming and reduction in runoff in comparison with other biomes (Åhlén et al., 2021).

The distribution of river wetlands in both the Temperate and Boreal zones is closely associated with the distribution of lowland river and floodplains on the Earth's surface. In the Boreal zone nearly all floodplains have been glaciated and so rarely contain sediments or landforms that pre-date the last glacial period. Functioning wetlands (so excluding paleo-systems) are preferentially located along the lower sections of river valleys where the geomorphology is conducive to wetland formation (an exception to this are flow-through mires located above glacial sills in upland valleys). In the Temperate zone the same applies in areas that were glaciated but outside these areas wetlands can be of greater antiquity, especially where there is a tectonic component producing long-term subsidence. This applies to several riverine wetlands such as Padul in Southern Spain and the Lake Balaton wetlands in Hungary. The largest areas of riverine wetlands occur along deltaic river reaches across the freshwater—marine transitional zone,

Type	Formational processes	Typical size (km^2)	Connectivity	Comments
Headwater flow-through mires	Cirques, springs, infilled tarns	0.01-1	High	Sphagnum peat dominated
Valley-floor mires	Glacial or fluvial erosion	0.05-5	High-moderate	Sphagnum peat, also woodland (fens), reedbeds
Channel cut-offs (oxbow wetlands)	River channel change (avulsions)	0.01-0.1 (dep. upon river size)	Moderate-low	Open water to wet woodland
Glacial depressions	Formed on low terraces due to dead-ice or subglacial erosion (kames, kettles etc.)	0.001-0.05	Low	Open water to sphagnum mires, can go ombrotrophic
Undefined alluvial backswamps	Fluvial or glacial erosion	0.1-10	Moderate-low	Sphagnum mires, reedbeds, wet woodland, can go ombrotrophic
Tectonic depressions	Graben-type subsidence	1-10s	Low (internal drainage)	Sphagnum mires, reedbeds, wet woodland, can go ombrotrophic
Delta backswamps	Avulsions, levee formation, coastal processes	0.1-10s	Moderate	Sphagnum mires, reedbeds, wet woodland (drained), can go ombrotrophic

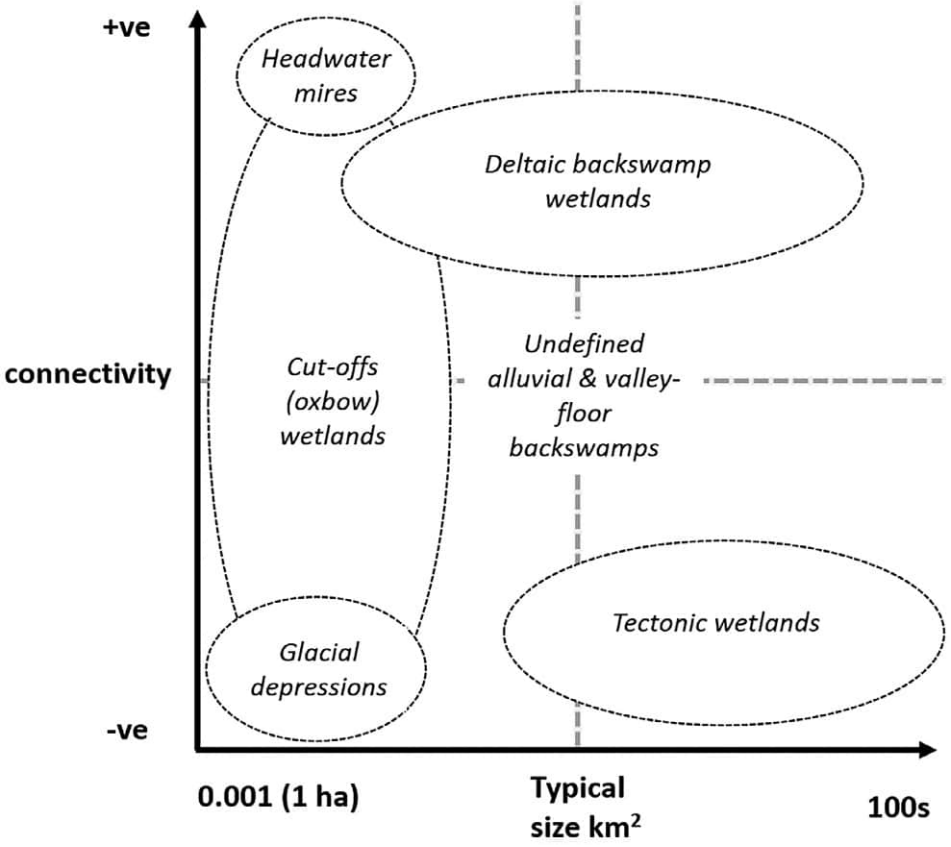

Fig. 1 A classification of temperate river wetlands with typical size and connectivity.

which would naturally make up much of the deltas of all the major rivers in the Temperate zone. However, most have been hugely impacted by channelization, drainage and agricultural improvement leaving only parts of a few such as the Rhone (Camargue), Loire (La Briere), Guadalquivir (Coto Doñana), Danube and Volga, with any functioning wetlands. These systems are also potentially liable to increased saline water-incursion with projected continuing sea level rise.

In glaciated areas there are three principal geomorphic features that produce wetlands; firstly, on-stream lakes that have partly or wholly terrestrialized, secondly back swamp areas with high water-tables but low rates of clastic (non-organic) sedimentation, and lastly cutoff river channels (paleo-channels or oxbow lakes/wetlands). The latter two types are a direct result of river behavior during this Interglacial, including whether the river system is multiple channel (anastomosing) or meandering, and the rates of channel change. An often overlooked mechanism for the development of organic deposits on floodplains is the development of river levees which form due to the rapid settling-out of suspended and saltating sediment from rivers when they flood. The other cause is permanent, or long-term, saturation by high groundwater-tables augmented by floods. Floodplains are normally located at the point at which the regional water-table intersects the land surface, and so springs are often found at the floodplain edge, with upwelling groundwater at topographic low points under artesian flow (pressurized flow). The wetland is also frequently connected at depth to the floodplain water-table and the river level (shallow groundwater).

Many studies have shown that it is the groundwater, and particularly this shallow (alluvial) groundwater, that maintains wetland water-tables and hence wetland biotic functions (Fig. 2). It follows that reductions in regional water-tables affect floodplain wetlands, and sensitive wetlands, where the water budget is finely balanced, are vulnerable to any change in water fluxes such as reduced precipitation. Since it is impossible for societies to control precipitation, and difficult to modify the river hydrograph, although not impossible (Lane, 2017), hydrological restoration of wetlands has therefore generally focused on the option of retaining water by reducing water losses. The fundamental driver of both floristic composition and biotic functions is the high water-table and its augmentation by both groundwater and nutrient inputs from the river. Isolated lakes or wetlands fed by non-calcareous groundwater progress through bryophytic succession to moss-carpets (sometimes forming floating mires) and then to raised or ombrotrophic (rain-fed) mires which rise to a dome above the floodplain surface. Although located on floodplains and draining into the river, these raised mires are not truly river wetlands as their inputs from the river and groundwater are minimal, or zero. However, where the groundwater is base-rich then fens form and since these cannot grow above the water-table (unless they become ombrotrophic) they tend to remain closely connected with the river system even if only in the largest floods. These are the most common river wetlands in the Temperate zone and include monocotyledon (grasses, sedges) dominated systems (e.g., reed-beds), shrublands and wet heaths, and forests in both North America, including Alaska (*Populus-Picea-Alnus-Salix*), and Europe (*Picea-Alnus-Salix*). Here nutrient cycling is controlled by both the groundwater input and also the quality and frequency of floodwater inputs from the river. All of these systems, including on-stream lakes, accumulate organic carbon largely from autochthonous (within lake) production.

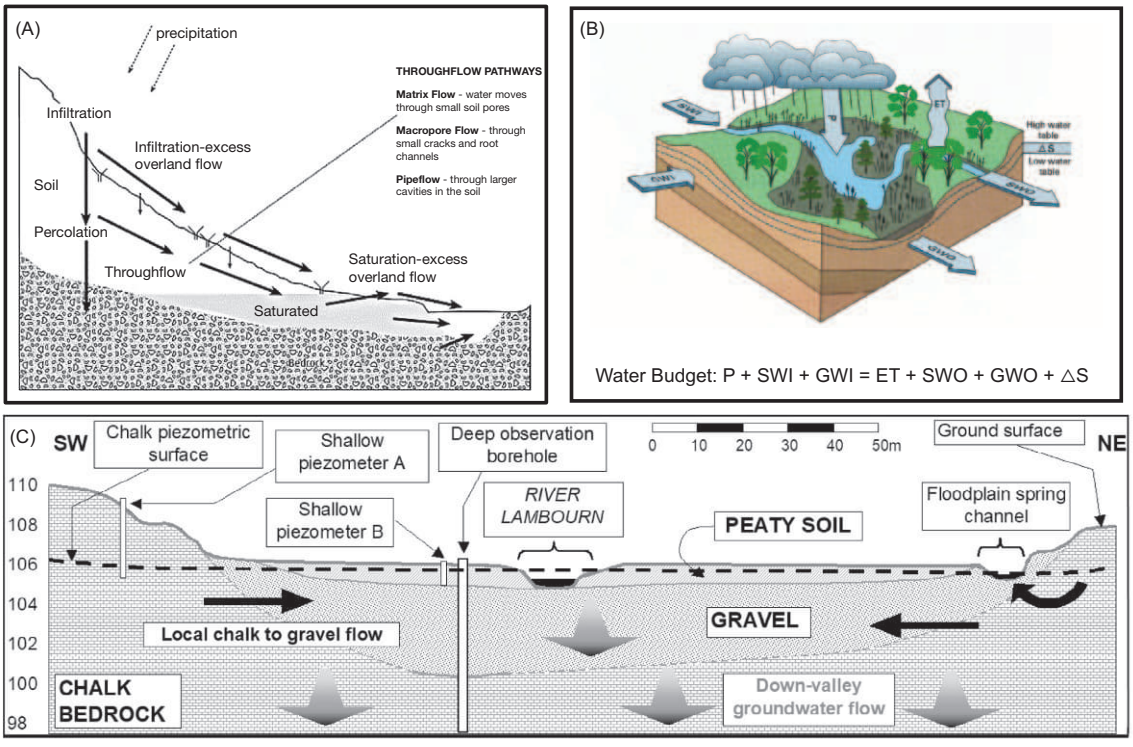

Fig. 2 Riverine wetland hydrology; (A) slope base river-marginal mire with throughflow pathways, (B) a riverine wetland water budget (Carter, 1996), (C) a conceptual model of the hydrological budget for a floodplain on pervious rocks from Grapes et al. (2006). In budget equation P = precipitation, SWI = surface water inputs, ET = evapotranspiration, GWO = groundwater outputs, △S is changes in storage. Riverine wetlands, carbon storage and ecosystem services

Carbon can accumulate and be stored in riverine wetlands because the annual addition of biomass from vegetation and other inputs exceeds the rate of decomposition and outputs. This is particularly common in the Boreal zone where for much of the year air and ground temperature are below 4 °C thus inhibiting decomposition, and even at higher temperatures soils are often water saturated and anoxic. However, for the rest of the year, and year-round in the Temperate zone, both aerobic and anaerobic decomposition occurs, so these wetlands can also be a source of C emitted to the air in the form of CH_4. It is therefore also possible that if the organic matter falls, or decomposition rates rise, then these wetlands can switch to becoming a C source rather than sink. There are few realistic estimates of the magnitude of C storage in floodplain wetlands but organic carbon (OC) accumulating in the floodplain generally has two sources, from in-situ biomass and from soil erosion upstream. River-borne OC can have three environmental fates: first it can be lost as CO_2 due to microbial activity within the channel system (Wohl, 2016); second, it can be transferred to the ocean bound to particulate matter or in dissolved form and; third, carbon can be stored in floodplains resulting in a long-term C fixation within alluvial wetlands. From a monitoring study of an on-stream boreal fen system Zhang et al. (2020) have shown how CH_4 emissions were lowest close to the stream and highest at intermediate distances.

A typical feature of pre-deforested Temperate floodplains and Boreal floodplains is the localized accumulation of peaty sediments in the form of rheotrophic-eutrophic fens. These peats are part of the sink term prior to disturbance that should be considered when assessing anthropogenic floodplain C, although they are often neglected (e.g., Stallard, 1998). These have about 40–80% organic matter (OM) whereas overbank silt clay deposits may have 2–4% OM on average. Typically, floodplain sediment profiles do not show systematic changes of past decomposition with profile depth, although organic-rich sediments can have a high sensitivity to compaction and humification and so mass accumulation rates should be adjusted for these effects (Ramade, 2003). Calculations from the River Frome, UK, suggest that OM storage in the upper inorganic unit amounts to 348 m^3 ha^{-1} (i.e., post-2700 BCE) whereas the underlying organic rich unit contains about 3500 m^3 ha^{-1} and although its date of initiation is not known it is unlikely to have been deposited over >4000 years ago (Brown et al., 2018). An approximation for a pre-deforestation temperate floodplain is a mosaic of wet woodland and open reed/sedge dominated fen (nutrients moderate to high). Alder (*Alnus*) leaves can contribute 5–10 t ha yr^{-1} and sedge fen and reed beds up to 20 t ha yr^{-1} (Lüscher et al., 2004). However, this is offset by carbon loss as methane (CH_4) and CO_2 outgassing associated with microbial metabolism which depends upon the morphology and connectivity with the main channel (Foster et al., 2012). Overall Ricker et al. (2013) have shown that riparian forest can sequester twice as much as upland plots primarily due to lower microbial respiration and CO_2 efflux.

Anaerobic conditions common on floodplains, particularly in the Boreal zone, are also conducive to methane (CH_4) and nitrous oxide (N_2O) production. In periodically inundated systems, such as floodplains, methane emissions can be highly variable. In a study of the carbon implications of floodplain restoration on a section of the river Danube, Welti et al. (2012) showed that the hydrology, and particularly length of water interchange period, regulated potential denitrification rates but that more efficient N and C cycling could produce an overall reduction in potential N_2O emissions.

A potential additional factor which may ultimately resolve the short vs. long-term dynamics question, is the discovery that anaerobic microbial decomposition is not just energy and mineral limited (reduction of N and S based compounds) but thermodynamically limited by microbes "ignoring" carbon compounds that do not provide enough energy to be worthwhile to degrade and so end up accumulating (Boye et al., 2017). From these results it would appear that in their entirety and in the short-term, floodplain wetlands may be either carbon sources or sinks, depending on their hydrological regime, and can switch between being carbon sinks to becoming net carbon sources at a variety of temporal scales. This switching can be a natural process due to seasonal or other factors or can be affected by human management (Wohl, 2016). Wetlands are also an important source of riverine carbon (e.g., Yukon—30% from wetlands) which can be characterized using fluorescence spectroscopy (e.g., Spencer et al., 2012) and Fourier transform infra-red (FTIR) absorbance spectroscopy and which can carry adsorbed pollutants (Gallé et al., 2004).

Carbon storage is just one of a number of ecosystem services that river wetlands can provide. One of the most fundamental is their potential to attenuate flood-peaks and it is the decoupling (or reduced connectivity) and drainage of alluvial wetlands that is partly responsible for increased flood peaks downstream (Wohl, 2016). The reconnection of large back swamp wetlands, and even river cutoffs, is therefore a practical and efficient way to reduce at least intermediate flood hazard (Acreman and Holden, 2013). A second ecosystem service is the stripping of nutrients and pollutants from river discharge. This is far more complex and less well understood, but data from constructed wetlands in the temperate zone suggest that they can be effective in trapping diffuse nutrients/pollutants, such as phosphorus, from agricultural land (Ockenden et al., 2012). This has implications for climate-driven changes in river channel behavior, such as an increase in bank erosion, which could result in increased remobilization of these stored nutrients into the fluvial system.

Concepts and models

There are four concepts that have increased our understanding of the ecology of river wetlands over the last 100 years.

1) *Terrestrialization and the hydrosere*—the infilling of floodplain waterbodies and the systematic trajectory of plants with decreasing water depth over time: as used by Dachnowski (1912) and Clements (1916) it remains fundamental to our understanding of wetland status and change (Mitsch and Gosselink, 2015), although, if there is a climax state at all, it is either wet-woodland or

sphagnum mire (Walker, 1970; Klinger, 1996). Wetlands may also expand into 'upland' forest through the rise in the water-table or paludification (Klinger, 1996). The vast majority of peatlands on floodplains in the Temperate zone have lake sediments under the peat revealing that they were formerly lakes. This is a function of our current interglacial state whereby biotic production and catchment erosion inputs sediment to fluvial systems. This can be shown now by new molecular techniques (see "Methods" Section).

2) *The river continuum concept and wetland trophic structure*—the systematic change in ecology, particularly feeding guilds and organic particulate matter downstream in rivers as first outlined by Vannote et al. (1980). Although only directly applicable to on-stream wetlands, and even then only partially, due to discontinuities (Ward and Stanford, 1983), the downstream changes it describes are important for the nature of the riparian and littoral zones and wetlands along a river system.
3) *The flood-pulse* concept explains how the hydrograph (flood and drought) controls the lateral exchange of water and nutrients from the river into the wetland (Junk et al., 1989). Its relevance is therefore directly proportional to the connectivity of a wetland to the river system. The input of sediment is also important especially in deltaic wetlands.
4) *Intermediate disturbance hypothesis* which states that levels of disturbance that are neither too rare, nor too frequent, promote high biodiversity due to the balance of competition to physical disturbance and limits to re-colonization. Although normally attributed to Connell (1978) its history goes back to studies of competition in herbaceous vegetation (Grime, 1973) if not earlier (Wilkinson, 1999). Again although not directly developed for wetlands this hypothesis appears to be particularly applicable to many systems with complex trophic structure and a strong abiotic element which is not constant. The work of beavers (*Castor fiber/canadensis*, see "Restoration" Section) are an obvious example, but the interaction of fluvial processes with wetland plants creates high inter-patch heterogeneity, short-lived niches and structural complexity, all of which help to maintain high biodiversity (Davis et al., 2007; Brown et al., 2021).

New methods

The methods available for both recording and investigating the distribution, extent and processes of floodplain wetlands have increased dramatically in recent years. In particular, our ability to map at high definition has increased due to the availability of high-resolution satellite imagery (sub-m with GeoEye-1) in multiple wavebands including near infra-red (NIR). This has been matched by a growth in even higher resolution airborne remote sensing and also Lidar (Light detection and ranging) which can produce cm-scale digital elevation models (DEMs). This potentially also allows automated estimation of biomass, although this is still challenging for structurally complex non-forested vegetation (Riegel et al., 2013) when terrestrial laser scanners (TLS) may be a better option (Owers et al., 2018). Important variables such as total N concentration can be measured from a variety of hyperspectral sensors (Luo et al., 2016) including the Sentinel platform for soil moisture (Dabrowska-Zielinska et al., 2018; Klinke et al., 2018). The full capabilities of these new technologies have yet to be realized, but they offer the potential of mapping vegetation type, or vegetation assemblages, and the estimation of vegetation cover, photosynthetic area and other physiological variables particularly through the use of NIR and hyperspectral sensors.

A second area of development has been in hydro-ecological instrumentation. Electronic miniaturization has now made it both possible, and affordable, to install multiple automatic weather stations, thermometers, tensiometers, water quality sensors and water-level recorders linked to cheap data-loggers. This potentially allows several sites to be measured, or for large sites enables intra-site variability to be quantified. One reason for this monitoring is to provide validation of remote sensing-based monitoring including synthetic aperture radar for surface temperatures and thermal dynamics (Kaplan et al., 2018).

The last area of method development has come from the explosion of molecular techniques and particularly environmental DNA (eDNA). It is now possible to use water, surface peat, or sediment samples to determine a large proportion of the species present on a site, including plants, invertebrates, fish and algae both today (Taberlet et al., 2018) and in the past (Capo et al., 2021). A major effort worldwide is taking place to maximize the efficacy of this methodology and there are various different strategies (shotgun sequencing, metabarcoding, capture-probes) but the aim is to record at least the presence of a very high proportion of the taxa present (Alsos et al., 2018), and even, as in the case of fish, some estimates of abundance or biomass. To-date these new techniques have still to be improved to assess the condition of river wetlands but the potential is there. A variant, sedimentary ancient DNA (sedaDNA) can even be used to record site history back in time (Capo et al., 2021). An example is the Holocene hydroseral record of a small infilled lake system in SW Scotland, United Kingdom shown in Fig. 3.

Restoration, rewilding and urban river wetlands

Although the ecosystem service and biodiversity value of riverine wetlands has been the driver for floodplain restoration for over 30 years (an early example being on the Upper Rhine (Moss and Monstadt, 2008)), there was relatively little progress in Europe until the adoption of the Water Framework Directive. Restoration, or rehabilitation, generally involves trying to reconnect the wetland with the river to recreate something approaching a natural inundation regime. Actions such as blocking drains, not clearing-out aquatic vegetation, scrub removal and mowing, have been shown to have potential climate-mitigating effects (Bereezowski et al., 2018). However, a major problem is that success varies depending upon the catchment hydrograph, sediment conveyance and water quality, which for transboundary rivers may not even be under national control. Some of the best known

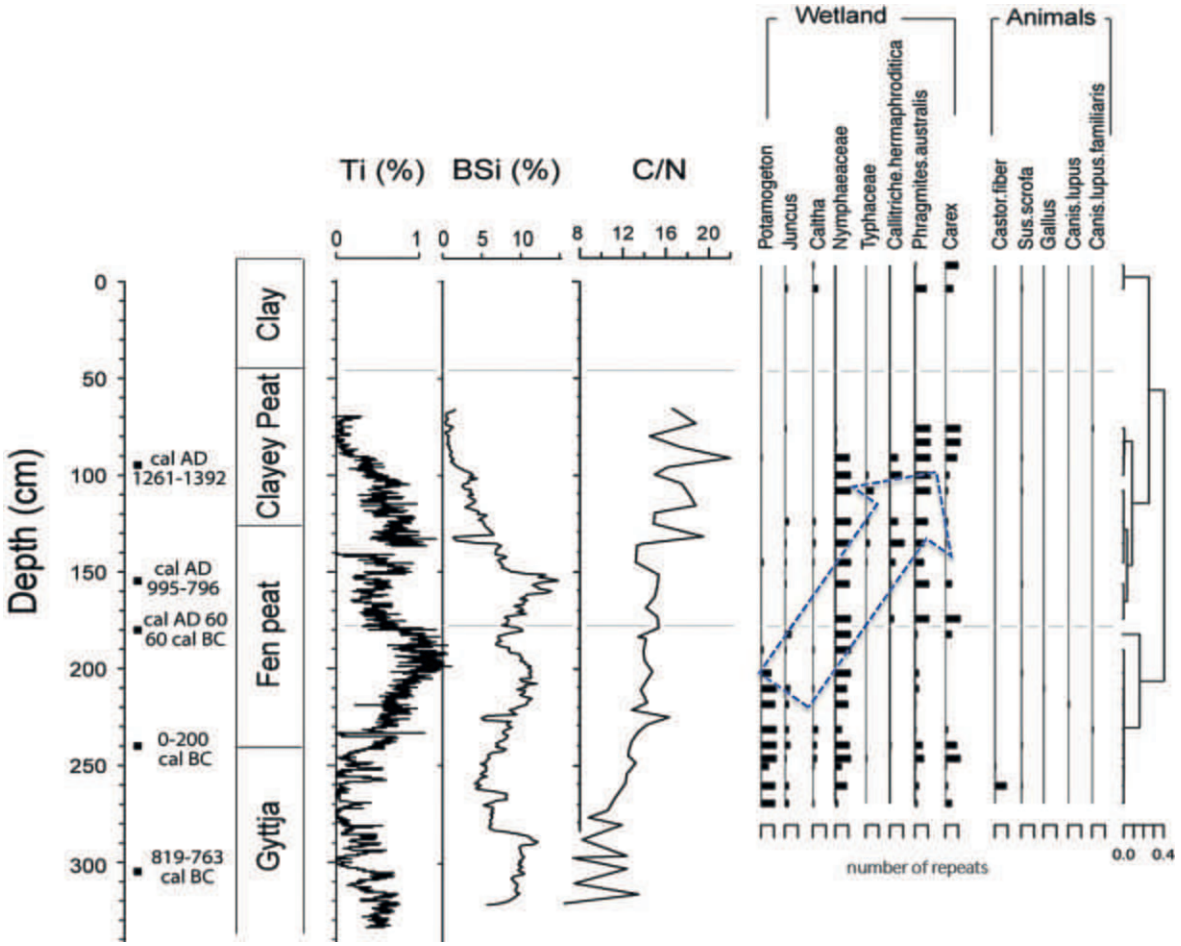

Fig. 3 The hydroseral succession signal of a terrestrialized on-stream lake-fen system form SW Scotland (Black Loch of Murton), United Kingdom determined using sedaDNA from metabarcoding. From van Hardenbroek Subm.

examples are attempts to reconnect wetlands with major rivers, such as reconnecting the Danube or the Rhine with more of its river corridor (e.g., van Alphen, 2019) and many smaller rivers in Europe (Gumiero et al., 2013; Brown et al., 2018). In some cases, this has also included attempts to restore biotic processes by re-introducing large herbivores such as ancestral (heck) cattle in the Netherlands and onto the Danube Delta (Stokstad, 2015). This is part of the growing fashion to 'rewild' wetland, or former wetland, areas. Whilst it can be argued that 'rewilding' is an inaccurate term, as these are still modified ecosystems, it can restore at least some biotic template functions. The best example is the recent fashion for beaver reintroduction across Europe (Vehkaoja, 2016; Brown et al., 2018). Re-introduction monitoring has shown that especially in headwaters, beavers increase dead wood and biodiversity in a range of organisms from beetles to bryophytes through paludification and increasing wetland area (Puttock et al., 2015; Brown et al., 2018).

Many cities in Europe were developed on or close to major wetlands (due their location as the lowest river-bridging point) and it follows that there is a huge potential for wetland restoration in these cities (Ehrenfeld, 2000). This also has been increased by the changing sewage treatment practices with the redundancy of so-called sewage farms and other large areas of effluent settling ponds. Cities with riverine wetland restoration schemes include London, United Kingdom (Barnes Elms reservoirs), Kristianstads, Sweden (Vattenrike), Amiens, France (Les Hortillonnages) and Bucharest, Bulgaria (Văcăreşti). This is part of the movement to create 'green' and resilient cities as recognized in the RAMSAR Wetlands Cities list.

Three examples

The three examples given here were selected to cover a range of spatial scales and river-wetland types. The first is typical of many, now isolated, wetlands on small temperate river floodplains, the second represents multiple small sites across the Boreal landscape, and the third typifies multiple wetlands in a large deltaic fluvial environment.

Small temperate floodplain wetland

Small wetlands on small-medium sized floodplains were extremely common up until the 18th–19th Century CE in both Europe and North America but were almost entirely drained for pasture, agriculture and development (Lewin, 2011). Small survivals occur including a 10 ha wetland on the river Soar in Central England (Narborough Bog; Lat. 52.575820 Long. –1.191096). The survival is so rare that local ecologists thought it had been created by the impeded-drainage following construction of a railway line in the 19th century CE. However, paleoecology and radiocarbon dating revealed that it had existed for the last 10,000 years accumulating at a slow rate of c. 0.1 mm year^{-1}. Pollen analysis has revealed that the site had a typical, but rarely preserved, vegetation history for lowland river wetland in the United Kingdom. It had been initiated about 10,000 years ago as a reed-bed in a wide-shallow cut-off channel, which was then colonized by birch (*Betula*), willows (*Salix* sp.) and finally alder (*Alnus*) surrounding areas of continued reed-bed. Whilst the wetland had this trajectory, the surrounding woodland changed its composition over time, and was cut-down and replaced by grassland and arable fields around 5000 years ago in the late Neolithic to early Bronze Age (Brown and Hatton, 2002).

From a management perspective, however, there was evidence that the reed-bed dominated by common reed (*Phragmites australis*) was drying out, and so the site was monitored from the early 1990s prior to modelling its water budget (Bradley, 1996, 2002). Using a three-dimensional groundwater model, coupled with monitoring, it was shown that the overall fluxes are highly sensitive to variations in hydraulic conductivity with depth and the water table configuration reflects the balance between horizontal and lateral water flow through the wetland complicating its relationship to stage. As Fig. 4B shows there are marked changes in the stratigraphy across the wetland that determines the 3D distribution of hydraulic conductivity. The modelling also enabled sub-surface flows from the wetland to the river Soar to be quantified, demonstrating the importance of sites like this in supporting river base-flow and probably flow through into the substrate (hyporheic flow).

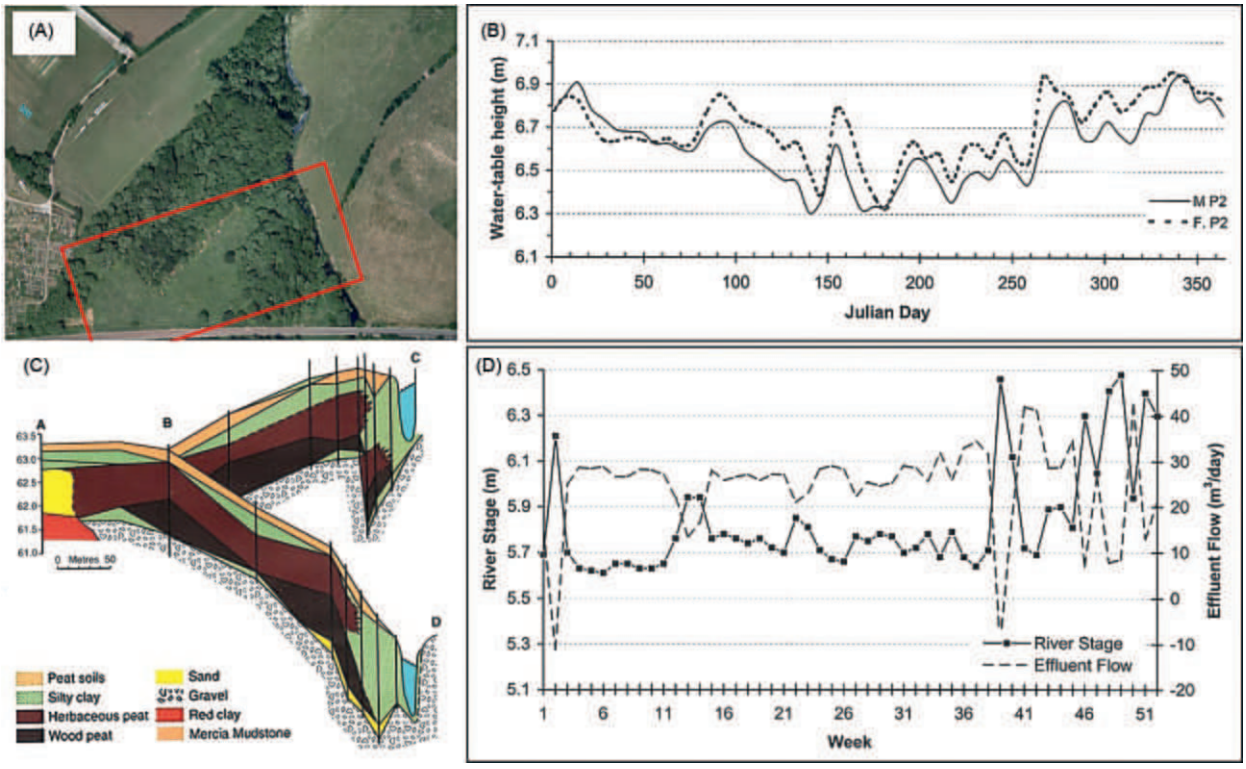

Fig. 4 Narborough Bog hydrological modelling. (A) aerial photography of the site with the modelled area (red box), (B) stratigraphy of the wetland, modelled (C) wetland water levels and d. effluent flow from the wetland to the river in 1992. Adapted from Bradley C (2002) Simulation of the annual water table dynamics of a floodplain wetland, Narborough Bog, UK. *Journal of Hydrology* **261**: 150–172.

Boreal swamp forests

Boreal swamp forests have been shown to be biodiversity hotspots in the relatively low biodiversity coniferous forests of Scandinavia. The rare surviving examples, which are dominated by old-growth Norway spruce (*Picea abies*), have particularly high bryophyte, lichen and fungal diversity (Hörnberg et al., 1998; Økland et al., 2001). Vegetation studies by Økland et al. (2003) have shown that approximately 20% of the enhanced biodiversity of vascular plants is due to the wetland conditions, but also that they show no biogeographical patterns related to local successional conditions. They are located at headwaters (i.e., first order streams) and are generally underlain by peat. An important aspect is the accumulation of dead wood and old trees and although they are affected by fires, it is at a lower frequency than the surrounding dry-land forest. Paleoecology (particularly pollen analysis) has suggested that at least some may have developed from birch-alder-pine (*Betula-Alnus-Pinus*) tall herb forest to spruce-bog moss (*Picea-Sphagnum*) swamp forest due to cultivation and grazing (Segerström et al., 1994). The conservation of this wetland type is largely dependent upon the cessation of logging in this region. However, a complication to both the history of these systems and their future is the presence, or absence, of beavers (*C. fiber*). Studies in Northern Finland have shown that beavers significantly increase both coarse and fine woody debris and create different saproxylic communities and increasing overall biodiversity (Thompson et al., 2016). The beaver today has a relatively restricted distribution in Scandinavia but was formerly much more widespread (Halley et al., 2012). In North America beaver is the major natural biotic engineer of Boreal and cool Temperate forest biodiversity damming both lakes and rivers (Martell et al., 2006; Naiman et al., 1988; Rosell et al., 2005). As many re-introductions across Europe have shown, the beaver's effects on all Temperate and Boreal landscapes is to increase the area of wetland through paludification, and so it is a critical biotic component of riverine landscapes both in the past and increasingly in the future as it offers a cost-effective method of ecological enhancement (Thompson et al., 2016; Brown et al., 2018).

Multiple wetlands in a large temperate deltaic system

The Danube Delta in Romania alone contains over 300 lakes, the ecology of which have been researched extensively due to the international importance of the system (RAMSAR site No. 521, 647,000 ha). Using a combination of remote sensing, hydrological and ecological monitoring, Coops et al. (2008) sub-divided these lake and wetlands into three types; (a) inflow lakes close to the river with a high flushing rate and high suspended sediment but low chlorophyll concentrations, (b) large relatively deep lakes with intermediate residence times and high pondweed (*Potamogeton*) cover that collapses during the summer and with high eurytopic fish, and, (c) smaller lakes a greater distance from the river with long residence times, in which water quality is strongly affected by large floating reed beds with a high vegetation cover of hornwort (*Ceratophyllum demersum*) and a stonewort (*Nitella obtuse*), and limnophilic fish population tolerant of low dissolved oxygen levels. From this and similar analyses (Tockner et al., 1999; Coops et al., 1999; Covaliov et al., 2003; Navodaru et al., 2002) the strongest driving factors are distance from the river and the interactions between seasonal plant growth and light conditions (Fig. 5). The persistence of high connectivity in the system means that there is still a high potential for large-scale restoration despite major hydro-geomorphological modification of the Delta and the three distributary channels of the Danube.

Although the history of the entire delta and the morpho-dynamics of its fluvial network are well-known (Giosan et al., 2005; Vespremeanu-Stroe et al., 2013) its vegetation history is rather poorly known as the first pollen diagram has only recently been completed (Hanganu pers. comm.). This shows that over the last 8000 years the aquatic ecology of the Somova-Parches wetland system (N45°12′23.54″; E28°39′40.51) has fluctuated in both structural and floristic composition in tandem with the lithology and connectivity with the Danube River. During periods of high connectivity, silt and clay is deposited and aquatics are low overall and dominated by cat-tail (*Sparganium*) and bulrush/reedmace (*Typha*), with water-lily (*Nuphar*) and *Myriophyllum* increasing as organic content has increased with reduced connectivity in the last 2000 years. Other aquatics, e.g., *Potamogeton* and water-starwort (*Callitriche*) appear and disappear more randomly. This also reflects increasing nutrient content in the system and is consistent with evidence from diatoms and dinoflagellates (Giosan et al., 2012), as well as the limited historical data that are available, and land use modelling (Pistocchi et al., 2015).

Conclusion and synthesis

River wetlands in the Boreal and Temperate Zone are geomorphologically created, hydrologically maintained and biologically mediated ecosystems that can provide valuable ecosystem services. The examples presented here illustrate the hydrological importance of site stratigraphy and hence landscape history, the role of small wetlands in creating biodiversity hotspots in Boreal forest, and the interaction between wetland connectivity and long-term changes in sediment quality and quantity. Despite wider recognition of their value, attempts at large-scale restoration are limited by the continued human pressures on floodplains and the need to improve water quality and supply at the catchment scale. Several new techniques (remote sensing, instrumentation and molecular monitoring) provide us with potentially powerful tools to improve our understanding of the unseen aspects of their dynamics which may provide clever solutions to the problems of restoration. This will also be required in order to estimate the sensitivity of these systems to the changes in temperature and precipitation that are occurring at a rapid rate especially in the northern Boreal Zone.

Knowledge gaps

- Biotic effects on wetland resilience to climate and catchment change.
- Flood-wetland interactions for both discharge and nutrients.
- Groundwater contributions to wetland budgets.
- Effects of ecological management strategies on carbon sequestration.
- Potential costs and benefits of biotic re-introductions.
- Potential disease sensitivity of riverine wetlands.
- Remote sensing of wetland hydrological balance variables.

Tropical Large River Wetlands

Florian Wittmann[a], Jochen Schöngart[b], Maria TF Piedade[b], and Wolfgang J Junk[c], [a]Department of Wetland Ecology, Institute for Geography and Geoecology, Karlsruhe Institute for Technology (KIT), Karlsruhe, Germany; [b]Ecology, Monitoring, and Sustainable Use of Wetlands (MAUA Research Group), National Institute for Amazon Research (INPA), Manaus, Brazil; [c]National Institute of Science and Technology in Wetlands (INCT-INAU), Federal University of Mato Grosso, Cuiabá, Brazil

Glossary

Anabranching River sections that divert from the main channel and rejoin the main channel downstream, often because of the formation of islands.
Catchment area Defined through water sheds, which are located upon the highest isolines (contour lines) of basins, the catchment area is the area of land from which water flows to the erosion base (river, lake, or depression).
Clay minerals Common ultrafine-grained weathering products, clay minerals are hydrous aluminum phyllosilicates with variable amounts of Fe, Mg, alkali metals, alkaline earths and further cations.
(Ecological) disturbance Temporary change in environmental conditions that causes a pronounced change in an ecosystem, including, for example, events such as fire, floods, storms, insect outbreaks, volcanism, or trampling.
(Ecological) succession Process of change in species structure of an ecological community over time.
Endemism Refers to species that are native and exclusive to a single defined geographic location (e.g. island, state, continent, or any other defined zone).
Flood pulse (concept) Explains how periodic inundation and drought (flood pulse) control the lateral exchange of water, nutrients, and organisms between the main river channel and the connected floodplain (Junk et al., 1989).
Hydrochory Dispersal of diaspores (fruits, seeds, spores) by water.
Ichthyochory Dispersal of diaspores (fruits, seeds, spores) by fish.
Macrophyte A plant that grows in or near water and is either rooted as emergent or submergent plant, or non-rooted (free-floating).
Net primary productivity Net carbon gain by plants, expresses the balance between the carbon gained by gross primary production (i.e., photosynthesis) and carbon released by plant respiration.
River terrace Bench or step that extends along the side of a valley and represents the former level of the valley surface—as a result of any hydrological or climatic shift that causes renewed down-cutting (incision).

Definition, distribution and extent of tropical large-river wetlands

Large rivers were first defined by Inman and Nordstrom (1971) and Potter (1978) by four main characteristics—they drain large basins, are very long, have high water discharge and transfer a considerable amount of sediment. There are several exceptions in one or more of Potter's characteristics of large rivers. The Nile River, for example, is the longest river on Earth, but is not included in the 50 largest rivers in regards to water and sediment discharge (Table 1). Likewise, the Negro River, an Amazon River tributary, ranks among the 10 largest rivers on Earth contributing approximately 35% of the immense total water discharge of the Amazon River, but carries less than 1% of the Amazon river system sediment discharge (Table 1). Here, we concentrate on tropical large rivers that rank among the largest rivers on Earth in either water or sediment discharge, or both combined.

Along their middle to lower courses, large river wetlands are mostly composed of fringing floodplains. These are defined as "low areas of land that are subject to inundation by lateral overflow waters from rivers or lakes with which they are associated"

Table 1 Selected tropical large rivers and associated floodplains of international importance.

	Mean annual discharge ($m^3 s^{-1}$)	*Drainage area ($10^3 km^2$)*	*Sediment discharge (Mt $year^{-1}$)*	*Countries within main drainage area*	*Associated wetlands*	*Sources (examples)*
South America						
Amazon	209,000	6100	1000	Ecuador, Bolivia, Peru, Colombia, Venezuela, Guyana, French Guyana, Surinam, Brazil	Large-river wetlands (várzea)	Junk et al. (2011, 2014)
Orinoco	35,000	950	150	Brazil, Colombia, Guyana, Venezuela	Llanos de Orinoco	Lewis et al. (2000) and Godoy et al. (1999)

Brahmaputra	20,000	610	520	China, India, Bhutan, Bangladesh		Islam (2016) and Kumar et al. (2019)
Mekong	15,000	795	145	China, Myanmar, Laos, Thailand, Cambodia, Vietnam	Tonle Sap	Wang et al. (2011)
Irrawaddy	13,000	414	364	China, Myanmar		Kravtsova et al. (2009)
Ganges	12,000	975	329	Nepal, India		Das et al. (2013)
Salween	6700	325	180	China, Myanmar, Thailand		Chen et al. (2019)

(Junk, 2002). This definition includes deltas (both coastal and inland) and estuaries (Tockner and Stanford, 2002). Following Brinson and Malvárez (2002), water sources contributing to inundation originate from lateral overflow, groundwater, upland sources, and direct precipitation. Besides floodplains that fringe river courses, several large tropical rivers also periodically inundate depressions during the rainy seasons mostly through backwaters which affect their tributaries or the main rivers during the high-water period, which creates large and important seasonal wetlands of international importance for biodiversity and ecosystem services. Examples in South America are the Pantanal (Paraguay River, Brazil-Bolivia-Paraguay) comprising 160,000 km^2, the Llanos de Moxos (Beni River, Bolivia) with 110,000 km^2, and the Brazilian Araguaia River wetlands (88,000 km^2, Irion et al., 2016) in the SW-Amazon. In Africa, most extensive wetlands associated to backwater effects are the Cuvette Centrale (Congo River, D.R. Congo, 145,000 km^2), and the Sudd (Nile River, South Sudan, 130,000 km^2). Smaller, but very important wetlands for biodiversity may also undergo huge seasonal changes in extension, such as the Okavango Delta, that increases from 3000 km^2 during the dry season to up to 16,000 km^2 during the rainy season (Mendelsohn et al., 2010). In Asia, freshwater marshes associated to rivers or lakes are the most common wetland type (Gopal, 2013), and most of them also expand several-fold during the flooding season. For example, the lake Tonle Sap in Cambodia shrinks and expands from 2500–15,000 km^2 as it gets flooded by the Mekong River (Campbell et al., 2006).

Global wetland estimates for the tropical and subtropical regions (excluding areas covered by open water) derived through remote-sensing range between 2.8 million km^2 (Cogley, 2003) to 4.8 million km^2 (GLWD-3 data, Lehner and Döll, 2004). A major problem in wetland mapping is the lack of classification systems that take into account specific hydrological conditions and plant communities (Junk et al., 2011, 2014). Most tropical large-river floodplains consist of a mosaic of habitat types, from year-round aquatic to entirely terrestrial, and in addition often include associated wetlands, such as internal deltas, river terraces, marshes and swamps, the latter often subject to inundation from local sources that drain through floodplains into the river system (Mertes, 2000; Hamilton, 2008). Therefore, permanently flooded habitats (i.e., swamps) and habitats with seasonally drying soils (i.e., marshes) are often not included as floodplains, although they may cover large areas in nearly all tropical large-river floodplains that are fed by rivers with seasonally oscillating water levels. Irrespective of the lack of a unified wetland classification system, the available global wetland data sets (Stillwell-Soller et al., 1995; Cogley, 2003; Lehner and Döll, 2004; Gumbricht et al., 2017) for tropical and subtropical regions agree that large-river wetlands are most extensive in South-America (approx. 1.6 million km^2), followed by Africa (1.3 million km^2), Asia (approx. 1.0 million km^2), North-and Central America (approx. 0.8 million km^2), and Australia and Oceania (0.3 million km^2). Out of these, large-river floodplains cover between 5% and 35%, depending on how floodplains are classified (i.e., if include associated swamps, marshes, and further wetland types).

Environment of large rivers

Flood regimes and inundation

Most tropical large rivers have highly seasonal discharges and their floodplains and associated wetlands are subject to predictable water-level fluctuations. Many experience a monomodal flooding pattern with one high-water and one low-water period during the course of the year. This pattern is driven by the annual shift of the Intertropical Convergence Zone and/or monsoonal climates that determine patterns of annual rainfall across a vast catchment area. Rivers that have catchments on both sides of the equator or that drain different (i.e., non-inner tropical) climate zones show slightly bimodal flood regimes, such as the Magdalena River in Colombia (Ricaurte et al., 2019) and the upper Negro River in the Amazon basin (Montero et al., 2014), or the Zaire River in Africa.

The magnitude of seasonal water-level changes along the mid- to lower courses of large tropical rivers may range up to 10–15 m, as in the Orinoco and Amazon rivers in South America, 6 m at the Niger and Benue Rivers and 2–3 m at the Congo River in Africa, 5–6 m at the Brahmaputra and Ganges Rivers, and up to 7–8 m in the Irrawaddy and Salween Rivers in Asia (Schwatke et al., 2015, Fig. 1). Variations in local flood regimes differ with geological and orographic framework of landscapes, the altitudinal ranges and slopes that rivers cross, channel widths and depths, the size of catchment areas, the presence of glaciers in their catchments, as well as the variability of water losses through evaporation and plant transpiration. The influence of anthropogenic activities in the catchment, such as water deviation, as well as the construction of dams, reservoirs and flow regulation of river channels strongly influence hydrology. Nevertheless, flood regimes of some tropical large-river wetlands tend to be stable over relatively long periods of time, a factor of particular importance for wetland organisms and communities, whose life histories and interactions are intricately linked to predictable annual variation in flood height and duration (Lewis et al., 2000).

Seasonal inundation regimes, or the flood pulse (Junk et al., 1989), provide the main environmental forcing factor for the biota in tropical large river wetlands. Organisms living in these floodplains not only tolerate, but require these water-level fluctuations for the long-term survival of their populations, including many fish and invertebrate species with spawning and feeding migrations between rivers and floodplains (i.e., Welcomme, 1979; Goulding, 1980; Lowe-McConnell, 1987; Adis and Junk, 2002; Correa et al., 2015). Many animal species synchronize their life cycles with the hydrological cycle, such as mammals, birds, reptiles and amphibians (i.e., Junk and da Silva, 1997; Tomas et al., 2011). Herbaceous and woody plant species have specific anatomical and physiological adaptations to overcome temporarily hypoxic conditions during the flooded periods, and reproductive strategies that are closely tied to the timing of floods. Many aquatic and semi-terrestrial herbaceous species are specialized to tropical and subtropical floodplains with numerous examples of wetland-specialized species and genera on each continent (Sculthorpe, 1985). In the Amazon basin, where seasonal water level oscillations are interpreted as relatively long lasting over evolutionary periods, a significant proportion of floodplain tree species are endemic to its floodplains (Wittmann et al., 2010, 2013, 2017).

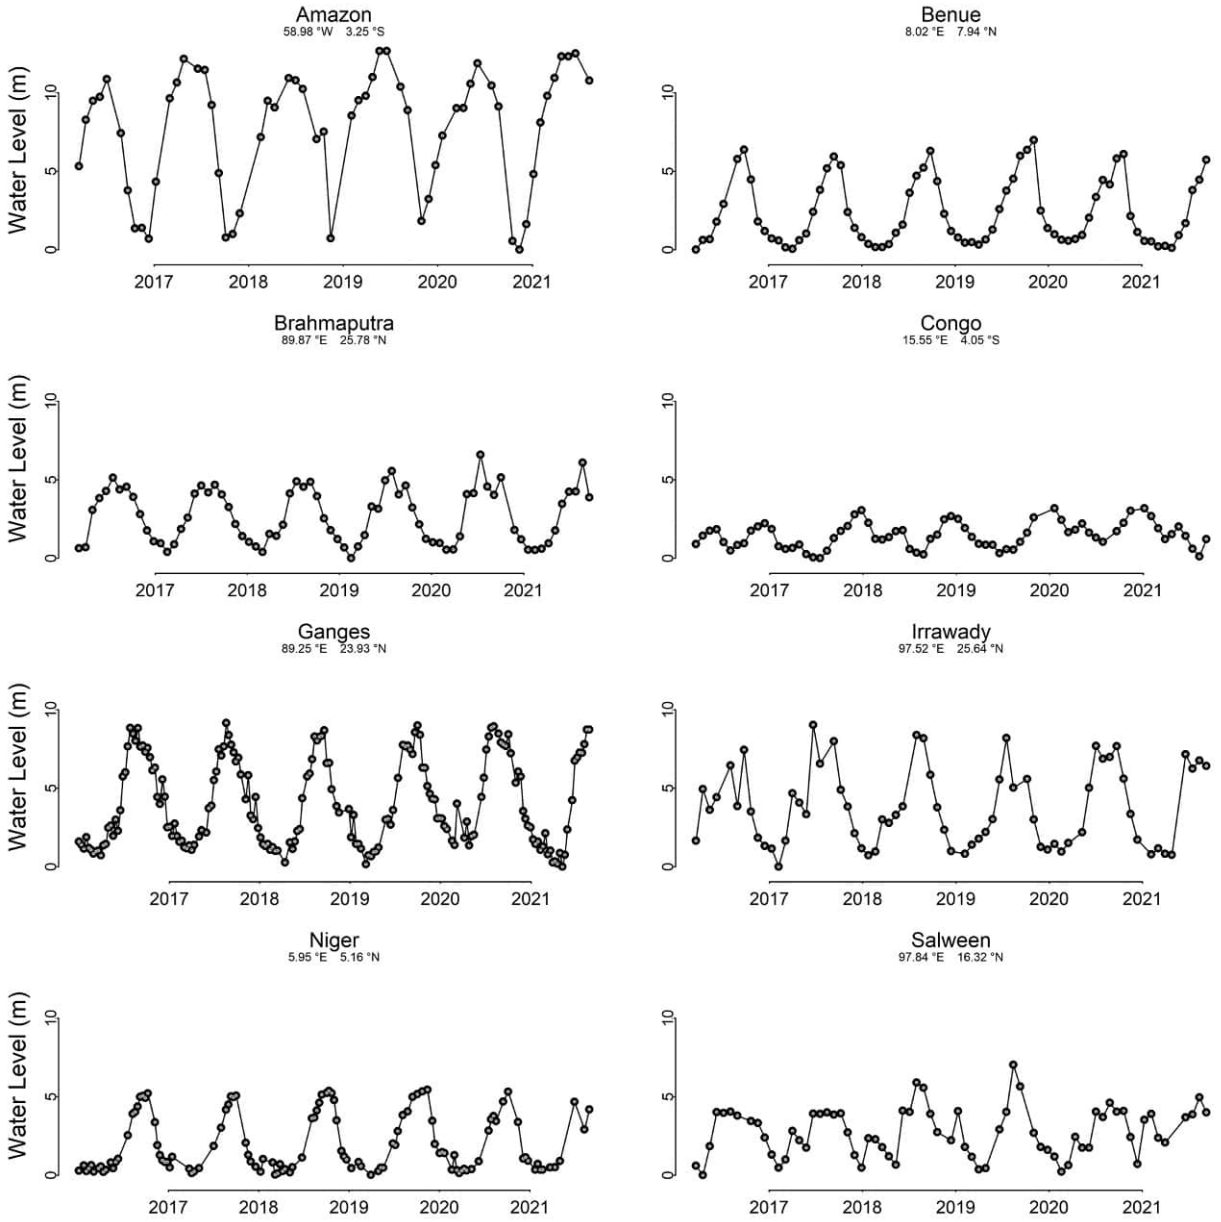

Fig. 1 Flood regimes of selected tropical large rivers, as recorded from water level time series from satellite altimetry in the Database for Hydrological Time Series of Inland Waters [DAHITI, Schwatke et al., 2015].

Geomorphology

Floodplains are formed by a complex interaction of fluvial processes (Nanson and Croke, 1992) where stream power on the one hand and sediment transport and deposition on the other, are the most important determinants of floodplain features and dynamics. Rivers are geomorphologically categorized as meandering, straight or braiding (Leopold and Wolman, 1957), and these channel patterns largely characterize floodplain development in tropical regions (Nanson and Croke, 1992; Latrubesse, 2008; Fig. 2). At their mid to lower courses, most large tropical rivers have anabranching channels with very low slopes and relatively fine-grained (medium- to fine-grained sand) bedload (Latrubesse, 2008). Large-tropical rivers with anabranching floodplains include the Amazon, Orinoco, Paraná, Congo and Brahmaputra (Latrubesse, 2008). Floodplains of anabranching channels are mostly formed by overbank deposition of fine-grained sediment that form islands with levees, backwater depressions, and lakes (Nanson and Croke, 1992). Occasionally, these rivers might also dispose of braided stretches, such as the Congo and Negro Rivers (Fig. 2). Lateral migration (i.e., meandering) floodplains with characteristic ridge and swale systems (scroll pattern) are also common tropical floodplain types. These rivers include, for example, the Mississippi, Purus, Juruá, and Paraguay (Fig. 2).

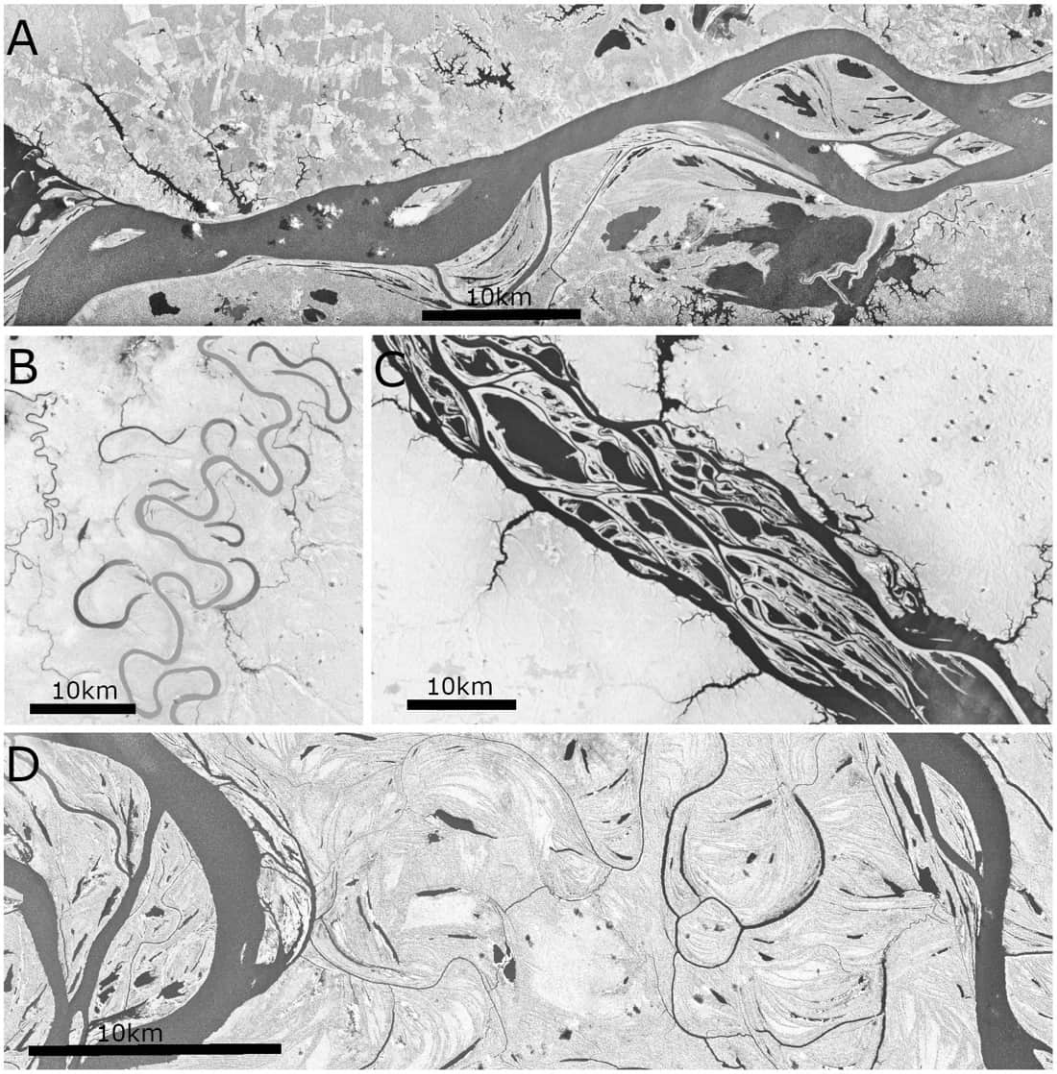

Fig. 2 Geomorphological styles of tropical large rivers and their floodplains: examples from the Amazon. (A) anabranching channel of the Solimões River with permanently connected, linear-shaped floodplain lakes and seasonally connected, dendritic shaped tributary lakes, central Brazilian Amazon. (B) Meandering channel of the lower Juruá River, with scroll lakes of varying hydrological connectivity and yazoo channels delimiting the active and paleo-floodplain, western Brazilian Amazon. (C) Braided system at the Anavilhanas arquipelago of the lower Negro River, with dendritic shaped tributaries, central Brazilian Amazon. (D) Mamirauá Sustainable Development Reserve, located between the Solimões (left) and Japurá (right) rivers. The linear shaped scroll lakes are seasonally flooded and part of the active floodplain, which is intermixed with mostly isolated lakes that are part of the paleo-floodplain, creating a complex system of geomorphic and hydrological gradients with high habitat diversity.

Because of their very low slope gradients (in the range of 1–50 cm km^{-1}), large-river channels and floodplains quickly change in response to environmental alterations that change flow and sediment regimes (Gregory and Lewin, 1987). Even slow tectonic movements or small changes in the base level propagate flow and sediment regimes to great distances upstream (Dunne and Aalto, 2013). For example, the last interglacial period affected the Amazon River system up to 2500 km upstream and largely defined the shape, geomorphology and fluvial styles of today's Amazon River and major tributaries (Irion et al., 1995). Over decades, centuries, or even millennia, only a small fraction of the total alluvium in a river valley is transported by the river, while the bulk is stored in contemporary floodplains or in ancient alluvial deposits (Nanson and Croke, 1992).

Hydraulic energy of flowing waters may be variable at small geographic scales, sorting deposited grains by size and weight. Thus, active floodplains are a complex mosaic of substrates of vastly different age and texture. Immense variation in substrate age, soil texture, and flooding is an important facet of habitat heterogeneity for flora and fauna and a principal driver of high beta-diversity, or species turnover, of large-river wetlands compared to terrestrial ecosystems (Wittmann and Junk, 2016).

In contrast to the linearly arranged active floodplains, the "geomorphological floodplain" may extend over large areas. Approximately one third of the area of the Amazon basin, or two million of km^2, is paleo-floodplain built up of Andean sediment, where geomorphological landforms, such as paleo-channels, slip-off and undercut slopes, levees, depressions, meander scars, and islands (i.e., Hudson, 2003; Peixoto et al., 2009) are clearly visible in the landscape (i.e., as river terraces) reflecting former flow regimes (Irion et al., 2010; Wittmann and Householder, 2017).

Substrates and soils

The amount and quality of dissolved and suspended solids determine primary and secondary productivity in wetlands (Junk, 2002) and, to some degree, also biodiversity. Wetlands of semi-arid and arid regions are usually richer in nutrients than their humid counterparts because of slowed weathering processes in their catchments, but also tend to eutrophication and salinization (Dumont, 1992). Wetlands of the humid tropics are generally characterized by relatively low nutrient status, as exemplified in the Amazonian black-water and clear-water floodplains (Junk et al., 2011) or the African Congo River floodplains. However, exceptions occur when rivers drain tectonically active regions and mountain ranges. Because rivers transport sediment long distances, the fertility of alluvial sediments can differ considerably from soils derived in situ on local material. Best examples are the nutrient-rich alluvial substrates in deeply weathered and nutrient-poor tropical landscapes, such as in large parts of tropical and subtropical South America, Africa, and India. Many large rivers flowing through these landscapes originate from uplifting mountain ranges, such as the Andes, Himalaya and Hindukush, or tectonically active regions, such as the East African rift-valley system, and deposit their suspension loads with high contents of relatively un-weathered and thus multi-layered clay minerals, such as illite, smectite, and montmorillonite, in the floodplains along their middle and lower courses. These clay minerals have high ion exchange capacities and release nutrients to alluvial substrates. For example, central Amazonian substrates of floodplains along white-water rivers draining the Andes have contents of Potassium, Magnesium, Calcium and Sodium that are 10- or even more-fold higher than the contents of these elements in non-flooded, ferralitic soils of the surrounding tertiary sediments that originated over millions of years from the Precambrian and Paleozoic basement (Irion et al., 2010). Consequently, plant and animal species with high fertility requirements can find refuge in alluvial settings where they would otherwise not survive local conditions. Those species often originate from biomes and ecosystems where climates and edaphic characteristics are different and thus form biogeographic disjunctions in river floodplains.

Arguably, human civilization arose along large-river wetlands characterized by high fertility, with examples from all continents. The Nile, Euphrates, Tigris and Indus Rivers were the economic basis for the high cultures of Egyptians, Sumerians, and Harappas, 5000 to 4000 years ago (Hammerton, 1972; Boulé, 1994). First records of agriculture originate from the Tigris-Euphrates and Indus floodplains, and rice paddy cultivation likely originated in the Ganges and Yanuma floodplains in India (Gopal, 2013). The fairly predictable inundation regimes combined with the periodical refreshment of soil nutrients from inundations favored the cultivation of productive aquatic macrophytes (i.e., rice, lotus, taro), lead to the domestication of animals (i.e., ducks, buffaloes), and allowed for the sustainable use of tropical floodplains by a dense human population (Fernando, 1980; Junk, 2002). In South America, Amerindian population density along sediment-laden rivers was about 10–20 times higher than in adjacent terrestrial ecosystems (Denevan, 1976). Indeed, the modern distribution of humans in the Amazon reflect similar patterns. Noteworthy is that the combination of high fertility with and high human density also favors the emergence and spread of many zoonotic diseases, which forced humans to create specific types of management for fertile substrates and floodplain resources. In the Amazon basin, most settlements and cities are located along river channels that still represent the only viable transport route for people. Most settlements are located along nutrient-poor black-water rivers, which reduces the exposition to mosquitoes and thus disease transmission, but still near white-water rivers (i.e., near river confluences or in distal parts of white-water floodplains) to ensure access to highly productive soils, and aquatic environments for fish and other natural resources from the fertile floodplains.

Biodiversity

Tropical large river wetlands are considered biodiversity hotspots (Gopal et al., 2000). Both, the adaption and speciation from regional species pools and ephemeral or migratory species that depend on wetland resources for the maintenance of their populations contribute to high biodiversity. Wetland habitats often account for an important fraction of regional habitat heterogeneity within biomes (Wittmann et al., 2015). While their relatively small coverage within larger biogeographic units means that wetlands are not necessarily richer in species at local scales than adjacent uplands, they do harbor mostly different species than surrounding uplands and thus significantly contribute to regional diversity (Sabo et al., 2005). Large-river wetlands are integrated into fluvial networks that provide wet dispersal corridors, these often crossing climatically different regions (Naiman et al., 1993). As such, rivers may be important vectors of range expansion for many semiaquatic and aquatic organisms. Wetland macro-habitats (sensu Junk et al., 2014) may also serve as local refuges (Kellmann and Meave, 1997). By mitigating environmental stressors in otherwise inhospitable regions, wetland occupation can allow organisms to tolerate larger temperature ranges as well as maintain more favorable edaphic and moisture conditions compared to adjacent, terrestrial habitats (Sculthorpe, 1985). In this sense, over evolutionary time, large-river wetlands are likely to have consisted of many habitats that have conveyed spatial and temporal resistance and/or resilience to populations of species living in constantly changing climatic contexts (Sedell et al., 1990). For example, in periods of reduced water availability during the Quaternary, wetlands, and especially those along large rivers, played crucial roles as refugia for drought-sensitive vascular plants and animals in both tropical and extratropical regions (Wittmann et al., 2015).

When rivers flow through semi-arid climate zones, soil moisture and the availability of near-surface ground waters provide important refuges for drought-sensitive plant and animal species. Floodplain and riparian areas in savanna climates are densely forested in contrast to adjacent uplands dominated by herbaceous species (Meave et al., 1991). Consequently, riparian habitats are usually the most species-rich ecosystems in savanna landscapes, where effects of seasonal drought, but also fire frequency are

comparatively low (Kellmann and Meave, 1997). In regions where rainfall seasonality is pronounced, the availability of surface waters in addition influences the migration behavior of many vertebrate species. For example, the African mega-fauna is highly dependent on water availability of seasonal wetlands. As soil moisture influences plant growth, plant zonation along flood frequency and duration gradients across tropical Africa provide a critical resource heterogeneity for herbivores, which graze on floodplain peripheries in the early dry season, but migrate to deeper floodplains and swamps during the late dry season and during droughts (Fynn et al., 2015). Similar patterns of species migrations along climate seasonality and spread out and shrinking of large river wetlands are known, for example, for crocodilians (Campos et al., 2006) and mammalian herbivores (Tomas et al., 2010) from the South-American Pantanal.

Higher vegetation

Tropical large-river wetlands are mainly forested in per-humid tropical climates, as for example in the Amazon and Congo floodplains. Highest tree species richness in large-river wetland forests was reported for the Amazonian nutrient-rich white-water floodplains (várzeas), where more than 1000 flood-tolerant tree species are reported to occur, and where tree species richness ($\geq$ 10 cm diameter at breast height—dbh) may account for up to 150 tree species ha^{-1} (Wittmann et al., 2006). Tree species richness in Amazonian black-water floodplain forests (igapó) account for approximately 70–80 species ha^{-1}, which is similar to the species richness reported for seasonally flooded forests in the northern Congo (Ifo et al., 2019). With increasing latitude, floodplain forests decrease in species richness, such as in the lower Mekong floodplains (some dozens of flood-tolerant tree species, Campbell et al., 2006), the Okavango Delta (approximately 10 flood-tolerant tree species, Ramberg et al., 2006) or northern Australian wetlands (approximately 5 flood-tolerant tree species, Finlayson, 2005). In climates with a distinct dry season, namely when the number of consecutive months with arid conditions increases to six or more, tree coverage is concentrated along moist riparian habitats, while macrophyte and herbaceous species of tree and shrub savannas become the dominant life form in floodplains, such as in the Llanos of Moxos, the Araguaia River wetlands and the Pantanal (South America), the Niger and Okavango Deltas (Africa), and the freshwater marshes of India and Mesopotamia (Gopal, 2013). If the number of arid months further increases, woody species may be either restricted to episodic riparian corridors, such as in the shrub savannas of the Caatinga (NE-Brazil), the woodlands of the Sahel zone (NE-Africa) or the Mara-Serengeti in Kenya and Tanzania (E-Africa), the Western Ghats in South-India (i.e., Johnsingh and Joshua, 1989), and the Kakadu region in Northern Australia (Finlayson, 2005), or are entirely replaced by macrophytes, namely emergent reeds (i.e., *Phragmites*), cattails (i.e., *Typha*), or sedges (i.e., *Cyperus*). Notably, herbaceous species richness is inversely related to tree coverage, reaching highest values in subtropical savanna regions. For example, species lists in the Okavango Delta report approximately 950 herbaceous taxa (Ramberg et al., 2006). Similar species numbers for herbaceous species are reported for the Pantanal (approximately 1150 species, Pott and Pott, 1994). Herbaceous species richness in tropical large river wetlands decreases both in direction to rainforest biomes, and also approaching extra-tropical regions. However, species numbers also strongly depend on habitat diversity, given that larger and geomorphological varied wetlands usually also present higher numbers of taxa (Junk et al., 2006).

Geomorphological landform, sediment and soil type, sediment turnover rates and the exposure to flood disturbance and light change at small geographic scales in tropical large-river floodplains and form complex environmental gradients that influence the occurrence and distribution of plant and, to some degree, also animal species (Hughes, 1997). Studies from many tropical floodplains show predictable patterns of plant species distributions along these gradients. Examples include Morison et al. (1948) on the Bahr el Ghazal floodplain in Sudan, Johnson and Little (1967) along the Mississippi (United States), Menalled and Adamoli (1995) on the Paraná (Argentina), Hughes (1988) on the Tana River (Kenya), Damasceno et al. (2005) on the Paraguay, Nunes da Cunha and Junk (2011) in the Pantanal, and Wittmann et al. (2004) on the Amazon River (Brazil). Most importantly, hydroperiod - defined through the location of plant species along the topographic gradient, is a powerful environmental filter because it impacts plant growth through reduced gas diffusion under waterlogged conditions that severely reduces soil oxygen availability for aerobic metabolism (i.e., Jackson and Colmer, 2005). In addition, if flood amplitudes are high, plants might be completely submerged and thus face reduced light conditions and even absence of light, which, combined with increased levels of CO_2, greatly hampers photosynthesis (Parolin, 2002, 2009). Depending on their location along the flood frequency and/or duration gradient, plant species need specific adaptations to overcome hypoxia during waterlogged periods. While the mechanisms of flood tolerance in plants are still not entirely understood, it is clear that most floodplain plants usually combine several adaptive strategies to withstand waterlogged periods (Parolin, 2009), and that these strategies likely developed numerous times in most phylogenetic groups. Adaptations can be morphological (i.e., aerenquimatic tissues, increase of root biomass, aboveground roots, pneumatophores; hypertrophied lenticels), biochemical (i.e., stimulation of fermentative pathways, accelerated glycolytic fluxes), or metabolic (i.e., leaf shedding, growth reductions, cambial dormancy) (i.e., Armstrong et al., 1994; Schöngart et al., 2002; Parolin, 2002; Jackson and Colmer, 2005; Kreuzwieser and Rennenberg, 2014). In addition, the reproductive phenology of many tropical floodplain species is linked to the seasonality of flooding, such as the timing of flowering, seed dispersal, germination and establishment (Voesenek et al., 2003), as well as the development or use of specific dispersal modes, such as hydrochory or ichthyochory (i.e., Correa et al., 2015).

While flood length and height are the dominant environmental filters for many tropical wetland plants and locally explain increasing species richness from long/high flooded to short/low flooded, it is important to state that inundation period is interlinked with multiple gradients that also include dry phases and drought, to which many organisms in tropical wetlands must be adapted (Parolin et al., 2010; Householder et al., 2021). Climatic droughts may be exacerbated by local edaphic conditions,

for example where coarse substrates (i.e., sand) desiccate more quickly relative to fine substrates (i.e., clay). The latter, however, may also limit oxygenation even in the absence of superficial flooding, and cracks formed during prolonged dry phases can damage fine roots of vulnerable seedlings. As such, the oscillating dry and wet phases provide very heterogeneous ecological niches that importantly shape local habitat diversity (Householder et al., 2021).

Along sediment-laden rivers, sedimentation and erosion processes constantly provide geomorphological disturbance. While alluvial sediments provide new habitats potentially available for new site colonization, they may also bury macrophyte and tree seedlings and thus act as another environmental filter. Pioneer plants colonizing these sites often have strategies to complete their life cycles within one terrestrial phase (i.e., annual macrophytes) or form new root layers (i.e., perennial plants such as trees) close to the surface in order to ensure water and nutrient uptake (Wittmann and Parolin, 2005). On the other hand, erosion along slip-off slopes destroys areas formerly covered by vegetation, and plant species maintain their populations at regional scales with effective strategies that allow new site colonization, including fast growth, long distance dispersal, and asexual reproduction (i.e., pioneer strategies).

Vegetation succession upon freshly deposited sediment follows the same ecological principles (i.e., allogenic versus autogenic successional pathways, Table 2) in tropical large-river floodplains as along rivers of extra-tropical climates. The first pioneer species to colonize newly deposited alluvial sediment are usually annual, followed by perennial grasses and herbaceous plants. This first group of colonizers may be extraordinarily productive, especially those with C_4-metabolism. From the Amazonian white-water floodplains, the net primary productivity of the grasses *Paspalum fasciculatum* and *Echinochloa polystachya* may amount to up to 70–100 Mg ha^{-1} year^{-1} (Piedade et al., 1991), twofold to threefold higher than the net primary productivity of fast-growing, early successional forests (Schöngart et al., 2010). If alluvial substrates are poor in nutrients, colonizing macrophytes are mainly low-productive sedges (Cyperaceae) (Junk et al., 2015). Pioneer species reduce water energy and trap further sediments, leading

Table 2 Relation of environmental and biotic factors during forest succession in Amazonian sediment- and nutrient-rich white-water floodplains (várzea), near the main river channel.

	Primary succession	*Early secondary succession*	*Late secondary succession*	*Late succession*
Environmental factors				
Hydraulic force	Very high	High	Intermediate	Low
Inundation height (m) and duration (days year^{-1})	8–12 (>300)	5–7 (230–270)	3–5 (50–100)	< 3 m (< 50)
Sedimentation rate	Very high	High	Intermediate	Low
Substrate grain size[a]	Coarse (i.e., sand)	Intermediate (i.e., fine sand)	Intermediate (i.e., silt)	Fine (i.e., clay)
Substrate compaction	Very low	Low	Intermediate	High
Relative photosynthetically active radiation (%)[b]	70–100	30–70	5–30	< 5
Substrate water retention capacity	Low	Very low	Intermediate	High
Litter and organic layer	Absent	Sparse	Intermediate	Thick
Biotic factors				
Vegetation type	Annual or perennial macrophytes	Shrubs	Trees	Trees
Tree density ha^{-1} (> 10 cm dbh)[a]	–	100–200	800–1000	400–600
Mean tree diameters (cm)[c]	–	10–15	15–30	> 30
Tree heights in the upper canopy (m)[a]	–	8–10	15–20	> 20
Stratification	–	Single	Double	Double or more
Max tree ages (years)[c]		10–15	35–100	> 100
Individual crown area (m^2)[d]	–	30–60	60–200	200–800
Aboveground root type[e]		Stilt roots	Stilt and tabular roots	Tabular roots
Wood density (g cm^{-3})[c]	–	Soft (< 0.4)	Intermediate	Hard (> 0.5)
Biomass (Mg ha^{-1})	70–100[f]	18 ± 3[c]	117 ± 9[c]	239 ± 11[c]
Net primary productivity (Mg ha^{-1} year^{-1})[c,f]	30–99[f]	11.25[c]	14.34[c]	6.46[c]
Biodiversity ha^{-1}	1–5 herb species	1–3 shrub species	10–25 tree species	> 80 tree species
Succession type	Allogenic	Mostly allogenic	Mostly autogenic	Autogenic

to the silting up and stabilization of local sites. In addition, they modify microclimates by shading. The modification of environmental site conditions facilitates the establishment of pioneer shrubs and trees, which usually establish a few years after the colonization of macrophytes. First colonizing pioneer trees usually form monospecific stands, but these are swiftly (during years to a decade) replaced by trees of early-secondary stages. These are, in turn, replaced by intrusion of late-successional or climax species (within decades or centuries) (Table 2). The successional sequence results in a continuous increase in species diversity but a decrease in stand densities. Succession is, moreover, characterized by a reduction in growth rate of woody species and an increase in mean wood density. Net primary productivity of stands is thus reduced as a consequence of the higher abundance of slow growing, long-living shade-tolerant species in late-successional forests (Wittmann and Junk, 2003; Table 2). This progression is often characterized as a transition from highly flooded "softwood" to low flooded "hardwood" forests (Ellenberg, 1963), which effectively captures how plant functional and life-history traits (i.e., growth rates, wood density, aboveground roots) and vegetation structure (i.e., canopy height, diameter distribution, biomass, diversity) are strongly linked to temporal shifts of local environmental site conditions (flood duration, hydraulic force, composition of grain sizes in alluvial substrates, and exposure to sun light). Exceptions in the progression may occur, when highly flooded forest patches are subject to relatively slow sediment deposition rates, as exemplified in the successional model provided by Wittmann et al. (2010). Worth mentioning is that successional processes might be highly variable in timing and duration, as they depend on the geomorphic dynamism of lowland rivers, in particular flow velocity and the amount of transported sediment and sediment turnover rates. For example, the entire successional sequence from first colonization of freshly deposited substrates through pioneer species until the development of late-successional forests may occur in a few hundreds of years where highly fertile floodplains are rapidly reworked by river dynamics, such as close to the Andes in the Peruvian Amazon (Salo et al., 1986; Kalliola et al., 1991). In contrast, where river dynamism is low, such as along the lower Negro River in the central Amazon basin, first pioneer tree species might show relatively slow growth rates and achieve ages of up to 100 years. Late-successional floodplain trees along these relatively stable rivers might achieve ages of up to 1000 years (Junk et al., 2015), demonstrating the comparatively slow successional processes in nutrient-poor and low-dynamic river floodplains.

Fauna

Tropical large-river wetlands range from permanent aquatic habitats in deep river channels to terrestrial habitats upon paleo-floodplains and represent complex functional units, where macro-habitats influence each other (Junk et al., 2014). They host among the highest numbers of taxa in many animals, including planktonic and benthic communities, aquatic and terrestrial invertebrates, and aquatic and terrestrial vertebrates that live in or are highly dependent on rivers and wetlands. Most species lists are far from being complete, and the rapid decline in global freshwater biodiversity likely means that many species will go extinct before their adequate taxonomic description. Invertebrates dominate the fauna of large river wetlands in terms of species diversity, abundance, and biomass (Williams, 2006). Because they are the link between primary production, detrital resources and the higher order consumers, aquatic invertebrates play an outstanding role in the food chain (Murkin and Blatt, 1987). Most invertebrates of tropical large-river wetlands have relatively short life cycles, which allows their rapid occupation of the new sites provided by fluctuating water levels and river dynamics (Irmler, 1981). Many invertebrates also migrate or drift in the water to new sites (Junk and Robertson, 1997). In large river wetlands, life cycles of most invertebrates are tightly coupled to the hydrological cycle, as, for example, shown for the Amazon floodplains (Adis and Messner, 1997; Adis and Junk, 2002) or the Brazilian Pantanal (Wantzen et al., 2016).

Globally, freshwaters of rivers, floodplains and lakes harbor approximately one third of all vertebrates and nearly half of all fish species (Balian et al., 2007; Vega and Wiens, 2012). Freshwater ecoregions with the highest fish diversity include Asia's Brahmaputra, Ganges and Yangtze basins, the lower sections of the Mekong, Chao Phraya (Thailand), Sittaung (Myanmar) and Irradwaddy, Africa's lower Guinea and Congo, and South America's Amazon, Orinoco, and Paraná (Abell et al., 2008). The Amazon basin alone likely hosts 2500–3000 fish species (Junk, 2013). About half of the total species number is estimated to occur in the large rivers and their floodplains and the other half in the headwater regions of smaller tributaries (Junk, 2007). Most of the former species have a large distribution area, whereas many species in the latter have a restricted distribution and are therefore much more vulnerable to extinction. Globally, fish species richness was shown to increase with drainage area, mean annual river discharge, temperature, and net terrestrial productivity within the basin, whereas historical climatic stability and geographic isolation had a minor effect (Oberdorff et al., 2011). Historical and biogeographic effects, however, strongly determine fish distribution ranges and species endemism. In global terms, the highest numbers of endemic fish species occur in the western Amazon and Magdalena rivers, east Brazilian São Francisco and smaller exoreic river basins, the lakes of the African rift-valley, and Asia's lower Mekong (Abell et al., 2008).

In an analysis of the geographical distribution range of more than 7000 freshwater animal species on the globe (including mammals, reptiles, amphibians, fishes, crabs and crayfish), Collen et al. (2014) state that absolute freshwater diversity is highest in the Amazon basin, which is particularly due to the high number of amphibians that accounted for more than 50% of the total of recorded freshwater species. Other outstanding regions for freshwater diversity include the south-eastern United States, the rift valley lakes in Africa, the Ganges and Mekong basins, as well as large parts of Malaysia and Indonesia. Local endemism is patchily distributed across the tropics, with hotspots in the rift-valley lakes, Thailand, Sri Lanka, and Papua New Guinea (Collen et al., 2014). In their global analysis, Brazil ranked highest in freshwater diversity (accounting for 12% of all investigated taxa), followed by United States, Colombia, and China (9–10% each). Megadiverse nations including tropical/subtropical climates with more than 50% of "political endemism" (Ceballos and Ehrlich, 2002) in freshwater species across the globe included Madagascar (96%), Australia (84%), United States (73%), Mexico (59%), China (55%), and Brazil (51%).

Worth mentioning is that many wetland-dependent vertebrate species (i.e., terrestrial, deep water and bird species) strongly depend on habitat and resources from tropical wetlands, which provide refuges from annual droughts or low temperatures during the winter at higher latitudes. Terrestrial animals migrate to the water, such as large herds of ungulates, which move between the Okavango Delta and the surrounding upland savannas, while aquatic animals migrate downstream to mainstem rivers when headwaters dry up or cool down (Sparks, 1995). Many water and shore birds migrate annually between breeding grounds and wintering areas, and tropical/subtropical rivers that cross different climate zones (i.e., N-S oriented, such as the Mississippi or Nile Rivers) are particularly important as long-distance migration corridors for water birds (e.g., ducks, swans, geese, herons, egrets), shorebirds (e.g., sandpipers), raptors (e.g., owls, hawks, eagles) and songbirds (e.g., warblers, finches) (Sparks, 1995). Fishes may undertake both longitudinal (i.e., along river channels) and lateral (i.e., from rivers to floodplains) migrations to spawning and feeding areas, because optimal conditions for both activities usually vary with the flood cycle and do not occur simultaneously in the same areas (Welcomme, 1985).

Lastly, tropical large-rivers also play a fundamental role in marine biogeochemical processes, salinity levels, food webs, and consequently biodiversity (i.e., Krumins et al., 2013), in particular in estuaries, deltas, and other terrestrial-marine transition zones. Global sediment input from rivers into the world oceans is estimated to account for more than 2×10^{10} t year^{-1} (Milliman and Meade, 1983). A few big tropical rivers including the Amazon, Yangtze, and Brahmaputra-Ganges drain tectonically active regions of uplifting, the erosion of which accounts for more than half of global river sediments supplied to the oceans (Williams, 2012). While the excess of river sediment through land use changes (e.g., deforestation) and intensified soil erosion including turbidity and increased levels of N and P as derived from pollution can have a detrimental effect on the biodiversity of marine and coastal ecosystems, such as coral reefs (i.e., Bartley et al., 2014) and mangroves (i.e., Ellison, 1999), tropical river sediments are crucial in providing nutrients that provide the trophic basis for a range of marine ecosystems, and here especially the sediment-associated biota (i.e., Levin et al., 2001). Damming large rivers considerably reduces down-river sediment transport which contributes to the destruction of river deltas, intensified coastal erosion, and loss of habitat and biodiversity (i.e., Vörösmarty et al., 2009), with numerous examples all over the globe (i.e., Yangtze, Mississippi, Mekong).

Threats

Tropical freshwater habitats are among the most threatened ecosystems globally. Extensive large-river floodplains have been lost due to regulation of rivers for flood control, irrigation, and hydropower generation. Meanwhile, inappropriate resource and land use, drainage, water deviation, channeling, damming, eutrophication, pollution, and climate change further fragment wetlands and threaten biodiversity. The degradation of tropical large-river floodplains is ongoing and even accelerating into the near future (He et al., 2019). Global water demand increased 10-fold during the 20th century (Biswas, 1998) and will increase in 50% by 2030. The decline in freshwater biodiversity during the last 50 years is estimated at approximately 80% (IUCN Water Knowledge Platform, 2021). Rapid growth of human population and economic development are tightly coupled with an increase in global energy demand and the use of renewable energy sources, namely hydropower. To date, almost half of all large-rivers on Earth are affected by dams (Nilsson et al., 2005; Lehner et al., 2011). This condition will increase as a result of an unprecedented global boom in dam construction since the 1990s (Zarfl et al., 2014), reinforced by the Paris Agreement for Climate Mitigation Strategies established in 2016 (Zarfl et al., 2019). Accelerating hydropower development is especially dramatic in highly diverse tropical river basins because it may cause the extinction of hundreds of freshwater species (Castello et al., 2013; Winemiller et al., 2016), and, in addition, also negatively affects marine biodiversity as previously described.

Because wetlands are often legally protected to some degree in most countries, a crucial legal problem for periodically flooded wetlands is the delimitation of their area. While conservation- and ecosystem-minded institutions may recognize the importance of a broad definition that encompasses varied flooded habitats (even those occasionally flooded) for the maintenance of biodiversity and services, economic institutions seeking to exploit wet areas usually favor more restricted definitions that limit borders to core wetland areas. In Brazil, for example, the delimitation of wetlands proposed by a group of scientists defines the wetland area as the area influenced during the mean maximum flood and includes permanent dry areas inside the wetlands as of vital importance for the maintenance of wetland integrity (Junk et al., 2014). This definition, however, is heavily contested by the Brazilian agroindustry. The latter accept the risk of losses in biodiversity but also of crops, live stocks and even human life during high floods. This problem will increase in the near future because of growing risks of extreme flood and drought events with climate change.

Deforestation and land-use change, in particular due to cattle ranching and agriculture, affects river wetlands in the short term because of locally altered hydrologic conditions, such as decreased rates of evapotranspiration, and increased runoff, water temperature, and stream discharge (Macedo et al., 2013). Long-term effects, however, include reduced precipitation regimes and alterations in rainfall seasonality, with increased frequency and intensity of extreme droughts and high-water events (Yin et al., 2014). It also increases soil erosion, sediment transport and changes water chemistry (Junk, 2013). Pollution through mining, agriculture, navigation, aquacultural activities and industrial and domestic wastewater affects many tropical rivers and floodplains. Mining activities also often alter stream and river morphology as a result of excavations that increase sediment loads (Wittmann and Junk, 2016). Large-scale mining also promotes deforestation, road, railway and pipeline constructions, as well as the construction of river dams and transmission lines for energy production.

River damming for hydropower generation is an increasing threat with perhaps the most disastrous consequences for the wetland biota at large scales, especially when it occurs along lowland rivers (Wittmann and Junk, 2016). Dams interrupt hydrological connectivity in multiple ways, lead to the alteration of hydrological cycles and flood pulses, trap sediments and nutrients, change water temperature, transparency, and chemistry in reservoirs and downriver, and act as dispersal barriers for fish and other aquatic organisms (Rosenberg et al., 1995; Nilsson and Berggren, 2000; Agostinho et al., 2008; Pelicice et al., 2014). While national policies still regard hydropower as a clean energy source, many dams and reservoirs are located far away from where energy consumption is needed and often operate significantly below initially designed energy outputs (Fearnside, 2006). In addition, greenhouse gas emissions from tropical hydropower plants may be as high or even higher than those emitted through fossil fuel burning (Kemenes et al., 2011; Fearnside, 2015), a fact still largely ignored by national governments. Although the construction of large dams in tropical regions is usually accompanied by studies of environmental impact, these concentrate on the floodable area of the reservoir and largely ignore environmental impacts far up- and downriver (Wittmann et al., 2015). The downriver impacts, however, including the death of floodplain trees and negative effects on floodplain food chains, may extend along river courses over hundreds of kilometers downstream of the dam, as shown for the Balbina dam in Amazonia (Schöngart et al., 2021) and the Engenheiro Sérgio Motta (Porto Primavera) reservoir at the Paraná River (Junk et al., 2021). In the latter case, after reservoir construction fish species composition changed more than 80% in 20 years, a nearly complete compositional turnover (Agostinho et al., 2008).

Most anthropogenic pressures on tropical large-river wetlands are reinforced through impacts caused by climate change. Global terrestrial water storage (TWS), which represents the sum of water stored in canopies, snow and ice, rivers, lakes and reservoirs, wetlands, and soil and groundwater, was recently modeled by Pokhrel et al. (2020) based on global climate models included in the Fifth Assessment Report of the IPCC, for the 21th century. Irrespective if moderate-to-severe or if extreme-to-exceptional climate models are applied, results indicate that climate change reduces TWS in many tropical regions, especially in the Southern Hemisphere, while increases in precipitation are most likely for Southern India, parts of SE-Asia, and northern Australia. Large part of South-America (with some exceptions in the western Amazon, eastern Brazilian Cerrado and along the Brazilian coast), and most parts of NW-, Central- and S-Africa and tropical Asia will be subjected to an increased frequency and intensity of droughts with varying severity. Along thousands of kilometers of river stretches, reduced precipitation combined with global sea-level rise will impact river discharge, dynamics, sediment balance, as well as habitat diversity that currently underpin this ecosystem's important function for biodiversity and human services, with so far mostly unknown consequences for human well-being.

Conservation

Many tropical countries have protected large wetland areas; however, increasing multiple pressures affect even the protected wetlands at the species, community and ecosystem levels. Local populations have managed many tropical wetlands sustainably for centuries or even millennia, but the rapidly growing population and globally-changing economic requirements have led to changes in political and economic strategies, new forms of land-use, new development priorities, and the rapid decline of traditional practices (Junk, 2002). While nature conservation globally is steadily increasing, only a few conservation efforts are effective for maintaining tropical freshwater biodiversity. Most protection is directed to the distribution of terrestrial taxa and therefore of limited use for the integrative conservation of freshwater systems (Peres and Terborgh, 1995; Abell et al., 2007). In addition, many protected areas of tropical wetlands are governed by laws that allow resource extraction, mining activities, hydropower generation and further economic activities affecting wetland ecosystem integrity.

While most tropical countries have established some form of environmental policy or have national programs that indirectly relate to wetlands—such as policies related to water resource management, biodiversity and genetic resources, forests, sustainable development, fisheries, water sanitation, etc.—only few countries (i.e., Australia), have specific policies regarding the integrative protection of wetlands at the national level (Wittmann et al., 2015). Most tropical countries signed the Ramsar Convention on Wetlands of International Importance, which targets the wise use, management and monitoring of important wetlands. While the number of Ramsar sites is continuously increasing (i.e., Ramsar, 2015), most signing countries are slow in meeting the requirements of the six major initial criteria of wetland conservation of international importance: (1) to provide a definition of wetlands, (2) to elaborate wetland classifications and delimitation, (3) to evaluate wetland conditions, (4) to implement the wise use of wetlands, (5) to implement national policies for wetland conservation, and (6) to manage wetlands and to monitor wetland characteristics. As an example, only a few tropical countries, (i.e., Australia, United States, Argentina, Brazil) have developed national wetland classification systems, while most of them lack specific wetland regulations, and have yet to complete national wetland inventories (Ramsar, 2015). Further exacerbating implementation is often limited financial and human resources, general lack of infrastructure, and limited monitoring capacity (Wittmann et al., 2015). In addition, many pressures on freshwater biodiversity, such as illegal fishing and hunting, aquacultural activities, poaching or the exploitation of bird and fish eggs continue in many wetlands in spite of protection measures.

Existing and newly emerging threats for freshwater biodiversity loss and ecosystem degradation of tropical large-river wetlands demands for urgent basin-wide, transnational or even worldwide solutions and efforts for effective conservation. The impoundment of large rivers flowing through different countries creates several trans-boundary water conflicts, which certainly will increase in the near future in a world of global climate change. However, while there are promising examples of transnational agreements on water security and the management of social water conflicts (i.e., Link et al., 2014), few efforts have been made regarding the transnational

conservation of freshwater biodiversity. Promising examples exist (i.e., Initiative for Conservation and Sustainable Use of Andean Wetlands, Initiative for the Conservation of Mangroves and Coral Reefs, Initiative of the La Plata basin, etc.), but much more efforts are required to protect system integrity and freshwater biodiversity of tropical large rivers and their wetlands, also considering both their terrestrial and marine interactions.

Future research

- Extend the wetland classification system of Brazilian wetlands (Junk et al., 2014) to tropical wetlands in Asia, Africa and Oceania to enable worldwide comparisons on biodiversity, wetland function, ecosystem services, and threats.
- Close knowledge gaps on habitat diversity, floristic and faunal composition, and ecosystem processes and functioning of African wetlands, particularly in the Congo basin.
- Investigate long-term effects of flow regulation, river dams and climate change on the tropical wetland biota, i.e., effects on ecological connectivity, species composition, diversity, and food webs, and extend investigations on impacts to coastal and marine ecosystems.
- Develop management options for the integrative protection and restoration of freshwater systems using a landscape approach, including cost-benefit analyses of traditional and modern land use, also extending to terrestrial and marine interactions.

Tropical Peat Swamp Forests

J Ethan Householder[a,b] **and Susan Page**[c], [a]Wetland Ecology, Institute for Geography and Geoecology, Karlsruhe Institute for Technology, Karlsruhe, Germany; [b]Botanical Research Institute of Texas, Fort Worth, TX, United States; [c]School of Geography, Geology and the Environment, University of Leicester, Leicester, United Kingdom

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Wolfgang Junk and Florian Wittmann.

Glossary

Alluvial Refers to sediments (clay, silt, sand, gravel) deposited by flowing water.
Carbon sink A reservoir that accumulates and stores carbon, thereby removing it from the atmosphere for long periods of time.
Carbon source A reservoir of stored carbon that releases more carbon to the atmosphere than it absorbs.
Fluvial Refers to physical features of the landscape shaped by erosional and depositional processes of streams and rivers.
Peat A type of soil derived largely from partially decomposed plant material under wet conditions, and thus characterized by its high organic, rather than mineral content.
Peat dome A convex-shaped peat deposit with greatest depths near its center, a condition driven by the maintenance of a higher ground water level in the center of an accumulating peat deposit.

Introduction

Swamp forests develop where topography results in poor drainage and permanent soil waterlogging. This unique hydrologic environment is not conducive to decomposition and plant debris tends to accumulate on the forest floor, the sustained buildup of which over long periods of time can lead to the formation of thick peat deposits (Blodau, 2002). As significant sinks or sources of carbon-based greenhouse gases, tropical peat swamps are increasingly linked to discussions of global climate change. In addition, as environmentally extreme habitats peat swamps make important contributions to tropical landscape heterogeneity and biodiversity. Here, we overview the environmental conditions that permit the development of peat swamp forests, from the local processes that allow peat accumulation, to the landscape and regional processes that determine their global extent and distribution. In doing so we also examine what is known about the amount of carbon stored in peat swamps, how it is measured, and which factors control its flux between soil and atmosphere. We then turn to assess the relevance of tropical peat swamps to biodiversity and the myriad ways in which local floras and faunas inhabit and interact with them.

Peat can be loosely described as a layer of soil composed mostly of partially decomposed organic material. Although working definitions vary among researchers, all are based on minimum thresholds of organic content (usually 50–65%) and the depth of the peat layer (30–40 cm) (Page et al., 2011). In the tropics, peat-forming swamps develop in a variety of conditions, but their greatest extents - and peat depths - are found at low elevations along fluvial valleys, over interfluvial divides, and fringing coastal areas (Cameron et al., 1989). Extensive peat swamps occur in tropical Africa, South America, and Southeast Asia (Gumbricht et al., 2017; Xu et al., 2018). Regardless of continent, however, these ecosystems have traditionally been regarded as biologically depauperate

and unproductive wastelands with little economic or scientific value. Scientific exploration has therefore lagged far behind that of other ecosystems, meaning that the biological, environmental, and societal significance of peat swamps has been habitually underappreciated. Consequently, management policies in many tropical countries have favored conversion to more productive agricultural uses, which have resulted in the wholesale deterioration of immense tracts of natural peat swamp area (Miettinen et al., 2012).

From relative disregard, tropical peat swamps have shifted to the fore of global scientific and societal discussion. This turn is largely the result of two lines of scientific inquiry over the past two decades. First, degrading peat swamps were found to be a considerable potential source of carbon to the atmosphere (van der Werf et al., 2009). In Indonesia, for example, estimates of carbon emitted to the atmosphere during dry season burning of peat swamps were of similar magnitude to the mean annual global carbon emissions from fossil fuels (Page et al., 2002). Second, vast areas of previously undocumented peat swamps were quantitatively described in both South America (Lähteenoja et al., 2009; Householder et al., 2012), and central Africa (Dargie et al., 2017), greatly increasing the known extent of peat swamps, as well as the tropical stock of peat carbon. These surprising revelations not only exposed severe knowledge gaps, but also anchored the discussion of tropical peat swamps to the foremost challenge of modern society - global warming.

A primary driver of global warming is the accumulation of carbon in the atmosphere resulting from human activities. The deep peats of many tropical swamps reflect a legacy of operating as a sink for atmospheric carbon, with a net cooling effect for the globe over millennia. Their large contact boundary with the atmosphere, however, also facilitates carbon effluxes from peat to atmosphere (Yu et al., 2010). Hence, large stocks of peat in carbon-rich swamps have tremendous potential to become a globally significant source of carbon to the atmosphere (Warren et al., 2017a; Wang et al., 2018). The magnitude of this potential carbon source and its possible negative or positive feedbacks on global climate is currently an active area of scientific research (Lawson et al., 2015).

Main topics/concepts

Local processes of peat formation

To more clearly understand the role of peat swamps as either carbon source or sink, awareness of the factors that regulate the carbon balance of peat-forming forests is a crucial starting point. Carbon enters a peat swamp system through biomass production of photosynthesizing vegetation, and leaves it via aerobic decay, anaerobic decay, and leaching (Fig. 1; Blodau, 2002). The rate of peat accumulation thus reflects the balance between carbon input and its removal, so that a peat deposit grows when plant primary production is high relative to its decomposition, and decreases when losses due to decomposition or transport become greater.

Various factors determine the relative balance of these processes, but among the most important is the position of the water table (Blodau, 2002; Wösten et al., 2008). Maintenance of the water level near the ground surface is a prerequisite for tropical peat accumulation as it results in anoxic conditions that considerably limit one of the main paths for carbon loss in soils - aerobic decomposition (Hirano et al., 2009). The activity of aerobic decomposers is generally high in warm and humid conditions of tropical environments. Thus, in well-aerated soils, organic material is rapidly oxidized, leaving little to accumulate as peat. A high water table restricts this process to a thin upper layer, while anaerobic decomposition predominates in the anoxic conditions that persist below the water level (Fig. 1). Because anaerobic decomposition is a much slower decay process, carbon effluxes are reduced and soil carbon accumulates in the form of peat. In addition, organic accumulation in the soil increases its water-holding capacity

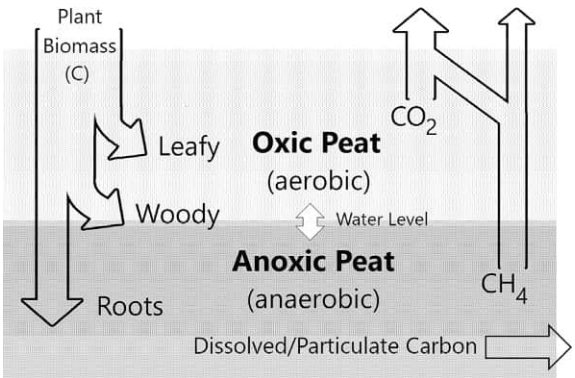

Fig. 1 A conceptual model of the carbon balance operating in a peat forming swamp. The level of the water table strongly mediates rates of both carbon input through plant productivity (left side) and carbon output (right side) that determine peat accumulation. Photosynthesizing plants incorporate atmospheric carbon into their biomass, which enters the peat carbon budget as separate litter fractions (left side) with differing rates of decay, determined primarily by the lignin content of the material and the level of anoxia where it is deposited. Carbon outputs (right side) occur primarily through gaseous fluxes mediated by soil microbes, as well as leaching, in the form of dissolved and particulate carbon. Carbon dioxide (CO_2) and methane (CH_4) are the principal carbon containing gases that result from microbial activity. Carbon dioxide is produced by aerobic decomposition in the oxic layer. Methane is the byproduct of decay processes in anoxic peat layers, a fraction of which is utilized by methanotrophs that are capable of oxidizing it to CO_2 (Jauhiainen et al., 2005).

and hydraulic conductivity, a condition that favors the upward capillary motion of soil water to further raise the water table, and thus soil anoxia, in a positive feedback. These processes can result in domed peat surfaces and deep peats to 20 m.

Another key factor influencing the balance of carbon in peat swamps is the nature of swamp vegetation, which in tropical peatlands is generally forested (Lawson et al., 2015). A diverse array of tropical swamp trees possesses effective morphological and physiological adaptations to sustain growth even in waterlogged conditions, which otherwise restrict growth of the vast majority of plant species (Draper et al. 2018; Householder and Wittmann, 2016; Page et al., 1999; Posa et al., 2011). Consequently, peat swamps often harbor multi-storied tree canopies that are able to support high levels of biomass production despite the locally harsh growing conditions. An important feature of this luxuriant growth in regards to peat accumulation is the production of different types of litter, ranging from fleshy leaves, woody debris such as branches and tree trunks, and underground roots. These various litter fractions all have different capacities for decay and therefore make different contributions to accumulating peat (Chimner and Ewel, 2005). Fleshy leaves contribute a high proportion of plant productivity, but their deposition on the soil surface leads to rapid, aerobic decay that yields little carbon for peat development (Yule and Gomez, 2009). Much of tropical peat is therefore derived from woody debris and roots. Woody debris from twigs and trunks of trees is deposited on the soil surface, but its higher lignin content and carbon:nitrogen ratios confer greater resistance to decomposition. Root systems of dominant peat swamp trees tend to be quite extensive, producing considerable biomass directly within anoxic layers of peat soils where their decomposition is strongly constrained (Chimner and Ewel, 2005).

The predominantly forested condition of tropical peat swamps contrasts with non-tropical peatlands dominated by *Sphagnum* mosses, which neither produce large amounts of recalcitrant wood nor root biomass. The forest vegetation is thus the principal component of tropical peat that determines its properties, rate of accumulation, and susceptibility to degradation (Könönen et al., 2016). Where peat swamp forest vegetation and its local hydrological environment are maintained over long periods of time, tropical swamps can accumulate peat rapidly, making them among the world's most effective terrestrial ecosystems for the long-term sequestration of atmospheric carbon (Dommain et al., 2011).

Regional and landscape processes of peat formation

While peat formation is the result of biogeochemical processes operating over small spatial and temporal scales, the unique hydrological conditions that enable these processes are determined by factors acting over the scale of the larger landscape. Three basic landscape requirements for peat swamp formation are (i) a local topographical depression, (ii) relatively stable water levels that persist over time, and (iii) a water source that carries limited sediment load. The first two sustain the waterlogged conditions that limit peat oxidation, while the latter prevents depressions from being plugged with mineral sediments at a faster rate than infilling of organic matter. These basic requirements are only satisfied under a combination of specific geomorphologic, geologic, and climatic contingencies.

Climate conditions are generally humid where peat swamps develop, with most concentrated in areas where yearly precipitation exceeds evapotranspiration. Strong rainfall seasonality can curtail long-term peat accumulation when prolonged dry periods lead to oxidative peat loss that exceeds organic accumulation. As such, the accumulation and maintenance of peat is sensitive to strong interannual climatic variability, such as El Niño-Southern Oscillation (ENSO). Long-term paleoecological records often report strong coupling of peat accumulation rates with climate variability over millennial time-scales, with expanding peats and rapid peat accumulation during wetter time intervals, and retraction with peat oxidation during drier intervals (Page et al., 2004; Dommain et al., 2011).

Although wet climates are favorable for peat swamp formation, the local conditions that actually sustain an appropriately wet environment are largely a function of the physical and geologic settings, which determine where and how water collects locally. In tropical lowlands, where the vast majority of peat swamps are located, topographic depressions are most commonly generated by dynamic fluvial processes. Indeed, most globally significant tropical peat areas occupy abandoned meander scars in river valleys (Householder et al., 2012; Lähteenoja et al., 2012), or alluvial terraces that have been subsequently bisected by river erosion (interfluves) (Dommain et al., 2011; Dargie et al., 2019). Although often embedded within fluvial settings, characteristics common to many tropical lowland rivers rarely favor peat swamp development. These include marked seasonal river level oscillations, large amounts of suspended sediment, or both (Latrubesse et al., 2005). Highly seasonal river-level fluctuations result in pronounced low water-table phases that expose peat to air and lead to rapid peat oxidation. During high river stages, on the other hand, organic accumulation on the surface can be carried away with currents. Overbank flow during floods can also bring in large amounts of suspended sediment, thus adding a significant mineral component onto accumulating organic material to create muck, rather than carbon-dense peat. In fluvial environments where rivers strongly regulate the hydrological setting, peats swamps are often associated with impermeable subsurface base layers such as clay strata or hard pans, which strongly modify the local hydrological setting. These subsurface layers inhibit drainage of rainfall, and often force groundwater laterally to cause local seepages. Hence, they establish favorable hydrological conditions for local peat accumulation by providing some level of hydrological independence from potentially fluctuating water table levels due to seasonal river discharge or rainfall (Dommain et al., 2011; Householder et al., 2012).

Global distribution and genesis of peat swamps

Tropical peat swamps have been documented on all major tropical land masses. Considerable uncertainty, however, still exists regarding their global distribution and extent. Indeed, scientific documentation of several large peat swamps has only recently begun. Despite significant knowledge gaps, it is clear that the geographic distribution of tropical peat swamps is noticeably unbalanced, with overwhelming concentration in only three large peat swamp complexes located in southeast Asia, northwest Amazonia, and central Africa (Fig. 2). This skewed distribution ultimately reflects the unique combination of regional climatic, geomorphologic, and geologic contingencies in these locations which have enabled peat accumulation over millennia.

Southeast Asia

In SE Asia, peat swamps are concentrated in the modern-day islands of Sumatra, Borneo, and parts of the Malay peninsula (Page et al., 2006). This island region is connected by the geologically stable and shallow continental Sunda Shelf, or "Sundaland," which has played an integral role in the genesis of the region's vast peat swamps (Dommain et al., 2011). During the last glaciation, shelf areas were exposed by lower sea levels, in which setting the eroding crystalline highlands formed extensive alluvial plains. It is in this flat alluvial setting where the majority of modern peat swamps have developed, primarily along river interfluves from coastal areas to over 200 km inland. Two regional developments during deglaciation were key for the initiation of these peat swamps. First, flooding of the Sunda Shelf in response to rising sea levels decreased the hydraulic gradient from river headwaters, impeding drainage on an already very flat landscape. Second, the climate became wetter, in part because of the newly formed regional evaporating area of the flooded shelf. Both developments led to increasing regional water tables that triggered the necessary waterlogging for peat initiation. The timing of peat initiation, however, varied along an elevation gradient from coastal to inland areas, a reflection of how the changing water table interacted locally with surface topography. In coastal areas at sea level, peat swamps arose only upon stabilization of sea levels in the mid-Holocene about 4000–7000 yrBP (Page et al., 2006). These relatively young peat swamps have depths from 1 to 3 m, forming over clayey substrates initially deposited under mangrove vegetation

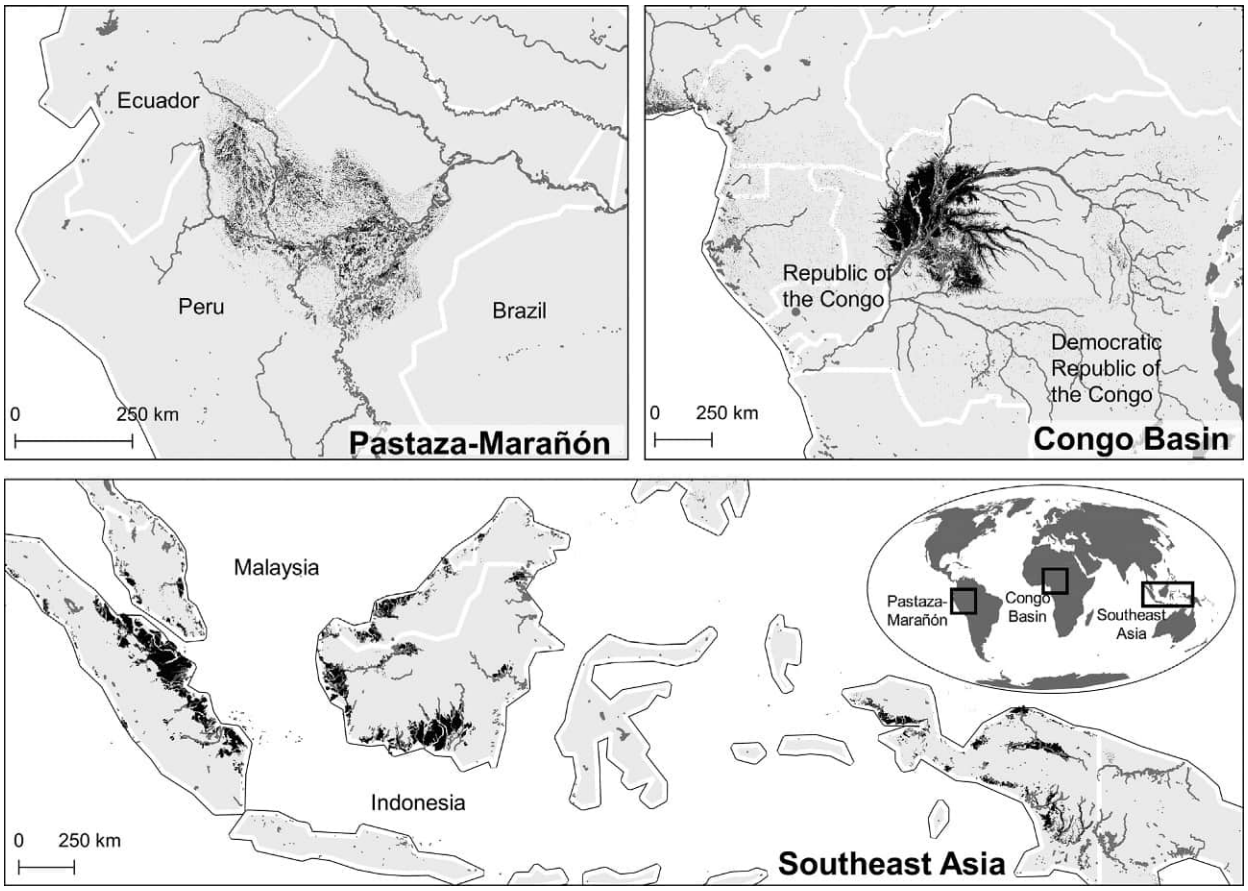

Fig. 2 Major regions of peat-forming swamps (black) in the tropics. Mapping is restricted to areas where large peat swamp complexes have been ground verified. Although permanent waterlogging drives peat accumulation in all regions through similar biogeochemical processes, the geomorphologic and geological contingencies that create and sustain the waterlogged conditions are quite different among regions. Peat swamp distribution data shown here are derived from remote sensing products obtained from publicly available datasets (consolidated by Xu et al., 2018, and in tropical regions largely based on Gumbricht et al., 2017 and Dargie et al., 2017).

(Cameron et al., 1989). Farther inland and at slightly higher elevation (5–15 m above sea level), peat swamps initiated slightly earlier (8000–9000 yrBP), in response to increasing sea levels and the rising water table. These domed peat swamps, up to 20 m deep, form in river interfluves, where water table mounds contribute to permanent waterlogging (Dommain et al., 2011) and natural levees limit floodwaters from adjacent rivers. The oldest peat swamps, initiating as early as 47,000 yrBP, are located at higher elevations to 30 m above sea level (Ruwaimana et al., 2020). The initiation of these older peats is too early to be explained by sea level rise associated with deglaciation. Many developed over podzolised sands with an impermeable hard pan in the substratum, a key feature defining the local hydrological setting in which peats well over 10 m have accumulated (Page et al., 1999, 2004). Others are the result of terrestrialization of lake basins.

Northwest Amazon

In tropical America, the most significant peat swamp complex is located in the northwestern Amazon (northeast Peru), which has developed within an actively subsiding foreland - the Pastanza-Marañon basin (Draper et al., 2014). The subsiding basin is linked to flexure of the continental lithosphere as a result of compressional tectonic forces and the uplifting of the Andes (Dumont, 1996). This ancient basin has formed a regional collecting point for rivers that drain an immense landmass with high and relatively aseasonal rainfall, thus establishing the waterlogged conditions appropriate for peat swamp development. Within this subsiding basin, fluvial sediments from Andean headwaters have built up several thousand meters of alluvial material (Räsänen et al., 1992) and it is in this highly depositional, and dynamic fluvial setting where peats up to 8 m in depth have accumulated, largely within river valley depressions formed by meander scars and abandoned arms of laterally migrating rivers (Lähteenoja et al., 2012). Peat formation generally commences in depressions only after overbank flood connections to sediment-laden rivers are minimized, which may happen as channels migrate away from developing peat swamps and sediment-free sources of rainfall and groundwater come to dominate local peat swamp hydrology (Householder et al., 2012; Lawson et al., 2014). Although suitable conditions for peat formation in the Pastaza-Marañon basin are likely to have persisted throughout the Quaternary, the basal peat ages that time stamp their initiation tend to be younger and more variable than their SE Asian counterparts. Whereas in SE Asia peat swamps initiated largely as a regional response to rising ocean levels after the last deglaciation, peat swamp initiation in the Amazon has tended to be a local response to river meandering (Householder et al., 2012; Lähteenoja et al., 2012). Meandering river channels not only generate local depressions for peat swamp development, but also cause the wholesale erosion of developing peat swamps, or alternatively, their burial under mineral sediments that are transported and deposited by river floods (Lähteenoja et al., 2012). As a result of this dynamism, individual peat swamps rarely exceed ages of 8000 years, and even within this short time span the constantly changing position of developing peat swamps with respect to the main river channel often brings about abrupt transitions and reversals of environmental conditions and vegetation succession (Roucoux et al., 2013; Kelly et al., 2017). The waxing and waning of fluvial influence over time is often reflected in complex peat stratigraphies, showing mineral layers (associated with river influence) intercalated with peat (Lähteenoja and Page, 2011). An important consequence of this fluvial dynamism is that peat can be buried under river sediments, thus forming a protective mineral cap that reduces peat to exposure and oxidation by drought, fire, and river erosion. The slow subsidence of this buried peat within the foreland basin is believed to be an efficient long-term carbon storage process that has presumably operated to remove atmospheric carbon throughout the Quaternary (Lähteenoja et al., 2012).

Congo Basin

Africa's largest complex of peat swamps has developed within the Congo Basin, also known as the Cuvette Centrale (Dargie et al., 2017). The Congo Basin is one of the least studied major river basins and considerable knowledge gaps exist regarding its geologic evolution. Its origins are most recently linked to extensional forces associated with continental rifting in eastern Africa, although its >800-million-year history is likely the result of varied (and still poorly understood) geological processes (Buiter et al., 2012). Reported sizes of the basin range from about 3.6 to 4.1 million km^2, and peat swamps are currently estimated to account for about 40% of its extensive wetland areas (Dargie et al., 2017). These peat swamps overlie river interfluves and show maximal peat depths of nearly 6 m at domed midpoints between bounding rivers. Basal peat ages between ~7000 to 10,000 years BP mark the initiation of conditions suitable for peat formation and coincide with increased precipitation of the African Humid period (Dargie et al., 2017). The current climate is slightly drier (between ~1100 mm yr^{-1} to 1900 mm yr^{-1} along an east-west trend), but swamps have nevertheless continued to accumulate peat since initiation. The hydro-geological scenario that generates the waterlogged conditions for peat swamp development is not yet well understood. Water levels on interfluves supporting peat are relatively stable and often a few meters higher than those of the immediately adjacent and more strongly fluctuating rivers (Alsdorf et al., 2016). Several other lines of evidence suggest that the interfluvial peatlands are primarily fed by rainwater, rendering them hydrologically independent of the fluctuating rivers that flank them (Dargie et al., 2017; Davenport et al., 2020). Under these circumstances interfluvial peat swamps remain inundated even during low-stage river levels and are unlikely to receive mineral input from overbank flooding.

Although far from an exhaustive account of the myriad settings in which tropical peat swamps can occur, what should be clear is that their formation reflects a unique set of climatic, geomorphologic, and geologic factors. These factors ultimately determine the local hydrological conditions that govern the distribution of peat swamps from landscape to global scales.

Carbon stock of tropical peat swamps and its measurement

Measurement of peat swamp carbon stocks at global scales has only begun within the last decade. Page et al. (2011) originally estimated tropical peat carbon stocks at 88.6 Gt C, a shocking amount equivalent to nearly 20% of the global peat carbon pool. Following emerging ground data from newly documented peat swamps in tropical America and Africa, carbon stock estimates of tropical peat have been significantly revised upwards to 104.7 Gt C (Dargie et al., 2017). This amount is equivalent to nearly half (45%) of carbon stored in living biomass of intact tropical forests (228 Gt C), but in only a fraction of the surface area (Pan et al., 2011; Dargie et al., 2017). Simultaneously, studies based largely on remote sensing of satellite imagery have suggested that large areas of tropical peat swamps with globally significant carbon pools may still remain unreported (particularly in the Amazon basin), although supporting field data continues to be lacking (Gumbricht et al., 2017; Xu et al., 2018; Riberio et al., 2021).

Considerable uncertainties still underlie all estimates of peat swamp carbon stocks (Lawson et al., 2015). Carbon stock is calculated as the multiplication of a peat swamp's aerial extent (m^2), peat thickness (m), dry bulk density of peat (kg m^{-3}), and peat carbon concentration. A first step in this calculation is often to map the aerial extent of peat swamps using a combination of ground reference data and satellite imagery. A wide variety of remote sensing satellite products reveal distinctive features of peat swamp vegetation, hydrology, and geomorphology, thus providing means of extrapolating ground reference points and identifying peat swamp habitat across larger areas. Underground peat properties (thickness, bulk density and carbon concentration) are most often addressed through field measurements using down-core sampling. Peat thickness can vary tremendously at small spatial scales because of complex subsurface geometries (Householder et al., 2012). Likewise, other underground peat properties such as bulk density and carbon concentration vary both vertically and horizontally within a peat swamp. As such, values of underground peat properties are often subject to a high level of uncertainty, particularly since they are often based on small sample sizes. These uncertainties are compounded when average values are extrapolated over broader peat swamp areas to estimate carbon stocks (Lähteenoja et al., 2012; Warren et al., 2017b). One promising approach to reduce the uncertainty of these extrapolations is to develop local relationships between underground peat properties and spectral properties derived from remotely sensed data. By taking into account the spatial variation of peat properties, these local relationships can be used to improve predictions at unmeasured locations and thus reduce uncertainty in carbon stock estimates (Draper et al., 2014).

Biological diversity

Globally, biological diversity peaks in tropical regions within lush and contiguous forest habitat growing on mineral soils. These forests have therefore been the traditional target of most scientific inquiry aimed at answering enduring questions of tropical biodiversity. Peat swamps, on the other hand, are relatively species-poor in most taxonomic groups, patchily distributed, and environmentally extreme. They are a striking departure from the diverse tropical forests that surround them, and therefore often perceived as anomalous exceptions that bear little relevance to questions of tropical biodiversity. This perception, combined with their remoteness and challenging working conditions, have contributed to a considerable lack of biodiversity information for peat swamp habitat.

It is increasingly recognized, however, that peat swamps form an important component of landscape environmental heterogeneity that contributes to regional biological diversity in important ways. The unique habitat often harbors a distinct set of species (Posa et al., 2011), novel species assemblages (Householder et al., 2016) or provides unique resources that are otherwise unavailable or rare outside of peat swamp habitat (Householder et al., 2010; Tobler et al., 2010). In addition, populations of species that encounter or inhabit peat swamps may undergo behavioral, morphological, or physiological change in response to the unique ecological setting, which itself underpins trait evolution and species diversification (Thornton et al., 2018). Far from anomalous exceptions to high tropical biodiversity, peat swamps provide a marked example of the importance of environmental heterogeneity in its maintenance and generation.

Flora

For the vast majority of vascular plants, year-round waterlogging is a significant environmental adversity because it greatly decreases the availability of soil oxygen for plant respiration. Local tree diversity thus often ranks low relative to the more diverse forests that grow on surrounding, well-drained, mineral substrate (Fig. 3; Draper et al., 2018; Giesen et al., 2018). In their oxygen-starved soils, plants require anatomical, physiological, or metabolic adaptations to obtain oxygen from above the soil surface or negotiate its scarcity in the substrate. Traits such as pneumatophores, lenticels and buttressed roots include some of the most outwardly visible manifestations of tree adaptation to a waterlogged environment. For the vast majority of plants, however, the suite of attributes that permit successful growth and regeneration in peat swamp habitat remain poorly understood.

In addition to complete water saturation, the peat swamp plant community responds strongly to local changes in nutrient availability, flooding depth and water chemistry, so that local vegetation is often markedly zoned along multiple environmental gradients (Page et al., 1999). It is not uncommon, for example, for closed forest to transition to an open herbaceous community within a matter of a few dozen meters. Strong variability in plant community composition among individual peat swamps is also commonly reported, reflecting differences among peat swamps in age, successional stage, disturbance history, abiotic conditions, as well as large dispersal distances between swamps that limit floristic exchange (Anderson, 1963; Posa et al., 2011; Householder et al., 2012, 2016).

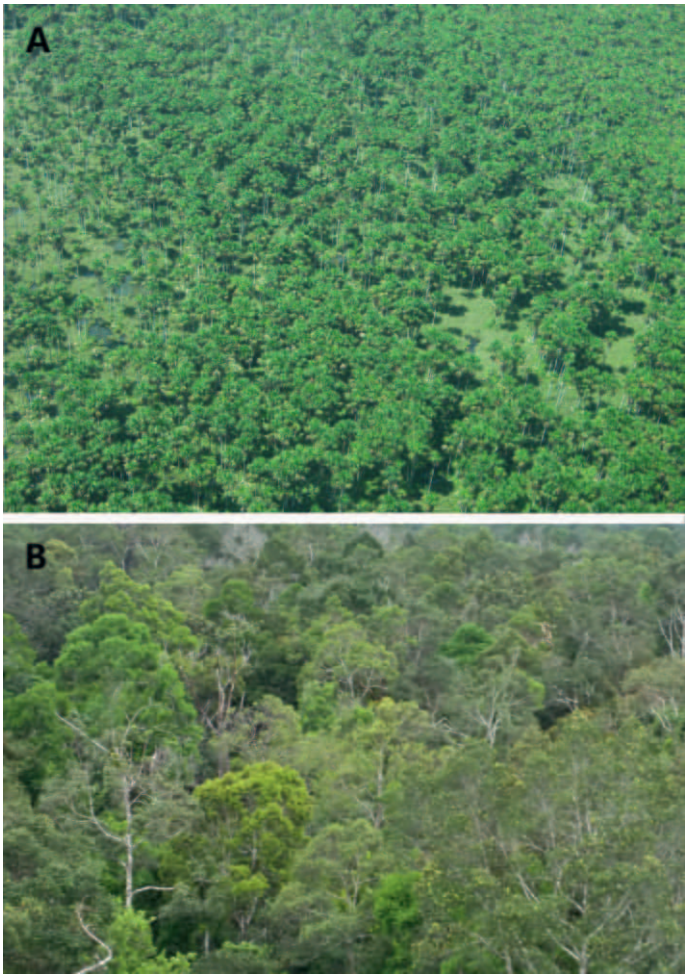

Fig. 3 Views over peat forest canopies in the (A) Peruvian Amazon, and (B) and Indonesian Sumatra. Peat swamp canopies in the Amazon region are dominated by a single species of arborescent palm (*Mauritia flexuosa*), which commonly achieves high densities of approximately 300 individuals per hectare. In this monodominant canopy, the largest fraction of floristic diversity is in the understory, which is often rich in shrubs, herbs, and epiphytes. Indonesian peat swamps, in contrast, have a much richer diversity of canopy species, ranging between 30 and 120 species per hectare (Giesen et al., 2018). Photo credits: M. Tobler (A), S.E. Page (B).

Peat swamp plant communities have long been regarded as highly unique and specialized to the novel environmental conditions that prevail in peat swamps (Anderson, 1963). Strict ecological specialization, however, tends to be rare among plants. A significant fraction of peat swamp floristic diversity, if not the largest, is composed of species that are also commonly found in forests of well-drained mineral soil, implying that many plant species of peat swamp habitat are broadly tolerant to a wide variety of soil conditions (Pitman et al., 2014; Giesen et al., 2018). Floristic ties to other environmentally extreme habitats are also prevalent, such as those on nutrient impoverished podzols, high elevation mountain forests, or seasonally inundated floodplains (Householder et al., 2015; Giesen et al., 2018). In such habitats where growth is similarly limited by abiotic extremes, plant traits required for survival and regeneration are also likely to be similar, thus facilitating floristic exchange among them (Householder et al., 2016). Although few plant species are strictly restricted to peat swamp habitat, it seems clear that peat swamps maintain large and biologically important populations of many species that are otherwise locally rare outside the habitat (Posa et al., 2011; Draper et al., 2018; Giesen et al., 2018).

Fauna

Information regarding faunal diversity in peat swamps is geographically unbalanced, most emerging from Southeast Asian swamps that have enjoyed a longer legacy of scientific exploration. It is also taxonomically biased, largely restricted to more conspicuous vertebrate members, and in particular large mammals and fish. Other groups such as insects, amphibians, reptiles, and small mammals have received scant attention. Few, if any, terrestrial vertebrate species are biologically dependent on peat swamp habitat. Rather, peat swamps tend to be one part of the larger ecological mosaic that local animal populations may utilize in a variety of important ways. In Amazonia, for example, fruits of the canopy dominant of peat forests (*Mauritia flexuosa*) are a valuable temporary food resource for large terrestrial mammals such as the lowland tapir (*Tapirus terrestris*) and peccaries (*Tayassu pecari*

and *Pecari tajacu*) (Tobler et al., 2010). Also, the dead, standing trunks of *Mauritia flexuosa* serve as a main nesting site for the blue-and-yellow macaw (*Ara ararauna*) (Brightsmith and Bravo, 2006). In SE Asia, peat swamp forests are an important refuge for some of the largest populations of a number of threatened animals, including orangutans (*Pongo* spp.), Bornean gibbons (*Hylobates albibarbis*), the false gharial (*Tomistoma schlegelii*), Storm's stork (*Ciconia stormi*) and the white-winged wood duck (*Asarcornis scutulata*) (Posa et al., 2011). Likewise, central African peat swamps are an important sanctuary for species whose habitats have been altered as a result of human land use, supporting considerable numbers of lowland gorilla (*Gorilla gorilla gorilla*), forest elephant (*Loxodonta cyclotis*), chimpanzee (*Pan troglodytes*) and bonobo (*Pan paniscus*) (Dargie et al., 2019). In contrast to terrestrial fauna, fish have been reported to exhibit higher levels of specificity to aquatic environments associated with peat swamp habitat, although most information regarding this group is still restricted to SE Asia (Ng et al., 1994). The aquatic habitats in peat swamp forest are characterized by their high acidity, high content of dissolved organic matter, low nutrient content, and often low levels of dissolved oxygen. This suite of conditions typically differs from nearby aquatic environments outside peat forest, offering habitat to unique assemblages of fish species that often exhibit high levels endemism (Ng et al., 1994). Posa et al. (2011), for example, estimated that about one third of the 219 fish species encountered in peat swamps could be endemics specialized to the habitat.

Threats

Tropical peat swamps face a variety of local and regional threats (Fig. 4). One of the most widespread and persistent is agricultural expansion into peat swamp habitat. Transformation to agricultural production initially involves both logging of the original forest and lowering of the water table by means of drainage ditches. These land use changes dramatically alter the carbon balance of peat

Fig. 4 A selection of images illustrating some of the major land use threats to peat swamp forests. (A) Peat fire in Indonesian Borneo. (B) Smallholder farming activity on peat in Indonesian Borneo. (C) Aftermath of recent peat fire in eastern Amazonia near cattle pasture from where the fire spread. Only the fire-tolerant *Mauritia flexuosa* persists. The dark bases of trunks are charred pneumatophores and adventitious roots. Their visibility high above the peat surface reflects a rapid lowering of peat by about one meter, likely a consequence of smoldering fires and drainage. (D) Felling of *Mauritia flexuosa* for fruits in Western Amazonia, driven by market demand of nearby urban centers. (E) Gold mining in a peat swamp in southwest Amazonia. Gold is concentrated in old meander scars where peat swamps also form. Miners have excavated a large area to create a deep black water pond where swamp forest with deep peat once stood. swamps by simultaneously reducing carbon input from plant productivity and increasing carbon output by stimulating aerobic decomposition and leaching. Changes to forest structure and composition under agricultural use can also drive carbon losses through direct harvest of plant biomass and changes in litter quality or soil compaction that impact rates of decomposition (van Lent et al., 2019). Under such conversions, peat does not accumulate, and peat swamps switch from primarily functioning as sinks of atmospheric carbon, to substantial sources (Murdiyarso et al., 2010). Indonesian peat swamps have suffered the largest losses to agricultural conversion (Fig. 4), largely through oil palm and pulp wood production, and only about 6% of peat swamps in Indonesia remain undisturbed (Miettinen et al., 2016). While peat swamps in tropical America and Africa are still relatively intact, encroachment is likely to increase in the near future. A wide variety of exploitative uses are arising from growing market demands, whether that be for non-timber forest products for consumption in local urban centers or commodities traded in global markets, such as gold and oil that are associated with peat deposits (Butler and Laurence, 2009; Householder et al., 2012; Draper et al., 2014; Dargie et al., 2019).

Change in precipitation with ongoing climate alteration is another significant concern, which will impact peat swamps through its influence on the water table and rainfall inputs. Although competing climate models disagree about future precipitation patterns in regions where extensive peat swamps occur, the majority predict either annual rainfall reductions or greater interannual variability, neither of which are conducive to sustaining peat swamp habitat and function (Li et al., 2007). Predicted drier or more seasonal climates are expected to greatly amplify degradation already initiated by land use change. This amplification is most dramatically played out through increased fire risk. Human activity provides ample opportunity for ignition, and under drought conditions superficial peat is highly combustible. Peat fires can smolder for months in subsurface layers, even under moist conditions (Fig. 4A). These fires rapidly consume peats that have accumulated over millennia and can have significant impacts on global levels of atmospheric carbon. During 1997–98, fires in Indonesia, for example, are estimated to have burned an amount of peat equivalent to 13–40% of the mean annual global carbon emissions from fossil fuels, contributing to the largest recorded annual increase in atmospheric CO_2 concentration in modern history (Page et al., 2002).

Conclusions and outlook

Tropical peat swamps are carbon-rich ecosystems that additionally support populations of valued plant and animal species. As such, they bear considerable importance in both global climate and biodiversity crises. They are also highly vulnerable and unable to absorb the increasing human activity that is often concentrated upon them by demand from local, regional and global markets. Current market mechanisms incentivize unsustainable land uses because short-term profits are captured by few, while the costs of degraded peat swamp are broadly distributed among many and overtime. While carbon credit–offset schemes such as REDD+ (reducing emissions from deforestation and forest degradation) offer market mechanisms and monetary incentives to protect remaining tropical peat swamps or restore degraded ones, it still remains unclear whether this is sufficient (Murdiyarso et al., 2010). Most peat swamps are located in regions of pronounced social inequality. Hence, a critical area of research should also focus on gaining a more complete understanding of how the health of peat swamp habitat interfaces with that of the livelihoods of local peoples (Dargie et al., 2019). In the end, the outlook for tropical peat swamps hinges on whether or not novel market mechanisms as well as future societal norms can successfully recognize (or monetize) both the true value of the habitat and the costs of its degradation.

Knowledge gaps

- What is the current surface area covered by peat swamp forest in the tropics?
- What factors determine the distribution of peat swamps forest?
- What is the current carbon stock of tropical peat swamps?
- How will carbon stocks in tropical peat swamps change in the future?
- What factors determine soil-atmosphere fluxes and how will these fluxes change with land use and climate alteration?
- What is the significance of tropical peat swamps for biodiversity?
- How should peat swamp forests be managed for carbon storage, biodiversity and human well-being?

Mangrove Forests: Structure, Diversity, Ecosystem Processes and Threats

Martin Zimmer, Leibniz Centre for Tropical Marine Research, ZMT GmbH, Bremen, Germany; Faculty 2: Biology & Chemistry, University of Bremen, Bremen, Germany

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Wolfgang Junk and Florian Wittmann.

Glossary

Blue carbon Carbon that is derived from carbon sequestration, i.e., the removal of CO_2 from the atmosphere, and stored in oceanic and coastal marine ecosystems. Mangrove forests, saltmarshes, seagrass beds and algal (kelp) forests, and other coastal wetlands, are considered the major players. While this implicitly refers blue carbon to organic carbon, recent debates pledge for including inorganic carbon, thus rendering reefs built by corals or other calcifying organisms blue carbon ecosystems, too.

Ecosystem process Physical, chemical or biological activity or reaction that links organisms and their environment, such as production, decomposition, or organic matter-turnover, nutrient-cycling and energy fluxes. Ecosystem processes are driven by organisms and their interactions, and underlie ecosystem services.

Ecosystem service Benefits people obtain from ecosystems; commonly categorized as *provisioning* (e.g., food- or water-supply), *regulating* (e.g., regulation of floods or droughts), *supporting* (e.g., soil formation or blue carbon-sequestration and -storage), or *cultural services* (e.g., offer of recreation, spiritual, religious or other nonmaterial benefits).

Ecosystem engineer Species that create, modify or maintain a physical habitat for themselves and other species by significantly changing abiotic environmental conditions.

Foundation species Dominant species of a biological community that, through their mere abundance and biomass, have a strong effect on other species, by creating conditions and stabilizing fundamental ecosystem processes, and thus community composition.

Keystone species Species that have a strong effect on other species, and thus community composition, upon strongly interacting with, or posing indirect effects on, other species, despite their low abundance; other than foundation species, keystone species are rare.

Sediment Mineral material deposited, off its site of formation upon weathering and erosion of a mother rock, through transportation by the action of wind, water, ice or by gravity. Sediments can become enriched in organic material of various allochthonous or autochthonous origins. The appearance of the stable and organic matter-rich forest floor of a mangrove growing high in the intertidal may render the sediment resembling a soil, but the allochthonous origin of the mineral portion determines this still as a sediment. By contrast, soil is the result of simultaneous weathering of the bed rock (from below) and biotic activity that incorporates organic matter (from above). The distinction from sediments is that the mineral compartment of a soil is autochthonous in origin and remains in place.

Introduction

Mangroves are trees and shrubs that grow on soft sediments in the upper intertidal zone of tropical and subtropical coasts. They can form dense and extensive forests (Fig. 1) of either monospecific stands or multi-species assemblages along sheltered coastlines, bays and lagoons, or estuaries. The global distribution of mangrove forests roughly coincides with the 20 °C-isotherm of the coastal oceans' surface water. Thus, they range from ca 30°N to ca 30°S (and further south in Australia), except for the west coasts of southern Africa and South America where the cold Benguela and Humboldt currents, respectively, hit the coasts. Close to the northern and southern distribution limit, as well as under otherwise unfavorable conditions, such as aridity or high sediment salinity, mangrove plants remain stunted and often form only sparse stands (Fig. 2).

While mangroves accumulate small sediment particles upon slowing down water movement (see below), they essentially depend on soft sediment environments for their settlement and establishment. Hence, mangrove forest mostly develop and dwell along coastlines that are protected from strong wave action, and thus, are rich in fine sediments. However, numerous cases are known where individual seedlings settle and establish in crevices of rocky shores or consolidated beach platforms, among

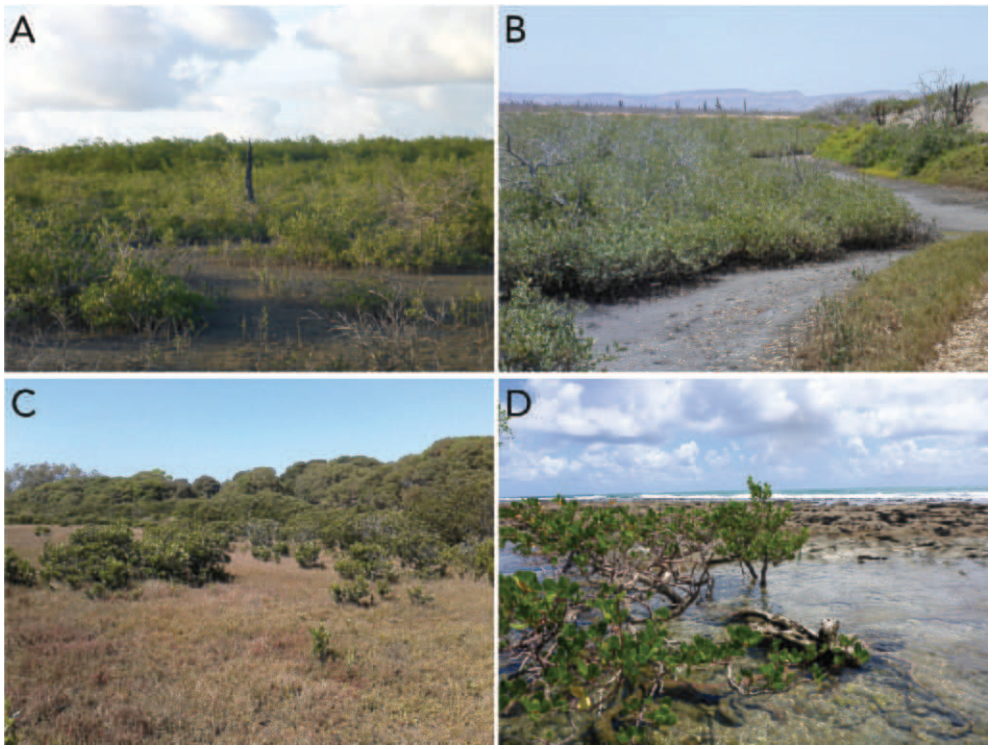

Fig. 2 Stunted *Avicennia germinans* on a hypersaline saltflat near Bragança, PA, (Brazil) (A); stunted *A. germinans*, next to desert vegetation, in an arid region near La Paz (Mexico) (B); sparse stand of stunted *Avicennia marina* in a mangrove-saltmarsh ecotone near Melbourne (Australia) (C); stunted *Laguncularia racemosa* on a degraded reef platform near Tamanadaré, PE (Brazil) (D).

boulders or on top of (partly protected) backreefs (Fig. 3). Such isolated trees may accumulate soft sediments and become cores of mangrove establishment, and eventually provide protection from wave action to the coastline and human settlements on the coast.

The attenuation of wave action, leading to sediment deposition and stabilization, thus contributing to coastal shoreline protection and prevention of coastal erosion, is among the manifold ecosystem services that mangroves provide to local societies and their wellbeing and livelihood, as well as to humankind worldwide. Mangrove forests are home to a rich and diverse fauna (Fig. 4) of both terrestrial and marine origin. Many of these species, along with other natural resources, form the basis for food and

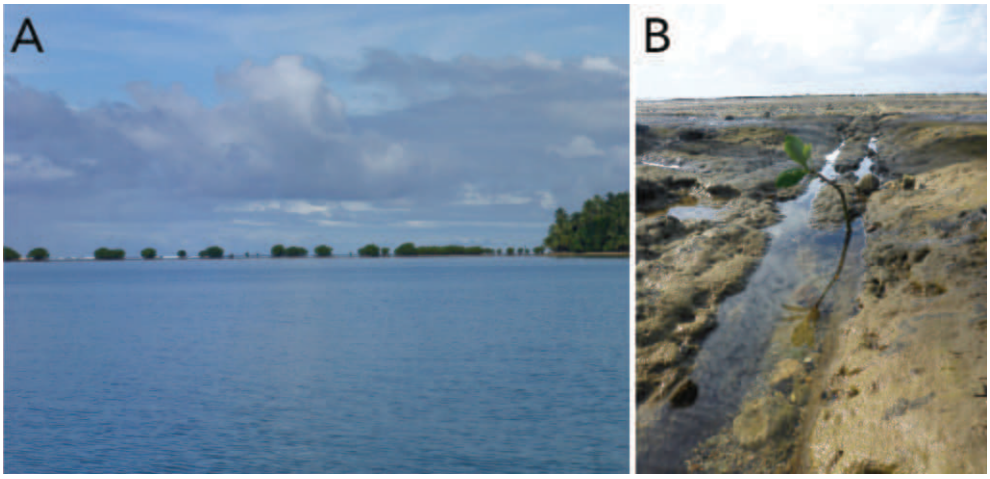

Fig. 3 Sparse *Rhizophora stylosa* trees on a backreef plateau (A) and recently established seedling of *R. stylosa* in crevice of a consolidated beach platform (B) of the main island (Viti Levu) of Fiji.

Fig. 4 Examples of mangrove fauna: tree-climbing *Episesarma versicolor* in Singapore (A; courtesy of Véronique Helfer, ZMT); *Goniopsis pulchra* (B), and dense population of fiddler crabs (C) in arid mangroves of Baja California (Mexico); mangrove (upside-down) jellyfish in a mangrove channel of San Andrés Island (Colombia) (D); epibionts on prop roots of *Rhizophora mangle* in Caribbean Colombia (San Andrés: E) and Senegal (F); barnacles on prop roots of *Rhizophora* sp. in Singapore (G); iguana (H) and crocodile (I) in the mangroves of Barra de Santiago (El Salvador); monitor lizard in Singapore (K); mudskipper (L) and mangrove snails (Cerithidea decollata) on *Avicennia marina* stem (M) in South Africa.

income for local stakeholders (Fig. 5). Mangrove crabs are collected and either used as food by the families themselves or sold on nearby markets, either as they are or upon processing by female family members. Consortia of women collect various shellfish species from the extensive root systems of mangroves or in sediments of nearby shallow waters. Mangrove forests act as nurseries –habitat, shelter and feeding ground– for juveniles of numerous fish and shrimp species that spend their adult lives in adjacent ecosystems (e.g., seagrass beds or coral reefs) or in the open sea, thus providing both rich fishing grounds for local fisher people and feeding areas for predators. Mangrove leaves, fruits and flowers are used for the production of fodder, teas and (alcoholic) beverages, food, honey and medicine. The wood of many mangrove species is not only dense and hard, rendering it an excellent construction material, particular for the use in seawater, but has high caloric values and is, thus, used as firewood or for charcoal production. Mangroves store vast amounts of organic carbon, derived from carbon dioxide (CO_2), and derivatives of other greenhouse gases in their above- and belowground biomass and, predominantly, in the sediment that is colonized by mangrove forests. Detrital organic

matter from inside the forest (mostly leaf litter but also fallen wood, rotting fruits etc.) and from the nearby ocean (drifting seagrass and algal wrack, deposited by the tides and retained by the complex three-dimensional architecture of root structures) is incorporated into the sediment, either by burrowing crabs or by sediment-moving wave action and sediment deposition. In the saline and anoxic environment of the mangrove sediment, the sequestered organic matter forms organic carbon (and nitrogen) stocks that are stable over centuries and millennia rather than being deposited into the atmosphere as greenhouse gases (CO_2, N_2O, CH_4) upon decay and decomposition.

Irrespective of the invaluable relevance of mangrove forests for local societies and the growing acknowledgement of their value worldwide, mangrove area has been, and is still being, lost at alarming rates. Over less than 20 years from the 1980s to the early 21st century, mangrove forests encountered a loss of about one quarter of their global area. Even though current loss rates are, on a worldwide average, well below 0.5% (Friess et al., 2020), we are still losing some 50 ha of mangroves every day. The major threats to mangrove forests encompass habitat degradation and clear-felling. Slow degradation is driven by either pollution from nearby settlements or industries, or eutrophication from agriculture in the hinterland or through untreated sewage.

Clear-felling is brought about by different agents, first and foremost forestry (Fig. 6). Selective felling of individual trees or small groups of trees for harvesting firewood or wood for constructing houses, boat piers or jetties, or fish cages, has been traditional for centuries. Such small-scale activities are commonly considered sustainable and appear to not harm the forest or its integrity. However, over the last decades, the use of mangrove wood for various purposes developed into large-scale industries in many places. Only few of them are, or try to be, sustainable, and mangrove forestry contributes significantly to the global area loss.

The second major driver of mangrove area loss is clear-felling for giving space to aquaculture ponds (Richards and Friess, 2016). Over decades, mangrove forests had been transferred into large-scale aquaculture areas in many regions of the world. While the ponds are usually abandoned after a decade or so, because of decreasing productivity and increasing risk of diseases, the changes in topography and hydrodynamics upon constructing the ponds render the area essentially inaccessible to natural recolonization by mangroves. In recent years, novel concepts try to avoid, or compensate for, large-scale area losses through implementing, for instance, Integrated Mangrove Aquaculture (IMA).

The construction of infrastructure for harbors, industry, settlements or even tourism has added to the pressure on mangroves, either directly through clear-felling or indirectly (see above). Further, roads or dykes near, or even inside, mangrove stands can change hydrodynamics and water regimes drastically (Fig. 2A). The same applies to dams built nearby or in the hinterland of mangroves, affecting freshwater inflow and sedimentation patterns. The results can be immediate, but more often negative effects do only become obvious slowly and over years or decades. Thus, drying, salinization or sediment depletion lead to reduced growth and productivity of individual trees and the entire forest, impoverished species composition, stunted growth forms of surviving (or recolonizing: Fig. 2A) trees and long-term degradation. Recovery is often only possible upon removing the drivers of change and reinstating suitable conditions, and usually takes years and decades for ameliorating environmental conditions and allowing for (natural or assisted) recolonization by mangroves.

Mangrove diversity

Growing in a dynamic soft-sediment environment that is driven by hydrodynamics and frequently and regularly changing water flows and tidal regimes, mangrove trees act as ecosystem engineers and foundation species by changing their environment and providing habitat for organisms that require a hard substratum. Both their aerial roots and their stems slow down currents and attenuate waves, thus releasing stress (and disturbance) from the benthic and epibiotic fauna. Their aerial roots are used as substratum by various sessile marine organisms (e.g., mussels, oysters, barnacles, sponges, algae) and offer shelter and feeding ground during high tide for motile marine organisms (e.g., fish, shrimps), many of which being of relevance as food and income for

Fig. 6 Large-scale forestry of *Rhizophora apiculata* in the Matang Mangrove Forest Reserve (Malaysia), considered sustainable through intensively monitored reforestation of clear-felled areas (A); small-scale cutting of *Laguncularia racemosa* stems for building fish traps in the extractive reserve of the Ajuruteua Peninsula (PA, Brazil) (B).

local societies. Birds nest, rest and roost in the canopy of the forest and find their food there or in the nearby coastal waters. Terrestrial mammalian grazers and browsers use mangroves as feeding ground during low tide.

On a smaller spatial scale, mangrove roots aerate an otherwise anoxic sediment and enrich the dissolved organic matter of the porewater with their exudates and, thus, nourish the sediment microbiota. Particulate organic matter of autochthonous (leaf litter, flowers and fruits, woody debris) and allochthonous (algal and seagrass drift) origin are retained inside the forest upon being entangled among the complex three-dimensional architecture of the aerial roots. This detritus becomes incorporated into the sediment, either as particulate or leached-off dissolved organic matter, and contributes to the organic matter stock of the mangrove sediment.

Mangrove trees themselves show a small-scale spatial distribution across the forest that depends on local geomorphological and ecological environmental conditions. Often, species-specific zones along, and parallel to, coastlines, tidal channel or river banks appear, suggesting zonation across the tidal gradient (Bunt, 1996; Satyanarayana et al., 2002; Snedaker, 1982). Such a zonation, however, is not a universal pattern. Many species-rich mangrove stands in areas with complex topography exhibit heavy species-mixing on small spatial scales (Fig. 1F), i.e., at similar tidal elevations (Leong et al., 2018). Hence, the concept of mangrove zonation has been challenged recently. Zonation patterns can be (1) very different regionally and do not always exhibit the same order of species; and (2) the result of succession of colonizing species upon horizontal sediment accretion and mangrove extension. Thus, long-term observations in Northern Brazil demonstrate that freshly deposited sediments along the non-eroding side of meandering tide channels are first colonized (and stabilized) by the saltmarsh species *Spartina alterniflora*. Entangled propagules of the pioneer species *Laguncularia racemosa* (White mangrove) soon form dense stands in which *Avicennia germinans* (Black mangrove) establishes and outcompetes the White mangrove. During later succession, the Red mangrove (*Rhizophora mangle*), being shade-resistant, takes over and replaces the Black mangrove in the long run (U. Mehlig, pers. comm.; c.f. Mehlig et al., 2010). Along the gradient of shoreline progression, this process in time leads to a spatial pattern that resembles a pattern of spatial zonation.

Nevertheless, the spatial distribution of trees of different species in mixed mangrove stands is driven by small-scale variation in tidal elevation (Leong et al., 2018). Based on a comprehensive review of trait information available from the literature, Quadros et al. (2021), however, concluded that many functional traits of mangrove species did not evolve according to the species' position along the intertidal gradient but bear a strong phylogenetic signal, i.e., are driven by the evolutionary origin of the species. Yet, some traits of mangrove trees render them similar to other wetland plants, while, according to other traits, mangrove trees are similar to sclerophyllous plants from dry environments, probably because the saline environment renders the intertidal a "physiologically arid" environment (Quadros et al., 2021).

Mangrove forests are home to a rich and diverse fauna of decapod crustaceans. Many of these crabs dig burrows in the soft sediment, often in close association with mangrove trees and their roots (Robertson and Daniel, 1989; Gillis et al., 2019), possibly because of their stabilizing of a mobile fine-grained soft sediment (c.f. Lim and Heng, 2007). Other crab species do not burrow themselves but use the burrows of other species, either upon abandonment or as co-inhabitants. Yet other crab species do not reside inside burrows but live on mangrove trees or shelter among roots, in leaf axles (of the mangrove palm *Nypa*) or below the bark of mangrove trees.

Burrowing crabs are ecosystem engineers themselves. Their burrows drastically increase the area of the oxygenated/aerated surface of the sediment, thus affecting the community-wide metabolism of the sediment microbiota (Gillis et al., 2019), and providing a larger habitat volume for the aerobic sediment infauna. The burrows themselves serve as space, shelter and protection from adverse environmental conditions or predators to other species that do not construct their own burrows. Through vertically translocating (anoxic) deeper sediment layers onto the oxic surface (and potentially vice versa) of the forest floor (bioturbation), burrowing crabs affect the physico-chemsitry of the sediment and drive changes and variation in (aerobic vs. anaerobic) sediment processes (Lohrer et al., 2004; Stahl et al., 2014; Xiao et al., 2019).

Many of these ecosystem-engineering activities and their magnitude depend on the crab species. While some species build very simple and shallow I-, J-, or L-shaped burrows (e.g., fiddler crabs of the family Ocypodidae: e.g., Qureshi and Saher, 2012), other species (e.g., of the family Sesarmidae) dig burrow of several meters depth and complex architecture (e.g., Thongtham and Kristensen, 2003). Many of the latter are leaf litter-feeders and pull freshly fallen mangrove leaves into their burrows (for discussion: Forgeron et al., 2021), thus preventing them from being washed out by the tides and contributing to the organic matter stock of the mangrove sediment. Often, these complex crab burrows are interconnected with other burrows and exhibit high temporal and spatial dynamics (Egawa et al., 2021).

While mangroves and mangrove forests occur throughout the tropical (and subtropical) belt worldwide, mangrove floristics distinguishes two biogeographic realms with clearly separate mangrove floras that share only a single species, the Golden mangrove fern, *Acrostichum aureum*. The Indo-West Pacific (IWP), from the east coast of Africa to South East Asia and Oceania, hosts the majority of the total of some 80 mangrove species (there is an ongoing dispute about some species whether or not to be "true mangroves": e.g., Quadros et al., 2021) from 32 genera of 15 families. The IWP originates from the east coasts of the former Tethys sea where the majority of mangrove species evolved during the late Cretaceous (some 66–145 Mio years ago) (Ellison et al., 1999). The Atlantic-East Pacific (AEP), covering the Atlantic coasts of Africa and the Americas, as well as the west coast of the Americas, is derived from the former (north-)western shores of the Tethys, and harbors a mere 14 species (of 12 genera and 9 families), of which only a handful can be considered common and abundant. Notwithstanding the much higher species richness of the IWP mangrove flora, some mangrove forests of the AEP exhibit similarly high productivity and biomass stocks (Giri et al., 2011; Hutchison et al., 2014). Indeed, the tallest mangrove trees worldwide (of the most tall-growing species *Avicennia germinans* and *Rhizophora mangle*: Quadros and Zimmer, 2017) reach heights of up to 60 m along the Central African west coast (Chen and Twilley, 1998). Hence, the

major driver of mangrove productivity, growth and carbon sequestration does not seem to be taxonomic biodiversity (species richness) but rather the functional dispersion of the tree community, i.e., the trait distinctiveness of the coexisting species (Rahman et al., 2021; Quadros et al., 2021).

Much less is known about the species richness or diversity of other mangrove components, flora, fauna and microbiota, or their geographical distribution. Overall, the number of mangrove tree species in a given area correlates positively with the number of mangrove crab species of that same region (Lee, 2008), but both underlying mechanisms or reasons and ecological, ecosystemic or societal consequences of this pattern remain largely unknown.

An important, albeit often overlooked, floristic component of mangrove forests is their understory and their epiphytes. While it had been accepted (and not questioned) for long time that mangrove forests throughout the world largely lack such understory flora (assuming a lack of species that adapted to the peculiar environmental conditions of intertidal forests: Janzen, 1985), we now understand that weeds, shrubs, vines or epiphytes can make up an ecologically essential part of the mangrove vegetation. The understory flora seems to be particularly well developed and rich in mangrove areas of high precipitation rates, such as along the Pacific coast of Colombia.

Mangrove ecosystem processes

The species composition of an ecological community drives processes of the hosting ecosystem. The global distribution of the majority of mangrove species is well recorded, and regional species compositions of particular mangrove forests are well known. Conspicuous or enigmatic faunal elements of mangroves, such as mammals, birds, fish or crabs have been studied faunistically in much detail. Much less is known about the majority of the remaining invertebrate fauna of mangroves, despite extensive local knowledge about the distribution of oysters and mussels, barnacles or sponges, colonizing aboveground mangrove roots, or clams and crustaceans in the nearby sediments.

However, our understanding of which species of a given mangrove ecosystem, or their interactions, drive which ecosystem processes under which environmental conditions, and how these processes translate into the manifold ecosystem services of mangrove forests, is still in its infancy. In particular the sediment infauna and the sediment microbiota (Allard et al., 2020) of mangroves are essentially black boxes, not even to mention resulting processes and details of their contribution to ecosystem services. However, even species-specific contributions of the mangrove flora to ecosystem services of global relevance, such as the sequestration and storage of greenhouse gases into the vast stocks of blue carbon, are only recently being tackled and understood.

For instance, the prop roots of *Rhizophora* spp. are much more efficient in retaining freshly fallen mangrove leaf litter inside the system by preventing them from being washed out with the ebb tide than are the finger-shaped pneumatophores of *Avicennia* spp., as long as the leaves drift on the water surface (Gillis et al., 2016). As soon as the litter ages and loses buoyancy, leaf-retention reaches the same efficiency in *Avicennia* roots as in *Rhizophora* roots. Over successional change of neotropical mangrove forests from *Avicennia*- to *Rhizophora*-dominated stands, the amount of organic matter-input to the forest floor through litter fall increases, but litter quality decreases (Quadros et al., 2019), and thus organic matter turnover and sequestration into the sediment decreases. Fast-growing *Avicennia* spp. store larger amounts of carbon in their sediments than *Rhizophora* spp. in young (restored) mangrove stands (Kathiresan et al., 2013). Along a similar line, the leaf litter of young trees of the species *Rhizophora apiculata* decays remarkably faster than those of mature trees of the same species in Malaysian mangrove forests (Pradisty et al., 2021). Hence, mangrove stands with distinct species compositions, as well as those growing in different regions under different environmental conditions, differ from each other in the size of their blue carbon stocks and the stability of the sediment organic matter against degradation (for discussion: Zimmer and Helfer, 2020). The major driver of these differences seems to be the distinctiveness of co-occurring mangrove species regarding their traits rather than their taxonomic diversity (Rahman et al., 2021).

Often, the productivity (i.e., biomass production rate) of plant communities is viewed as a function of their (taxonomic or functional) biodiversity. However, species-poor mangrove forests of the AEP can develop almost the same standing stocks of aboveground biomass as species-rich forests of the IWP (Giri et al., 2011; Hutchison et al., 2014). Following the same line of argument as Rahman et al. (2021), Quadros et al. (2021) conclude that the productivity and standing stocks of mangrove forests are potentially driven by the trait distinctiveness of their mangrove species. The relationship between biodiversity and ecosystem processes in mangrove forests remains unclear. In this context, the observation that different mangrove crab species of the same family exhibit similar trait expressions adds to the conundrum. Functional redundancy of coexisting crab species of the same family (e.g., burrowing detritivorous sesarmids) will not add to the rate of ecosystem processes, but may increase the tolerance of a mangrove forest to (anthropogenic) disturbance that reduces species richness (Cannicci et al., 2021). The corresponding ecological equivalence of related species, on the other hand, may be the reason that mangrove forests in different regions of the world, hosting entirely different communities of crabs (and other faunal or floral elements), provide similar ecosystem services.

The differential effects of genus-specific root structures on wave attenuation and, thus, coastal protection have been studied (reviewed in Koch et al., 2009) and modelled (reviewed in Le Minor et al., 2021) in some detail. Thus, *Sonneratia* spp., developing finger-shaped pneumatophores above an extended sediment surface area, reduces wave height about twice as efficiently as *Kandelia candel* with buttress roots next to the stem (discussed by Koch et al., 2009). Further, the mechanisms of wave attenuation may differ among different root types, and thus, the period of the tidal cycle at which root structures mostly contribute to wave attenuation may be species-specific. Thus, we might hypothesize that a mangrove stand with distinct root types (i.e., with high functional distinctiveness of species, such as for *Avicennia* and *Rhizophora*) is more efficient in protecting the coastline against waves and storm surges than one with several species of the same genus that all bear the same type of roots.

Mangrove conservation and afforestation

During the two decades from the 1980s to the early 2000s, we lost some 25% of the global mangrove area. Considering the previous three decades or so, the loss probably sums up to 40–50%. During the past decade, the global average annual loss rate has dropped to way below 0.5% (Friess et al., 2020). However, we are still losing some 50 ha of mangrove forests worldwide every day. Effective mangrove protection and conservation is, thus, pivotal for sustaining their numerous services to local communities and humankind worldwide, and should be given highest priority. When and where mangrove forests are degraded or lost, their re-establishment aims at re-instating ecosystems that provide these services.

Among the many causes for mangrove degradation and area loss (see above), climate change and its direct consequences are most controversially debated. On a global scale, mangroves might benefit from the extension of (sub-)tropical conditions toward the poles through expanding their distribution range polewards (Saintilan et al., 2014). Within the tropical belt, increases in water and air temperature may exert negative effects on mangrove trees or entire stands (Jennerjahn et al., 2017). However, surface-near air temperatures are overall predicted to increase more rapidly and to a larger extent in high latitude regions than inside the tropical belt (Collins et al., 2013; Kirtman et al., 2013). Thus, indirect effects of atmospheric warming, such as regionally differing changes in precipitation patterns, and thus freshwater supply from the hinterland, or altered circulation patterns of the coastal ocean, affecting the distribution of mangrove propagules (Duke, 2017), will possibly affect tropical mangrove forests and their inhabitants –positively or negatively– more strongly (Jennerjahn et al., 2017).

Mangrove forests, besides their vast potential of sequestering greenhouse gases into their biomass and sediments, are more and more valued as mitigators of consequences of sea level-rise for coastal and lowland communities. At the same time, they face the issue of a spatial shift of their intertidal habitat upon sea level-rise themselves. While it is widely accepted that mangrove forests, in the long run, can respond to sea level-rise by adjusting their distribution along the intertidal zone that is transitioning upwards, this potential response will depend upon a range of hydrological, sedimentological and ecological factors (e.g., Rogers, 2021). The width of this adaptive response to spatial shifts of the suitable habitat is determined by the "accommodation space", defined as the space where sediments accumulate in the intertidal by Jervey (1988). By sharpening this definition to '*the thickness of a space which will have been filled with sediment*,' Muto and Steel (2000) stress the vertical dimension of the accommodation space. The translation of this vertical dimension into the change in the '*potential vertical range*' (Rogers, 2021) of mangrove distribution is the basis for spatial predictions of the future mangrove distribution and range perpendicular to the coastline. While this vertical range is expected to shift as the sea level rises, potentially opening areas for future mangrove colonization, many current mangrove areas worldwide are restricted by limitations to moving landwards. Either changed hydrodynamics do not support mangrove recruitment and sediment accumulation in future tidal zones, or landward structures, such as infrastructural constructions, buildings or roads, prevent a landward extension or shift of habitats suitable for mangroves. Further, numerous indirect consequences of sea level rise that affect mangrove processes and dynamics indirectly mediate sea level-rise effects (c.f. Jennerjahn et al., 2017).

This showcase exemplifies the relevance of providing a suitable habitat for mangroves in the future of a changing world as one of the major challenges of mangrove conservation, rehabilitation or afforestation. The choice of areas for protection versus (sustainable) use (Spatial Conservation Prioritization: Helfer and Zimmer, 2018) should consider both the present situation and integrity of ecosystems and projections, predictions and scenarios of their future distribution, extension and status (e.g., Ragavan et al., 2020). Will a current mangrove habitat still host a mangrove stand upon environmental change (see above: pollution, land-use change, sea level-rise)? Is it worth protecting this habitat for the sake of mangrove conservation? Are rehabilitation efforts reasonable in an area that will potentially become unsuitable for mangroves in the near future, or should afforestation in recent non-mangrove areas that are predicted to become suitable be a preference?

According to the Traffic Light Concept (Helfer and Zimmer, 2018), mangrove forests can be assigned as currently valuable (regarding the provisioning of non-extractive ecosystem services) but highly delicate and sensitive to disturbance through anthropogenic pressure or human activities. Such "red" areas need full protection from human use and further pressure. "Green" areas, on the other extreme, are currently degraded and/or predicted to be unsuitable as habitat for mangrove stands in the near future; investing in their conservation does not seem to promise much gain. Mangrove forests that are considered and predicted to be resistant (or tolerant) against disturbance and environmental change and consistently provide ecosystem services are flagged as "yellow" areas that should be managed under the umbrella of sustainable use of their natural resources. This, or similar approaches, will prove invaluable for finding the balance between the protection and use of mangrove forests for the sake of their conservation and sustainable management (e.g., Ragavan et al., 2020).

Conservation cannot be pursued against human needs, and any reasonable protection measure has to take into account requirements for the (sustainable) use of natural resources by local communities. Ecosystem-Based Management (EBM) considers site-specific information for ensuring the persistence of mangroves in a given area (Ragavan et al., 2020). Recognizing previous failures of management of marine ecosystems, EBM aims at combining conservation, sustainable utilization and fair allocation of benefits from natural resources (Cowan et al., 2012). Among 15 key principles of EBM, Long et al. (2015) identified the most important ones as Ecosystem Connection, Appropriate Spatial and Temporal Scales, Adaptive and Integrated Management, Stakeholder Involvement, and Use of Scientific Knowledge. Thus, EBM obviously requires in-depth and accurate information about the ecosystem to be managed. While it is still a long road to this aim from where we are, regarding mangrove forests, the urgency of the situation warrants that we accept "informed guesswork" where our knowledge and understanding are still incomplete, in concert with efforts to fill the corresponding knowledge gaps.

An alternative to the free use of degraded mangrove habitats of the "green" category according to the Traffic Light Concept is their rehabilitation or restoration (Fig. 7). While rehabilitation aims at re-establishing a degraded habitat for initiating a trajectory toward recovery of mangrove ecosystems, restoration encompasses actions of reinstating mangrove forests in a state that is similar to the lost forest. Alternative approaches to the (re-)establishment of mangrove forests range from facilitating natural recolonization of restored habitats to the active planting of a selected set of species that provide those ecosystem services that are mostly urgently needed in a given area.

The former approach is exemplified by Community-Based Ecological Mangrove Restoration (CBEMR) (MAP, 2021). Based on the concept of Ecological Mangrove Rehabilitation (Lewis and Brown, 2014), CBEMR acts on mitigating mangrove stressors and facilitating natural regeneration through re-instating pre-disturbance conditions of, e.g., topography and hydrodynamics. A focal aspect of Ecological Mangrove Rehabilitation (EMR) is the engagement of local communities and sincere consideration of social, economic and ecological factors before undertaking any action, and the monitoring of the success of all actions.

While usually avoided by EMR and CBEMR, assisted recolonization of degraded mangrove areas through plantation might prove necessary, when, e.g., hydrodynamics cannot be restored or propagule supply from nearby systems is limited. In these cases, many reforestation efforts over the past decades have been failures with little to no establishment success of the mangrove seedlings. Reasons for this are manifold (e.g., Kodikara et al., 2017; Worthington and Spalding, 2018). The major critique of such unsuccessful efforts stresses the attempt of planting monocultures of the wrong species in an unsuitable area, be it along the intertidal gradient or with respect to hydrodynamics and sediment supply. A recent White Paper of the IUCN Mangrove Specialist Group (MSG, 2020) pledges for thorough consideration of strategies and alternatives before investing in, and wasting efforts on, planting hundreds and thousands of mangrove seedlings in vain. While resulting in low biodiversity of reforested mangrove stands, commonly being criticized as a weakness of this approach, it might be advisable to keep the number of replanted species low (c.f. Rahman et al., 2021; see below). The approach of mangrove reforestation has become well perceived in society, possibly based on (successful) reforestation activities of terrestrial forests. The many advertisements for diverse commercial products that promise the planting of trees upon purchase are more and more including references to mangrove reforestation. As recent reports in the media illustrate, however, some of these offers are unserious or even used as opportunities for scam. The lack of command over actual actions and their success by the consumers or investors from the private sector warrants the development of control mechanisms and certificates.

A special case of mangrove restoration is the establishment of Integrated Mangrove Aquaculture (IMA; also referred to as "silvo-aquaculture"), aiming at finding an optimized compromise between the economic gain of aquaculture and the socio-ecological benefit of maintaining, or re-implementing, mangrove cover around and inside aquaculture ponds. While mostly considered as compensation for mangrove area loss in the context of blue carbon-storage and climate change-mitigation (e.g., Ahmed et al., 2017), the other beneficial effects of mangrove cover (see above), such as protection of the coastline and nearby infrastructure from damage through wave action or storm surges or provisioning of natural resources, should not be disregarded in the argumentation. Further, mangrove stands can be used for the treatment of nutrient-enriched aquaculture effluents before discharging the wastewater into the adjacent coastal water (see below: Ecosystem Design): planted mangrove trees stabilize the pH value, reduce the nutrient load and increase the oxygen concentration of the water (e.g., Peng et al., 2009). It remains unclear whether the reduced risk of shrimp diseases in IMA ponds are an indirect effect of improved water quality or might be driven by antibiotic properties of leaf leachates or root exudates.

Other than the above reforestation, afforestation refers to planting and establishment of mangroves in areas that were not covered by mangrove forests in the recent past. Such new areas might be the result of recent events of sediment deposition, opening space that is not occupied by other vegetation for mangroves, a consequence of ongoing sea level-rise, or the outcome of coastal land-reclamation. Yet, planting mangroves in "non-mangrove areas" has repeatedly been criticized by various organizations and practitioners, on one hand because of the often limited success, as "mangroves cannot grow where mangroves don't grow," on the other hand, because these actions often destroy other valuable coastal ecosystems. The Global Mangrove Alliance (GMA, 2021) has explicitly included newly established potential mangrove habitats in the updated formulation of their goals. A prerequisite for such

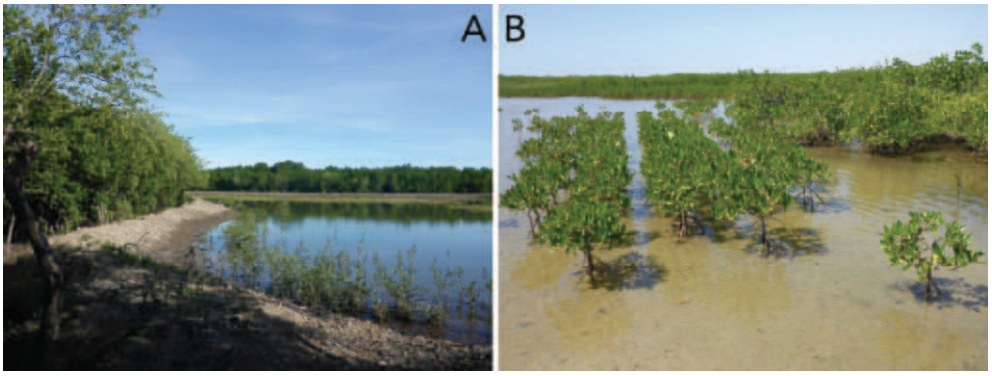

Fig. 7 Mangrove saplings established on the border of an aquaculture pond in Honduras (A); plantation of *Rhizophora mangle* in the Sine Saloum delta (Senegal) (B).

activities being justified and both socio-ecologically and environmentally reasonable is, however, that the environmental conditions in the to-be-established area are suitable for mangroves, any existing ecosystems are disturbed as little as possible, and the implemented species are regionally native (and propagules stem from the region).

While high biodiversity and near-to-natural ecosystem structure are at the very heart of most mangrove restoration and rehabilitation efforts, a recent approach focuses on the provisioning of ecosystem services according to human needs and demands: Ecosystem Design (Zimmer, 2018) aims at (re-)implementing those (simple) communities that most efficiently provide (a set of) ecosystem services of high human demand. In contrast to traditional restoration that focuses on the ecosystem, ecosystem design centers around the use of ecosystem benefits by local communities. Thus, designed ecosystems do not (necessarily) aim at high biodiversity but rather restrict the community to a number of species that, in concert and interaction, are most efficient in driving those ecosystem processes that underlie the required ecosystem service(s). As for EBM, Ecosystem Design requires detailed understanding of species-specific environmental requirements and ecophysiology, as well as of interspecific interactions – in many cases of mangrove trees and other mangrove inhabitants, we do not yet have this in-depth knowledge. Hence, for the time being, Ecosystem Design –just as EBM: see above– may have to rely on "informed guesswork". Accordingly, Ellison et al. (2020) consider the anthropocentric and high-intervention approach of "building with nature" through Ecosystem Design –as opposed to, e.g., the ecocentric "bringing nature back"-approach of EMR– a strategy of the future. At the same time, similar approaches had been implemented already (Cheong et al., 2013; Nengshi et al., 2018), and monitoring the success of deliberately implemented communities and designed ecosystems in driving the desired ecosystem processes and providing ecosystem services, thus considering Ecosystem Design a long-term experiment on mangrove restoration, will provide detailed ecological insight into how ecosystems and their processes are controlled and deepened understanding that is needed for sustainably managing them.

Synthesis

Mangroves form intertidal forests on soft-sediment coasts throughout the tropical belt. These forests provide numerous ecosystem services to local human societies and to humankind worldwide. According to their species richness and composition, they are split in two biogeographical realms, the species-rich Indo-West Pacific (IWP) and the species-poor Atlantic-East Pacific (AEP). Despite this marked difference in taxonomic diversity, mangrove forests in the AEP can be as productive as those of the IWP. The benthic fauna of mangrove forests seems to follow a similar pattern of biodiversity distribution. As ecosystem processes in different mangrove regions, however, seem to resemble each other, strong ecological equivalence of different species can be assumed.

Despite their ecological and societal relevance, mangroves are under anthropogenic pressure, and their conservation, also taking into account management and sustainable use, is of utmost importance. Degraded mangrove areas have been –more or less successfully– attempted to restore or rehabilitate over the last years and decades. These efforts reach from natural and assisted recolonization to active planting and afforestation. Specific-specific contributions of mangrove species to ecosystem processes and resulting ecosystem services could be the basis for designing ecosystems with simple communities that provide the most urgently required services most efficiently.

Knowledge gaps

- spatial distribution of species (e.g., within AEP vs. IWP) vs. traits (also across realms)
- taxonomic versus functional diversity of mangrove plants and other mangrove inhabitants
- drivers of ecosystem processes and services derived therefrom
- changes in species distribution, and consequences for ecosystem processes, upon climate or land-use change or other environmental changes
- response of mangrove forests (including all their inhabitants) and the distribution of individual species to (relative) sea level-rise and consequences for organic matter stocks (climate change-mitigation) or coastal protection (climate change-adaptation)

Glossary

Aquiclude A hydrogeologic unit of impermeable material bounding an aquifer.
Carbonate Rock A rock that consists of one or more carbonate minerals.
Doline Simple closed circular depression with subterranean drainage, and commonly funnel shaped.
Estavelle An intermittent spring, active only in wet seasons. Typically, it acts alternatively as a swallow hole and as a rising according to ground-water conditions.
Hydroperiod The period in which a soil area is waterlogged.
Karst Landscape in soluble rock where solution rather than erosion is the primary geomorphic agent, typically with caves, sinkholes, and springs.
Marl Unconsolidated sedimentary rock consisting largely of calcium carbonate and clay.
Polje A large, spring-fed karst depression with a flat floor commonly associated with river sediment.
Stygobiont Obligate, permanent resident of aquatic subterranean habitats.
Uvala A multi-coned closed depression.

Introduction

In a karst landscape, the forces of solution (chemical weathering) are an important agent in molding the landscape. In non-karst landscapes, chemical weathering is unimportant and erosion (mechanical transport) predominates. The word karst is a Germanized form of the Slovenian name (*kras*) for a carbonate plateau situated just north of the Adriatic Sea immediately north of Trieste, Italy (Jones and White, 2019). Nearly all aspects of the landscape are the result of the dissolution of the underlying bedrock, and erosion is little in evidence. In general the dissolution of bedrock depends on the action of carbonic acid (itself the result of the dissolution of CO_2 in water) on limestone ($CaCO_3$) and related bedrock types. A variety of unique landforms occur on karst-karren, dissolutional pavements, closed depressions (dolines and sinkholes), cones and towers, poljes, large springs, and blind valleys. Other landforms are absent or rare—streams, lakes, and wetlands, though there is also an underground landscape in karst—that of caves.

If we define karst as a landscape of exposed carbonate (limestone and dolomite) or gypsum rocks (Jones and White, 2019), then it covers about 15% of the earth's surface. Many karst regions are also modified by the presence of non-carbonate rocks (fluviokarst), strong physical transport such as occurs in alpine karst, or by the action of glaciation (glaciokarst). However, all have frequent rapid vertical movement of water into and through bedrock of sufficient purity for dissolution.

Globally, the occurrence of major wetland areas is nearly the opposite of the distribution of karst areas (Fig. 1; Balász, 1977). Wetlands are commonest at far northern latitudes (50°–70° N) and near the equator; regions with poor soil drainage resulting in hydric soils. In contrast, karst regions are concentrated at intermediate northern latitudes (30°–50° N). Of 65 major world wetlands (Mitsch and Gosselink, 2015), only three are unequivocally in karst areas. One of these is the Hudson Bay lowlands in Canada, among the most extensive wetlands in the world, but it is the relatively low relief and Pleistocene glaciations that define this

wetland, not the underlying karst topography (Abraham and Keddy, 2005). Cuatro Ciénagas in Mexico, a 1500 km^2 wetland, is formed in a valley by more than 200 springs and home to a number of endemic obligate aquatic subterranean invertebrates (Minckley and Jackson, 2007). But this is a boundary karst wetland, i.e., forming as a result of exit water from karst (see below), and not an interior karst wetland. The Big Cypress Swamp, part of the Everglades wetlands, is a karst area with numerous sinkholes (Quintero and Cohen, 2019).

Overview of wetlands in karst

Hydrologically, the most striking aspect of karst landscapes is that the drainage is predominantly internal. In this case of extreme karstification, the only places where surface wetlands can occur is at the exit of the water, or where water sinks, both often at the boundaries between carbonate and non-carbonate rocks.

Downstream of a karst area, water emerges in springs of many sizes and morphologies (Ford and Williams, 2007; Kresic, 2010). Some, if not all, are wetlands as they have permanently or seasonally moisture-saturated soil and support vegetation typical of saturated soils. These include marl wetlands (Bartgis and Lang, 1984) and any situation where carbonate rocks are underlain by, or intersect with, impermeable layers. By their nature, springs are at the discharge end of the wetlands continuum (Euliss et al., 2004).

At the upstream end of a karst area, water may be slowed as it sinks at the carbonate/non-carbonate contact (or at contact of two carbonate rocks of different solubilities), perhaps at swallets. Only one case where the movement of water into the subsurface is impeded to the extent that wetlands form is known: the rather enigmatic disappearance of the Santa Fe River in Florida and it re-emergence in the Suwanee River. The region around the swirling input periodically floods and the sink of the Santa Fe has some characteristic wetland vegetation (Tan and Judd, 1995), such as bald cypress (*Taxodium distichum*). It is enigmatic because there is so little vertical relief in this region of Florida that is difficult to understand how hydraulic gradients develop.

Interior karst wetlands are perhaps more interesting from a karst science perspective, and are not karst boundary wetlands or subterranean wetlands, but wetlands surrounded by karst.

Focus and scope of the review

The overall goal of this review is to place interior karst wetlands in a wetlands context, and to indicate their major features and unique characteristics. After an overview of the distribution and types of interior karst wetlands, we provide detailed descriptions of three wetlands in Slovenia, one of the most extensive and well developed karst regions anywhere:

1. Cerkniško jezero/polje
2. Planinsko polje
3. Pivka intermittent lakes

We focus on several questions in these descriptions:

1. What is the role of karst and karst processes in the formation and functioning of these wetlands?
2. What is the connection with groundwater and what is the effect on hydroperiod?
3. What is the overall regional role of karst wetlands?
4. Are there any biological features shared by karst wetlands?

Characteristics of interior karst wetlands

One of the defining features of karst regions is the presence of closed depressions, the most common and familiar of which are sinkholes or dolines. Sauro (2019) divides closed depressions into five types, based on size:

1. Rain pits or rain craters (1–3 cm in diameter).
2. Solution pans and karst pans (cm to m in diameter).
3. Dolines (sinkholes) (a few m to over 1 km in diameter).
4. Compound depressions (hundreds of meters to a few kilometers).
5. Poljes (reaching up to tens of kilometers).

The last three have been extensively studied by hydrogeologists and geologists, because of their connection to water supply and their potential as geohazards (Waltham et al., 2010).

Rain pits are surface solutional features in carbonate bedrock, more generally known as karren, but are too small to be of interest in a wetlands context.

Solution pans and karst pans are small closed depressions in the karst landscape that are relatively isolated from the groundwater system and typically lack internal drains, such as the Tennessee Barrens (United States) (Wolfe, 1996). It is not entirely clear whether the closed depressions given the name "karst pans" by different authors are the same (O'Driscoll and Parizek, 2003, 2008; Wolfe, 1996), or whether they are all solutional features of bedrock rather than the overlying soil. Karst pans apparently form as a consequence of percolating water creating solution chambers in bedrock with the concomitant slumping of the overlying soil. Though these wetlands are very small, they are often the only wetlands where they occur and frequently harbor a distinct flora (Wolfe, 1996).

The most common closed depressions are sinkholes (dolines),[1] typically with a circular or sub-circular plan and a bowl- or funnel-shaped concave profile (Sauro, 2019). Given the relatively few shapes sinkholes can have (Cvijic, 1895), it is perhaps surprising that they form in a variety of ways (Gutiérrez et al., 2014; Parise, 2019). While they may form by solution, subsidence by collapse, sagging or suffusion as well, the frequency is increased by groundwater drawdown. Though karst wetlands are almost entirely closed depressions, most (nearly all) closed depressions are dry, as the connections with the surface are too open and there is usually no impermeable clay layer at the bottom. In areas of low relief with the water table close to the surface, many sinkholes form small ponds and lakes, as is the case in many sites in Florida (Upchurch et al., 2019).

Hydrostatic pressure, which is mediated by estavelles (Fig. 2; Vineyard and Feder, 1982) also keeps sinkholes (and compound depressions, see below) filled with water. At low flow, estavelles act as swallow holes; at high flow they act as springs. Many karst wetlands are connected to groundwater via estavelles (see section on "Pivka intermittent lakes" below).

As sinkholes age, they tend to get deeper and wider, and may coalesce to form multiple sinkholes, sometimes called uvalas. Closed depressions in karst may have irregular shapes due to these karst processes or other morphogenetic ones (e.g., tectonic, fluvial, glacial). Many turloughs, the seasonally flooded wetlands of Ireland (Sheehy Skeffington et al., 2006) and perhaps elsewhere (Sheehy Skeffington and Scott, 2008), may qualify as compound sinkholes.

Poljes are the largest closed depressions observed in karst terrains. The original definition of "a large karst depression, with a wide, flat and nearly horizontal floor, completely enclosed between steep slopes" (Cvijic, 1895) does not adequately distinguish poljes in practice or explain their genesis (Sauro, 2019). The flat floors may be tens of kilometers long. Their formation cannot be explained solely through karst processes. The main environmental peculiarity of poljes is the absence of a permanent lake, but with an ephemeral lake, the draining of which occurs solely through subterranean flow, typically through estavelles. Flooding is controlled by several parameters, e.g., recharge conditions, drainage capacity of ponors and presence of estavelles, and characteristics of aquifer draining the polje (Mayaud et al., 2019).

Most poljes occur in tectonic depressions and, although first described from the Dinaric karst, they occur in other karst regions in both temperate and tropical zones. They are the dominant wetland type throughout the Dinaric karst (from Italy and Slovenia to Albania), and comprise about 4% of the land surface. Upchurch et al. (2019) use the term polje to describe a wetland type in Florida, but it is in a radically different geological setting, and developed in different way.

[1]The term doline is used in somewhat different ways. In North American usage it is synonymous with sinkhole, but in English/European usage, it tends to refer only to steep sided sinkholes.

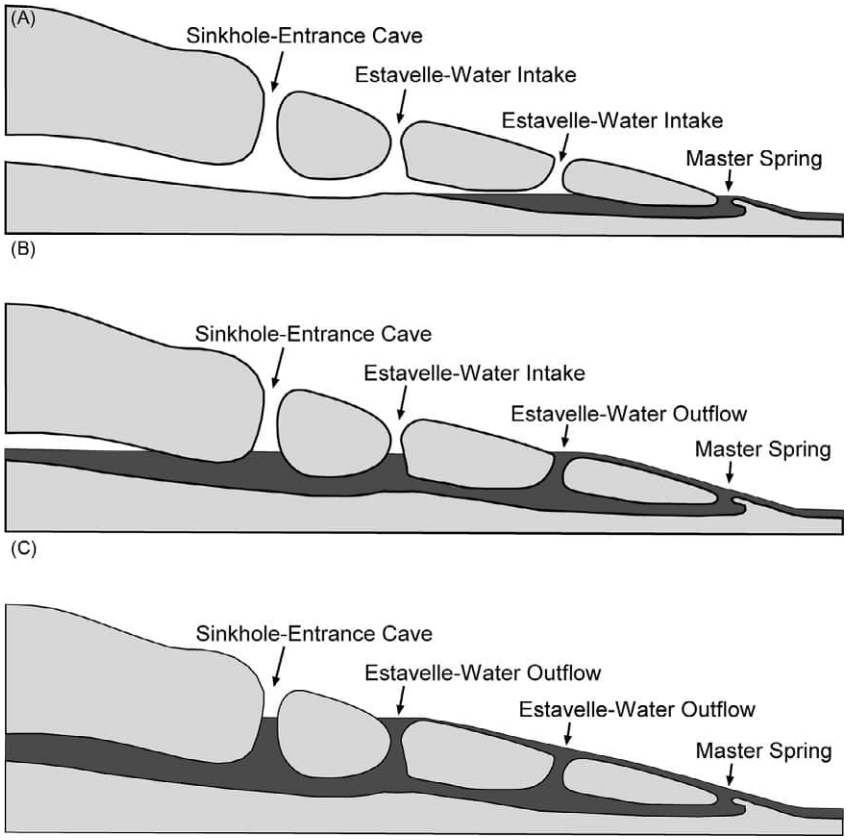

Fig. 2 Hypothetical stream profile showing sequential reversal of flow in estavelles. (A) Low flow, only lower section of karst drainage system is flooded and the estavelles act as swallow holes. (B) Medium flow, headward flooding of the system and the lowest estavelle acts as a spring. (C) High flow, storage capacity of karst system exceeded and all estavelles become springs. Representative karst wetlands

Cerkniško jezero/polje

Cerkniško jezero (= lake) is an intermittent lake appearing at the bottom of the depression Cerkniško polje (549 m a.s.l.). The polje is about 11 km long and 4–6 km wide, covering a surface area of 41.7 km^2 (Smrekar, 2002). It is located in the heart of Notranjska region between the Dinaric Mountains and the Alps, one of the many poljes in the depression along the Idrija fault (Kranjc, 2002a).

The "vanishing" lake has inspired the imagination of local people and visitors for centuries, attracting numerous researchers who tried to decipher the mystery of the lake. The first detailed written information dates back to 1679, when the Slovenian polymath J. V. Valvasor, published an essay on the lake with a map of the area (Rupel, 1951), and a hypothetical diagram of the subterranean drainage.

Cerkniško polje (Fig. 3) is influenced by Mediterranean and continental temperate climates. Relatively high annual precipitation (from 1700 to 1800 mm) (Zupančič, 2002) significantly contributes to the hydrological regime. The bottom of the polje consists of carbonate bedrock, i.e., Triassic and Jurassic dolomite, and Jurassic and Cretaceous limestone (Kranjc, 2002b). The bedrock is covered by young Pleistocene and Holocene alluvial sediments up to 16 m deep (Gospodarič and Habič, 1978). The polje is a floodplain of the Stržen stream, which is one of seven streams that make up the Ljubljanica river. The Stržen stream meanders through the polje, cutting its river bed through alluvial deposits (Fig. 4; Skoberne, 2004). Water level fluctuations influence sediment deposition and erosion (which currently prevails), shaping the lake bottom (Kranjc, 2002b).

The catchment area of Cerkniško jezero extends over 475 km^2 (Kranjc, 1986, 2002b). The polje is characterized by extreme water level fluctuations, due to the high local precipitation, an extensive karst watershed and water runoff into an extensive underground drainage system in carbonate rocks (Gams, 1994). The hydrologic regime is characterized by spring and autumn floods coinciding with the highest monthly average precipitation (200 mm in November, Zupančič, 2002) and summer droughts, when water only remains in the Stržen stream bed and its tributaries. During "normal" floods, the water covers an area of 20.3 km^2 (Smrekar, 2002).

Water coming from the subsurface accounts for 80% of the lake water. The only significant surface tributary is the Cerkniščica stream. In the distant past, the input to Cerkniško polje was completely karstic and only in the last glacial period (the middle Würm) did the Cerkniščica stream turn toward Cerkniško polje (Šušteršič and Šušteršič, 2003). During rainy periods, water flows from the

Fig. 3 Cerkniško jezero (A) when it is flooded on the south and dry Cerkniško polje (B) at the eastern side. Photographs by S. Polak, used with permission.

springs at the E and SE edge and from estavelles in the bottom of the polje (Kranjc, 2002b), collecting in the wide Stržen stream bed which gradually increases in level. Usually it takes only a few days to flood the whole area (Fig. 5). There is no surface outflow and the drop in water level depends on the drainage of water underground, mainly to the vertical ponors (sinkholes, Fig. 6) and ponor caves at the N and NW part of the polje. A significant amount of water is also lost by evapotranspiration. On average it takes 3 to 4 weeks for the lake to dry out (Kranjc, 2002b).

Cerkniško jezero is a very complex, biodiverse ecosystem (Dolinar et al., 2010a). The plant communities depend on the water regime and soil properties (Gaberščik et al., 2003). Aquatic plant communities (e.g., *Myriophyllo-Nupharetum*, *Charetea fragilis*, *Rorippa amphibia-Eleocharitetum acicularis*) develop in tributaries, the main Stržen stream and in the polje depressions, while wetland communities (e.g., *Phragmitetum australis*, *Scirpetum lacustris*, *Caricetum elatae*) at the areas where regular floods of at least 6 months duration prevent further succession, and water does not exceed 1–2 m of depth (Martinčič and Leskovar, 2002). The edge of inundation zone is colonized by fen and wet grassland communities.

The water level fluctuations result in intermittent exchanges of oxic and anoxic conditions in the sediment that accelerate organic matter decomposition and nutrient release (Boulton and Brock, 1999; Urbanc-Berčič and Gaberščik, 2001, 2004). The dense swamp vegetation also functions as a sink for nutrients discharging into the lake (Gaberščik et al., 1994, 2003).

The more or less regular changes with a long aquatic phase (9–10 months) in the cooler part of the year are favorable to ecosystem resilience. However, in recent decades, flood and drought events have become more irregular, altering processes and conditions for many species. Many studies have demonstrated the effects of changing water regime on plant diversity and

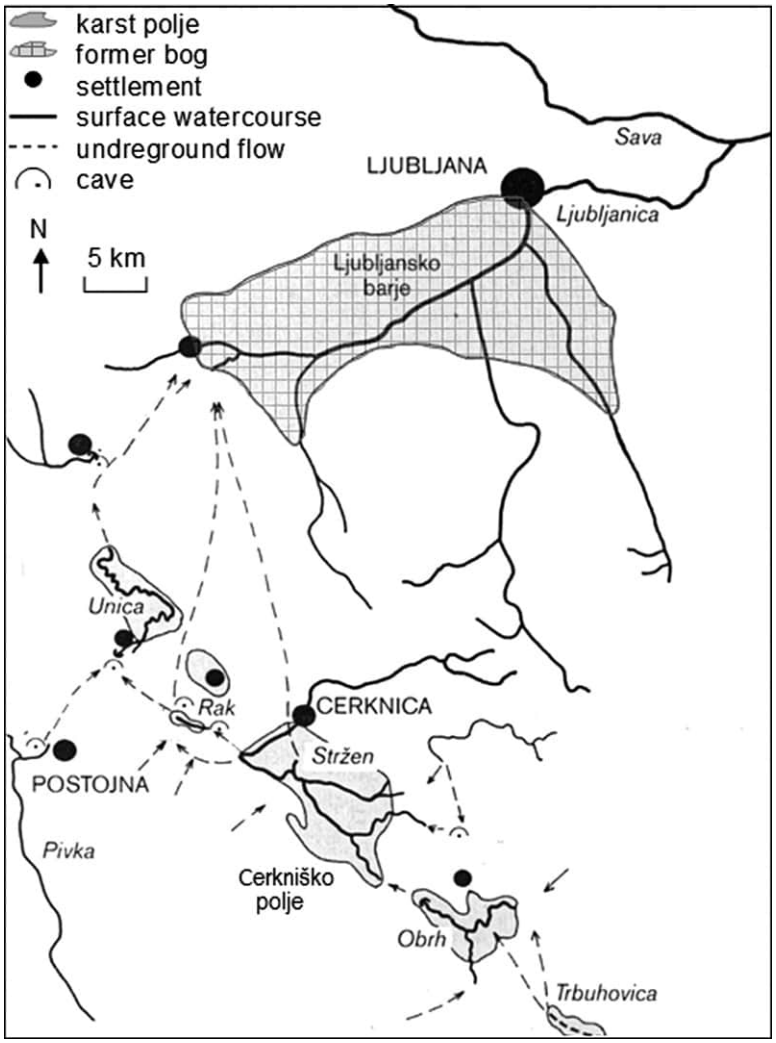

Fig. 4 The figure presents the sequence of poljes (Cerkniško polje with the stream Stržen and Planinsko polje with the stream Unica), the surface watercourses (solid lines), and the directions of underground flows (dashed arrows). From Skoberne P (2004) *Ljubljanica Od Izvira Do Izliva*. Mladinska knjiga: Ljubljana.

succession, their production, transpiration rate and fungal colonization of roots (Dolinar et al., 2010a; Dolinar and Gaberščik, 2010), on organic matter turn-over (Dinka et al., 2008; Dolinar et al., 2010b; Urbanc-Berčič et al., 2005) as well as on fish (Povž, 2002) and bird populations (Trontelj, 2001; Bordjan and Bordjan, 2014).

Planinsko polje

Planinsko polje is the second most studied polje. In comparison to Cerkniško jezero/polje, it is much drier, and the period of flooding is much shorter. During the 1954–2014 period, high waters on the polje occurred on average 38 days per year, the longest period in 1 year was 137 days. High water levels usually occur after mid-autumn rainfall peaks, winter rains and snow melting, and the flooded area can reach 10.3 km^2 (Ravbar et al., 2019).

It is typically referred to as a polje, not a jezero (lake). The geological setting for Planinsko polje and poljes in general is quite complex, typically aligned along tectonic axes, and covered with alluvium. Two main springs drain into Planinsko polje (Fig. 7) from the Javornik and Snežnik massifs, a string of poljes including Cerkniško polje, and from the Pivka River basin (Petrič, 2010). One of the springs, Unica, drains the large Postojna Planina Cave system. Unica river flows across Planinsko polje and plunges underground in a series of ponors at the eastern and northern end of the polje.

Since the polje is dry for most of the year, it is an important terrestrial habitat for mammals such as the wildcat, *Felix sylvestris*, many birds, butterflies and beetles. Postojna Planina Cave System, whose waters exit at Unica spring, is the richest cave in the world in terms of number of obligate cave-dwelling species. Especially during high water, the cave salamander *Proteus anguinus* washes out of the cave and can be found in the surface part of the Unica River.

Fig. 5 During snow melting and heavy rains in spring, water floods Cerkniško polje within a week. Polje is surrounded by hills; the NE part is closed by Slivnica (1114 m a.s.l.; in the background), while the SW part by high karst formations of Javorniki (1269 m a.s.l.). Fig. 6 Vertical ponors in the bottom of Cerkniško jezero. Photo courtesy of Archive of Notranjska Regional Park.

Fig. 7 Flooded Planinsko polje (January 2014). Photograph by F. Drole, used with permission.

Since there is a permanent stream across the polje, there is a persistent zonation of plants, from terrestrial to aquatic. Much of the land is used for grazing and some crops. Its position at the junction of Dinaric and Alpine regions accounts in part for the high floristic diversity. A species of hyacinth, *Scilla litardierei*, is limited to Dinaric karst wetlands and is common in Planinsko polje. Other species characteristic of Planinsko polje are *Gladiolus illyricus*, *Iris sibirica*, *Iris pseudacorus*, and *Ophioglossum vulgatum*.

Pivka intermittent lakes

The upper part of the Pivka River basin, southwest Slovenia, is formed on well karstified Cretaceous limestone. The river is dry during low waters and the water table is close below the surface in a relatively shallow karst aquifer underlain by Eocene flysch rocks of very low permeability. After more intensive or long-lasting precipitation the water table rises and water emerges through intermittent karst springs along the river-bed and recharge the Pivka River (Petrič and Kogovšek, 2005). Karst depressions, mostly on the slopes of the Javorniki and Snežnik mountains fill with water and up to 17 Pivka intermittent lakes are formed (Fig. 8). Depending on their altitude, morphology, karstification, and bottom sediments they differ significantly in size and duration. The biggest is Palško jezero, and the lowest in altitude is Petelinjsko jezero (lake bottom at 532 m a.s.l.), which has the longest flooding duration.

At the Pivka spring the water table is approximately 10 m below the surface during low waters and near Prestranek, more than 20 m below the surface (Fig. 8). The water table in wells and caves near the lakes oscillates several tens of meters, the highest measured being 50 m in the cave Matijeva jama at the edge of lake Palško jezero (Kovačič and Habič, 2005). The cave acts as estavelles. The other lakes also fill and empty through several karst fissures and channels.

Hydrological data describing the extent of the lakes are rare. The biggest floods were recorded in November 2000 when all 17 lakes were active after many decades (Kovačič and Habič, 2005). The surface of Palško jezero reached almost 2 km^2 and the water volume 23×10^6 m^3 (1 km^2 and 7×10^6 m^3 during average flooding).

More detailed observations from November 2006 to December 2007 (Kirn, 2016) were compared with meteorological data and discharges of the Pivka River (Fig. 9) (Daily Precipitation, 2013; Archive Hydrological Data, 2013). Petelinjsko jezero had the longest duration (84 days observed, but probably filled for additional 10 days in the beginning of January 2007 when the lakes were not observed) in a relatively dry hydrological year 2006/07 (11 Dec. 2006–30 Sep. 2007). Its occurrence is in close correlation with the discharges of the Pivka River at Prestranek—the lake is active when the discharge exceeds 1 m^3 s^{-1} (Kirn, 2016).

According to this assessment, Petelinjsko jezero is active 26–56% of a year (3–7 months per year respectively). Usually it is filled with water, typically intermittently, from November to February, and less likely from October to June. The duration of other lakes is shorter, and some of them are not active each year, but only at extreme hydrological conditions. The largest lake, Palško jezero, was active 46 days and 16% of hydrological year 2006/07—approximately from 1 to 3 months per year. At least five lakes that flood every year, most closely resemble turloughs, though the hydroperiod is shorter and more likely to be intermittent (Sheehy Skeffington and Scott, 2008).

The seasonal flooding of the Pivka intermittent lakes creates special growing conditions for interesting plant species as the floods last from some days to, in extreme circumstances, even more than half a year. Typically, the Pivka lakes have a thin and rocky soil on the lake margins, becoming deeper toward the center, making it more suitable for agriculture. In general, open meadow-like flooded areas and dry meadows at the margin of the lakes are important plant habitats (Tome, 2000). In the areas that are flooded for longer periods, purple willow (*Salix purpurea*) overgrows meadows and pastures in the absence of cultivation or grazing, though it is absent

Fig. 8 Hydrogeological map of the area of Pivka intermittent lakes. Legend: (1) karst aquifer; (2) porous aquifer; (3) rock of very low permeability; (4) permanent surface flow; (5) intermittent surface flow; (6) intermittent karst lake; (7) intermittent karst spring; (8) precipitation station; (9) main direction of groundwater flow; (10) direction of groundwater flow at high waters.

from Petelijnsko jezero, which has a flood duration of up to 6 months. Although a major part of the Pivka lakes is floristically poorly examined, more than 180 species of plants are recorded (Tome, 2000; Sheehy Skeffington and Scott, 2008). As with the turloughs and Cerkniško jezero, there is a zonation in the lake basin, related to flood duration.

Among endangered and rare species that grow in the Pivka intermittent lakes are the mouse garlic *Allium angulosum*, Siberian iris *Iris sibirica*, wild gladiolus *Gladiolus illyricus*, and solitary clematis *C. integrifolia* (Mulec et al., 2005). Rare plant communities include the wild gladiolus—purple moor grass (*Gladiolo-Molinietum*), and tufted hairgrass—tall plantain (*Deschampsio-Plantaginetum altissimae*) communities.

While the species list is very incomplete and excludes insects, it comprises stygobionts, species adapted to temporary waters and generalist species (Pipan, 2005). One copepod (*Diacyclops charon*) and one isopod subspecies (*A. aquaticus cavernicolus*) are stygobionts. The European cave salamander *Proteus anguinus* can also be found in the lakes as a result of washing out from springs and estavelles (Pipan and Culver, 2019).

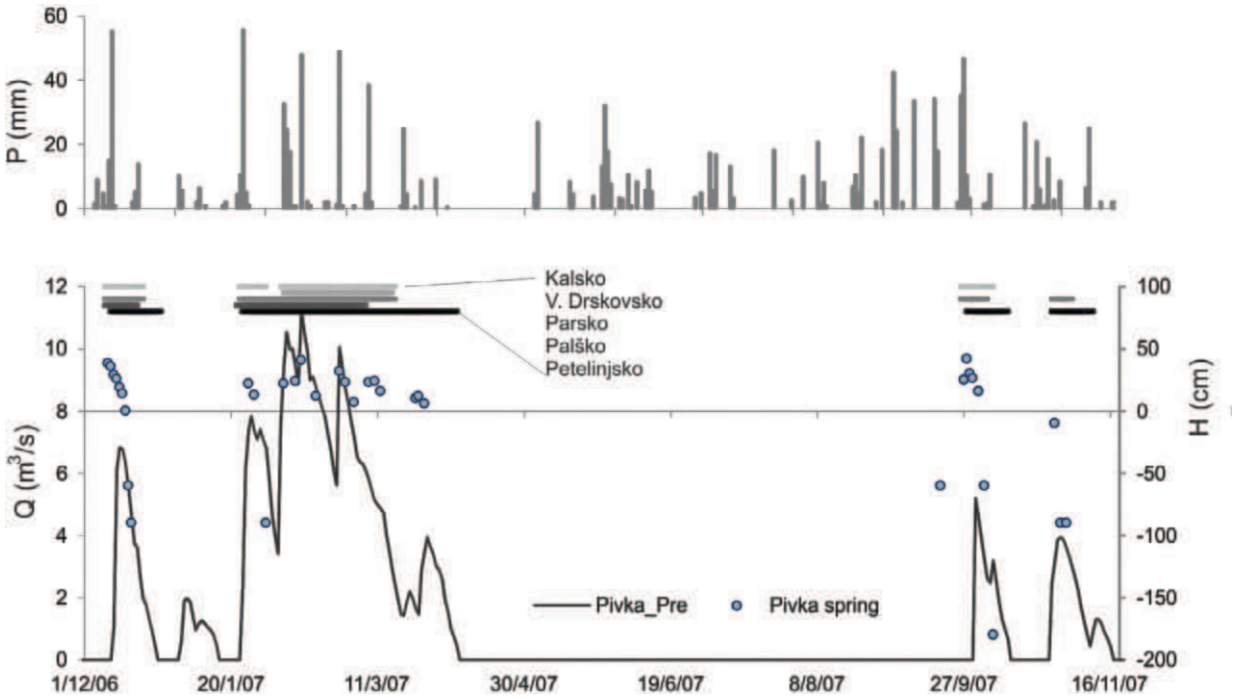

Fig. 9 Comparison of duration of selected Pivka intermittent lakes (duration marked with horizontal lines) with daily precipitation, water levels in the well at the Pivka spring and discharges of Pivka River.

Petelinjsko jezero is populated by an endemic species of karstic fairy shrimp *C. croaticus*. The population was probably destroyed in its type locality, a small lake in southern Croatia, as was a small population near Cerkniško jezero in south-central Slovenia. Petelinjsko jezero is now the only documented location for *C. croaticus* in Slovenia, where its population is apparently permanent and appears each year (Brancelj and Gorjanc, 1999), though recently a permanent population of the species has been found in lake Jeredovce (S. Polak pers. comm., see Fig. 8). It is threatened by the destruction of natural habitats and pollution, including fertilization of meadows.

Conservation and protection issues

The basic physical and biogeochemical processes in karst wetlands are similar to those in fluctuating water level ecosystems and temporary water bodies (Odum, 1971), where ecosystem structure and function depend on the timing of the aquatic or terrestrial phase as well as on frequency, extent and duration of flooding (Boulton and Brock, 1999). As disturbances, water level fluctuations also interfere with the process of succession, maintaining the ecosystem in an early, relatively productive stage of development (Odum, 1971). Regular water level fluctuations may support ecosystem stability, since they enable the community to adapt to the changing environment.

Because karst wetlands are uncommon, they play at least two key roles. One is as stopovers for migratory waterfowl, in regions where lakes are rare. In the Dinaric karst region, regularly flooded poljes cover 1500 km^2 in the 130,000 km^2 region and are key resting sites for the Western Siberian/Black Sea-Mediterranean populations of ducks, geese and swans (Stumberger, 2010). Second, karst wetlands, mostly due to their intermittent flooding, typically contain plant and animal communities not found elsewhere in the region even in the very small Tennessee karst pans.

There are a variety of country- or region-specific laws that are important in wetlands protection, such as the European Union's Habitat Directive and the United States' Clean Water Act. Internationally, the most important structure is the Ramsar Convention on Wetlands, adopted in 1971. Utilizing a broad definition of wetlands and a process by which individual countries nominate a site, over 2301 freshwater and marine wetlands have been designated as of February 2018 (https://rsis.ramsar.org). One of the wetland types is "karst and other subterranean hydrological systems." A total of 130 sites are included in this designation (Fig. 10), Cerkniško jezero being one of them. The designation of Ramsar karst wetlands has been utilized to varying degrees by different countries. Mexico has the most Ramsar karst wetlands, with 32, nine of which are in the state of Quintana Roo in the Yucatan Peninsula. By contrast, the United States has only three Ramsar karst wetlands and Canada has none (Fig. 10). The focus on Quintana Roo is especially timely because of the growing threats from development along the coast.

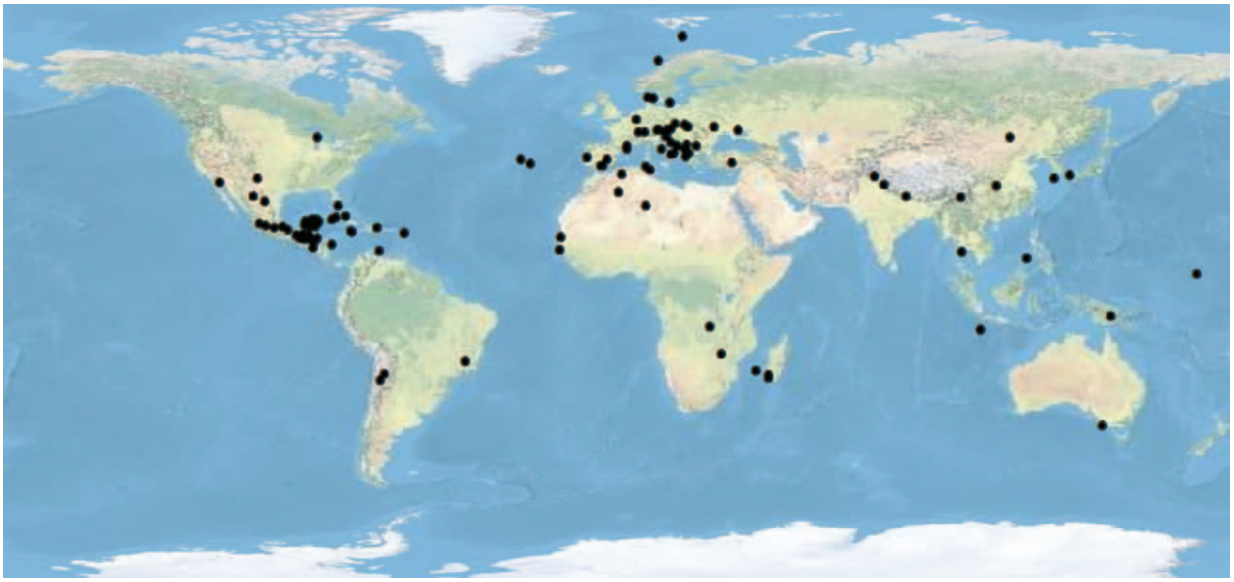

Fig. 10 Distribution of Ramsar karst wetlands. From https://rsis.Ramsar.org (accessed 15 February, 2018).

Discussion and overview

Although we know of no quantitative data on the density of wetlands in karst compared to non-karst areas, aside from Fig. 1, it seems likely that at least interior karst wetlands are much less common than wetlands in non-karst areas, especially in temperate zones. By contrast, closed depressions (e.g., sinkholes) are much more common in karst areas, and are a dominant feature of many karst landscapes. However, most of these closed depressions rarely, if ever, hold water. After all, limestone and other carbonate rocks typically have high primary and especially secondary porosity. Three conditions seem to promote water retention and an increase in hydroperiod in karst depressions: (1) proximity to the water table (e.g., Pivka intermittent lakes); (2) close subsurface connections via estavelles (Fig. 2) or a combination of ponors and springs (Cerkniško jezero); (3) presence of clay and other aquicludes (e.g., karst pans). Although beyond the scope of this review, it seems likely that permanent lakes in karst regions are even more uncommon, largely for the same reasons.

The existence of most karst wetlands does depend on karst processes, especially the formation of closed depressions. All of the karst wetlands reviewed here depend wholly or in part on the formation of closed depressions, along with dissolution of the underlying carbonate rock. Tectonic forces may also be involved in the formation of poljes. There are other processes on karst that may increase or decrease the likelihood of wetland formation in these depressions. These include the presence of clays and other sediments that act as aquicludes. Glaciation of karst areas would certainly increase the amount of sediment, and in some glaciated wetlands, like the Hudson Bay Lowlands, it is difficult to ascribe any role to karst processes. Wetland formation is also more likely if there is a close connection to groundwater, which in turn is relatively close to the surface.

It seems unlikely that any generalizations are possible concerning the hydroperiod of karst wetlands compared to non-karst wetlands. Nowhere is this more apparent than in Slovenia, where some wetlands flood every year with relatively long hydroperiods (e.g., Cerkniško jezero/polje and Planinsko polje), and some of the Pivka intermittent lakes rarely flood at all. Poljes in the Dinaric region include some that are almost always dry and others that are typically water-filled all year, although this last is rare (Stumberger, 2010). The reason for these disparate hydroperiods in regions of nearly identical climate is due to the local geological setting, especially distance and connection to groundwater.

A very small number of karst wetlands have been studied, and a greater range of types than reviewed here need to be examined. Perhaps most important is that wetland scientists recognize the unique features of karst and karst scientists recognize the unique features of wetlands.

Salt Lakes

Brian V Timms, Centre for Ecosystem Science, School of Biology, Earth and Environmental Sciences, University of New South Wales, Sydney, NSW, Australia

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Wolfgang Junk and Florian Wittmann.

Glossary

Arheic Areas without streams.
Athalassic Inland waters with no contact with the ocean.
Dimixis Lake stratifies twice per year, in winter and in summer.
DW m^{-2} y^{-1} Dry weight per meter squared per year.
Endorheic Internal drainage basin within a land mass.
Euhypersaline Very saline, generally >200 g L^{-1}.
Exorheic Drainage basin opening to the ocean.
Graben A lowland caused by downfaulting on both sides.
Halobionts Salt loving organisms, usually defined in the range 10–50 g L^{-1}.
Halophiles Salt loving organisms, usually defined in the range 50 to greater than 100 g L^{-1}.
Hypersaline Concentrated salty water, usually defined as greater than 50 g L^{-1}.
Hypolimnion The bottom part of a stratified lake.
Hyposaline Salt water usually defined within the range 3–20 g L^{-1}.
Meromixis/meromictic A stratified lake with a permanently stratified bottom layer but with upper layer either dimictic or monomictic.
Mesosaline Salt water usually defined in the range 20–50 g L^{-1}.
Monimolimnion Refers to the permanently stratified bottom layer of a meromictic lake.
Monomictic/monomixis Lakes stratify once a year in summer.
mS cm^{-1} Millisiemens per centimeter.
Playa Large shallow lake, often holding water temporarily.
Polymixis Lake stratifies many times a year, sometimes daily or for a few days.
Thalassic Lake of sea water or in contact with sea water.

Introduction

Saline lakes are distinct from fresh waters by having a salt content greater than about 3 g L^{-1} (Williams, 1964). For more details of salinity measurements, see "Measurement" section. Additionally, they commonly occur in closed endorheic basins where evaporation is greater than precipitation plus inflow and their organisms are almost entirely of freshwater affinities (e.g., Bayly and Boxshall, 2009). This later feature notably separates them from marine relict waters. Although most common in arid and semiarid regions, salt lakes occur worldwide (Fig. 1) and indeed combined contain almost as much water as freshwater lakes (Shiklomanov, 1990).

Some saline lakes are large, deep and permanent e.g., Dead Sea in the Middle East, while many are shallow and ephemeral, e.g., Australia's Lake Eyre. Although these waters share many characteristics with ordinary lakes such as geomorphic processes and

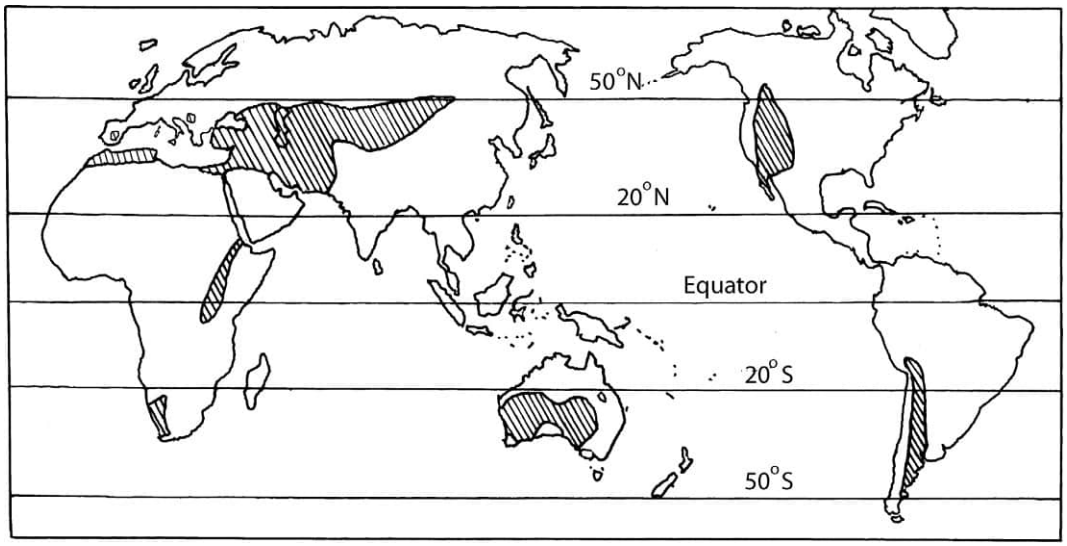

Fig. 1 Geographical distribution of major areas with saline lakes. Note that some occur outside these areas and on Antarctica. Modified from Williams WD (2002) Environmental threats to salt lakes and the likely status of inland saline systems in 2025. *Environmental Conservation* 29: 154-167.

thermal relationships, it is their restricted unique fauna according to salt concentrations which places them apart and drive ecological differences from fresh waters. Besides thus needing separate study, their decreased diversity permits easier ecosystem analysis.

Origins of salt lakes

Endorheic basins

Salty lakes are a result of climatic influences across endorheic basins. Most occur in semiarid and subhumid climates with their intermediate rates of evaporation and precipitation (Fig. 2). In arid and hyper-arid climates (e.g., Sahara), evaporation is too high and precipitation generally too low. By contrast, in humid climates, e.g., in almost all of Europe, a land of many freshwater lakes, high precipitation and low evaporation result in large river flows and exorheic basins and flushing of any salts.

It is in endorheic basins where there may be sufficient water flow but closed surface hydrology so that water is ponded to form lakes and salts can accumulate in them. Such basins are most common in the middle latitudes (20°–50°), and aided by conducive climates, the greatest world concentration of saline lakes occur there (Fig. 1).

Arheic regions

In some arid and hyper-arid climates rare local rainfall landing directly on the surface of a salt flat or similar can create a shallow lake. It may be wetted long enough to be inhabited by a distinctive fauna. There is a myriad of such lakes in the western half of Australia filling perhaps once per 20 or many more years and inhabited when wet by a variety of brine shrimps (Timms and Hudson, 2009). World distribution is unknown, as is their relationship to salt flats (see later); remoteness and short human timescales vis-a-vis the rare fillings of these lakes limit knowledge.

Modes of origin

Physically, the dominant modes of origin are tectonic in upland regions often resulting in large deep lakes and deflation on the plains which foster smaller shallow lakes. Less common are the influence of volcanism and glaciations and many are remnants of larger basins in Pleistocene pluvial times.

Specific tectonic mechanisms and examples (Table 1) include block faulting in western United States to form Walker Lake with Great Salt Lake lying in sedimented grabens within the once huge Lake Lahontan, many east African lakes lying in the grabens of the Great Rift Valley which extends to the Dead Sea in Israel-Jordan, and the Tertiary uplifted and subsequent local faulting to produce the salinas and salares (see later) of the Altiplano in South America. Volcanism has formed lakes in numerous ways, including crater lakes (Red Rock group in Victoria), maars (Zuni Salt Lake and Big Soda Lake in western United States, Bishoftu "Craters" of Ethiopia), and by damming and collapse (Lake Corangamite). Pleistocene continental glaciations are responsible for many shallower lakes across North America, including many the Canadian prairies such as in kettles, many in former glacial channels

(e.g., Manitou and Humboldt), some by scouring (Quill Lakes), a few by damming by moraines (Basin Lake). All are relatively shallow though the local subhumid climate means almost all are permanent.

Wind action forming saline lake basins is important in semiarid regions with many examples containing water but temporarily. Small pans and bigger playas are common in many places including Australia, Texas, north and southern Africa, the Pannonian Plain centered in Hungary, the steppes of Russia, northern China, with a few in India (Sambar Lake) (Cole, 1968). There are impressive arrays of playas along former draining channels in inland Western Australia, whether on the large scale of "Salinaland" (Van de Graaf et al., 1977) or a local scale of the Yenyening lakes (Davies and Carling, 2012). Blocking dunes can be important in places (e.g., Moses Lake in Washington, United States; the lakes of the Nebraska sand dunes).

Of unusual origins, the Beachport-Robe lakes in South Australia formed between coastal dunes and originally marine, but dried. Similarly, Lake Mariotic in Egypt has been isolated from the Mediterranean and lost its thalassic character.

Details on origins are available in Hammer (1986), Timms (1992) and Touchart (2000).

Physical features of salt lakes

Amounts of water

Some saline lakes are among the world's largest. Excluding the Ponto-Caspian region, the fifth deepest is Kazakhstan's Issyk-Kul with a maximum depth of 702 m, an area of 6200 km^2, and volume of 1985 km^3. Also exceptionally large (in order) are Van in Turkey, Dead Sea (Israel, Jordan), Balkash (Kazakhstan), Qinghai (China), and Karakul (Tajikistan), all of tectonic origin. Of the shallower lakes, Lake Eyre when rarely full is the largest at 8806 km^2, volume 32 km^3 and up to 6 m deep (Kotwicki, 1986). Laguna Mar Chiquita of Argentina is 5770 km^2 in area, volume 21.4 km^3 and 3.7 m deep (Bayly, 1995).

Because most saline lakes occupy terminal basins, lake surface levels fluctuate. This is minimal in large deep lakes such as Issyk-Kul, but in very shallow lakes relatively obvious by large changes in surface area (caused by just a few meters change in depth) and also noticeable in many lakes of moderate area and depth like Nevada's Lake Walker with a drop of 55 m from 1882 to 2016 (Wurtsbaugh et al., 2017). Such big changes drastically affect salinity and ecological function.

Some saline lakes dry occasionally and those in arheic regions are dry most of the time. For instance Lake Chilwa (Malawi) has dried five times in the last 100 years (Hammer, 1986). A few are episodic, filling and drying cyclically over years, such as Lake Wyara (Queensland) filling in La Niña years and drying in El Niño years on an approximate 10–11 year cycle (Timms, 1998). Many are seasonal, mainly in Mediterranean climates. At the other extreme others rarely fill—Lake Eyre gets a minor inflow every few years, but major inundations are many decades apart (Kotwicki, 1986). Nearby Lake Torrens has filled only twice in 200 years (Williams et al., 1998).

Transparency

As in freshwater lakes, transparency ranges from turbid to crystal clear but the tendency in salinas is for light to penetrate deeper as the abundant ions in salinas usually cause clays and organics to settle. Acting against this is attenuation due to much phytoplankton in highly productive lakes and/or wind disturbance of bottom materials in shallow lakes. The spectral quality of light may vary more than in fresh waters and between lakes, due to different salinities, layering of phytoplankton, and ionic composition. These same factors influence color so that a great range is possible. Blooms of *Dunaliella* (Order Volvocales, Class Chlorophyaceae) produce color and severely limit the penetration of light.

Thermal characteristics

On average, saline waters heat a little more than fresh waters but more marked is the depression of the freezing point (e.g., –4.1 °C in Little Manitou Lake Saskatchewan at 120 g L^{-1} and Na_2SO_4/Cl waters). Hypersaline and monomictic Deep Lake in the Vestfold Hills, Antarctica, rarely freezes because the freezing point depression is about –20 °C (Ferris and Burton 1988). The normal spectrum of polymixis, monomixis and dimixis is encountered governed largely, in sequence, by shallow depths, maritime climates, continental climates, modified by altitude and latitude. Meromixis is more common than many texts admit; this is probably a function of the remoteness and hence poor monitoring of saline lakes, and of greater water stability promoted by salinity. An example is West Basin Lake in Victoria (Fig. 3) hidden in a small volcanic crater and persisting despite early calculations predicting its soon demise (Timms, 1972).

Oxygen

Dissolved oxygen is of critical importance in lakes, particularly those that stratify. Saline lakes present extra problems due to the reduced solubility of oxygen with increasing salinity. As in freshwater lakes, oxygen concentrations in saline waters vary with photosynthesis, organic decomposition, temperature and wind action. Deoxygenated hypolimnions in summer stratifications in deeper lakes, can be more severe in saline lakes due to lower solubilities and hence fish can be more affected. Shallow lakes can experience wide variations from supersaturation to deoxygenation (e.g., Tswaing Crater Lake (=Pretoria Salt Pan) has recorded values from 415% to 12% (Ashton and Shoeman, 1983)). The monimolimnions of meromictic lakes are permanently devoid of oxygen, and have much H_2S and high bacterial populations (Fig. 3).

Salts

Measurement

There are various methods of measurements of salt content of saline waters. Most thorough is the concentration of all the ionic constituents present, but this is the most time consuming to achieve. It can be simplified a little by analyzing for just the major ions, Na, K, Ca, Mg, Cl, $HCO_3/C0_3$ and $S0_4$. Results are usually expressed as g L^{-1} but there are many other measures. A quicker rougher measure is to determine the Total Dissolved Solids (=total filterable residue) by gravimetry. An even quicker method is measure conductivity, but there are some constraints on this method but it can work well for a defined series of lakes. Results are expressed in mS cm^{-1} at a specified temperature (often 18 °C or 25 °C).

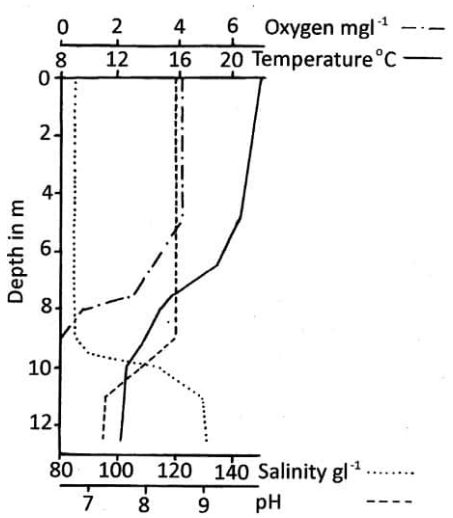

Fig. 3 Summer depth profiles in the meromictic lake, West Basin, Victoria. Modified from Timms BV (1972) A meromictic lake in Australia. *Limnology and Oceanography* 17: 918–922.

Variation

Large deep saline lakes vary little in salinity temporarily or seasonally, but shallow lakes do, both with season and secularly (Fig. 4). It is all a matter of the balance between gains and losses tempered by different lake volumes (Bayly and Williams, 1966). All waters are athalassic and can be characterized by their salinities as hyposaline 3–20 g L^{-1}, mesosaline 20-ca. 50 g L^{-1}, and hypersaline >50 g L^{-1}, based largely on salinity tolerances of component organisms (though other terms and salinity ranges may be used for specific groups of lakes) (Hammer, 1986). The term "brackish" is not applicable as this applies strictly to dilute seawater only. In most lakes salinities are increasing over time (Wurtsbaugh et al., 2017), due at least in part to climate change (see later).

Origin of salts

The salts in saline lakes originate (a) by weathering of soils and rocks in the catchment, and/or (b) via the atmosphere ultimately from marine sources and/or (c) underground from lake evaporates formed from (a) or (b) above. Controversy can rage over the proportion from each source, none more so than in Australia where atmospheric (or "cyclic") salts are important in southern lakes. Salt is lost by deflation in lakes that dry or perhaps by precipitation from the water column and/or burial by sediments.

Types of salts

The types of salts vary considerably between lakes, though there is regional similarity (Hammer, 1986). Considering anions first, there are carbonate, chloride or sulfate waters. Carbonate waters occur particularly in East Africa, Lake Chad in Africa and in Europe (Hungary) with some in North America. Most are hyposaline. Chloride waters are the most common and dominate particularly in Australia and South America and notably also include the Great Salt Lake of Utah and the Dead Sea. Sulfate waters are common in North America and Asia. All types of intermediates occur. Classification by cation dominance is even less distinct although among the nine types listed by Hammer (1986), sodium lakes are the most common, with magnesium lakes second.

Ionic ratios change as salts accumulate. Geochemical evolution is a popular study first promoted by Clarke (1924) with many later authors contributing (e.g., Kilham and Cloke, 1990; Svartsev et al., 2014). Sequences are complex and variable depending on ions present, but a broad precipitation sequence with increasing salinity is calcium carbonate, magnesium carbonate, calcium sulfate, sodium carbonate, sodium chloride, and magnesium chloride.

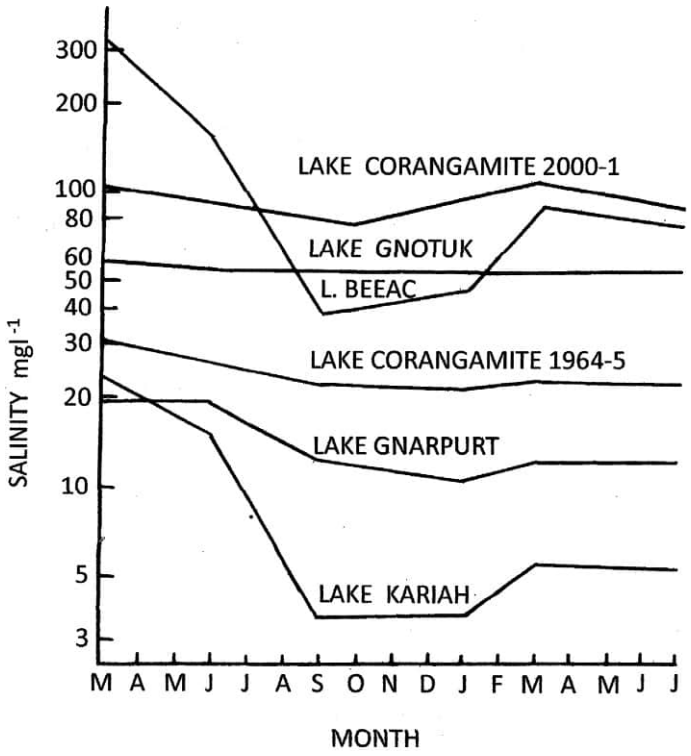

Fig. 4 Seasonal variation in salinity in six lakes in western Victoria. Variability is largely related to lake volume, Lakes Gnotuk and Corangamite (1964-5) have the largest volume and lakes Beeac and Kariah the smallest. Adapted from Bayly IAE and Williams WD (1966) Chemical and biological studies on some saline lakes of south-East Australia. *Australian Journal of Marine and Freshwater Research* 17: 177–228, with addition of Corangamite 2000-1.

Nutrients

Nutrients such as phosphorus, nitrogen and silicon can be high, which is not surprising given the endorheic status of most saline lakes (Hammer, 1986). Phosphorus (as orthoP) is greater than 100 mg L^{-1} in some and generally greater than 1 mg L^{-1} which in most cases mean saline lakes are very productive, if not hypereutrophic. Total nitrogen is very variable seasonally but values up to 30 mg L^{-1} are known, but usually much less and sometimes in amounts limiting to production. Ammonia and nitrite N can be important in reducing situations and gaseous N is fixed by some bacteria and cyanobacteria in some lakes thus overcoming shortages for high productivity. Silica can be limiting for diatom growth in freshwater lakes, but in saline lakes it can be abundant (to 730 mg L^{-1}) particularly in African and Asian waters. However low values (< 0.1 mg L^{-1}) are just as common (e.g., in Australian salinas) and perhaps limiting. Unusually high concentrations of other generally less important elements are known, such as boron and lithium and exploited commercially.

pH

The pH of saline lakes tends to be basic ca. 8, but to 11 in alkaline waters (e.g., in East African soda lakes) (Schagerl, 2016), Hungarian soda pans (Boris et al., 2014) but even lakes with more neutral pH may reach 9.5 during strong photosynthesis. Values may decrease with depth often associated with hydrogen sulfide accumulation, as in meromictic waters. Throughout southern Western Australia and in limited areas in elsewhere in the world, groundwaters tend to be acid and when exposed in playas these can be as low as pH 3 (Timms, 2009). Origins of such water are complex and are due basically to ferrolysis and/or reduction of sulfates (Lillicrap and George, 2010).

Diversity of life

Factors driving diversity

Species richness/alpha- and beta-diversity in saline lakes decrease with increasing salinity till few, if any, macroinvertebrates and algae are present beyond ca. 250 g L^{-1}. This relationship is often expressed linearly and the slope may change with drought conditions which affect insects far more than crustaceans (Fig. 5). In reality, once halophiles dominate, the decrease beyond 50 g L^{-1} is appreciably less in the mesosaline and particularly the hyposaline range (Williams et al., 1990).

While salinity per se is the major influencing factor (Timms, 1997), acidity adversely affects diversity in many mesosaline lakes in southern Western Australia (Timms, 2009), so that only one to two species are present at pH 3, just as in euhypersaline conditions (salinity >250 g L^{-1}). Another factor is heterogeneity of shores—in inland Australia beta-diversity is promoted by many small lakes

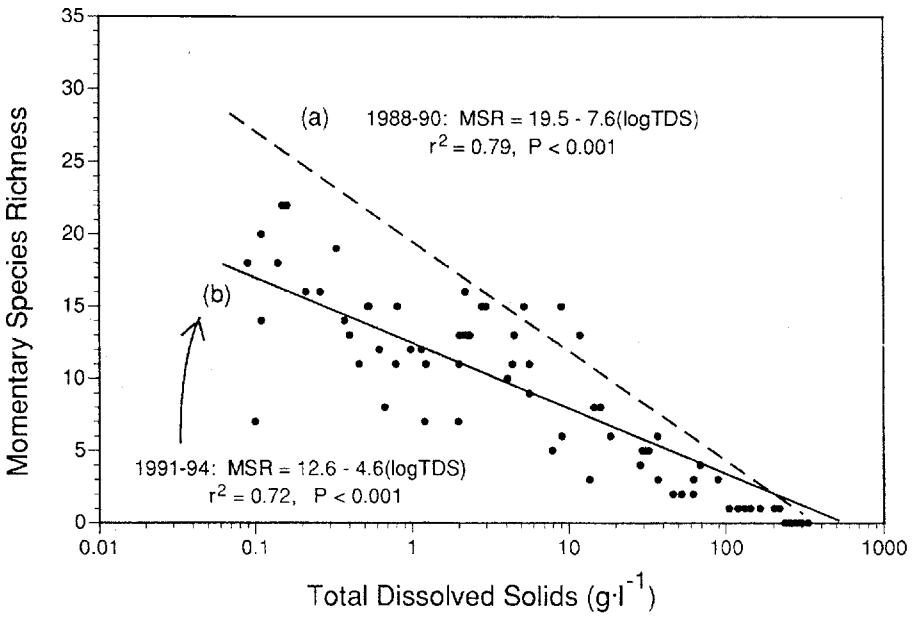

Fig. 5 Momentary species richness (alpha diversity) as a function of salinity in saline lakes in the Paroo, New South Wales in (A) 1988–90, the "wet" years and (B) 1991–94, the "dry" years. Original in Timms BV (1997) Further studies on the saline lakes of the eastern Paroo, inland New South Wales, Australia. *Hydrobiologia* 381: 31–42.

vis-a-vis large windswept lakes like Lake Eyre (Timms, 2021). This effect can be counterbalanced in deep vs. shallow lakes due to the addition of a distinct benthic community in the former. Diversity can be influenced by season as seen in lakes with irregular filling regimes, for insects are adversely affected in winter fills verses summer inundations (Timms, 2018). Another complication is provided by relict species of ultimate marine origin that may inflate species richness at higher salinities as in the coastal lakes in Crimea (Anufriineva and Shadrin, 2018). Details are given in Timms (2021).

Flora

Life cycles and ecological relationships of flora in salt lakes are usually similar to those in fresh waters, so no attempt will be made to highlight these in saline lakes. Instead attention will be given to the groups of organisms likely to be found in saline waters and their salinity tolerances (Hammer, 1986). Among microscopic organisms, there is a large variety of protists in saline waters, with a bewildering variety possible in hypersaline situations. Diatoms are extremely diverse in hyposaline waters decreasing linearly but still many in hypersaline lakes. Most have characteristic salinity ranges, and given their good preservation in bottom sediments, studies of bottom cores can be used to reconstruct past conditions in lakes. Much the same applies to the diversity of green algae and cyanobacteria, though many do not preserve as well in sediments. Most of these species are cosmopolitan, thus aiding in universal schemes for modeling. Among charophytes there are only a few hyposaline and mesosaline species with just *Lamprothamnium papulosum* penetrating into hypersaline waters. A few hundred angiosperms live at least in hyposaline waters with many of limited world distribution and only two genera, *Lepileana* and *Ruppia* in hypersaline sites.

Invertebrates

Overall, across the world there is surprising diversity of invertebrates in hyposaline waters with most freshwater higher taxa represented in at least moderately saline waters (10–15 g L^{-1}) in many/most salt lake districts (e.g., Hart et al., 1991). About the only exceptions for this restriction are cnidarians, platyhelminthes, polychaetes, hirudineans, bivalves, syncarids, ephemeropterans, and plecopterans all of which have only rare examples in waters beyond 3 g L^{-1}. Diversity across the world is much less in mesosaline waters with various crustacean groups well represented (branchiopods, copepods, ostracods, amphipods, but hardly any isopods and decapods) and the most likely insects are odonates, corixids, coleopterans and dipterans, though lepidopterans and trichopterans are occasionally represented. Also the gastropod *Coxiell*a occurs abundantly in mesosaline waters in Australia. Hyposaline and mesosaline waters also support diverse arrays of rotifers. It is in hypersaline waters that diversity is restricted mainly to brine shrimp (*Artemia, Paratemia*), rotifers (*Brachionus, Filinia*) and dipterans such as ceratopogonids (*Dasyhelea*) chironomids (*Chironomis, Tanytarsus*, culicids (Aedes), ephydrids (*Ephydra*) and a few other minor families and perhaps ostracods and copepods. Euhypersaline waters (>200 g L^{-1}) are almost the exclusive domain of brine shrimps. Only a few species of invertebrates are cosmopolitan (e.g., *Artemia franciscana, Brachionus plicatilis* sensu strictus) though many genera are shared across at least a few continents.

Fish

Fish are not diverse in saline waters due to many problems including osmoregulation, access, and impermanence (Hammer, 1986). Species present are of different phylogenetic origins in each continent, rarely penetrate beyond middle hyposaline range and then only to upper mesosaline with just a few, usually species of marine origin, surviving in hypersaline waters (e.g., the cyprinodont *Aphanius dispar* in Mediterranean coastal marshes to 145 g L^{-1}). Other examples of remarkable salinity tolerance include the cichlid *Alcolapia grahami* living in hot springs in Kenya and Tanzania and *Craterocephalus eyresi* in Lake Eyre. Fish do better in sodium chloride waters then in sulfate and especially alkaline waters, and if they do survive, reproduction may be suppressed.

Waterbirds

Representatives of flamingos, grebes, ducks, geese, swans, pelicans, cormorants, herons, egrets, cranes, waders, gulls, terns and phalaropes are variously prominent in salt lakes. The great majority of these are tolerant freshwater species; the difference is in how they use the richer resources of salt lakes. Representative of salt lakes particularly attractive to water birds include the Great Salt Lake, Utah (Jehl, 1994; Frank, 2016), Lake Albert, Oregon, (Senner et al., 2018), Lake Nakuru, Africa (Bennum and Nasirwa, 2000), Mar Chiquita, Argentina (Castro and Torres, 2014), Lakes Eyre and Wyara, Australia (Kingsford and Porter, 1993, 1994).

Suitable lakes with abundant invertebrates as a feeding resource lie between 10 and 150 g L^{-1}, but often narrower (30–80 g L^{-1}, Herbst, 2006). Sometimes high salinities can be physiologically limiting to the birds. Numbers per lake can exceed 250,000 (>5000 ha^{-1} in places), but fluctuate greatly seasonally/secularly (Roshier et al., 2002; Bennum and Nasirwa, 2000). In many cases, particularly among the migrating waterbirds of North America, lake phenology and bird life cycles are closely matched, (e.g., Wilson's Phalarope, Jehr, 1988) whereas in Australia with its unpredictable episodic flooding/filling regimes waterbirds move enigmatically to the Outback salinas, breed and then disperse outwards again (e.g., Banded Stilt, Burbridge and Fuller, 1987). Without doubt the ecologically most interesting waterbirds are the flamingos with their adaptations for living in highly saline waters and niche separation when species co-inhabit (Castro and Torres, 2014).

Regionalization

Although some hypersaline species occur across the world, in general each continent's saline flora and fauna is distinct. The greatest similarly occurs across the Nearctic and Palaearctic both formally extensively glaciated and their saline systems established in the Holocene. African and South American saline systems are somewhat older and unique, but it is in isolated and old Australia that the fauna of saline lakes is the most distinctive. This is contributed to by *Parartemia* instead of *Artemia*, an abundance of ostracods, the prominence of the snail *Coxiella*, the presence of the isopod *Haloniscus* (to name a few outstanding invertebrate genera) and also an adaptation to higher salinities in general (Williams, 1972, 1978). Copepods are more prominent in saline lakes in Europe than elsewhere (Hammer, 1986).

Saline biogeography in Australia is further distinguished by regionalization much more so than elsewhere—the faunas of each of southern WA, Eyre Peninsula SA, the southeast of SA, eastern and central Inland and southern Victoria plus Tasmania are distinct. Contributing to this is isolation, evolutionary history and separate climates (Williams, 1984).

Productivity

Introduction

Some saline lakes are thought of as being more productive, others less productive, than fresh waters. This ambiguity has encouraged many studies to quantify production in inland saline waters, particularly of the basic step, primary production of the phytoplankton. There are many methods, none perfect, and even the most widely used, incorporation of ^{14}C into algal tissue, can underestimate or overestimate production (e.g., Pierson, 2012). Besides method inaccuracies, the use of different units in reporting is confusing.

Production by phytoplankton

Many saline lakes across the world have now been studied ranging from small to large, and many chemical types (mainly carbonate, halite, sulfates, and borax lakes). Results vary widely, but in general hyposaline lakes exhibit the highest primary production and hypersaline lakes the least (Table 1). Carbonates seem to be advantageous to production, none more so than the Victorian examples, and borates could be depressive. The world's most productive salina is the small shallow Red Rock Tarn in Victoria. Conversion efficiencies of sunlight and biomass are in general higher by 2–8 times the average 1% expected in many ecosystems, but those in hypersaline lakes are significantly lower. As in most freshwater lakes, production occurs in the upper few meters, but in saline lakes this can be restricted to the uppermost meter or less by light attenuation due to dense algal crops. Sometimes production is inhibited very near the lake surface by high light intensities. While production usually tracks the daily flux in total radiation and is much higher in summer than in winter, inexplicable fluctuations are common particularly in shallow lakes where the environment can be quite unstable. For instance, Pink Lake in Victoria can have high rates for a very limited time, but almost nothing for days on end (Table 2). Winds and resultant high turbidities contribute to this problem. Readers are referred to Hammer (1986) for an analysis on primary production in saline lakes across the world and to the peculiarities in Pink Lake.

Production by macrophytes

In saline lakes there have been far fewer studies on macrophyte primary production and even fewer of the attached periphyton community. From these it seems production can be significant and add 20–50% to the whole lake primary production. Factors such as extensive shallow water, low turbidities and moderate salinities are positives (Wetzel, 1964).

Limnetic secondary production

Studies on secondary production often deal with one species or those of a particular habitat, with major variation between lakes (Hammer, 1986). Starting with rotifers which can be particularly common in hypo- and mesosaline lakes, production in Lake Werowrap has varied from 29 to 1909 g DW m^{-2} $year^{-1}$ which was 0.7% of phytoplankton production. A figure for Nakuru was an order of magnitude greater. Brine shrimp are usually efficient convertors of algal production into shrimp flesh with figures of 208 g $m^{-2}day^{-1}$ reported in cultures, but rarely in nature. Even so in Great Salt Lake a conversion efficiency was once recorded at 25%, similar to that for *Parartemia zietziana* (23%) in Pink Lake, but the latter could have got some energy from windblown detritus. Respiration can account for 60–80% of assimilation, leaving insufficient for life, resulting in mass deaths. While many cladocerans occur in salt lakes and life cycles have been studied, no information is available on productivity. Copepods are even more diverse in saline lakes and much is known of their life cycles and salinity tolerances. Two production studies yielded very different productivities—259 to 385 mg DW m^{-2} day^{-1} for *Lovenula africanus* in Lake Nakuru at 15–25% conversion efficiency and 7 mg C m^{-2} day^{-1} for *Diaptomus connexus* in Saskatchewan's Waldsea Lake at 7% of annual phytoplankton production. Ostracods are usually small and benthic, but in Australia many are large and planktonic, and while data are available on salinity tolerances, production is unstudied.

Table 2 Values for primary production in selected lakes arranged from least to most saline.

Lake	*Country*	*Daily P (mg C m^{-2} day^{-1})*	*Max P* (mg C h^{-1})*	*Efficiency (%)*
Hyposaline				
Mariiotic	Egypt	9611	–	–
Humboldt	Saskatchewan	7968	2.20	3.80
Pyramid	Nevada	2780	–	–

P = production.

Based on Table 7.14 in Hammer UT (1986) *Saline Lake Ecosystems of the World*. Dordrecht: Junk.

Benthic production

The benthos of many salt lakes have been studied and many standing crop figures are available. As in freshwater lakes, diversity and biomass decrease with depth, with generally higher figures in hyposaline lakes but little or no macroscopic benthos in hypersaline lakes. This relationship is best seen in a series of lakes as in Victoria where average biomasses decrease with increasing salinity, perhaps with a peak in the lower hyposaline range no doubt related to their higher primary productivity/nutrient load (Timms, 1983) (Fig. 6).

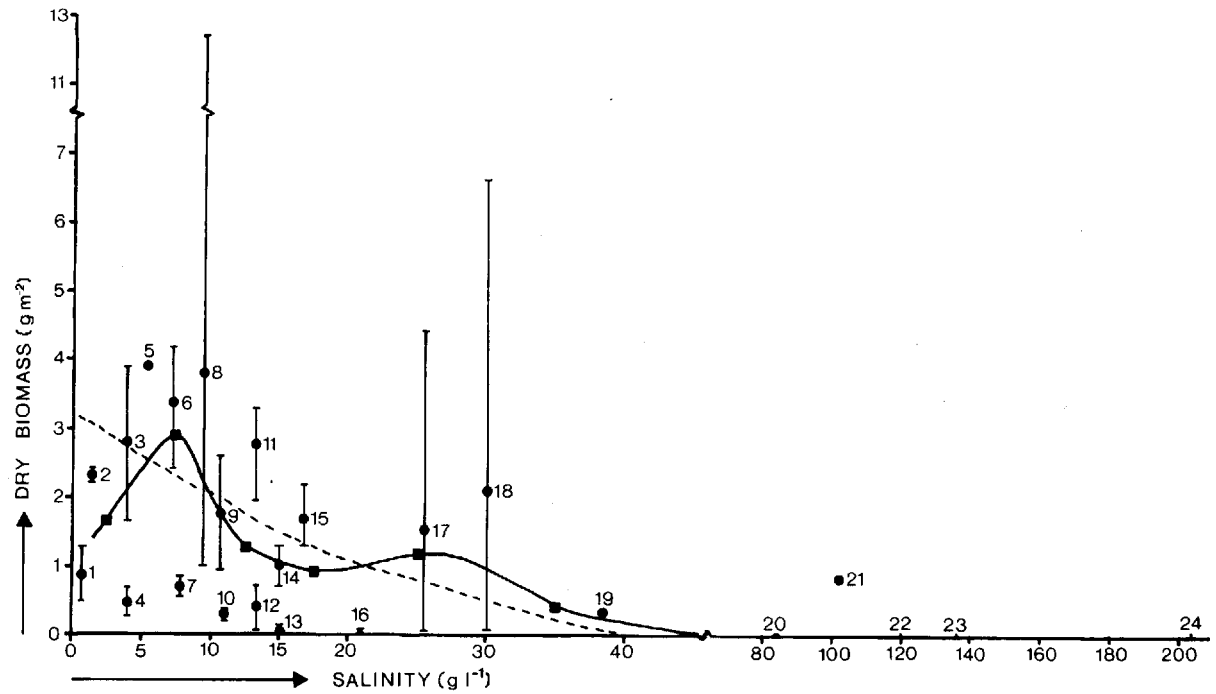

Fig. 6 Relationship between benthic biomass and salinity in 24 shallow saline lakes in Victoria. The solid circles indicate the mean value for each lake, and the bars the range of values. The solid heavy line shows an approximate relationship between the two parameters in that it connects six points (as squares) marking average biomass values for lakes within four (0–20 g^{-2}) and two (>20 g^{-2}) g m^{-2} intervals. The dashed line represents a mathematical solution for the relationship expressed by the equation x –g e^{hy} where g = 51.184 and h = 0.135. Note the scale changes on both axes. Original in Timms BV (1983) A study of benthic communities of shallow saline lakes of western Victoria, Australia. *Hydrobiologia* 105: 165–77.

Production figures are available for some lakes (Table 2). Lake Werowrap is the most productive of all lakes, due to its moderate salinity, shallowness, high primary production, and growth of 8 generations of chironomids per year (Paterson and Walker, 1974). Nukuru is next; it is also shallow and has 10 generations of chironomids per year (Vareschi and Jacobs, 1984). The reason for Soap Lake's productivity is claimed to be its high primary productivity and lack of fish to prey on the chironomids (Lauer, 1963). The long winter of no growth and hence only one generation of chironomids per year is negative for Soap and Waldsea and an extra depressive factor for Waldsea is possibly the ill effects of magnesium ions (Swanson and Hammer, 1983).

Ecophysiology of organisms

Introduction

This has been a favorite topic for investigators over the years. While the essence is known (Bayly, 1972), some aspects have yet to be elucidated. Central is how halophilic and halobiont organisms survive the salty environment.

Crustaceans

The most powerful osmotic regulators are anostracans *Artemia "salina," Parartemia zietziana* and by taxonomic affinity, all species in these genera. In mesosaline and hypersaline waters these brine shrimp (Fig. 7) maintain their body fluids at 350 mOsm L^{-1}, which can be as low as 10% of the environment. They do this by active regulation, swallowing the medium, removing Na and Cl across the gut wall and secreting these ions through the gills. This requires energy, which can exceed metabolic gain at extreme salinities and result in death. Australia has an unusual crustacean in its saline lakes, an oniscoid isopod *Haloniscus searli* of terrestrial origins. It can osmoregulate to 160 g L^{-1} (Fig. 7).

Many lower crustaceans in saline waters (branchiopods, copepods, amphipods) osmocomform in hyposaline and even mesosaline conditions. Perhaps in some cases, like those in hypersaline waters, survival is by ionic regulation. The situation is just not known.

Insects

Some mosquito larvae (e.g., *Aedes detritus*) survive in waters to 100 g L^{-1} by a similar process to that in brine shrimps, but removal of ions is by the malpighian tubules. Ephydrids (brine flies) are also strong osmotic regulators. *Ephydra cinerea* in Great Salt Lake can live in 300 g L^{-1} NaCl waters helped by an impermeable cuticle but in Mono Lake *E. hians* is adapted to alkaline waters and survives only to 200 g L^{-1}, with any chloride water above 200 g L^{-1} antagonistic to its survival. Some chironomids (e.g., *Ch. salinarius*) are weak hypo-osmotic regulators. Many corixids have some ability to osmoregulate, as do some beetles (e.g., *Hygrotus salinarius* in Saskatchewan), but it is unknown how many beetles regularly survive in waters greater than 50 g L^{-1}. Surely an impermeable cuticle helps.

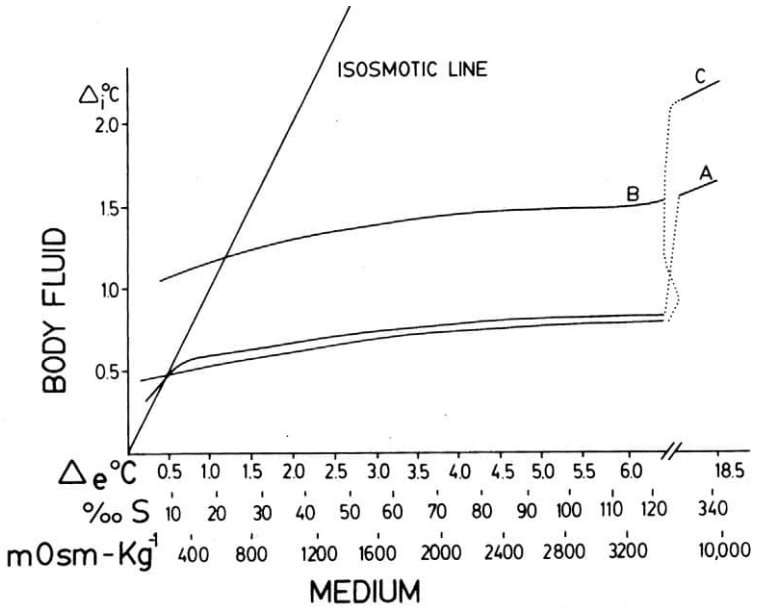

Fig. 7 Osmotic response curves for crustaceans in athalassic saline waters. (A) *Artemia "salina"* at 21° ± 3 °C (Croghan, 1958); (B) *Parartemia zietziana* at 18 °C (Geddes, 1975); (C) *Haloniscus searli* at 20 °C (Bayly and Ellis, 1969). Modified from Hammer UT (1986) *Saline Lake Ecosystems of the World*. Dordrecht: Junk.

Plants

The mechanism for survival of algae and angiosperms in saline waters are well known. Algae such as *Dunaliella* uses glycerol to maintain intracellular osmotic balance (Borowitzka and Brown, 1974). Some diatoms and some charophytes can regulate internal osmotic pressure by controlling KCl concentrations. Angiosperms use a variety of mechanisms, from selective salt uptake, salt exclusion by roots, increase in succulence and salt extrusion. Some use organic molecules such as proline. Similar use of organics by animals has hardly been investigated.

Adaptations for acid waters

Of similar interest to survival in mesosaline waters is living in acid salinas wherein below pH 6.2 no free CO_2 is available. However at least one brine shrimp in Western Australia, *Parartemia contracta*, is able to use respiratory CO_2 in its ATP to run its sodium pump for osmoregulation (Conte and Geddes, 1988). It is not known whether other brine shrimp such as *Parartemia acidiphila* which lives down to pH 3 uses the same mechanism or some novel method.

Microbial ecology

Introduction

Microbes are everywhere but they are arguably more noticeable, important and unusual in saline lakes, salares and salterns (Oren, 2002). What is more is that this is an active area of research bringing great rewards as new species are found, genome sequences compiled, metabolic diversity realized and biotechnological uses explored. Major discoveries have been made in the Dead Sea, Mono Lake, Great Salt Lake, alkaline soda lakes of Kenya such as Lake Magadi, and solar salterns especially those in Spain. In Deep Lake, Antarctica, two strains of a *Halobacterium* survive in one of the most extreme aquatic environments on Earth (salinity close to 350 g L^{-1} and temperatures approaching −20 °C) (Ferris and Burton, 1988).

Taxonomic diversity

Phylogenetically, halophilic and halotolerant microorganisms occur in all three life domains: Archaea, Bacteria and Eucarya. Archaeans are the most halophilic and they often comprise the greatest biomass in many highly saline sites. The Halobacteriales are a prominent group. The Bacteria include many types of halophilic and halotolerant microbes with a majority in moderate rather than extreme habitats. The Eucarya are in general the least tolerant and common, but the alga *Dunaliella* is an exception, being an important component in many moderate salinas and some strains even in extreme environments.

Osmotic solutions

There are two strategies to deal with the high environmental osmotic pressures. In the first and most common is to accumulate organic solutes to provide osmotic balance. A wide variety of such compounds are known and include glycerol, ectoine and glycine betaine. A second strategy is to accumulate K^+ and Cl^- ions at the expense of Na^+ to maintain osmotic balance. This is used by the Halobacteriales and some true bacteria and is less energetically demanding.

Metabolic activities

These microbes display a huge range of metabolic activities (Oren et al., 2009), many important ecologically such as photosynthesis, denitrification, sulfate reduction and other functions specific to certain species and situations, e.g., methane formation from acetate, or autotrophic ammonia reduction. Some activities release little energy, others much, and some occur at high salt concentrations, others have much lower limits. Many are important in mineral recycling and in the food chain of saline lakes, though exactly the processes and organisms responsible are not well known in most lakes (Fig. 8). In food chains, there are a range of protozoa that consume bacteria and it is probable that ubiquitous *Artemia* may help regulate bacterial densities too. However, at extreme salinities, bacteriophages seem more important in regulating prokaryote densities than protozoans.

Microbialites: Benthic microbial mats

Benthic microbial mats occur in many situations across the world (Prieto-Barajas et al., 2018) and can be photosynthetic or heterotrophic. They are made by an array of cyanobacteria, diatoms and other eukaryotic algae plus bacteria and can be mucilaginous films easily broken up or persistent due to lithification by carbonates. Originating over 3 billion years ago, such microbialites contributed to oxygenating the atmosphere. These days microbial mats in salt lakes are one of the alternate regime states in their ecology, favored by higher salinities, low nutrient status and wet-dry hydrology (Sim et al., 2006).

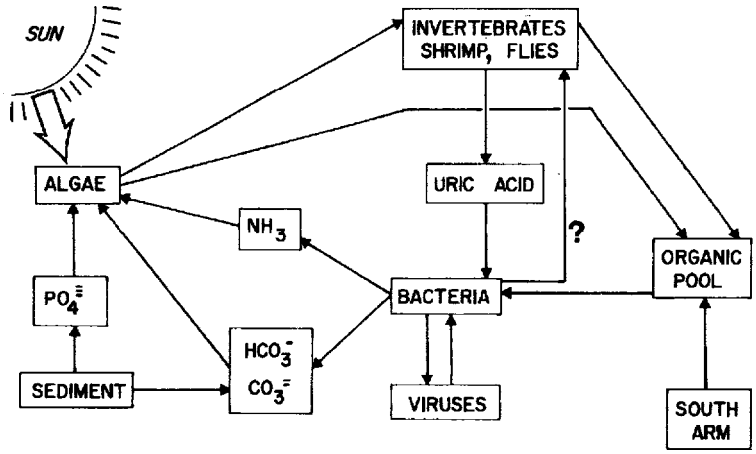

Fig. 8 Model showing the central role of bacteria in the ecology of Great Salt Lake, Utah. Original in Post FJ (1981) Microbiology of the Great Salt Lake, north arm. *Hydrobiology* 81: 59–69.

Microbialites: Stromatolites and thrombolites

Akin and far less common are stromatolites and thrombolites in which sediments are incorporated too and the structure is likely to grow into a dome or column. In stromatolites the sediment is in layers, while in thrombolites the sediment is spongy. The world's best modern examples occur at Hamelin Pool (thalassic), and Lakes Thetis and Clifton (athalassic) in coastal Western Australia.

Salares, salterns and salt flats

Salares

Salares, *sensu stricto*, are paleolake remnants, sometimes with shallow saline water but often with no water over a salt base or just pools and springs, and located mainly in the altiplanos of South America and in Tibet. They are subject to daily/seasonal/episodic extremes of climate including temperatures of –10 to +25 °C, precipitation of 50–300 mm annually and salinity range of fresh water to crystallizing brine. Adding to the tough physicochemical conditions is high solar radiation and generally negative water balance.

Their waters can sometimes support macroinvertebrates at lower salinities but it is the rich endemic microbial diversity that is characteristic particularly at higher salinities. Recent discoveries using molecular analyzes of 16S rRNA gene sequences have revealed exciting diversity in the Chilean Altiplano (Dorador et al., 2013). Up to 275 species, 32 phenotypes and 94 clones have been discovered in individual sites and what is more, adjacent pools can have very different microbes. Bacterial communities are dominated by Bacteroidetes and Proteobacteria while archaeal diversity is much lower and dominated by the Euryarchaeota. Just what each species does chemically is largely unknown, but possibilities for useful biotechnical applications are endless.

Salterns and salt flats

Salterns, salt flats, salt pans and salinas are much simpler systems, but still with harsh environmental parameters. They occur worldwide, salterns being the final stage in salt production, either from a marine or continental base; life in them is dominated by *Artemia*, *Dunaliella* or various bacteria including *Halobacterium*. Salt flats/pans are simply salty expanses that rarely contain water, and when they do they may support a limited hypersaline fauna and microbes. Their formation needs a closed basin, an arid climate and in most cases they are the remnants of paleolakes (as for Salares). However, the numerous pans/salinas of inland Western Australia are due to ponding along relict rivers and subsequent enlargement by wind action (Davies and Carling, 2012). The famous Bonneville Salt Flats of Utah rarely contain water and fauna, but those in inland Western Australia are episodically filled from cyclonic rainfall and their fauna is typical of a local meso- to hypersaline lake. The exact relationship of these to rainwater filled salt flats (see earlier) needs elucidation.

Management issues

Denial of water inflow

While there is some commonality in management between fresh and saline lakes, the fact most saline lakes lie in endorheic basins in arid/semiarid lands, leads to unique problems with water inputs (Jellison et al., 2008). Surface inflows are often diverted for irrigation or groundwater levels are lowered for the same reason resulting in increased salinities and/or reduced lake volumes or even drying the lake, despite their generally large size. There are a plethora of examples across the Middle East, central Asia, northern China and North America (Wurtsbaugh et al., 2017) such as the Dead Sea (Israel-Jordan), Tuz Lake (Turkey), Urmia (Iran), the Aral

Sea (Uzbekistan, Kazakhstan), Lop Nur and Sogo Nur (China), Lakes Walker, Owens ad Mono (western USA), and La Alberca (Mexico). Mexican lakes are particularly impacted by groundwater pumping. Fewer examples occur in South America (Mar Chiquita), Africa and Australia. The situation in Australia's Lake Corangamite is a little different as the main inflow has been diverted to prevent flooding and maintenance of the status quo of valuable nearshore land (Williams, 1995). Even more upsetting is the drying of the nearby unique Red Rock crater lakes (Red Rock Tarn holds the record for the highest primary production and Lake Werowrap for the greatest secondary production) due to completely unplanned groundwater pumping (Timms, 2005). Adding to the woes in most cases is global climate change, though increased temperatures do not necessarily mean greater water evaporation as increasing cloud cover and aerosol concentrations are reducing pan evaporation (Roderick and Farquhar, 2002). In some instances, long term climate change has resulted in fluctuating water levels, such as in Lake Van (Turkey) and Great Salt Lake (USA). Interestingly most of the affected lakes are Ramsar sites indicating their value in landscape ecology.

Other management issues

Other generally smaller salinas are affected by secondary salinization, particularly in southern Australia. In these, changing land use has mobilized salts dissolved in groundwater thus bringing them to the surface resulting in salinization of the land and any nearby lake. Also of significant but of localized impact is mining of evaporites in or near salt lakes. For instance, mining for halite and lithium has destroyed or scarred many salt lakes in inland China. In some places mineral deposits such as gold in Western Australia occur within the floor of salt lakes and their extraction results in damage, but these days limited by government control. Then in some lakes there are problems due to pollution or overfishing or invasion by exotic organisms (e.g., Caspian Sea for all three); these problems are shared with freshwater lakes, and though not as common, are ecologically similar. Also similar to freshwater sites, shallow ephemeral salinas can be subject to deflation with lunette formation and/or sedimentation, particularly in northern China, Texas, southwest South Africa and inland Australia.

Conclusion

The prognosis for most salt lakes is indeed bleak, due, in approximate order, to denial of water, secondary salinization, mining, organic pollution, overfishing, and invasion by exotic organisms (Jellison et al., 2008; Timms, 2005; Williams, 2002; Wurtsbaugh et al., 2017).

A case study

Lake Werowrap is a small (21.6 ha), shallow (1.4 m), saline lake (23–56 g L^{-1}) in a scoria cone ca. 140 km southwest of Melbourne, Australia. (Fig. 9 Photo). Its simple ecosystem epitomizers the value of saline lakes in ecosystem studies. Also it tended to be highly

Fig. 9 Red Rock Crater, Victoria. Foreground Lake Werowrap, right background, crater containing Red Rock Tarn (lake hidden). Picture taken 1971.

Table 3 Comparison of benthic production by dominant chironomids in four lakes.

Lake and country	*Salinity g L^{-1}*	*Chironomid species*	*Production g m^{-2} $year^{-1}$ DW*	*Efficiency (%)*
Nakuru, Kenya	12	*Leptochironomus deribae*	14.6	6.3
Soap, Washington	19	*Tanypus nubifer*	11.3	16
Waldsea, Saskatchewan	16	*Cricotopus ornatus*	0.08	6.3
Werowrap, Victoria	35–56	*Tanytarsus bartitarsus*	73.4	7.9

productive but variable, two common traits of salt lakes and what is more it has suffered from water denial, in fact complete drying, the fate of many lakes. It was studied during 1968–70 mainly by Walker (1973). The lake has now dried permanently due to nearby groundwater pumping (see earlier).

Volume and lake salinity was explained by rainfall/evaporation balance, but influenced by groundwater seepage. Water was of the chlorocarbonate type with a high pH of 9.8. There was rapid light attenuation due to dissolved organic matter and dense plankton populations, and nutrient levels were high partly due to nesting gulls, though inorganic nitrogen was depleted at times.

During 1968–70 the lake supported few species; three in the phytoplankton *(Anabaena spiroides, Gymnodinium aeruginosum, Chroococcus* sp.), four in the zooplankton (*Brachionus plicatilis, Hexarthra jenkinae* and two ciliates), one main littoral organism (beetle *Nectersoma penicillatum*) but a few more when salinity was lower early in the study and one benthic species (chironomid *Tanytarsus barbitarsus*). Phytoplankton production was high (Table 2), the main influencing factors being radiation and temperature. There was considerable "dark" ^{14}C assimilation indicating important bacterial activity. Secondary production by the rotifers was low but very high for the benthic chironomid (see "Productivity" section). It is possible that there was significant periphyton production in 1968 but not later when salinities were higher (Table 3).

When the lake was fresher (<20 g L^{-1}) in pre 1968 and 1982 it had the tolerant freshwater copepod *Boeckella triarticulata* and the predatory chironomid *Procladius paludicola* and more littoral beetles and dipterans. A bottom core had *P. paludicola* at depth and the tolerant freshwater chironomid *Chironomus duplex* near its base. These are indicators that the fauna of this lake changes with salinity, as is typical of shallow salinas. What was seen in 1968–70 was just a brief window in its existence.

Acknowledgments

I sincerely thank Ian Bayly for his insightful comments on the manuscript.

Wetland Soils: Physical and Chemical Properties and Biogeochemical Processes

Courtney Mobilian and Christopher B Craft, O'Neill School of Public and Environmental Affairs, Indiana University, Bloomington, IN, United States

This article was reviewed for the *Encyclopedia of Inland Waters*, Second Edition by Section Editors Wolfgang Junk and Florian Wittmann.

Glossary

Gleization Soil-forming process that occurs under anaerobic conditions and involves the reduction of ferric iron and leaching of ferrous iron, resulting in the formation of grey or greenish-blue soils, or gley soils.

Hydric soils Soils formed under conditions of saturation, flooding or ponding long enough during the growing season to develop anaerobic conditions in the upper part (United States Department of Agriculture, Natural Resources Conservation Service, 2018).

Paludification The accumulation of organic matter in poorly drained soils that can result in the formation of histosols (organic soils) over time.

Pedogenesis Complex phenomenon leading to soil formation from mineral and organic parent material through factors including climate, parent material, topography, organisms, and time, and processes such as additions, losses, translocations, and transformations.

Redoximorphic features Features formed by the reduction, translocation, and/or oxidation of iron and manganese oxides (Vepraskas, 1995).

Introduction

Inland wetlands consist of freshwater marshes, prairie potholes, peatlands, and freshwater-forested wetlands. Each of these wetland types have unique soil characteristics based on their hydrology and physical and chemical properties of the soils. Wetland soils are a critical part of wetland functioning. It is where biogeochemical processes take place that are responsible for functions such as carbon sequestration and removal of nutrients. Due to their anaerobic conditions that slow the rate of decomposition, wetland soils, per unit area, store more organic matter than terrestrial soils and can serve as a sink for carbon (C) and nutrients (nitrogen (N) and phosphorus (P)). Microbial communities, vegetation, and organisms interact within wetland soils to facilitate these processes. Plants add organic matter to the soil, whereas microbes catalyze reducing reactions such as denitrification that enhance water quality and methane (CH_4) production (methanogenesis), a greenhouse gas.

Soil definition

Soils are defined as "a natural body comprised of solids (mineral and organic matter), liquid, and gases that occur on the land surface, occupies space, and is characterized by one or both of the following: horizons, or layers, that are distinguishable from the initial material as a result of additions, losses, transfers, and transformations of energy and matter *or* the ability to support rooted plants in a natural environment" (United States Department of Agriculture, Natural Resources Conservation Service, Soil Survey Staff, 1999, pp. 9).

Wetland soils are hydric soils, which are defined as "soils that formed under conditions of saturation, flooding or ponding long enough during the growing season to develop anaerobic conditions in the upper part" (United States Department of Agriculture, Natural Resources Conservation Service, 2018, pp. 1). Wetland soils can be either mineral or organic (discussed in more detail in Section "Mineral vs. organic soils") and support hydrophytic vegetation, which are plants that are adapted to growing in low-oxygen or anaerobic environments. Hydric soils have distinct characteristics from non-hydric, or upland, soils including color, formation of soil horizons, and biogeochemical processes, which will be discussed throughout the chapter.

Soil formation

Soils form through geochemical and pedochemical weathering. Geochemical weathering involves inorganic (non-biological) processes and includes oxidation, reduction, solution, hydrolysis, and hydration. Pedochemical weathering depends on biologic processes and involves oxidation-reduction cycles. Pedogenic, or soil-forming, processes are also important in soil formation and include additions (alluvial, colluvial and eolian deposition, leaf litter), losses (erosion and leaching), translocations (pedoturbation, melanization), and transformations (decomposition, mineralization, gleization, paludification) of materials.

Soil formation is driven by five factors: parent material, climate, topography, organisms, and time (Jenny, 1941). For mineral soils, "parent material" consists of rock or rock-weathered material including sedimentary, siliceous crystalline and mafic rock. Parent material is also material that has migrated from other areas, such as material brought in from wind (eolian deposition) or water (alluvial deposition). Organic soil parent material is of biologic origin (plant debris), such as in peats soils.

"Climate" includes temperature, precipitation, and microclimate. Temperature and precipitation are important global factors in controlling rates of chemical reactions and weathering, soil wetness, soil temperature, and vegetation.

"Topography" depends on landscape or geomorphic position and slope. Topography is important because slope affects erosion, deposition, and movement of water through the soils. Topography can also affect soil temperature, reactivity, wetness, color, and organic content.

"Organisms" consist of plants, fauna, and microorganisms. Plants add organic matter to the soil while fauna are important in mixing the soil and in the physical breakdown of leaf litter. Microorganisms are critical for decomposition of organic matter and mineralization of nutrients.

Finally, the degree of soil formation is a function of "time." Sufficient time is needed for the five factors in tandem with pedogenic, or soil forming, processes (below) to produce soils with unique characteristics.

Soil-forming processes include additions of mineral material and organic matter, losses from erosion and leaching, translocation of material downward from leaching and upward from bioturbation, and transformations such as decomposition of organic matter. Over time, soil-forming processes interact as new materials are being formed and added, lost, translocated and transformed resulting in the development of soil layers, or horizons, that are approximately parallel to the soil surface. In soils that are well drained (upland soils), soil horizons consist of (Fig. 1A):

- "O horizon" (usually a thin layer of organic material, plant litter and partially decomposed plant tissue).
- "A horizon" (mineral layer; mineral soil darkened by additions of organic matter).
- "E horizon" (mineral layer; zone of eluviation, leaching of clay, iron, aluminum, and organic matter).
- "B horizon" (mineral layer; zone of illuviation, accumulation of clay, iron and aluminum oxides, some organic matter).
- "C horizon" (mineral layer; not strongly affected by pedogenic processes; very little biological activity occurring).
- "R horizon" (mineral layer; bedrock).

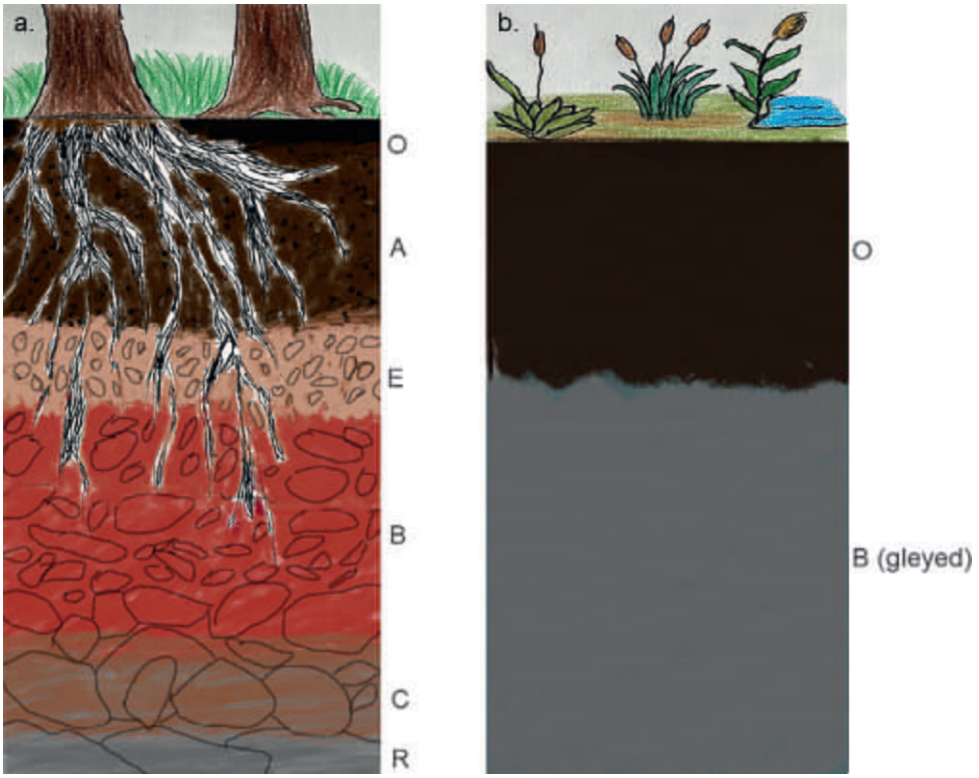

Fig. 1 (A) Typical profiles of an (A) upland and (B) wetland soil.

Wetland soils, however, differ from upland soil profiles in that the soil forming processes of gleization (reduction and leaching of soluble ferrous iron resulting in grey or greenish-blue soils, or gley soils) and paludification (accumulation of organic matter in poorly drained soils) predominate. Since wetland soils are saturated or inundated much of the time, downward translocations that occur in upland soils are less important, leading to the formation of fewer horizons (Fig. 1B). Wetland soils tend to have thicker O horizons than upland soils due to slow decomposition rates, and, in poorly drained soils that dry out periodically, a mottled B horizon below the O horizon where iron reduction occurs. In wetland soils that are very poorly drained and experience continuous anaerobic conditions, the soil may consist of only an O horizon followed by a uniform grey or black gleyed B horizon.

Mineral vs. organic soils

Hydric soils can be either mineral or organic. Organic soils, also known as "Histosols," are formed primarily from deposition and accumulation of plant material. The anaerobic conditions of wetland soils slow decomposition of organic matter leading to accumulation of above- and below-ground plant material. To be classified as a histosol, soils must contain at least 12–18% organic carbon (20–30% organic matter), depending on the clay content. They must also have an organic layer that is at least 40 cm thick (United States Department of Agriculture, Natural Resources Conservation Service, 2018). Soils that do not meet these requirements are classified as mineral soils.

Histosols can be further classified into suborders based on the degree of decomposition of the plant material. In fibric Histosols or "Fibrists," plant fibers compose more than 2/3 of the mass. The organic matter produced by peat mosses such as *Sphagnum* typically are classified as Fibrists. In hemic Histosols ("Hemists") plant material is more decomposed and fibers compose 1/3–2/3 of the mass, such as peat soils. "Saprists" (Fig. 2) are the most highly decomposed and fibers compose less than 1/3 of the mass. Muck is an example of a saprist. Hemists and Saprists usually form from herbaceous or even woody vegetation. Histosols form only in wetlands and under continuous inundation or soil saturation.

In contrast to organic soils where paludification is the dominant soil forming process, mineral soils of wetlands produce distinct changes in soil chemistry and color in response to inundation and saturation. These changes produce redoximorphic features that form through the reduction, translocation, and/or oxidation of iron and manganese oxides (Vepraskas, 1995). Microbial processes are responsible for the formation of redoximorphic features, which include redox depletions, redox concentrations, and reduced matrices and can be identified by soil color characteristics that are discussed in more detail in Section "Color".

Mineral and organic soils also differ in other properties besides the amount of organic matter and carbon content: bulk density and porosity, hydraulic conductivity, nutrient availability, and cation exchange capacity (Craft et al., 1991, Table 1).

Physical properties

Physical characteristics of wetland soils include texture, bulk density, porosity, and color. Bulk density, texture, and porosity of soils are particularly important because they directly affect soil processes such as water holding capacity and hydraulic conductivity.

Texture

Soil texture is the relative percentages of sand, silt, and clay particles that make up the mineral (inorganic) fraction of soil (Fig. 3). Sand particles are the largest and range from 2.0 to 0.05 mm in diameter. Silt particles are smaller, ranging from 0.05 to 0.002 mm. Clay particles are smaller than 0.002 mm. Texture affects other soil properties such as bulk density, water holding capacity, permeability, and porosity. For example, soils that primarily consist of sand particles have high permeability and low water holding capacity compared to soils with higher silt and clay content.

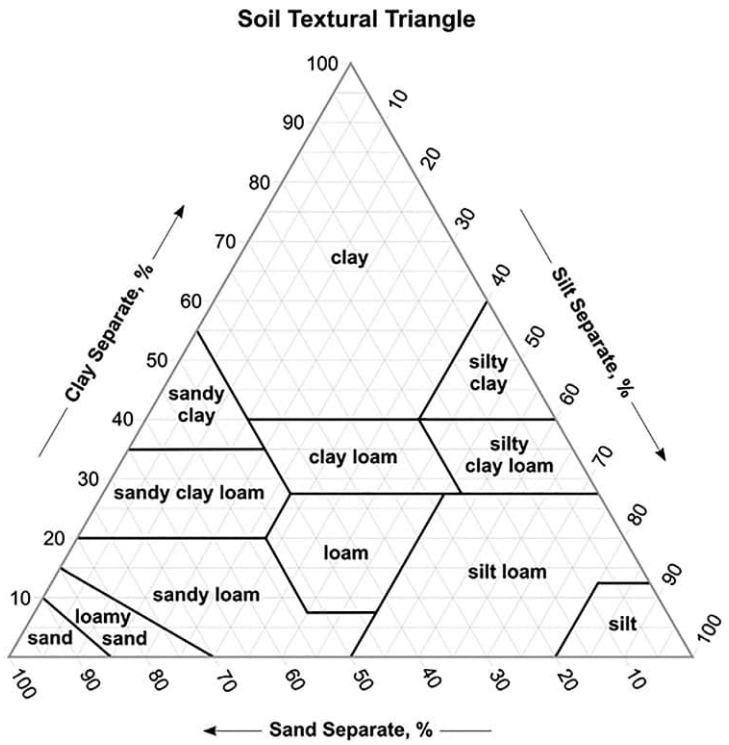

Fig. 3 Textural triangle describing the relative proportion of sand-, silt- and clay-sized particles.

Bulk density and porosity

Bulk density is the mass of dry soil per unit volume, typically expressed as g cm^{-3}. The proportion of mineral versus organic particles, to a large extent, determine bulk density. Organic soils have much lower bulk density compared to mineral soils (Table 1). In organic soils, bulk density ranges from about 0.1 g cm^{-3} for Fibrists to 0.2–0.3 g cm^{-3} for Hemists and Saprists. In wetland mineral soils, bulk density ranges from 0.5–1.5 g cm^{-3}.

Porosity is the volume of soil that is filled with either water or air. It is inversely related to bulk density; as bulk density increases, porosity decreases. Soil texture is an important determinant of porosity. Porosity of mineral soils is often around 50% for both sandy and clayey soils. However, the pores of sandy soils are large (macropores) whereas clayey soils have smaller pores (micropores). The macropores of sands promote air and water movement but limits their water holding capacity. Clays, because of their micropores, have excellent water holding capacity but poor air and water movement and, hence poor drainage. Organic soils, because of their low bulk density, tend to have much higher porosity compared to mineral soils (Table 1). The pore space of wetland soils is often filled with water, in contrast to upland soils where the pores are filled with air most of the time.

Color

Soil color is an indicator of the hydrology (wet or dry) in soils and is classified based on (1) hue, (2) value, and (3) chroma using the Munsell color chart (Munsell Color, 2010). Hue is the overall color of the soil, such as red or yellow. Value is the lightness or darkness of the soil color and chroma is the intensity or greyness of color. Hydric soils typically have a chroma of 2 or less, which indicates anaerobic conditions and long-term inundation or saturation. Iron (Fe) and manganese (Mn) play important roles in the color of wetland soils and the formation of redoximorphic features (redox depletions, redox concentrations, and reduced matrices, discussed below).

Redox depletions occur when the soil has a chroma of 2 or less, a value of 4 or higher, and iron and manganese oxides have been solubilized and leached from the soil. When the soil is continuously flooded or saturated, it may appear grey, black, greenish-grey, or blue-grey in color (Fig. 4). This process is known as gleization and results from the reduction of iron and manganese (see Section "Iron (Fe) and Manganese (Mn) Reduction"), producing what is known as "gleyed" soil. When a soil is flooded seasonally or for only a portion of the year, it takes on a mottled color (Fig. 5) of redox depletions, the grey-colored areas, and redox concentrations (discussed below). In their oxidized forms, iron and manganese give soils a red, orange or yellow color (Fig. 6). When soils become saturated and oxygen is depleted, ferric iron (Fe^{3+}) is reduced to ferrous iron (Fe^{2+}), which is a soluble form with a consequent change in color to grey. Manganese is also reduced to its soluble form (Mn^{2+}) under saturated conditions.

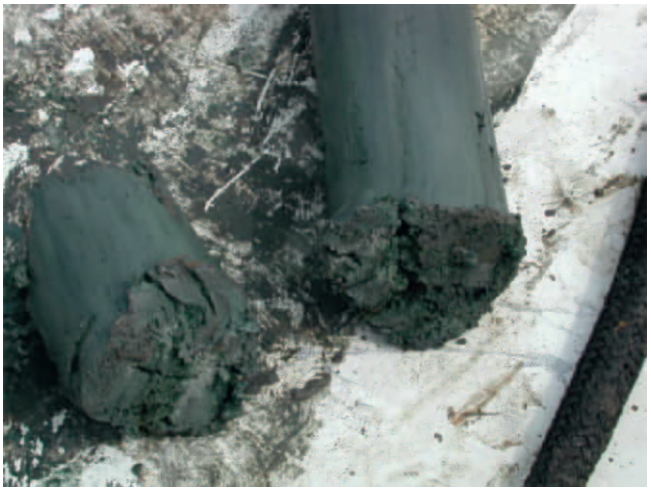

Fig. 4 Gleyed soils. Note the bluish-greenish color produced by continuous (year-round) flooding and anaerobic conditions. Photo by Chris Craft.

Fig. 5 Mottled soils containing redox depletions (grey areas of Fe^{2+}) and redox concentrations (red areas of Fe^{3+}). Soils such as this indicate periodic or seasonal flooding and dry-down. Photo by Chris Craft.

Redox concentrations are areas of iron and manganese oxide accumulations that are evident in mottled soils (Fig. 5). Redox concentrations appear as areas of yellow or reddish color where the iron is in its oxidized (Fe^{3+}) state. Oxidized rhizospheres, which are red and orange areas adjacent to roots where oxygen leaks out of plant roots, are also an example of redox concentrations.

Dark black or brown surface soils with a low value on the Munsell color chart indicate organic matter enrichment. The dark color results from the decomposition of organic matter and the formation of humus, which is black or dark brown in color.

Chemical properties

pH

Soil pH is a measure of H^+ ion activity and is an important chemical property that affects vegetation growth, microbial activity, decomposition rates, and nutrient availability (nitrogen, phosphorus, calcium). In particular, acidic (low pH) soils may be toxic to vegetation and microbes, reducing inputs of organic matter to the soil and slowing decomposition and other microbial processes. Soil pH depends on concentration of acidic and non-acidic-forming cations. H^+ and Al^{3+} are acid-forming while elements such as Ca^{2+}, Na^+, and K^+ are base-forming (Jackson et al., 2014). Soil pH is influenced by parent material of the soil, oxidation-reduction reduction (redox) reactions, and the dominant water source. For example, wetlands that are primarily fed by precipitation, such as bogs, generally are more acidic while wetlands such as fens that are fed by groundwater tend to be more neutral (Jackson et al., 2014).

Fig. 6 Upland soils with their well oxidized yellow and red color produced by oxidized (Fe^{3+}) iron. Photo by Daniel Markewitz.

Table 2 The sequence of microbially driven reducing reactions that occur when a soil is flooded.

Redox Reaction	Reactants		Products	Approximate *Eh*
Aerobic respiration:	CH_2O (C^{4+} + H_2O + $4e^-$) + O_2	→	CO_2 + H_2O + energy	>300 mV
Denitrification:	CH_2O + $2\mathbf{NO_3^-}$ + $6e^-$ + $8H^+$	→	CO_2 + $\mathbf{N_2}$ + $5H_2O$	~ +200 mV
Nitrate reduction:	CH_2O + $\mathbf{NO_3^-}$ + $2H^+$	→	$2CO_2$ + $\mathbf{NH_4^+}$ + H_2O	~ +125 mV
Manganese reduction:	CH_2O + $\mathbf{Mn^{4+}}$ (MnO_2) + $3e^-$ + $4H^+$	→	CO_2 + $\mathbf{Mn^{2+}}$ + $3H_2O$	~ +125 mV
Iron reduction:	CH_2O + $\mathbf{Fe^{3+}}$ (FeOOH) + e^- + $3H^+$	→	CO_2 + $\mathbf{Fe^{2+}}$ + H_2O	~ +50 mV
Fermentation:	$2CH_2O$ + H_2O	→	$HCOO^-$ + CH_3OH + H^+	~ 0 mV
Sulfate reduction:	CH_2O + $\mathbf{SO_4^{2-}}$ + $4e^-$ + $6H^+$	→	CO_2 + $\mathbf{H_2S}$ + $3H_2O$	~ -100 mV
Methanogenesis:	CH_3OH + $\mathbf{CO_2}$ + $12e^-$ + $10H^+$	→	$\mathbf{2CH_4}$ + $3H_2O$	< -200 mV

Decreasing Energy Yield ↓

All reactions require an electron donor, organic matter (CH_2O) and acceptor (O_2, NO_3^-, Mn^{4+}, Fe^{3+}, SO_4^{2-}). For some reactions (fermentation), organic matter can serve as both an electron donor and acceptor.

Soil pH also changes as the soils become reduced and pH generally shifts towards neutrality; pH in acidic soils tends to increase while pH in alkaline soils tends to decrease. The changes in pH largely depend on iron and organic matter content. For example, acidic soils with high organic matter and oxidized iron will see an increase in pH as Fe^{3+} is reduced to Fe^{2+}, a reaction that consumes hydrogen (see Table 2). In alkaline soils, organic acids and CO_2 are produced as a result of reducing reactions, which lowers soil pH (Ponnamperuma, 1972).

Redox potential (*Eh*)

Redox potential is the tendency of a chemical species to either be reduced by accepting electrons or oxidized by donating electrons (Reddy et al., 2000). Oxidation-reduction involves the transfer of electrons from one ion or molecule to another. Oxidation is the donation of electrons to other substances and reduction is the acceptance of electrons from other substances. Redox potential indicates how oxidized or reduced (anaerobic) the soil is as well as the electron availability in the soils. Redox potential of upland soils is greater than +300 mV whereas, in wetland soils, redox potential is less than +300 mV and may decline to −100 to −200 mV. When soils are flooded or inundated, redox potential decreases as the oxygen is consumed by microbes and plant roots to support respiration. Lower redox values indicate more anaerobic and reduced conditions while higher values indicate aerobic or less extreme anaerobic conditions.

Redox potential generally decreases with depth in wetland soils that are beneath the thin, oxidized surface layer. This oxidized surface layer is a result of oxygen diffusion from the overlying water, but the diffusion rate is slow enough that the oxygen is consumed in this zone and does not diffuse to the subsurface layers (Craft, 2000). Redox potential controls oxidation-reduction reactions, or redox reactions (see Fig. 7), which are critical in wetland nutrient and biogeochemical cycles (discussed in detail in Section "Biogeochemical processes").

Cation exchange capacity

Cation exchange capacity (CEC) is the ability of soils to hold (sorb) cations and is affected by clay and organic matter content and soil pH. Clays and organic matter possess a negative charge that sorb cations such as hydrogen and base cations, calcium, magnesium, potassium, and sodium. Cation exchange capacity is higher in clays than in sandy or silty soils. Organic matter also contributes to CEC and CEC increases as organic content increases.

Biogeochemical processes

Redox reactions

Microbially driven reducing reactions play a critical role in wetland nutrient cycling and decomposition and, in some cases, in global biogeochemical cycles. In most wetlands, a thin transitional zone exists between the oxygen-rich air, or water, above and the anoxic reduced soil below. This is known as the "reducing zone" and is where many redox reactions take place. As important metabolic processes, redox reactions control such processes as greenhouse gas emissions and water quality benefits through removal of nutrients (N and P).

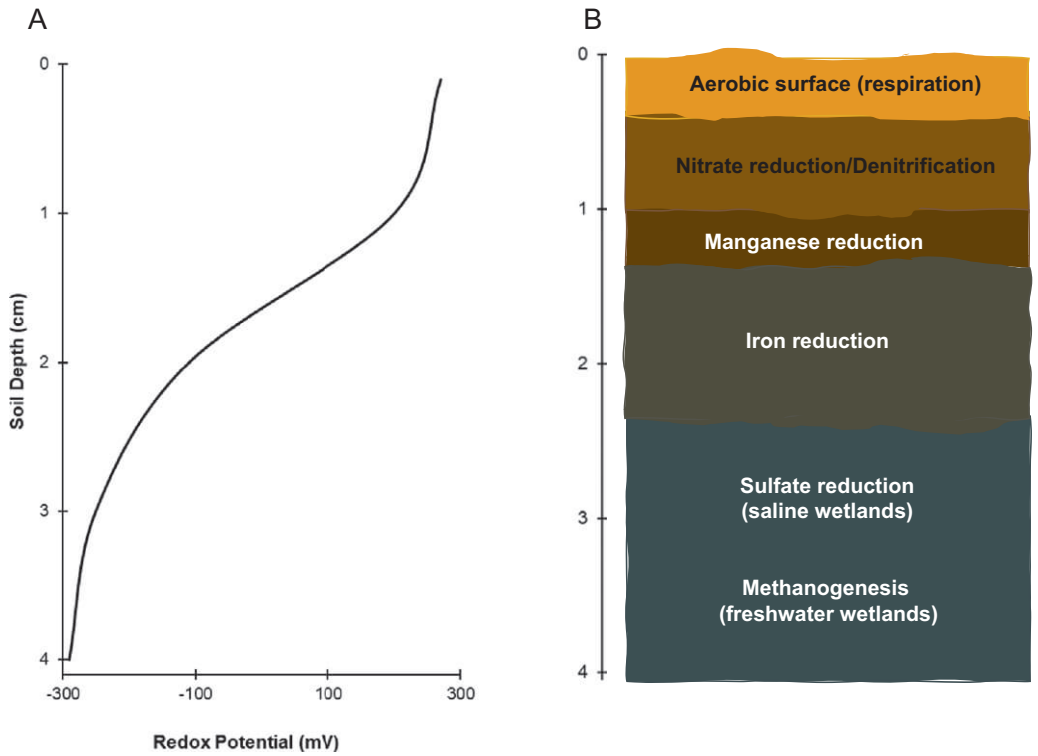

Fig. 7 (A) Redox potential (*Eh*) variation with depth and (B) nitrate, manganese, iron, sulfate and methane redox reactions as they vary with depth and redox potential.

Oxygen is the strongest electron acceptor and yields the most energy. When soils become flooded, vegetation, fauna, and aerobic microorganisms will quickly consume oxygen to support respiration. When oxygen is used up, facultative anaerobic microbes can use secondary electron acceptors as a source of energy for respiration, though these secondary acceptors yield less energy. These secondary electron acceptors include nitrate, oxidized forms of manganese and iron, organic matter (humic substances), sulfate, and carbon dioxide. As soils become flooded and oxygen is depleted, the sequence of reduction generally is as follows (in order from greatest to least energy yield): denitrification, nitrate reduction, manganese reduction, iron reduction, fermentation, sulfate reduction, and finally methanogenesis (Table 2, Fig. 7). All of these reactions require organic matter (carbon) as an electron donor. Terminal electron acceptors and a source of organic matter, which typically is abundant in wetlands soils, are both are needed to fuel these reactions. Redox reactions vary with depth and redox potential and this sequence of reactions can also be observed within the soil profile of hydric soils (Fig. 7).

Many of these redox reactions also involve the consumption of hydrogen ions, which raises the pH of soils and makes them less acidic. Several of these redox reactions are particularly important in global nitrogen (denitrification), phosphorus (iron reduction), sulfur (sulfate reduction), and carbon (methanogenesis) biogeochemical cycles.

Denitrification and nitrate reduction

Once oxygen is depleted in the soils, denitrification is the next reducing reaction that takes place as denitrifying bacteria can use nitrate as a source of energy. Denitrification is the reduction of nitrate (NO_3^-) to atmospheric N_2 and N_2O and the availability of nitrate is generally the limiting factor for denitrification in wetlands. Since nitrate is considered a water pollutant that can lead to eutrophication of aquatic ecosystems, especially estuarine and coastal waters, denitrification helps improve water quality. Some studies suggest that under less anaerobic conditions (such as on the edge of aerobic/anaerobic zones) incomplete denitrification results in higher production of nitrous oxide (N_2O), a potent greenhouse gas, rather than dinitrogen gas (N_2) (Hernandez and Mitsch, 2007). This is due to the fact that the enzyme involved in N_2 production is diminished by the presence of oxygen to a greater extent than the enzymes involved in N_2O production (Wrage et al., 2001).

Another form of nitrate removal is dissimilatory nitrate reduction to ammonium (DNRA), which is also carried out by microbes. Instead of being converted to gaseous nitrogen forms, nitrate is converted to ammonium (NH_4^+), which is also a form that can be taken up and used by vegetation and organisms.

Iron (Fe) and manganese (Mn) reduction

Iron reducing microbes can utilize Fe as an energy source, reducing ferric iron (Fe^{3+}) to ferrous iron (Fe^{2+}), leading to changes in soil color. The reduction of ferric to ferrous iron produces grey soil color, including mottles and gleying, as the ferrous iron is solubilized and leached from the soil (discussed in Section "Color"). Iron reduction also leads to the dissolution of iron-bound phosphorus (Fe-P) compounds, releasing soluble phosphorus, which can cause eutrophication of aquatic ecosystems, especially freshwater systems.

Manganese reducing microbes utilize Mn as an energy source and reduce Mn^{4+} to Mn^{2+}. Similar to iron, manganese significantly affects soil color and becomes soluble in its reduced state. Manganese is responsible for black color in soils in its oxidized state but can leach out of soils once it is reduced, resulting in gley soils (see Section "Color").

Fermentation

Fermentation occurs when organic matter, such as sugars or organic acids, serves as both the terminal electron acceptor and the electron donor. External electron acceptors are not needed for fermentation, which is carried out by obligate or facultative anaerobic bacteria. The end products of fermentation can include hydrogen, organic acids and carbon dioxide, which can serve as substrates for other microorganisms such as methanogens.

Sulfate reduction

Sulfate reducing bacteria (SRB) use sulfate (SO_4^{2-}) as an energy source and hydrogen sulfide (H_2S) is produced which can be toxic to vegetation and organisms. Hydrogen sulfide is also responsible for the distinct "rotten egg" smell in wetland soils, especially saline wetlands which have more sulfate than freshwater wetlands.

Methanogenesis

Methanogenesis, which yields the least amount of energy, takes place in the most extreme (reduced) anaerobic conditions. Methanogens carry out methanogenesis which produces methane (CH_4), a potent greenhouse gas. There are three pathways for methanogenesis to occur: acetoclastic methanogenesis, methylotrophic methanogenesis, and hydrogenotrophic methanogenesis. "Acetoclastic" methanogens use acetate as an electron acceptor while "methylotrophic" methanogens use methanol or methylamines. "Hydrogenotrophic" methanogens use H_2 and CO_2 to carry out methanogenesis. Hydrogenotrophic and acetoclastic methanogenesis are the most common pathways in freshwater systems (Fenchel et al., 2012). Further, studies have shown that bogs are typically dominated by hydrogenotrophic methanogenesis in contrast to fens, where the acetoclastic pathway tends to be dominant (Bridgham et al., 2013).

Wetland soils as nutrient and carbon sinks and sources

Wetlands can act as sinks, sources, or transformers for carbon, nitrogen, phosphorus, and sulfur. Organic matter accumulation leads to the storage of nitrogen and organic carbon while sedimentation and sorption to mineral soil particles leads to storage of phosphorus.

Carbon

Wetlands play a major role in global carbon cycling and, per unit area, wetland soils store much more organic carbon than upland soils. The stored carbon provides an energy source for microbial processes and accumulation of carbon depends on the balance between productivity and decomposition of organic matter. Due to the anaerobic conditions of wetland soils, carbon losses from decomposition are much less than inputs from primary productivity, allowing these systems to accumulate organic matter. Recent estimates suggest that in the top 1-m alone, wetland soils store up to 158 Pg of soil organic carbon, or nearly12% of the 1325 Pg of soil organic carbon stored in soils globally within the top 1-m (Kochy et al., 2015). However, wetlands can also be sources of greenhouse gases, especially methane. Total global methane emission estimates range from 500 to 700 Tg CH_4 $year^{-1}$ (Dlugokencky et al., 2011; Kirschke et al., 2013), with wetland emissions ranging from 80 to 280 Tg CH_4 $year^{-1}$ (mean of 166 Tg CH_4 $year^{-1}$) (Bridgham et al., 2013).

Nitrogen

Soils generally make up the largest nitrogen pool in wetlands and these pools include particulate and dissolved organic nitrogen, nitrogen in microbial biomass, inorganic forms such as NH_4^+ and NO_3^-, and gaseous end products. Organic nitrogen makes up the largest pool and accounts for about 95% of the total nitrogen (Craft, 1996). Forms of organic nitrogen in the soils include living forms such as in microbial biomass and other fauna and non-living forms such as peat and plant detritus (Reddy and DeLaune, 2008).

Nitrogen in wetland soils can undergo different transformations including nitrification, denitrification, dissimilatory nitrate reduction to ammonium (DNRA), and anaerobic ammonium oxidation (anammox). These processes are driven by microorganisms and, with the exception of nitrification, occur under anaerobic conditions. Denitrification (Section "Denitrification and nitrate reduction") is the major pathway of nitrogen removal from wetlands.

Anaerobic ammonium oxidation (anammox) is another microbially mediated mechanism for nitrogen removal from wetlands. Anammox is the oxidation of ammonium coupled with reduction of nitrite to produce nitrogen gas (N_2) and is carried out by a unique group of bacteria in the phylum *Planctomycetes* (Mulder et al., 1995; Strous et al., 1999). Estimates of the contribution of anammox to nitrogen removal from wetlands vary. Recent studies estimate that anammox is responsible for anywhere from ~2% to 20% of nitrogen gas (N_2) produced from wetland soils (Hou et al., 2015; Shen et al., 2016; Zhang et al., 2020).

Phosphorus

Unlike nitrogen and carbon, the phosphorus (P) cycle does not have a gaseous phase and so wetlands can act as phosphorus sinks through sediment deposition, sorption and precipitation to particles, as well as through uptake by plants (macrophytes, algae).

Soil phosphorus exists in organic and inorganic forms. Inorganic forms include phosphorus bound to iron, aluminum, and calcium while organic forms are associated with soil organic matter, detritus, vegetation, animals, and microorganisms. In wetlands with organic soils, organic phosphorus makes up a higher percentage (50–90%) of the total phosphorus compared to organic phosphorus in mineral soils (10–50%) (Reddy and DeLaune, 2008). In mineral soils iron and aluminum play a major role in the ability of mineral soils to retain phosphorus.

Adsorption and precipitation are two processes that retain inorganic phosphorus. Adsorption occurs when soluble inorganic phosphorus moves from the soil porewater to the (solid phase) sediments where it can adsorb to aluminum and iron oxides or hydroxides and accumulate in the sediment. Adsorption capacity is affected by soil texture and increases with increasing clay and mineral content. Adsorption occurs rapidly at first and then rates decrease as it reaches equilibrium with phosphorus concentrations in the porewater. Over time, the sorption sites become saturated. Precipitation occurs when phosphate reacts with metal cations such as iron, aluminum, calcium, or magnesium to form phosphate precipitates. Precipitation with Al and Fe predominates in acidic soils whereas precipitation with Ca occurs in circumneutral and basic soils (Reddy and DeLaune, 2008). Both processes are important for long-term retention of P. However, in soils with high iron-bound P, flooding leads to reduction of Fe^{3+} to Fe^{2+} (Section "Iron (Fe) and manganese (Mn) reduction") with consequent release of P into the water.

Sulfur

Sulfur enters wetland systems through atmospheric deposition, surface- and tidal-water exchange and, like C and N, sulfur transformations are mediated by microorganisms. Sulfur cycling is well studied in saline wetlands (salt marshes) due to the abundance of sulfate in marine systems (up to 2700 mg L^{-1}) compared to freshwater systems (~10 mg L^{-1}) (Mitsch and Gosselink, 2015). Major sulfur pools in wetlands include soil and soil organic matter. Sulfur can go through several transformations in wetlands including sulfate reduction, sulfide oxidation, and sulfur oxidation. In wetland soils, sulfate (SO_4^{2-}), which is used as a terminal electron acceptor in sulfate reduction under anaerobic conditions, is particularly important in the sulfur cycle. Sulfate reduction is the dominant sulfur transformation, especially in salt marshes and estuarine wetlands (Reddy and DeLaune, 2008). Recent studies, however, suggest that sulfate reduction may be more prevalent in freshwater wetlands and plays a larger role in

carbon cycling than previously thought due to the rapid recycling of sulfide to sulfate (Pester et al., 2012; Martins et al., 2017). Some studies estimate that sulfate reduction can account for up to 50% of organic carbon mineralization in freshwater systems as a result of the rapid recycling of reduced sulfur to sulfate (Pester et al., 2012). Additionally, sulfate reduction leads to the production of hydrogen sulfide (H_2S) which can be toxic to plants and animals. Many wetlands are sources of H_2S to the atmosphere, though typically salt marshes and estuarine wetlands have higher H_2S emissions (up to 79 μg S m^{-2} h^{-1}) compared to freshwater wetlands (~0.30 μg S m^{-2} h^{-1}) (Reddy et al., 2002).

Conclusion

Wetland soils are unique, with patterns and processes characteristic of both upland (oxidized) soils and aquatic (reduced) sediments that vary spatially and temporally. Periodic to continuous inundation and saturation drives a number of aerobic and anaerobic microbial processes that provide critical ecosystem functions and services, including water quality improvement through denitrification and cycling of carbon and greenhouse gases, CO_2 and CH_4. Because of their often high plant productivity and slow rate of decomposition, wetland soils are an important global sink for carbon. The variable physical (texture, bulk density) and chemical (pH, redox potential) properties of wetland soils affect the ability of wetlands to perform these ecosystem services and act as carbon and nutrient sinks.

Knowledge gaps

- How does the balance between plant production and decomposition, the opposing processes that build soil organic matter (SOM), vary with the duration and frequency of inundation and soil saturation?
- What is the long-term (centuries to millennium) rate of C storage and how does decomposition of (older) organic matter vary over these time scales?
- What is the contribution/importance of alternative microbial processes (DNRA, Anammox) that convert NO_3^- to N_2?
- How will climate change-induced changes in wetland hydrology affect soil-based functions such as carbon storage and denitrification?

Glossary

Biogeochemical cycle Exchange processes or pathways of essential elements of living matter through biotic and abiotic compartments of Earth. Net storage sites are called sinks or pools, net release sites are called sources, mostly however, both processes occur simultaneously at different rates. Here it is mainly referred to carbon exchange processes between the atmosphere and the wetlands within their surrounding ecosystems. The term biogeochemical emphasizes interdisciplinarity and suggests that biological, geological, and chemical elements of each cycle have to be considered.

Carbon sequestration The process of gathering carbon and storing it in a carbon pool.

Carbon storage The process of keeping carbon from cycling between the different ecosystem compartments or spheres of earth. In the case of wetlands, the carbon content often increases due to conditions inhibiting the complete mineralization of organic matter to carbon dioxide or methane.

Decomposition, Organic Matter Processing, Mineralization The stepwise breakdown of complex organic matter (mostly, dead plant parts) into less complex organic and inorganic compounds. Plant parts are often comminuted by detritivorous animals (shredders) or by physical impact (leaching, bleaching, erosion), while enzymatic activities of microbes (bacteria and fungi) continue the processing and transformation of organic matter on the molecular level. The "mineralized" end products are dissolved salts or gasses like carbon dioxide and methane (CO_2 and CH_4). A large part of the OM, however, becomes stored or, together with the decomposers, integrated into the detritus-based food chain. Therefore, the term Organic Matter Processing is more commonly used.

Greenhouse gasses Gaseous constituents of the atmosphere, both natural and anthropogenic, that absorb and emit radiation at specific wavelengths within the spectrum of terrestrial radiation emitted by the Earth's surface, the atmosphere itself, and by clouds. This property causes the greenhouse effect. Water vapor (H_2O), carbon dioxide (CO_2), nitrous oxide (N_2O), methane (CH_4) and ozone (O_3) are the primary GHGs in the Earth's atmosphere (see also Shukla et al., 2019).

Mineral associated organic matter (MAOM) Organic matter that is protected from decomposition or cycling by its binding to mineral matter. Minerals can prevent microbial access to organic matter and therefore hinder or slow decomposition.

Organic matter (OM) Matter that originates from the biomass of organisms (plants, animals microorganisms), mostly a mixture of decaying plant material and decomposing organisms. Important source of organic compounds (mainly

hydrocarbons). Abbreviations: DOM, dissolved OM; POM, particulate OM, similar abbreviations for carbon forms (DOC, POC); Soil organic carbon (SOC), the carbon part of organic matter in the soil, and volatile organic compounds (VOCs).
Radiative forcing The change in the net, downward minus upward, radiative flux (expressed in W m^{-2}) at the tropopause or top of atmosphere due to a change in a driver of climate change, such as a change in the concentration of carbon dioxide (CO_2). It is the scientific basis for the greenhouse effect on planets, and plays an important role in computational models of Earth's energy balance and climate, see Shukla et al. (2019).
Recalcitrance Chemical properties that makes organic matter intrinsically resistant to decomposition (Kleber, 2010), such as high concentrations of shredder-repellent substances (e.g., plant polyphenolics Haase and Wantzen, 2008) or inadequate ratio of compounds concerning the ecological stoichiometry of the consumers (e.g., C/N ratio).
Units Carbon storage is indicated as mass per size unit, often as g m^{-2} for localized studies, t ha^{-1} (1 ton = 1000 kg = 1,000,000 g = one mega gram (Mg), 1 ha (ha) = 10,000 m^2 = one hundredth of a square kilometer) for interbiome comparisons and Pg (petagram, which is identical to Gt (Gigaton) = a unit of mass equal to 10^{15} g) for global comparisons. In spite that ton and Gt are no SI units, they are commonly used. The conversion factor from g m^{-2} to t ha^{-1} is 0.01.

Introduction

Wetlands are highly diverse, varying in size, inundation period and geography. They occur as small, water-filled holes to huge ecosystems and as permanent bogs in the tundra or sporadic wetlands in deserts (Mitsch and Gosselink, 2015). Wetlands typically develop in topographic depressions and therefore accumulate substances, including organic matter (OM) and water. Low oxygen levels are characteristic, as oxygen is used for decomposition but the supply is hampered as its diffusion rate is 10^4 times lower in water than in air. Oxygen limitation hampers the process of OM breakdown. Consequently, despite the small proportion of land covered by wetlands, they store a disproportionally large amount of carbon (20–30% of the global soil carbon, Kayranli et al., 2010) while having a huge potential for carbon sequestration (Lal et al., 2018). Wetlands are still underestimated in global carbon budgets (Bastviken et al., 2011). Moreover, the assessment of the size of wetlands is difficult, especially if they are small sized or seasonally variable. The global estimation of land covered by wetlands (6–8%, Mitsch and Gosselink (2015) is contested by regional studies, e.g., 20% of South America (Junk, 2013) and 22% of the boreal zone by permafrost soils alone (Obu et al., 2019). In addition, linear-fringing wetlands may escape classical airborne habitat assessments (Guo et al., 2017). The uncertainty of wetland sizes translates into a large source of uncertainty of the contribution of wetlands to the global carbon cycle, for example important for the quantification of continental wide methane budgets (Grunwald et al., 2012). Certainly in geological time scales, wetlands can be seen as a sink for atmospheric carbon having accumulated biomass transformed into coal and petrol now released as fossil fuels.

Their variable character adds to the great importance of wetlands in global biogeochemical cycles. Carbon is stored and released at the same time, making wetlands both sink and source for atmospheric carbon. Depending on external forces the net flux rapidly switches between these two functions (Vega et al., 2014). For developing models and carbon budgets, it is necessary to understand the relationship between the main biotic processes at play, namely primary production and organic matter processing (decomposition or mineralization of organic matter). The environmental parameters driving these biotic processes mainly relate to climate (precipitation, temperature, solar irradiance) and soil properties (nutrient content, texture, drainage), which control water and oxygen dynamics. Moreover, wetlands are connected to other ecosystems, so that carbon may be imported or exported. Despite an obvious control of climate on wetland occurrence and functioning, most wetland types occur in any climatic region. This article deals with inland wetlands leaving out coastal and marine wetlands, such as mangroves, salt marshes and other mudflats despite their importance to the global carbon cycle (see, e.g., Ouyang and Lee (2020) for a review).

The interdependences of the above-mentioned basic elements of the carbon cycle of inland wetlands are in the focus of this article, while elucidating the conditions that may provoke switches from the processes of carbon storage to carbon release. This is done using a functional typology of wetlands concerning the carbon cycle and their specific sets of environmental parameters. Furthermore, historical and current impacts of Climate Change and Land Use Changes on wetland carbon budgets are discussed, and recommendations to maintain carbon-relevant ecosystem functions and ecosystem services by wetlands are presented.

Main topics

Parameters steering carbon storage and release in wetlands

Wetlands receive carbon as organic matter (OM), which is partially taken up by consumers but sooner or much later inevitable mineralized by microorganisms to CH_4 or CO_2.The delay depends on the cycling in microbial loops, being it the adsorption to minerals or the export to other ecosystems. The interrelations between the individual processes are manifold (Fig. 1). In simple words, carbon storage occurs if the input is higher than OM decomposition and carbon export.

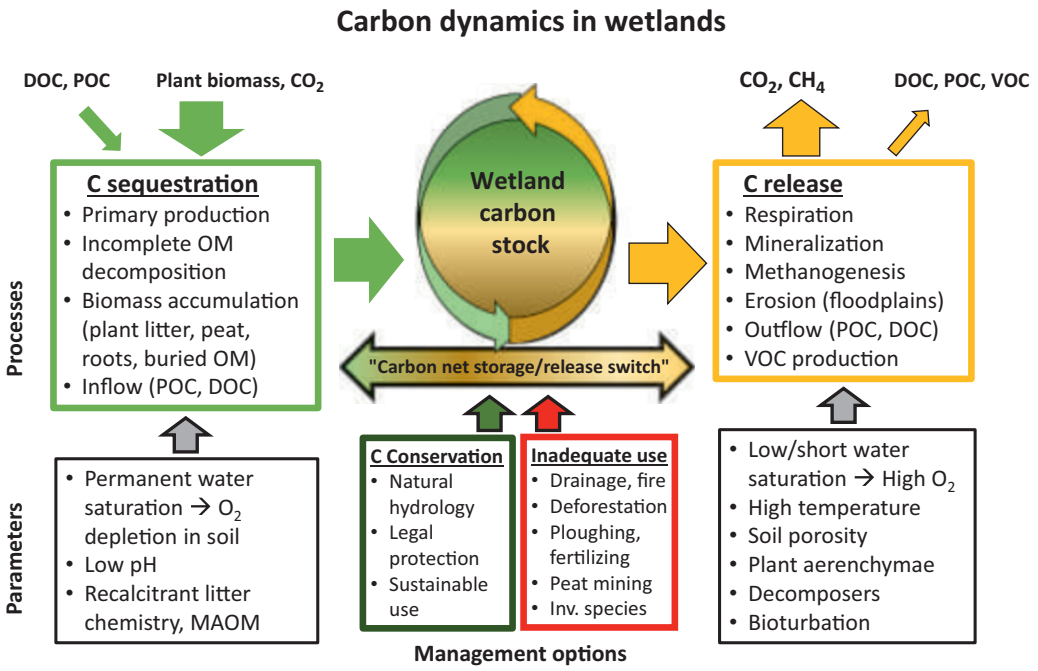

Fig. 1 Processes, parameters, and management options that favor carbon sequestration (left) or carbon release (right) in wetlands. See Glossary for abbreviations.

Microbial respiratory processes and coverage with stagnant water or water-logged soils result in anoxia, which, along with leachates from the OM (e.g., phenolic substances or organic acids), slow down decomposition processes. Favorable conditions for decomposition and mineralization such as high temperatures and oxygen concentrations transform organic matter into gasses (mostly CO_2 and CH_4) released to the atmosphere. Transport processes are generally mediated by water flow and sediment dynamics. Solid particles and dissolved forms of OM can be removed, carried and deposited along with sediments during flood events, and gas release triggered by hydrostatic pressure differences (e.g., during receding floods). However, OM can also be physically fixed by chemical processes such as the calcite precipitation in karstic springs (on mosses) or in lakes (on planktonic algae or macrophytes), or by clay particles and pedogenic metals (see below).

To measure the patterns and processes of wetland carbon budgets several methods exist. Sample collection depends on the physical state of the samples. Gaseous forms become collected with sampling chambers tightly exposed over the wetland surface, dissolved forms can be stored in water bottles, and solid samples are directly cut from the vegetation or retrieved from soils using specific soil corers. For the sampling of liquid sludge, corers that can be locked are used. The main problems consist (a) in adequate sample treatment (e.g., to avoid mineralization processes during sample storage) and (b) in setting up sampling strategies that correspond to the most important turnover processes. Along aquatic-terrestrial gradients, these often occur in spatially and temporally discontinuous patterns referred to as biogeochemical and biotic hot spots and hot moments (McClain et al., 2003; Wantzen and Junk, 2006). Carbon analysis is generally based on the attenuation of infrared light; for solid samples, total carbon analyzers exist, while gaseous samples (e.g., methane) are analyzed gaschromatographically by flame ionization detection (e.g., Mitsch et al. (2013)). For a review on methods, see, i.e., Villa and Bernal (2018).

A simple carbon budget can be established if stocks, net input and output fluxes are known or estimable. Mechanistic modeling based on the quantification of individual processes and their interactions can help to predict changes in fluxes and stocks due to changing environmental conditions, such as climate change.

Biomass contribution to wetlands

Organic biomass generally results from autotrophic CO_2 fixation by plants or microbes. Plants or animals supply soils with OM either directly belowground via roots (litter, or rhizodeposition) or indirectly from above by litter fall, death, or excretion. In most cases, plants growing directly in the wetland (algae, mosses, macrophytes, trees) deliver the bulk of the biomass, the *autochthonous* OM. In stream and river floodplains (and partially in lakes), carbon fixation processes may have occurred in neighboring terrestrial ecosystems (e.g., forests) all over the catchment. These OM types, i.e., litter fall of leaves, twigs, fruits etc. can be imported as *allochthonous* OM by wind and water (Wantzen et al., 2008c). Liquid contribution (leachates, dissolved OM) may be inconspicuous in mass but trigger important microbial consortia influencing the carbon stocks. Moreover, soil carbon that has been accumulated in earlier periods in the catchment (e.g., during interglacial warm phases in temperate zones) may become eroded and transported

downstream and accumulate in riparian wetlands. The analysis of tracers using chemical methods (lignin compounds, stable isotope analysis) or microscopy (phytoliths, pollen, fibers) may help to identify the origin of the organic matter in different layers of a sediment core and inform about land use changes (Behling and Hooghiemstra, 2000; Denham et al., 2003). Carbon sequestration is generally estimated by soil dating methods such as with cesium and lead (^{137}Cs and ^{210}Pb) isotopes (Mitsch and Mander, 2018).

Primary production depends on light, temperature, water, and nutrient conditions, as well as plant growth type. Due to permanent waterlogging and nutrient availability, some wetlands with grass-like vegetation are among the most productive ecosystems worldwide, e.g., Amazonian floodplain meadows (dry biomass up to 576 kg m^{-2} in communities of the perennial species *Paspalum fasciculatum*, Junk and Piedade (1993)), and lacustrine *Papyrus* swamps have a net primary production (NPP) of dry biomass of 2.51–3.09 kg m^{-2} year^{-1} (Saunders et al., 2014). Woody plants may contribute various types of OM, from nutrient-rich fruits to roots with high lignin content that may take decades to decompose. In Amazonia, their living belowground biomass (roots) varies from 7.5–40 ton ha^{-1} in whitewater floodplain and an aboveground coarse woody biomass (AGWB) of 15–307 ton ha^{-1} in whitewater and 68–324 ton ha^{-1} in blackwater floodplains (Schöngart et al., 2010). In a boreal forest (Bonanza Creek near Fairbanks Alaska, covered with *Populus* and *Alnus* bestanden, Gower et al. (2001) report AGWB of 4.8 g ton ha^{-1} (see both papers for further data). Care should be taken when comparing data between sites, due to natural variations within the studied areas, and to the different methods applied (e.g., exact below-ground biomass measurements require that trees become uprooted and weighed). Studies often consider either living biomass and net primary production or soil organic matter, but rarely both.

In peat bogs, wetness coupled to anoxia, nutrient poor water supply originating from rainfall and acidic soil may lead to very low GPP rates of ca. 0.8 kg m^{-2} year^{-1} (Drollinger et al., 2019). Bacteria may produce large organic mats when groundwater seeps to the surface. With the exception of termites and ants, animals contribute little to the direct biomass budget (e.g., carcasses of fish dying in drying wetlands, earth worms being killed during flooding, shells of invasive *Dreissena* mussels e.g., in the Great Lakes), but due to their migratory behavior, they may transport large amounts of nutrients against landscape gradients within short time (e.g., salmon run, migratory birds and their feces, mass emergence of insects). The foodwebs based on these migrations and the resulting allochthonous nutrient inputs may foster primary production in wetlands (Hocking and Reimchen, 2009). Moreover, the movements of animals in sediments (bioturbation), ranging from small midge larvae to large, digging crocodiles (Schmitz et al., 2014; Bezerra et al., 2020) strongly influence oxygen concentrations. The nutrient contribution to wetlands by the water inflow varies strongly between different origins of the water, e.g., rain water and deep groundwater (generally low), river water (medium to high), surface runoff and surface-near groundwater (high nutrient contents). Hence, the three-dimensional, annual and multi-annual flow conditions should be considered when assessing organic matter budgets (Junk and Wantzen, 2004; Wantzen et al., 2005; Keizer et al., 2014).

Organic matter processing

The proportion of the primary production that finally builds up the huge carbon stocks of wetland soils depends on biomass processing (Wantzen et al., 2008b; Baerlocher et al., 2020). The living plant biomass is partly consumed by animals entering the decomposer foodweb as feces but plant litter is the bulk contribution. Fungi and bacteria colonize live plant parts and activate as soon as antimicrobial defense mechanisms of the plants weaken. When plant litter falls from emerging plants into the water, a continuum of terrestrial to aquatic, microbial consortia becomes active. Under acidic conditions, this attack is predominantly carried out by fungi as bacteria require a higher pH to thrive (Rousk et al., 2010). The microbial biomass makes OM more attractive for decomposing invertebrates. These so-called shredders break up the structure into smaller pieces, allowing further microbial decomposers to act more efficiently. In riparian zones, where wet-and-dry conditions alternate, both, aquatic and terrestrial species can consume the plant parts, and the resulting plant detritus can be moved between both zones, resulting in faster decomposition (Wantzen et al., 2008b). Once the organic matter is exposed to anoxia, decomposition is slowed or stopped.

Organic matter persistence: Chemical quality vs. lack of access

Different plant parts become mineralized at different velocities due to their chemical quality. Environmental conditions like temperature and nutrient availability influence the processing dynamics. Plant secondary compounds, especially phenolics, and fibers (lignin and celluloses) in leaves and wood, but also silicates in grasses may additionally slow down both, the microbial and invertebrate decomposition processes, whereas energy-rich compounds, such as sugars and proteins, accelerate decomposition. Some plant associations have developed specific capacities to modify the soil/water phase to slow down decomposition, e.g., trees of Asian peat swamp forests (Lim et al., 2009) or many herbs in mires (Fukao et al., 2019) (see below). Analyzing the chemical compounds of OM helps to understand if plant parts are recalcitrant, or quickly decomposable (Baerlocher et al., 2020). The presence of microbial biomass may favor decomposition of OM ("conditioning") by shredders (Wallace and Webster, 1996), and the coverage by algae can directly or indirectly favor decomposition (Rier et al., 2014). The priming effect, i.e., the increase in soil organic matter (SOM) decomposition rate after fresh organic matter input to soil is supposed to result from the competition for energy and nutrient acquisition between the microorganisms specialized in the decomposition of fresh organic matter and those feeding on polymerized soil organic matter(SOM) (Fontaine et al., 2003).

Moreover, if decomposers lack access to OM, its decomposition can be hampered or even stopped. This can happen when mineral-associated OM (MAOM) is formed, for example, by complexes with clay minerals or surface bindings to pedogenic iron or aluminum oxide surfaces (Córdova et al., 2018). Thus, the lack of access for decomposing microbes may interfere with the positive or negative effects of plant chemical compounds on OM processing. These processes and their interferences need to be better understood for wetlands in order to improve wetland biogeochemical modeling.

Microbial processes: Carbon release to the atmosphere

Microbes mineralize OM to greenhouse gasses (GHG) like carbon dioxide (CO_2) and methane (CH_4). Natural wetlands are natural sources of GHG (Dušek et al., 2020), however the release rate is strongly influenced by human activities. Methanogenesis is a strictly anoxic process that may follow the previous release of CO_2 from decomposing OM (Conrad et al., 2010). As long as surface water and sediment layers of wetlands are well oxidized, bacteria transform most of the CH_4 back to CO_2, and their biomass can represent an important food source to the ecosystem (Jones and Grey, 2011). Therefore, CH_4 becomes released to the atmosphere only under specific circumstances (Saarnio et al., 2009). These include ebullition (release of large bubbles, e.g., when depressurizing a dam lake during drawdown), synchronous release of large amounts of methane (e.g., during drainage of mires and peat swamp forests, thawing of permafrost soils Schuur et al., 2015), or bypassing through aerenchyma (e.g., in rice paddies and locations of other plants having aerenchyma, Aulakh et al., 2000; Dušek et al., 2020). Stable isotope analysis and experiments with substances inhibiting methanogenesis can be used to reveal the balances between CH_4 vs. CO_2 pathways (Conrad et al., 2010). The release of greenhouse gasses from wetlands to the atmosphere can be assessed using gas chambers with a defined surface, or by eddy covariance. Long-term annual budgets have evidenced that inland wetlands can be significant sources of CH_4 and hydroperiods are the major determinants of the emission rates (Mitsch and Mander, 2018). Volatile organic compounds (VOCs, Keefe et al. (2004)) are rarely studied in wetlands. These short-chained C_2-C_{10} hydrocarbons (VOCs) and halogenated hydrocarbons (VHOCs) are released in small amounts compared to the gasses mentioned above (Hellén et al., 2006), but they are relevant as GHG.

The influence of wetting and drying of wetland soils

As anoxic conditions slow down the mineralization process, the highest carbon storage can be expected in soils of permanently anoxic systems (peatlands). On the other hand, drying up inverts the situation, as oxygen can penetrate deeply into the soils and sediments (Paranaíba et al., 2020). This process already begins when the water level approaches the sediment surface, due to increased surface temperatures (due to lacking transpiration cooling and heat absorbance by the water), increased evapotranspiration by plants, bioturbation due to smaller (invertebrates) and larger animals (e.g., wild boars searching for food). Especially in clayey soils, shrinking and cracking results in deep penetration of oxygen into the ground, resulting in fast OM decomposition but also in release of carbon dioxide.

Alternating wet and dry wetlands, e.g., river floodplains or savanna wetlands, undergo cyclic phases of OM accumulation and carbon release, whereby the duration of the inundation phase acts as a switch between sink and source function of the wetland (Vega et al., 2014). Climatic variations may cause multi-year periods of wetter and drier years with substantial effects on the carbon stored from macrophyte production (Wantzen et al., 2005). High release of GHG occurs during changes, i.e., either if wetlands that have been waterlogged for long periods become dried up for the first time, as it happens when peatlands are drained for land use purposes (see below), or when drained or dry-fallen wetlands are re-wetted (Hiraishi et al., 2014; Krüger et al., 2014). Rewetting of peatlands after drainage is an long-term strategy for environmental restoration and an important tool for carbon sequestration (see below), even if short-termed GHG release may occur just (Günther et al., 2020).

Major group types of wetlands according to their carbon dynamics

There is large variety of wetland types and typologies (Finlayson, 2003; Keddy, 2010; Junk et al., 2014; Mitsch and Gosselink, 2015). Here we use a strongly simplified typology explaining the major phenomena in their carbon dynamics, which is mostly based on the directions of carbon fluxes.

Permanently wetted wetlands with low vegetation cover: Bogs, fens and mires

In some wetland systems, persistent water saturation up to the topsoil and resulting anoxia slow down OM processing so that partially decomposed plant biomass becomes a major component of the soil. The resulting material (with $\geq$15% C content) is called *peat*, landscapes made up by a superficial peat layer of at least 30 cm thickness are called *peatlands* in soil science terminology, and under peat forming conditions, they are called *mires*, even if the superficial peat cover is <30 cm. *Bogs* are rain-fed (ombrotrophic) and *fens* groundwater-fed (minerotrophic); *transitional mires* represent a mixture of both types. Different plant structures may form peat, including fine roots (radicels), larger roots, rhizomes, leaves of herbs, and woody tissue. Macroscopic determination of formerly peat forming vegetation is often possible even after millennia of its formation, provided that pH and nutrient concentrations are low. In the case of bogs and some fens, a very low pH of 3–4 may occur if the ground- and/or rainwater is nutrient- and cation-poor. *Sphagnum* mosses are the most prominent ecosystem engineers in peatlands (except in tropical lowland regions); they actively acidify their habitat by ion exchange, release of organic acids, and maintain humidity so that bacterial activity

becomes suppressed and peat accumulated (van Breemen, 1995; Harpenslager et al., 2015). *Sphagnum* species occur mainly in the Northern Hemisphere in peat bogs, conifer forests, and moist tundra areas, but also in Chile, Argentina, New Zealand and Tasmania, and in sub-alpine zones of the tropics and sub-tropics.

In all mires, anoxia promotes carbon degradation processes to require alternative electron acceptors as nitrate, iron or sulfate, and at final stages acetate and recalcitrant peat itself. At these final stages, carbon dioxide as well as methane are resulting end products. These processes make mires CO_2 sinks, but also sources of CH_4 (Nilsson and Öquist, 2009). Moreover, the acidification may release CO_2 from carboniferous bedrock (Harpenslager et al., 2015). When drained, peat becomes aerated and the resulting aerobic microbial pathways make such sites CO_2 sources of global significance, contributing at least 5% to the annual anthropogenic CO_2 emission, despite covering only about 0.45% of the global land surface (Leifeld and Menichetti, 2018). It is therefore imperative to keep peatlands wet and to rewet drained peatlands in order to preserve their important carbon storage.

Peat swamp forests

Tree species that survive in permanently water logged soils have developed adaptive traits such as lenticels and pressurized aeration of their root systems (Graffmann et al., 2008) allowing them to survive soil anoxia and permanent attack by microbes. Peat swamp forests are highly diverse, especially in SE Asia (Posa et al., 2011). Antimicrobial substances in fallen tree leaves (Jackson et al., 2009; Lim et al., 2014) may have an additional effect to the above-mentioned parameters that slow down decomposition, resulting in extremely slow decomposition rates in spite of high concentrations of dissolved oxygen in the water covering the organic layers. From small tropical stream valleys (Wantzen et al., 2012), to huge forests of Amazonia (150,000 km^2) and Indonesia (200,728 km^2) (Lähteenoja et al., 2009), or in the Congo basin (145,500 km^2) (Dargie et al., 2017), peat swamp forests may accumulate enormous carbon stocks in peat layers reaching depths of 18 m (in Amazonia: 5.9 m, Lähteenoja et al. (2009), 12 m, Householder et al., 2012).

Like in all wetlands, hydrology is key for the maintenance of the carbon storage, and the increasing drainage for encroachment for land use like ranching, farming or oil palm and *Acacia* plantations (Charters et al., 2019) has detrimental effects for the atmospheric carbon (CH_4, CO_2) budgets. In SE Asia, only 36% of the historical peat swamp forest area remains, with only 9% currently in designated protected areas (Posa et al., 2011).

Alluvial floodplain wetlands

Alluvial wetlands are the floodplain zones accompanying the depositional zones of rivers. They can occur along the entire river continuum like "beads on a string," but they generally become more contiguous, wider, and longer and more predictably flooded in the lower sections of the rivers (Tockner and Stanford, 2002; Junk and Wantzen, 2004). The landscape gradient and hydromorphological dynamics play a crucial role for determining the duration of the inundation and organic matter accumulation. Especially in stream wetlands, there may be a large heterogeneity on small scales (Wantzen et al., 2008c). Flooding often acts as a fertilizing event, as nutrients become imported from the catchment during floods. Consumers of living and dead organic matter profit by the phase change, e.g., fish consume fruit falling from trees during high water, and scavengers consume stranded fish during the low water phase in reciprocal subsidies (Wantzen et al., 2002; see Fig. 2). Thus, wet-and-dry cycles mobilize nutrients, which often

Fig. 2 Wet and dry cycle in seasonal wetlands, (A) flood phase, (B) low water phases. Graph modified after Wantzen KM, Machado FD, Voss M, Boriss H, and Junk WJ (2002) Seasonal isotopic shifts in fish of the Pantanal wetland, Brazil. *Aquatic Sciences* 64: 239–251.

results in luxurious growth of vegetation (Junk and Piedade, 1993) and secondary production (Bayley, 1991). Floods (understood as overbank flow) transport sediments into the floodplain, which may cover organic layers, resulting in carbon "burial" (D'Elia et al., 2017). Alluvial wetlands may or may not develop peat soils, depending on the interplay between aerobic and anoxic conditions described above. Mineral alluvial soils (fluvisols according to FAO's World Reference Base, WRB) become logged by variable proportions of groundwater or overbank flow, resulting in different chemical settings and carbon transport pathways. The OM compounds in the soils derive from many autochthonous and allochthonous sources, yet most carbon is accumulated by litter accumulation and rhizodeposition. Especially during floods, alluvial minerals (clay) may become deposited in close contact with organic particles, so that they form MAOM associations that restrict microbial accessibility to carbon resources. Mechanisms that mobilize carbon from floodplains are transport by water (drifting of organic particles, including entire plant associations such as large macrophyte mats Wantzen et al., 2005 or tree logs, or washout of dissolved organic matter), and the above-mentioned decomposition pathways, which can be accelerated by wet-and-dry cycles (Wantzen et al., 2008c). Releases of gaseous carbon forms can be accelerated by plant structures such as aerenchyma and lenticels (lens-shaped openings on stems for the aeration of the rhizosphere Pangala et al., 2017).

Lake littoral wetlands

In a lake (lentic) setting, wetlands are usually riparian zones where macrophytes (as reed or cattail) rooted in the soil emerge through the water column. Like lotic wetland settings, lakeshore wetlands may experience water level fluctuations, sedimentation or resuspension of suspended solids and an import of export of matter (as carbon) by moving water or organisms (Wantzen et al., 2008a). Lake morphology is crucial for the determination of the relationship between littoral wetlands to permanently flooded, limnetic lake areas. In shallow lakes, macrophyte growth and increased organic matter storage can occur on the entire surface, revealing similar carbon uptake and release features as those described for river floodplains. Lakes, especially their deltas (Scott and Wohl, 2017), act as important sinks for carbon originating from their terrestrial catchment (Cole et al., 2007). The amount of carbon and nutrient stripping in lake littorals from terrestrial sources via aerial pathways (pollen deposition, wind-blown leaf litter) or of algal biomass from the limnetic zone depends very much on the wind exposure and the surrounding vegetation. Reeds can skim out floating organic particles and produce large amounts of biomass themselves that contribute to the carbon budget (Brix et al., 2001; Li et al., 2009). Sediments of the profundal zones accumulate carbon deriving from the phytoplankton-based food chain. Consumption by zooplankton and fish, and selective uptake of compounds by bacteria (lake snow, Grossart and Simon, 1998) result in a continuous degradation of the organic particles on their way to the (mostly anoxic) lake sediments. High temperatures in shallow lakes may produce optimum conditions for methanogenesis. Bioturbation, e.g., by tubificid worms, chironomids, or *Chaoborus* larvae may oxygenate the sediment surface (resulting in an improved oxidation of methane), but also help to "pump" methane bubbles into the water column (Bezerra et al., 2020). Degassing of sediments also occurs spontaneously (Langenegger et al., 2019).

In arid zones, lakes may become saline when evapotranspiration exceeds lake water recharge, resulting in an accumulation of salts in the sediments. In such a setting, production and decomposition of carbon may be controlled by salinity, as increased salinity decreases both processes. Although some salt-affected sediments have a high OM content, studies in freshwater ecosystems affected by marine intrusion have shown that increased salinity will promote carbon decomposition by a shift to sulfate reducing conditions and increased mineralization of organic matter (Weston et al., 2011).

Seasonal wetlands

In seasonal wetlands, poorly drained plains situated become alternatingly wet and dry due seasonal water availability, e.g., due to monsoon rainfall or snowmelt. They may connect to lakes or river floodplains, or are interspersed with more or less permanently wetted mires (for example, North American prairie wetlands and potholes Euliss et al., 2006). Their vegetation includes woody and herbaceous growth forms. The turnover of the biologically fixed carbon between the dry and wet seasons is even more expressed than in river floodplains. Especially the non-woody plant cover becomes largely decomposed or consumed when the phases change between wet and dry. Aquatic macrophytes decay quickly even before they become stranded (Fellerhoff et al., 2003). The lowermost areas concentrate the remaining water-bound nutrients and biomass during the falling waters. Before the soils fall completely dry, there is a vivid growth of annual plants in the first weeks, followed by a kind of "mummification" (conservation by drought) of the biomass during the peak of the dry season. Intensive solar radiation and high soil surface temperatures during drought also result in mineralization of the soil organic matter in the topsoil. Terrestrial grasses may remain longer, and continuous years of shallow or absent flooding may result in accumulation of biomass and increased fire risk. Fires may occur naturally and mineralize a large part of the above-ground biomass. The first rainfalls may then "strip out" the dissolved carbon of the terrestrial plant biomass, even before the water levels rise (Hamilton et al., 1995; Hamilton et al., 1997). With increasing water levels, a luxurious growth of algae and macrophytes sets in, as long as the nutrients from the mineralized terrestrial biomass are available (Loverde-Oliveira et al., 2011).

The carbon that escapes from this annual cycling is either stored in woody biomass (living or dead trees and their roots), or in the wetter layers or areas of the wetland. Studies in Neotropical seasonal wetlands have revealed a critical wetting time of about 250 days per year as a threshold between carbon storage or carbon depletion of the topmost 20 cm of soils (representing a "carbon switch," Vega et al., 2014). This sensitive balance makes seasonal wetlands specifically vulnerable to climate change and land use change. On the other hand, wise wetland management is an important tool for the mitigation of climate change effects, as most of the carbon retention by wetlands occurs in tropical/subtropical zones (Mitsch et al., 2013).

Global review on carbon storage in wetlands

Most carbon in wetlands is stored in the soils. Soil carbon stocks may exceed the amount of carbon that is sequestered in above-ground biomass by the factors 10–18.5 (Jaenicke et al., 2008; Silva et al., 2013). Soil carbon concentrations and stocks differ strongly between the different wetland types and climatic regions (Table 1). Long-term carbon sequestration is highest in permanent wet peatlands due to permanent anoxic soil conditions (Page et al., 2004; Cole et al., 2007; Leifeld and Menichetti, 2018). Thus, they play a key role (Lorenz and Lal, 2018) by storing 600–644 Gt soil organic carbon globally (Lorenz and Lal, 2018), representing the major soil carbon stock of wetlands and more than one quarter of the global soil carbon stocks on only 3% of the land surface (Yu et al., 2010; Page et al., 2011; Leifeld and Menichetti, 2018). Tropical Peat Swamp Forests alone may store more than 100 Gt carbon with highest carbon densities of all ecosystems of 1280–3500 t C ha^{-1} (Filoso and Palmer, 2011; Dargie et al., 2017) (see Table 1). Northern peatland average carbon stocks range between approx. 1100 and 1470 t C ha^{-1} (Gorham, 1991; Immirzi et al., 1992). The second largest long-term carbon stock, although often not included in global carbon balances, are terrestrial lake sediments with estimates between 400 and 800 Gt carbon accumulated during the Holocene (Cole et al., 2007). Mineral wetland soils are reported to store between 50 and 230 t C ha^{-1} (Mazurczyk and Brooks, 2018). Among those, seasonal pothole wetlands in the US may accumulate 44–66 t C ha^{-1} (Tangen and Bansal, 2020). Despite these numbers it is clear that the role of freshwater wetlands in the global carbon cycle is still not sufficiently understood on the global and regional scale. The knowledge base on C stock and C sequestration rates in wetlands remains small given the diversity of wetland types world-wide, and the diverging methods and reference units (especially soil depth). All presented numbers can only be approximate, and especially for the Tropics there are many uncertainties (Sjogersten et al., 2014).

Even though most of the carbon that enters wetlands is lost either through decomposition or aquatic export (Bade et al., 2007; Nahlik and Fennessy, 2016), up to 0.83 Gt C per year net may be sequestered by wetlands globally. This represents approximately 12% of the carbon annually released from fossil fuel combustion. Annual net C sequestration rates (the positive total C balance) in peatlands remain comparably low showing higher rates in tropical Peat Swamp Forests (0.46–0.88 t C ha^{-1} $year^{-1}$, (Page et al., 2010)) due to higher net productivity than in northern herbaceous peatlands (0.1–0.4 t C ha^{-1} $year^{-1}$ Frolking et al., 2011). The weighted average sequestration rate for wetlands is 1.18 t C ha^{-1} $year^{-1}$ (Mitsch et al., 2013). Variations range from 0.02 to greater than 6 t C ha^{-1} $year^{-1}$ depending on wetland type, location, and primary C source (see Tangen and Bansal, 2020 for a detailed review).

Wetlands are net C and radiative sinks despite being natural sources of CH_4 emissions of 0.45 Gt per year (see Table 1 for different wetland types). Radiative forcing of CH_4 is lower than CO_2 over time horizons of hundred and more years, reducing the negative effect of CH_4 emissions on global warming compared to the amount of CO_2 sequestered by wetlands (Mitsch et al., 2013; Günther et al., 2020).

Human impacts on carbon stocks and carbon dynamics of wetlands

Human activities interfere with all processes of carbon dynamics occurring in wetlands (Mitsch and Gosselink, 2015). The most critical ones concern the acceleration of carbon release (mostly by drainage and conversion towards cropping or blocking of freshwater access), the reduction of carbon inputs (e.g., due to deforestation or man-made fires) and the complete removal or transformation of wetlands, turning them from net sinks into net sources of carbon. The direct use of carbon stored in peatlands as

Table 1 Selection of carbon dynamics in wetlands worldwide.

fuel has a long history in the northern temperate and boreal zones (Holmgren et al., 2008), while the degradation of peat swamp forest and other wetlands, e.g., in Asia is relatively recent (Nguyen et al., 2016; Page and Baird, 2016; Dohong et al., 2017; Hu et al., 2017; Meng et al., 2017).

As the ecosystem services of wetlands have been underestimated or even neglected too long time, their transformation into land use by humans has progressed without hesitation, e.g., agricultural use or just as dumping sites. Up to 89% of the SOC in a wetland can be lost by conversion to cropland (see Xu et al., 2019 and citations therein). Resulting changes in soil texture and related reduced water retention capacity, reduced plant organic matter inputs, increased erosion and higher temperatures determine higher SOC decomposition (Knops and Tilman, 2000). Case studies have indicated average losses of SOC of 10.1 t ha^{-1} on over 16 million ha of wetlands in North America (Euliss et al., 2006), and of 0.24 Gt carbon in north-eastern China (Xu et al., 2019). Degrading peatlands emit 1.3 Gt CO_2 $year^{-1}$, equivalent to 5% of the anthropogenic annual GHG emissions, from only 0.45% of the global land surface (Hiraishi et al., 2014).

Most urban wetlands have vanished in the Global North during the Industrial Age, whereas fast urban development in the Global South eliminates them very recently (Wantzen et al., 2019). All megacities are endorheic zones, i.e., they absorb much more water than the area they cover receives from precipitation, therefore the falling groundwater levels in the vicinity of cities cause dry falling of wetlands. Similarly, agriculture is increasingly tapping water from nearby wetlands, e.g., the illegal oblique water mining in the surroundings of the world-famous Spanish Cota Donana wetland (Zorrilla-Miras et al., 2014). Drainage or erosion by agriculture can quickly deteriorate wetland ecosystems that have stored carbon for millennia (Wantzen et al., 2012). Another impact on the carbon storage in this context is the spread of (native, and non-native) invasive plants that may result in a transformation of peat into mineral soils (Gogo et al., 2011).

All these trends are aggravated by current Climate Change, which often results in less predictable, shorter rainfall periods and more pronounced, hot droughts. Increasing temperatures and reduced water availability increase the decomposition of organic matter in wetlands leading to increasing C losses from wetlands as GHG emissions. The thawing of the permafrost of the sub-arctic wetlands for example is considered one of the tipping points of global warming leading to potentially very high SOC losses to the atmosphere as methane (Hugelius et al., 2020). Temperature is generally a critical parameter in land (and wetland) degradation and SOC losses (Joosten, 2014).

Conservation of wetlands and their ecosystem services concerning the carbon cycle

Conservation of wetlands and their many Ecosystem Services becomes more and more important, given the fact that more than one third is lost mainly due to human impacts (Hu et al., 2017). Important wetland ecosystem services are the shelter of biodiversity, their carbon storage, the provision of clean water, food and fodder and even cooling of the local climate (Mitsch et al., 2015). Moreover, wetlands fulfill many social and cultural ecosystem services (McInnes et al., 2017). International frameworks such as the Ramsar Convention, the SDGs, the UNFCCC and others explicitly or implicitly address wetland conservation. The latter implies countries to assess and report on the impact of human activities on wetland carbon budgets (Hiraishi et al., 2014), which since the Paris Climate Agreement implies a complete stop of wetland conversion until 2050.

Besides the conservation of wetlands, the increasing importance of their restoration is acknowledged by the UN Decade of Ecosystem Restoration (UN, 2019) and the EU sustainability objectives (Tanneberger et al., 2021). This is underlined by a recent modeling study which predicts that the land system would turn into a global net carbon sink by 2100, as projected by current mitigation pathways, if about 60% of present-day degraded peatlands were rewetted in the coming decades, next to the protection of intact peatlands (Humpenöder et al., 2020).

The re-establishment of natural hydrology and revegetation (active or passive) are key elements of wetland restoration (Keddy and Fraser, 2000; Keddy, 2010; Mitsch and Gosselink, 2015). Removal of dams that are retaining flood water and sediments worldwide (Grill et al., 2019) and thereby drain or disconnect floodplain wetlands is an important step especially considering that in Europe alone 10% of the 1.2 million barriers are obsolete (Belletti et al., 2020). Since wetland hydrology is closely linked to the whole catchment, effective conservation should address issues on a catchment scale. Wetland restoration has two implications for their carbon budget: (1) carbon losses due to degradation are reduced or stopped. Rewetting peatlands for example would avoid emissions between 25 and 60 tons $CO_{2\text{-eq}}$ ha^{-1} $year^{-1}$ in Central Europe (Couwenberg et al., 2011) and between 70 and 117 tons $CO_{2\text{-eq}}$ ha^{-1} $year^{-1}$ in Southeast Asia (Cooper et al., 2020). (2) Wetland restoration has the potential to re-stimulate C sequestration, with potentially 0.38 Gt of organic carbon that could be stored over a 10-year period (Euliss et al., 2006). Additionally, constructed wetlands are estimated to provide high C sequestration rates (Lal et al., 2018). To make use of wetlands as carbon sinks with efficient climate mitigation potential they need to be restored and maintained for long time periods (Günther et al., 2020).

Concepts of sustainable use of wetlands can be a way of preserving or restoring important wetland ecosystem service and simultaneously allowing production, as for example, paludiculture for peatlands (Biancalani and Avagyan, 2014; Wichtmann et al., 2016). Rural participatory appraisal of wetland ecosystem services (Ricaurte et al., 2014) can help to identify the cultural relationships to the nature of wetland and deliver both motivation and traditional ecological knowledge about sustainable use of wetlands (Wantzen et al., 2016).

Conclusion/Synthesis

Size does not matter to address relevancy adequately. Wetlands are prominent examples, as they cover only a small proportion of the Earth's terrestrial surface but perform outstanding functions in the water and carbon dynamics. They offer a wide range of ecosystem services, due to their simple function to collect water, organic material and mineral sediments. This holds true despite the great variety (diversity) of freshwater wetlands. Great storage is the result of higher input than output fluxes. Even if a dynamic equilibrium is reached (usually inputs to wetlands are higher than outputs) are these continuous biotic, physical and chemical processes determined by climate, topography, soil and time. External stress can easily tip this dynamic state from atmospheric carbon sinks towards sources of greenhouse gasses to the atmosphere. In the Anthropocene we are living in, the external stress is usually caused by humans. Indirect stress would be climate change that could increase feedback processes by increased temperatures and declining precipitation and additionally threaten wetlands. Draining wetlands for agriculture etc. (see Fig. 1) would be a direct impact leading to the loss of their carbon sink function. Their outstanding role for climate protection has been widely accepted, but clear actions to protect or even restore wetlands are still scarce. Effective wetland protection and restoration need to be further integrated in political frameworks on all levels and implemented in land use planning and management. Those need scientific guidance and despite the great knowledge already gained, more is needed to properly manage these fragile ecosystems. It will help to develop alternative uses of wetlands that allow or favor natural wetland processes after restoration of degraded wetlands.

Knowledge gaps

In spite of an increasing scientific interest in wetland ecology in the past decades, many important lacunae persist, i.e.,:

- Identify the carbon storage/release switches in different types of wetlands.
- Compensatory effects of decomposition-favoring (priming by labile, energy-rich, or stochiometrically rare substances) vs. decomposition-hindering processes ("recalcitrance" caused by plant secondary compounds, or "capping" of OM by MAOM, mineral associate organic matter).
- Effects of global warming on microbial soil organic matter decomposition and oxidation—temperature sensitivity of SOM decomposition.
- Sustainable Land use practices, that allow economic use of restored wetlands while maintaining ecological functions and biodiversity (e.g., Paludiculture on peatlands).
- Improve social awareness and valuing of wetlands and their ecosystem services (including cultural values) to achieve better political support for restoration and conservation measures.

Glossary

Alluvial river Self formed river in which the bed and banks are made up of mobile sediment.
Azonal vegetation Plant communities that depend on local extraordinary habitat characteristics e.g., microclimate, inundation, see also zonal vegetation.
Boreal zone Regions of the northern hemisphere with cold temperatures approximately between 50° to 70°N latitude.
Braided rivers Rivers characterized by mobile, multi-thread channels within gravel or sand-dominated fluvial corridors.
Ecological niche The match of a species to a specific environmental condition.
Endemic The state of a species being native to a single defined geographic location.
Floodplain Flat land area adjacent to a stream which is within the influence of the hydromorphodynamics of the river.
Fluvial Processes and landforms created by the flowing water.
Glacier fore-fields The region between the current front of the glacier and the moraines of the latest maximum.
Gravel-bed rivers Coarse-grained alluvial rivers which are particularly characterized by dynamic fluvial processes that constantly change and renew the surface and subsurface of the river's valley floor.
Last glacial maximum The LGM was the most recent time during the Last Glacial Period where the ice sheets were at their greatest extent.
Phreatophytes Deep-rooted plants that obtain a significant portion of the water that it needs from the phreatic zone (zone of saturation) or the capillary fringe above the phreatic zone.
Riparian vegetation Plant communities of floodplains (synonym floodplain vegetation).
Riverine Processes, landforms or species relating to or produced by a river.
Shear stress The external force acting on an object or surface parallel to the slope.
Taiga The boreal forest throughout the high northern latitudes, between the tundra and the temperate forest, from about 50°N to 70°N.
Trait Any morphological, physiological or phenological feature measurable at the individual level of a species.
Tundra Open, treeless landscape (mostly) over permafrost soils of the subpolar climate zone.
Wetland ecosystems Comprise areas that transition between terrestrial (land) areas and aquatic (water) areas.
Zonal vegetation Plant communities that depend on the large-scale habitat characteristics of the macro climate—see also azonal vegetation.

Introduction

Gravel-bed rivers and particularly braided rivers represent extraordinary wetland ecosystems due to their high disturbance regimes (Bornette and Amoros, 1996; Müller, 1998; Plachter and Reich, 1998). In contrast to groundwater- and flood-dominated wetlands, the main ecological factor is the geomorphological dynamics (Piégay et al., 2006). Their disturbance-adapted characteristic plant species create distinctive azonal vegetation types, contrary to the large-scale zonal vegetation in the surrounding areas (Fig. 1). Consequently, under natural conditions they contribute significantly to global biodiversity (Tockner et al., 2006).

However, due to the worldwide human impacts in the hydrological and sediment regimes by dams, diversions, flood control and river regulation (Hauer et al., 2016; Hohensinner et al., 2021) their characteristic native species have become extirpated along many river corridors (e.g., Müller, 1995; Tockner et al., 2008). Another threat to their biodiversity is their vulnerability to invasion of non-native plant species because the braided river floodplains provide regularly open sites for seedling colonization and the rivers serve as seed dispersal pathways (Liendo et al., 2015).

There have been many case studies of riparian vegetation existing in single mountain ranges (e.g., for Asia, Africa, Europe, Asia), but overviews of larger mountain regions similar to the analyses of the European Alps (Egger et al., 2019a,b; Kalníková et al., 2021) are lacking.

With this chapter we provide a global review of the riparian vegetation of gravel-bed rivers in mountain ranges, focusing on two questions:

- Which native plants are characteristic and abundant in the different successional phases of the riparian vegetation?
- Which invasive non-native plants are frequent within the riparian vegetation communities?

Mountain ranges

Mountain ranges of similar climatic conditions with frequent occurrences of gravel-bed rivers and including a high proportion of braided rivers were grouped into nine reference regions using data of ESRI (2010, 2016) and Natural Earth (2018) (Figs. 2 and 3).

Based on the data of Maier et al. (2022) the reference regions were selected to cover a wide range of abiotic factors. This includes their location on different continents of both hemispheres, different altitudes of mountain ranges, and varying percentage of current

Fig. 1 Gravel-bed rivers are shaped by high morphodynamics, drought and periodic flooding and are therefore colonized by adapted pioneer plants. This applies in particular to braided rivers like the shown Bush River that drains from the Columbia Icefields of the Canadian Rocky Mountains west. (Photo: S. Rood).

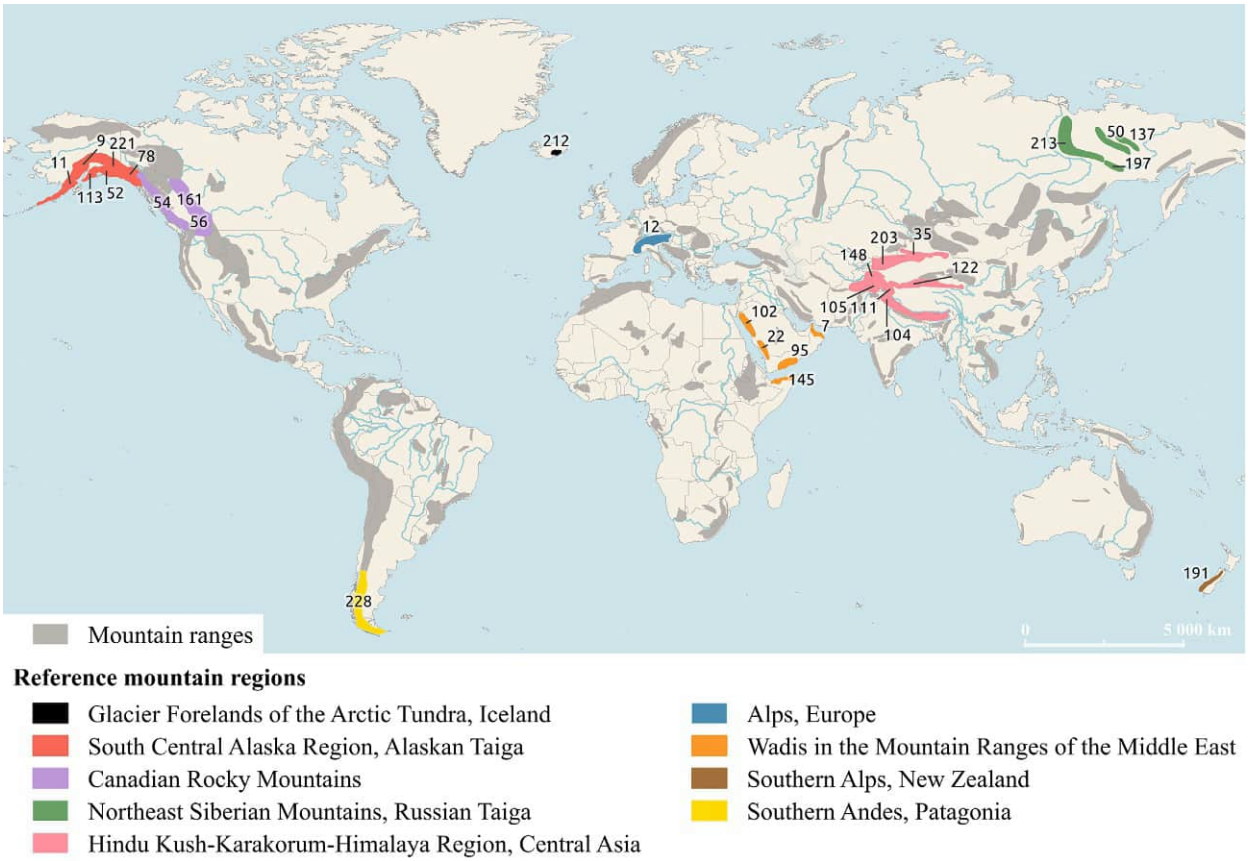

Fig. 2 Main global mountain ranges (grey) and reference regions with high proportions of braided rivers (described in chapters 4–12).

and historical glaciation. Climatic factors range from tropical to boreal and arctic climates, resulting in different floristic regions that influence riparian vegetation communities. Additionally, different extents of human impacts and land use intensities were considered. The reference regions include different numbers of regional mountain ranges, ranging from one main range such as the Patagonian Andes to several mountain ranges that occur in Central Asia. Each region is considered as representative of the associated mountain range for analyses of the riparian vegetation characteristics.

Reference regions and their riparian vegetation

The description of the nine reference regions and of their riparian vegetation, including their native and invasive non-native plant species, is based on published reports and was undertaken in close collaboration with regional experts. Invasive non-native plants (or 'invasive exotic species') indicates non-native species which have harmful effects on native biodiversity (CBD, 2010; Richardson et al., 2000). Plant species names were assigned according to Taxonomic Name Resolution Service (Boyle et al., 2013).

Commencing each subchapter, a short geographical introduction is provided using data from Linke et al. (2019), Masutomi et al. (2009), and RGI Consortium (2017). The subsequent description of the riparian vegetation is focused on the characteristic and frequent native and invasive non-native plants. Selected species of the nine reference mountain regions are provided in Table 1, with information about frequency, endemic status, occurrence of main habitat types and succession phase.

For the categorization of the riparian vegetation we used the 'fluvial biogeomorphic succession concept' proposed by Corenblit et al. (2007, 2011, 2015). Following this concept, river corridors worldwide are characterized by four consecutive succession phases. The concept starts with the initial 'geomorphic phase' with large areas of vegetation-free gravel sites, e.g., after total destruction of a site by a flood event. The areas are mainly shaped by the flow regime and the sediment properties (Corenblit et al., 2007). The open sand and gravel bars offer many sites for plant germination, but colonization is aggravated by the strong morphodynamics especially in braided river systems. Pioneer plants can only establish during a suitable window of opportunity (Balke et al., 2014) in the 'pioneer phase.' These pioneer plants are still particularly influenced by the hydrogeomorphic processes and require a set of functional traits to cope with the frequent disturbances and stressors in river corridors (Gurnell et al., 2016). In general, key traits relate to plant reproduction, growth and survival (Violle et al., 2007) with adaptive traits along braided rivers to resist strong shear stress, sediment deposition and uprooting (Bornette et al., 2008). Through these specialized adaptations and response traits

(Violle et al., 2007), plants increase their resistance ('maintaining structure') and resilience ('restoring structure') to disturbances (Holling, 1973) and also generate biogeomorphic feedback that reduces morphodynamics. The aboveground biomass modifies the flow field, increases roughness (Bennett et al., 2008; Gurnell, 2014; Gurnell et al., 2016; Liu et al., 2010) and retains sediment (Zong and Nepf, 2010), while the underground biomass reduces the erosion capacity of the land surface and thereby contributes to its stabilization (Gurnell, 2014). These interactions set the 'biogeomorphic phase' of succession in motion. Especially colonized sites by ecosystem engineers (Jones et al., 1994) are more resistant to disturbances and destruction due to their enormous effects on the morphodynamics. The final 'ecologic phase' is characterized by more stable habitats and autogenic ecological processes. Vegetation is less influenced by the river, succession processes continue and long-lived plant communities begin to establish (Bazzaz, 1979). In the presence of reduced fluvial processes, the late-successional stages transition into the surrounding zonal vegetation. We expanded the 'ecologic phase' into an 'early' and a 'late successional phase'. Characteristic trees of the 'early successional ecologic phase' establish on open bars, grow rapidly, are shade intolerant, and are well adapted to high hydro-morphodynamics. In contrast, trees of the 'late successional ecologic phase' establish on stable sites, are more shade tolerant and grow more slowly (Egger et al., 2019a).

Glacier Forelands of the Arctic Tundra, Iceland

The reference mountain region of the Arctic Tundra is located in the Vatnajökull mountain range (No. 212; Fig. 2) in south-eastern Iceland. The area is dominated by the Vatnajökull Glacier which currently covers over 80% of the mountain range. The glacier covers almost 7800 km^2 and is the largest ice cap of Iceland and outside of the Arctic. About 30 outlet glaciers flow from the ice cap, which reaches over 2000 m in altitude, and end in an extensive moraine landscape in the lowlands and highlands to the north of the glacier. These are closely interwoven with a number of fens of braided rivers, some several km wide, along with alluvial outwash terraces. Numerous large and small glacial rivers fall from the glaciers and the rivers flowing out of the mountain range to the South are mainly sparsely vegetated along their courses (Fig. 4). In general, the mountain range is scarcely forested and anthropogenic impact is very low with a population density of only 0.01 person per km^2. The median annual temperature is 0.9 °C and precipitation 1.380 mm.

The vegetation colonization of the braided river corridors in the glacier fore-fields is determined by a complex interaction of several environmental factors and succession is generally slower in the cooler Artic than in temperate climate regions (Glausen and Tanner, 2019; Vilmundardóttir et al., 2014). Following the glacier's maximum extent in the last Little Ice Age at the end of the 19th century, the glaciers of Vatnajökull have been continuously receding. The ice-free moraine fields vary in length and are gradually colonized by vegetation during different succession phases. In the area of braided river corridors, primary succession is additionally dominated by the alluvial hydro- and morphodynamics of the glacial streams (Vilmundardóttir et al., 2014).

The young alluvial soils are wet to dry, nutrient poor, and characterized by low carbon content. Most areas of these highly dynamic rivers are un-vegetated or sparsely vegetated. Common plants of the 'pioneer phase' are *Agrostis stolonifera*, *Festuca richardsonii* and sporadically *Arabidopsis petraea*, *Armeria maritima*, *Carex maritima*, *Cerastium fontanum*, *Equisetum arvense*, *E. variegatum*, *Juncus arcticus*, *Rumex acetosella*, *Silene uniflora* and *S. acaulis*. In addition, there are moss species such as *Racomitrium ericoides*, which form the largest cover, as well as *Drepanocladus aduncus* and *Philonotis fontana* (Magnússon et al., 2016; Vilmundardóttir et al., 2015) (Fig. 5).

Flat, sandy floodplains with organic soils are dominated by *Juncus arcticus* meadows. In addition, *Carex nigra*, *Empetrum nigrum*, *Salix arctica* and *S. lanata* are predominant (Fig. 6). Further characteristic plants are grasses like *Agrostis stolonifera*, *A. vinealis*, *Calamagrostis neglecta*, *Festuca vivipara*, *Luzula multiflora*, *Trisetum spicatum* and herbs including *Bistorta vivipara*, *Cardamine hirsuta*, *Epilobium palustre*, *Equisetum arvense*, *E. variegatum*, *Filipendula ulmaria*, *Galium normanii*, *G. verum*, *Leontodon autumnalis*, *Parnassia palustris*, *Platanthera hyperborea* and *Rhinanthus minor* (Magnússon et al., 2016).

Fig. 5 Vatnajökull dry gravel foreland, approximately 30 to 50 years old, dominated by *Racometrium ericoides* mossheath with *Empetrum nigrum* and *Thymus praecox* and several other vascular plants. (Photo: S. Metúsalemsson).

Fig. 6 A moist sandy floodplain at Vatnajökull. The *Juncus arcticus* meadow includes *Carex nigra, Calamagrostis neglecta, Salix lanata, S. phylicifolia* and numerous other vascular species and provides a habitat rich in bird life. (Photo: S. Metúsalemsson).

On more stable habitats—the 'biogeomorphic phase'—young successional dwarf shrubs occur, such as the spreading *Empetrum nigrum* and *Calluna vulgaris*. In addition to the listed species of the pioneer phase, *Thymus praecox* ssp. *arcticus*, *Alchemilla alpina*, *Botrychium lunaria*, *Campanula rotundifolia*, *Cerastium alpinum*, *Erigeron borealis*, *Luzula spicata*, *Minuartia rubella*, *Poa glauca*, *Saxifraga oppositifolia*, *Silene suecica* also establish here (Magnússon et al., 2016). Further, low-growing willow species such as *Salix lanata*, *S. phylicifolia* and *S. herbacea* and *Betula pubescens* are also present (Aradottir and Eysteinsson, 2005; Vilmundardóttir et al., 2015). As succession progresses, habitats become increasingly species-rich and a number of further mosses, such as *Racomitrium lanuginosum*, *Pogonatum urnigerum*, *Ceratodon purpureus*, *Lecanora polytropa*, *Placopsis gelida*, *Tremolecia atrata*, *Cetraria muricata*, *Cladonia borealis* and *Stereocaulon alpinum* are present in addition to *Racomitrium ericoides*.

On undisturbed moraine sites that have been ice-free for 60–120 years, mosses and lichens became more dominant in the 'early successional ecologic phase'. On sites more heavily grazed by sheep, these transition to the widespread *Vaccinium-Empetrum-Racomitrium* heaths in the lowlands of Iceland (Magnússon et al., 2016). Also, on the oldest sites with moderate sheep grazing, dense and species-rich willow scrubland and birch woodlands occur with *Betula nana*, *B. pubescens* and *Sorbus aucuparia* and in the understory *Salix lanata*, *S. arctica* and dwarf shrubs such as *Vaccinium uliginosum*, *Vaccinium myrtillus*, *Calluna vulgaris*, *Arctostaphylos uva-ursi* and *Empetrum nigrum* are present as well as grasses, tall forbs, and *Equisetum* spp. (Aradottir and Eysteinsson, 2005; Glausen and Tanner, 2019; Magnússon et al., 2016).

Despite the fact that nearly 336 alien plant species have been recorded in Iceland from 1840 to 2012, with about three new taxa added annually, only *Lupinus nootkatensis* and *Anthriscus sylvestris* can be currently classified as invasive non-natives along the rivers (Wasowicz et al., 2013). Originally from Alaska, *L. nootkatensis* occurs mainly in the 'pioneer phase' and is also common in the lowland areas of the moraines around Vatnajökull, where it is expected to spread extensively in the near future (Guðjohnsen and Magnússon, 2019).

South Central Alaska Region, Alaskan Taiga

This reference region covers the mountain ranges of southern Alaska and includes the Alaska Range (no. 9), Aleutian Range (no. 11), Chugach Mountains (no. 52), Elias Range (no. 78), Kenai Mountains (no. 113) and Wrangell Mountains (no. 221) (Fig. 2). These geologically relatively young, Cenozoic mountain ranges lie in the boreal climate region and have median elevations between 520 and 1200 m with the highest peak being Mount Logan (5959 m) in the Elias Range. Conversely, the Aleutian Range in the far west of Alaska has lower altitudes, lower precipitation and warmer temperatures.

The Aleutian Range and Alaska Range in the southwest currently have small areas covered by ice (below 8%). In the other mountain ranges the area covered by glaciers ranges from 16% to 31%. In the last glacial maximum these were almost completely glaciated. Current vegetation cover across these mountain ranges varies between 54% and 84%. The tree line drops to 500 m near the Gulf of Alaska which is relatively low compared to other reference regions and peaks in the Wrangell Mountains with around 1300 m.

The largest rivers of the south-central Alaskan region are the Copper, White, and Kenai Rivers and the headwaters of the Tanana River, such as the Delta, Nenana and Chisana River.

The braided rivers of this study region are generally characterized by extensive areas of gravel (geomorphic phase) (Figs. 7 and 8). The subsequent 'pioneer phase' on these floodplains of the bare alluvium include colonization of herbs common in the Alaskan taiga such as *Saxifraga aizoides*, forbs like *Lupinus polyphyllus*, *Solidago canadensis*, and grasses like *Phalaris arundinacea*.

Fig. 7 Susitna River in the south of Denali National Park (Alaska Range). (Photo: G. Egger).

Fig. 8 Riverbed of the Delta River, a tributary of the Tanana River, with large amounts of dead wood (large woody debris). (Photo: G. Egger).

This system progresses in the 'biogeomorphical phase' through stands dominated by *Salix alaxensis,* one of the most common and widespread pioneer willow species of the mountain regions of south central Alaska (Fig. 9). One of the most common pioneer trees of the 'early successional ecologic phase' is *Populus balsamifera,* which is abundant in the boreal regions across Canada. This fast-growing and generally short lived tree grows trans- continentally on upland and floodplain sites, where it has the best growing

Fig. 9 An early successional woodland with dense willow shrubs dominated by *Salix alaxensis* and young *Populus balsamifera* trees along the East Fork Chulitna River, Alaska. (Photo: G. Egger).

conditions. Along Pacific drainages, the closely related *Populus trichocarpa* (syn. *Populus balsamifera* ssp. *trichocarpa*), the largest of the American poplars, forms extensive groves at low elevations. *Alnus incana* is an abundant, large shrub on wetter sites on sand and gravel bars, in glacial and riparian shrublands and wet uplands from central to southern Alaska (Larson, 1994). Widely distributed along streams, rivers and in swamps and moist alluvial bottomlands from Alaska to the South of California and south-eastwards across North America, *Salix lucida* is a fast growing, deciduous large shrub or small tree.

In addition, a number of other representatives of early successional willows are found such as *S. arctica*, the northernmost woody plant in the world (Woodward, 2014), and *Salix glauca*. Both are very common willows in shrubby riparian and tundra habitat. Other willows are less common such as *Salix lanata*, *S. arctophila*, *S. pseudomyrsinites*, *S. interior*, *S. pseudomyrsinites*, and *S. brachycarpa* ssp. *niphoclada*. *Salix exigua*, a widely-distributed species occurs on finer sediments of floodplains and lower elevations to lower montane habitats across western North America. Other willows and willow hybrids also occur including *Salix arbusculoides*, which is widespread along river banks from central Alaska to Hudson Bay, colonizing fresh alluvial deposits and glacial outwash.

When initial trees of the "early successional phase of the forest" reach their maximum age and die, the dominant tree of the subsequent mid to 'late successional ecologic phase' is *Picea glauca*. This shade tolerant tree dominates the extensive boreal forests of Alaska and Canada. It occurs in all stages of boreal forest succession and also on recently disturbed sites. At poorly drained back swamps *Picea glauca* is replaced by *Picea mariana*.

In the largely remote and relative pristine regions, there are relatively few invasive plant species along the braided rivers in the Alaskan taiga, including *Sorbus aucuparia*, *Sonchus arvensis* and *Tanacetum vulgare*.

Canadian Rocky Mountains

This region comprises the mainly boreal Coast Mountains (no. 54), Columbia Mountains (no. 56) and the Canadian Rocky Mountains (no. 161) (Fig. 2). Compared to the Alaskan region, the mountain ranges of this region are older (Mesozoic), current ice cover is lower and vegetation cover is higher (82–97%). The highest peak is Mount Waddington in the Coast Mountains and the largest rivers are the Yukon, Fraser, Columbia and Kootenay Rivers.

The Canadian, or northern Rocky Mountains display braided, multi-thread river channels of three types. First, and similar to some other mountain regions on the Globe, as the mountain rivers drop down to shallower gradients, glacial scour and alluvial sediments are deposited, choking channels and leading to channel deflection and bifurcation. This generates very dynamic braided segments with sparse vegetation. The gravel bars of the 'pioneer phase' (Fig. 10) are commonly colonized by pioneers such as *Dryas drummondii*, which supports symbiotic actinorrhizal nitrogen fixation that is beneficial in an environment of nutrient-deficient mineral surfaces. Disturbance responsive plants like *Epilobium angustifolium* ssp. *angustifolium* create by aggradation slightly higher and more stable areas on which willows (listed below) and eventually *Pinus contorta* forests establish. As rivers flow downstream,

Fig. 10 Pioneer phase with *Dryas drummondii* at the Sunwapta River in Alberta, Canada. (Photo: S. Rood).

there are commonly progressive transitions from braided to meandering forms. These support arcuate bands or vegetation patches that result in a shifting mosaic of riparian community types. On the lower elevations the wet meadow zones that are commonly inundated, include the sedges *Carex aperta*, *C. aquatilis*, *C. lenticularis* and horsetails (*E. arvense*, *Equisetum fluviatile*). The willows include *Salix bebbiana*, *S. boothii*, *S. brachycarpa*, *S. drummondiana*, *S. eriocephala*, *S. geyeriana*, *S. monticola*, *S. planifolia*, *and S. wolfii*, with complexities in classification due to hybridization and introgression. *Cornus sericea* occurs on slightly higher surfaces of the 'biogeomorphic phase' contributing to the riparian shrublands. These blend into the slightly higher 'early successional ecologic phase' with riparian forests composed of *Populus balsamifera* along eastern drainages and *P. trichocarpa* (Fig. 11) along Pacific drainages. *Alnus incana* is common, and sometimes birches (*Betula occidentalis*, *B. glandulosa*) and *Acer glabrum*. *Picea glauca* and hybrids co-occur or follow with forest succession that may lead to the 'late successional ecologic phase', with *Thuja plicata* in wetter zones (Egger et al., 2015) (Fig. 12).

Fig. 11 Colonization of black cottonwoods (*Populus trichocarpa*) following a flood of the Elk River in British Columbia, Canada. (Photo: S. Rood).

Fig. 12 White spruce (*Picea glauca*) forest (late successional ecologic phase) with a few black cottonwoods (*Populus trichocarpa*; center of picture) representing a remnant from the previous early successional ecologic phase at the Elk River in British Columbia, Canada. (Photo: G. Egger).

The second type of regional river braiding, anastomosed channels, are very different relative to dynamics and vegetation distribution (Makaske et al., 2002). These occur in the broad and very shallow gradient glacial valleys, where post-glacial sediment deposition produces wide and flat floodplains with an interwoven complex of braided channels, wetlands and ponds. The complex braiding has been somewhat stabilized and natural levees flank the larger channels, following overbank sediment deposition. This inverts the elevational profile, with the higher surfaces adjacent to the river channel. Similar plants occur along the anastomosed channels but with opposing distribution. The black cottonwood (*Populus trichocarpa*) bands are directly along the channel on the elevated levees, and then sloping downward away from the channel to shrublands occur with willows (*Salix* spp.) and dogwood (*Cornus sericea*), and then lower surfaces with wet meadows and wetland ponds.

A third type of river channel braiding occurs as rivers flow into natural lakes or artificial reservoirs. Sediment deposition creates the river delta with shallow topographies and distributaries form as the channels are choked and redirected. The same riparian vegetation communities form as along the other regional channel types, with the same spatial transitions with increasing elevation and correspondingly reduced inundation: from wet meadow, upwards to riparian shrubland, riparian forest and then the transition to upland, coniferous forest. In addition, with lower zones or with sediment lenses that limit drainage, there may be wetland zones with perennial ponding that support bulrushes and other emergent aquatic plants.

Across these different braided and meandering channels and delta zones, a common invasive plant is *Phalaris arundinacea* (Spyreas et al., 2010). This plant is regionally native but vigorous hybrids have been developed and distributed as forage crops and these have invaded natural areas. A number of knapweeds (*Centaurea diffusa*; *C. maculosa*) and leafy spurge (*Euphorbia esula*) are also invasive in the riparian zones, especially in drier regions (Sheley et al., 1998).

Northeast Siberian Mountains, Russian Taiga

Northeast Siberia's mountains east of Lena River, Verkhoyansk Range (no. 213 including Suntar-Khayata Range (no. 197)) and Cherskiy Range (no. 50 including Momskiy Mountains (no. 137) (Fig. 2) stretch for approximately 1000 km from north to south, and cover nearly the same distance in a longitudinal direction. Median elevations are 510–1380 m (max. 3003 m a.s.l.). The largest rivers are the Indigirka River (Fig. 13), Yana River, and Kolyma River. Despite the boreal climate with low mean annual temperatures of about 16 °C and limited precipitation of below 300–420 mm, there are very few current glaciers. In contrast, at the last glacial maximum 20–84% of the mountain ranges were covered by ice.

The vast area of Siberia, along with complex geomorphology, determines the diversity of vegetation patterns there. In the highlands, belts developed along the slopes according to the Verkhoyansk-Kolyma altitudinal zonation type (Ogureeva et al., 1999): mountain taiga, subalpine shrubs, mountain tundra, epilithic lichens belt, and the high mountains above snow line ("nival belt"). Along with that ecosystem diversity, narrow and deeply incised river valleys support specific vegetation complexes that include forests and shrubs intermixed with meadows, bogs and aquatic vegetation.

The mountain taiga belt is limited to 600 m a.s.l. in the north and 1300 m in the south and is represented by the northern taiga of *Larix gmelinii* (Isaev et al., 2010). Valley complexes are most developed within this belt. Riparian forests of the 'late successional

Fig. 13 View into the valley of a tributary to the Indigirka river in its middle reaches in the Cherskiy Range with icing. (Photo: E. Troeva).

ecologic phase' with *Larix gmelinii, Alnus alnobetula* ssp. *fruticosa* and *Rosa acicularis* in the understory are more productive than the upslope communities. Along with larch, the late-successional forest stages in the Verkhoyansk Range features *Picea obovata* (Nikolin, 2014). At the lower floodplain levels, rapidly growing pioneer woodlands of the 'early successional ecologic phase' (*Populus suaveolens, Chosenia arbutifolia, Betula pendula, B. pubescens*) establish (Nikolin, 2012, 2013). *Chosenia arbutifolia* is a characteristic riparian species adapted to mountain rivers' high hydro- and morphodynamics. It germinates and establishes upon open gravel and sand banks along the active channel. After 12–25 years it can also dominate the 'biogeomorphic phase', growing up into deciduous forests approximately 25–30 m high. These floodplain forests can subsequently get ages of 60–120 years (Moskalyuk, 2016; Fig. 14).

In the border areas along the active channels, arborescent willow stands (*Salix schwerinii*, *Sapromyza rorida*, *Salix viminalis*, etc.) form intermixed with forb and grass meadows. Within the subalpine shrub belt (*Pinus pumila, Betula divaricata*, ca. 1000 m a.s.l.), low shrubs (*Betula nana* subsp. *exilis*, *Salix pulchra*, *S. saxatilis*) separate slope communities, and riparian willows (*Salix alaxensis, S. boganidensis*, *S. dshugdshurica*, *S. pseudopentandra*) grow along the active channels. Occasionally, *P. pumila* extends downslope down to the river. Shrubs alternate with bogs (*Carex* spp., *Eriophorum* spp.) and small patches of meadow (*Carex* spp., *Kobresia* spp.) (Nikolin, 2014).

Open gravel alluvium is a substrate for the 'pioneer phase' with communities of *Equisetum arvense*. Further silt accumulation provides habitat conditions for *Chamerion latifolium* (Fig. 15) and graminoid meadows (*Bromus* spp., *Leymus* spp., *Calamagrostis* spp.).

When considering the Northeast Mountains' river corridors, it is necessary to recognize the unique phenomenon of aufeis, or icing (Fig. 13). Sheet-like masses of aufeis form from successive flows of groundwater during freezing temperatures. Melting icings are surrounded by communities of *Equisetum variegatum*, which is a valuable forage plant for horses and for native ungulates and other herbivores. Towards the edges of gravel-bed rivers, these are replaced by meadows of *Calamagrostis neglecta*, *Carex* spp., *Pedicularis* spp., *Primula* spp., *Ranunculus* spp. and other plants (Efimova et al., 2010).

The river valleys are less systematically developed within the mountain tundra belt (1110–1500 m a.s.l.). Complex tundra communities (*Ledum palustre*, *Arctous alpina*, *Koenigia tripterocarpa*, *Andromeda polifolia*, *Empetrum nigrum*) with sparse shrubs of *B. nana* subsp. *exilis* represent a transition between upslope and riparian vegetation. On sandy-gravel alluvia, mesic meadows (*Leymus interior*, *Bromus pumpellianus* s.l.) develop. Ribbon-like thickets of low-growing willows (*Salix alaxensis, S. lanata, S. glauca, S. pulchra*, etc.) with sporadic *Calamagrostis purpurea* communities are confined to stream banks (Efimova et al., 2010; Nikolin, 2014). There are no serious invasive non-native plants in these riparian zones.

Fig. 15 *Chamerion latifolium* is a characteristic species of the pioneer phase of river corridors in the mountains of northeast Siberia. (Photo: E. Troeva).

Hindu Kusch-Karakorum-Himalaya-Region, Central Asia

The very high mountains of this region are heterogeneous in terms of global climatic types. These range from the monsoon-shaped subtropical south-eastern part of the Himalayas (no. 104) with extremely high tree lines up to 4000 m m.a.s.l. to the Eurasian winter humid subtropics in the Hindu Kush (no. 105) and the western Karakoram (no. 111), and to the north-western slope of the Hindu Kush Pamirs (no. 148) characterized by the winter humid continental dry climate. These also include the temperate climate of the Kunlun Shan (no. 122), the cold continental climate of Tian Shan (no. 203) on the Tarim Basin's edge, and the Borohoro Mountains (no. 35) (Fig. 2). The global climatic zones are strongly dominated by altitude and determine vegetation structure to a large extent (Schultz, 2005). Thus, the mountain ranges of Central Asia differ substantially from the other selected mountain regions of the arctic and temperate boreal zones of the northern and southern hemispheres, or the wadis of the Middle East. With exception of the Borohoro Mountains, these mountain ranges have maximum elevations of more than 7.150 m m.a.s.l. and comprise the highest peaks of the world. As a consequence, runoff from snow and glacier melt is very important for the rivers especially in the arid part of this region, even though the current ice cover ranges only from 2.7% to 14.5%. Several large rivers have their sources in these mountains, notably the Ganges, Indus, Brahmaputra, Yarkand and Ili Rivers.

In addition to the regional climatic complexity, vegetation spreads over several floristic provinces providing additional complexity for a comprehensive overview (Grubov, 2010). Information on these region's floodplain ecosystems is scarce and consequently we focus on the rivers of the Tian Shan, where scientific studies have been undertaken (Betz, 2021; Kamelin, 1973).

One distinctive riparian vegetation type in Central Asia is the Tugai floodplain forest. It extends far beyond the mountainous regions and is centered in the continental, cold winter deserts. These floodplain forests stretch from the middle reaches of rivers in the mountains to the lower reaches of the major inland rivers in Uzbekistan, Kazakhstan, Tajikistan (Fig. 16) and Turkmenistan. Major rivers include the Amu Darya and Syr Darya in the Aral Sea Basin. Tugai forests also occur along the Chu and Ili Rivers in Kyrgyzstan and Kazakhstan. Tugai forests have also been described in the eastern Tian Shan region along the Tarim River as well as in the Gobi Desert of Western Mongolia (Schulz and Kleinschmit, 2019; Tesch and Thevs, 2020; Treshkin et al., 1998). The key species of Tugai forests along the middle and lower reaches of the rivers are *Populus pruinosa* and *P. euphratica* (Aishan et al., 2015; Thevs et al., 2008, 2012). In the 'early successional ecologic phase', these poplars occur in association with *Elaeagnus angustifolia*, *Tamarix ramosissima*, *T. hispida*, *T. elongate*, *Halostachys caspica*, *Halimodendron halodendron*, *Alhagi sparsifolia* and *Myricaria pulcherrima* (Aishan et al., 2015; Thevs et al., 2008; Treshkin et al., 1998). In some cases, *Salix songarica* and *S. wilhelmsiana* also occur (Rüger et al., 2005; Treshkin et al., 1998). However, these species and *Populus pruinosa* were severely disturbed due to anthropogenic impacts to the river regime (Halik et al., 2019; Rüger et al., 2005). In the frequently inundated zone closer to the river, the 'biogeomorphic phase' is composed of a mosaic of *Populus euphratica* shrubs, *Phragmites australis* and *Calamagrostis pseudophragmites* (Thevs et al., 2008).

Tugai forests dominated by *Populus euphratica* stretch along the lower reaches of the Central Asian rivers and differ significantly from the riparian forests along the upstream river reaches in the mountains. Betz (2021) has described the riparian plants along the Naryn River in Kyrgyzstan, a braided gravel-bed river along most of its course. For the 'pioneer phase', juvenile individuals of *Salix babylonica*, *Populus nigra*, *Tamarix chinensis* and *Hippophae rhamnoides* are typical (Betz, 2021).

Fig. 16 A braided river section of the Obikhingo River valley in Tajikistan. (Photo: N. Lashchinskiy).

The most frequent species of the 'biogeomorphic phase' are *Hippophae rhamnoides* (Fig. 17), *Salix babylonica* and *Populus nigra*. The last species becomes dominant in the 'early successional ecologic phase' (Fig. 18). In its understory, thickets of *Rosa* spp., *Berberis vulgaris, Elaeagnus angustifolia* and *Caragana spinosa* are accompanied by *Carex* spp., *Artemisia vulgaris* and *Phragmites australis*.

This species composition is consistent with the findings of Imanbardieva (2015), for floodplain vegetation along the At Bashe River, a tributary of the Naryn River. River terraces form the boundary of the floodplain forests along the Naryn River, whereas

Fig. 17 Sallow thorn (*Hippophae rhamnoides*) is a typical species in the pioneer and biogeomorphic phases along the Naryn River, Kyrgyzstan. (Photo: F. Betz).

Fig. 18 Poplar forest (*Populus nigra*) on the floodplain of the Naryn River, Kyrgyzstan. (Photo: F. Betz).

hardwood forests of the late-successional stage are unusual (Betz et al., 2020; Betz, 2021). The absence of late-successional forests is also characteristic for the Central Asian floodplains, where climatic conditions lead to a transition of the early successional woodlands directly into forest-steppe, steppe or desert forests (Pfadenhauer and Klötzli, 2014).

In the middle reaches of the Western Tian Shan and Pamir-Alay rivers, and especially in valleys open to the west, there are riparian forests composed of *Fraxinus* species in the tree layer or forest canopy and well-developed, species rich herbaceous layers providing the understory (Kamelin, 1973, 1990; Lashchinsky et al., 2019). The mild climate of these valleys preserves *Fraxinus* forests as late-successional stage vegetation (Fig. 19) and these forests could be considered as relicts of Paleogene subtropical floodplain forests (Kamelin, 1973).

Fig. 19 *Fraxinus* riparian forest in the western Tian Shan mountains. (Photo: N. Lashchinskiy).

In the upper reaches of Pamir, Tian Shan and Pamir-Alay regional rivers, riparian birch forests with *Betula tianschanica* and *B. procurva* are common on the floodplains (Kamelin, 1973; Safarov, 2003). *Salix fragilis* is another common woody species in the riparian forests of Central Asia (Pfadenhauer and Klötzli, 2014).

There are relatively few alien plant species in the riparian forests of Central Asia, with *Ailanthus altissima* as the most common invasive plant for the 'early successional ecologic phase' of riparian forests in the middle reaches of the Tian Shan rivers.

Alps, Europe

The Alps in Europe (no. 12) (Fig. 2) have a mean elevation of 840 m and their maximum peak of 4.810 m with Mont Blanc in France. The moderate to Mediterranean climate with a mean annual temperature of 7.4 °C, mean precipitation of 1.023 mm and only about 1.2% glaciation of the mountain range allows for the development of extensive vegetation cover over about two thirds of the Alps.

The early human influences on the alpine rivers through 19th century included bank stabilization and later increased hydraulic-engineering and river regulations enabled human land use and resulted in current population densities of almost 100 inhabitants/km^2. About one third of the alpine river catchments is covered by settlements or croplands and the largest rivers of the Alps include the Rhine, Sava, Inn, Drava, Rhône and Tagliamento Rivers (Fig. 20).

The most active channels of braided rivers in the European Alps are dominated by gravel bars without vegetation. Less frequently disturbed bars are sparsely vegetated with herbaceous plants and shrubs, often with only a few species.

Characteristic plant species restricted to braided river corridors in the 'pioneer phase' include *Calamagrostis pseudophragmites, Chondrilla chondrilloides, Epilobium fleischeri, E. dodonei, Scrophularia canina* and *Typha minima*. These are accompanied by common species from the surrounding vegetation (Egger et al., 2019a; Kalníková et al., 2021).

For the 'biogeomorphic phase', *Salix eleagnos* is often the most frequent species of river corridors in the Alps. Further characteristic species are *Salix purpurea*, *S. daphnoides*, *Myricaria germanica* (Fig. 21) and *Hippophae rhamnoides* subsp. *fluviatilis*.

Less disturbed but regularly inundated floodplain areas characterize the 'early successional ecologic phase' with riparian forests dominated by *Alnis incana*. These extend up to an altitude of about 1.400 m in the Eastern Alps and 1.900 m in the Western Alps. The lower limit is about 250 m a.s.l. in the Southern Alps (Italian Eastern Alps) and about 900 m a.s.l. in the French Western Alps. In lower altitudes of the Western Alps *A. incana* (Fig. 22) is replaced by *Populus nigra* and in the Mediterranean locations, and complemented by *Populus alba*. In the lower Alps and the alpine foreland, *Salix alba* often dominates the floodplain forests.

Common deciduous trees of the 'late successional ecologic phase' are *Quercus robur*, *Carpinus betulus*, *Ulmus laevis*, and *U. minor*. Today these forests have become rare due to the extensive human impacts on the river ecosystems since the 19th century. On dry

Fig. 20 The Tagliamento river in the Southern European Alps (Italy) is the longest and largest remaining unregulated braided river of the Alps. (Photo: B. Kaltenböck).

Fig. 21 *Myricaria germanica* is well adapted to the high morphodynamics that characterize braided rivers like at the Upper Isar in the Alps. (Photo: I. Becker).

Fig. 22 The grey alder (*Alnus incana*) floodplain forest is the most widespread woodland community along the rivers of the Alps. (Photo: G. Egger).

gravel bars that are no longer inundated, *Pinus sylvestris* forests can be found throughout the Alps. The riparian corridors of the montane to subalpine zones are often associated with *Alnus alnobetula* and in the late successional phase with *Picea abies*.

In the European Alps, a large number of invasive non-native species especially from North America and East Asia have spread along the corridors of the braided rivers. The introduced plants are especially frequent in floodplains where river dynamics have been altered by humans and/or in floodplains at lower and warmer elevations. Most invasive species can be found in the 'pioneer phase,' including *Ambrosia artemisiifolia*, *Bidens frondosa*, *Impatiens glandulifera*, *Oenothera biennis* agg. and *Xanthium strumarium*. In the shrub communities of the 'biogeomorphic phase', *Amorpha fruticosa*, *Buddleja davidii*, *Fallopia japonica* and *Solidago canadensis* are frequent. In the understory of floodplain forests of the 'early successional ecologic phase', *Solidago gigantea* often competes with the native species. In floodplain forests of the 'late successional ecologic phase' *Ailanthus altissima* and *Robinia pseudoacacia* are frequent throughout the Alps (Egger et al., 2019b; Müller and Okuda, 1998).

Wadis in the Mountain Ranges of the Middle East

A different kind of gravel-bed rivers occurs in the tropical climate present in this region. The rivers are located in the mountain ranges at the western and southern coastal regions of the Arabian Peninsula, named as the Al Hajar (no. 7), Asir (no. 22), Hadramaut (no. 95) and Hejaz Mountains (no. 102). The Ogo Mountains (no. 145) in Somalia at the Horn of Africa are also included in this type (Fig. 2). Deil and Al Gifri (1998) distinguish three major montane vegetation types for the Arabian Peninsula, the: (1) north-western Mediterranean vegetation type (majority of annual rainfall of 50–150 mm in winter and early spring), (2) south-western Afro-montane type (majority of 200–500 mm of rainfall in spring and to a lesser extent in summer) and (3) eastern Omano-Makranian type (150–300 mm of rainfall mostly in the winter and early spring, with an additional summer rainfall peak in some years). The regional mountains were not glaciated in the last glacial maximum and remain non-glaciated today.

Wadis (or the Arabic, 'Oued') are river beds in the Saharo-Arabian desert. Water flow can be seasonal as in sub-humid mountains with a rainy season, or after short, heavy rainfall, which is episodic or erratic with the arid climate. These river systems are accompanied by common, near-surface groundwater flow. Big wadis with large catchments can have permanent water channels along parts of their length, but no permanent river drains into the Red Sea or the Gulf of Oman. In broader river valleys with low gradients and nearly flat plain deserts, sudden but infrequent heavy rainfall causes flash floods (the Arabic, 'Sayl') and the erosion, re-deposition and accumulation of sediments. This leads to the formation of braided channel patterns of mixed gravels and sands.

Braided wadis concentrate in the transition zone from the mountains of the Musandam Peninsula to the foreland, and from the Southwest Arabian Escarpment to the Central Arabian Desert, the Rea Sea coastal plain ('Tihama'). For the latter area, a typical sequence of hydrological conditions including the riverbed gradient, frequency and intensity of water flow, groundwater level and characteristic riverine plant species is presented with the example of Wadi Mawr (Yemen; Fig. 23). It is an allochthonous wadi, with

Fig. 23 Wadi Mawr in the Basin of At Tur, Mountainous Tihama, Jemen. Gallery thickets with evergreen shrubs (*Tamarix nilotica*, *T. aphylla*, *Salvadora persica*) colonize the sandy terraces. Terraces in the foreground were cleared for millet cultivation. (Photo: U. Deil).

Fig. 24 The Wadi Labtah, Syria, with remnants of gallery forest with broadleaved species (*Combretum molle*, *Berchemia discolor*, Combretaceae) and raingreen umbrella-shaped trees (*Acacia johnwoodii*, *Tamarindus indica*, Fabaceae). (Photo: U. Deil).

water flow in the semi-arid Basin of At Tur and the arid coastal plain triggered by rainfall events in the sub-humid upper parts of the catchment area. The sequence starts in the higher Escarpment with riverine trees of the 'late successional ecologic phase' such as *Breonadia salicina*, *Ficus* spp. (*F. vasta*, *F. populifolia*, *F. sycomorus*, *F. cordata* ssp. *salicifolia*) and the palm, *Phoenix reclinata*. These are replaced in the lower Escarpment and Mountainous Tihama by the broad-leaved, freshwater phreatophytes of the 'early successional ecologic phase' such as *Combretum molle*, *Berchemia discolor* and *Trichilia emetica* (Fig. 24). Sandy riverside terraces are colonized and stabilized by the *Acacia ehrenbergiana-Jatropha curcas-Desmostachya bipinnata* community of the 'biogeomorphic phase'. The riverbeds in the arid coastal plain (Tihama) contribute to this phase and are colonized by salt-tolerant evergreen *Tamarix* shrubs (*Tamarix nilotica*, *T. aphylla*), *Salvadora persica*, the flash flood resistant tall bunchgrass, *Saccharum spontaneum*, and by the soft-wooded shrub, *Calotropis procera* (Fig. 25). Intermittently flooded low terraces along broad wadis and active channels with fine grained sediments are covered with a layer of creeping and rooting herbs of the 'pioneer phase', including *Bacopa monnieri*, *Eclipta alba*, *Fimbristylis* spp. and *Phyla nodiflora* (Deil and Müller-Hohenstein, 1985; Patzelt, 2015). A liana veil with *Cissus quadrangularis*, *Leptadenia arborea* and *Cocculus pendulus* may border the riverine thickets.

Relief, substrate texture (grain size), hydrology and morphodynamics (stream velocity) are the main differentiating factors across the wadis. The vegetation patterns, characteristic plant species and life forms of a small wadi with remnants of gallery forests are documented by transects and riverside catenae by Deil (1986), Deil and Al Gifri (1998) and Deil and Müller-Hohenstein (1985).

Common wadi species throughout the Arabian Peninsula are *Tamarix* shrubs (*T. nilotica* s. str., *T. senegalensis*, *T. mascatensis*, *T. aucheriana*, *T. aphylla*) and tall bunch grasses of the genus *Saccharum* (*S. spontaneum*, *S. kajkaiense*, *S. griffithii*, *S. ravennae*). Additionally, *Jatropha* species (*J. glauca*, *J. pelargoniifolia*) characterize alluvial plains in the frost-free tropical lowlands, *Rhazya stricta* is common in the wadis with extratropical climates of the Arabian Peninsula (Deil and Al Gifri, 1998). In less arid conditions, *Rhazya stricta* is replaced by *Nerium* species (*N. oleander*, *N. mascatense*). A *Saccharum griffithii-Nerium mascatense-Dyerophytum indicum*-community was described from United Arab Emirates (Deil and Müller-Hohenstein, 1996) and further wadi species on the Peninsula are *Retama raetam* in the northwest, *Pistacia atlantica* in the north, and the widely distributed phreatophytes, *Prosopis cineraria* and *Ziziphus spina-christi*.

Intermittent water flow through the braided river corridors from the sub-humid mountains to the arid coastal plains is used for agriculture by diverting flash floods into walled fields (Sayl irrigation). Alluvial groundwater is overexploited by pumping for irrigation and by plantations of the deep-rooting date palm (*Phoenix dactylifera*).

A noxious weed and aggressive invader of sandy terraces and irrigation runnels is *Imperata cylindrica*. This plant has wide native ranges from Africa to Asia but is non-native to the wadis of the Middle East.

Fig. 25 *Saccharum spontaneum* and *Calotropis procera* stabilizing fine sediments in Wadi al Kharid, in the Eastern Yemeni highlands. (Photo: U. Deil).

Southern Alps, New Zealand

The Southern Alps on the South Island of New Zealand (no. 191) (Fig. 2) are characterized by temperate rain forests in the west, partially glaciated summit regions (current ice cover 2.6% of mountain range) with extremely high precipitation of 3.000–4.000 mm/year or more in the central region, and progressively drier lowlands to the east. Here, a number of large, braided rivers such as the Rakaia, Rangitata and Waimakariri (Fig. 26), with riverbeds up to about 500 m wide, flow eastward from the Southern Alps.

Species of the genus *Raoulia* are the most frequent and characteristic plants in the 'pioneer phase' of the extensive braided river corridors. On dry gravel alluvia in the mountain valleys with moderate to high rainfall, the lichen species *Raoulia tenuicaulis, R. haastii, R. monroi, R. parkii* and *R. australis* are widespread. These are associated with *Epilobium* species such as *E. brunnescens, E. nummularifolium* subsp. *nerterioides, E. microphyllum, E. melanocaulon* and *E. glabellum* (Meurk and Williams, 1989; Wardle, 1991; Woolmore, 2011; Fig. 27). Additionally, there are common widespread grasses such as *Lachnagrostis lyallii* and *L. filiformis*, and along the subalpine and lower alpine gravel-bed rivers also *Rytidosperma setifolium* and *Poa novae-zelandiae* (Wardle, 1991).

The most widespread shrub of the sparsely vegetated 'biogeomorphic phase' is *Coprosma brunnea*. Further woody plants on stabilized alluvium include *Muehlenbeckia axillaris*, *Coprosma brunnea* and additionally *Helichrysum depressum*, *Carmichaelia nigricans*, *C. grandiflora, Discaria toumatou* and *Leptospermum scoparium*, along with the mosses, *Polytrichum juniperinum* and *Racomitrium* spp. (Wardle, 1991; Meurk and Williams, 1989; Müller et al., 2017).

In the western region of the South Island, there are still natural floodplain forests of the 'ecologic phase', as described by Miller (2004). The most common species in the canopy and sub-canopy of these 'late successional' communities are the conifers *Dacrycarpus dacrydioides, Dacrydium cupressinum, Prumnopitys ferruginea,* the evergreen tree *Leiospermum racemosum,* and *Nothofagus menziesii*, the most widely distributed beech taxon in New Zealand. In the upper shrub tier, the tree fern *Dicksonia squarrosa* is very common.

In contrast to the western slopes, the lowlands in the east had already been extensively cleared by the turn of the 20th century, and the natural riparian forests are highly fragmented.

Under natural conditions, the flora of New Zealand is characterized by about 80% endemic species (McGlone et al., 2001). Today, many river corridors are dominated by alien species, with abundances of up to 60% (Williams and Wiser, 2004). While the headwaters still tend to be dominated by native species, the lower river reaches are often dominated by alien, non-native plants (Woolmore, 2011). Additionally, alien species cover is higher in rivers with higher maximum flows, especially in areas with fine substrate textures and on higher terraces along the rivers (Brummer et al., 2016). Frequently, invasive non-native species from the

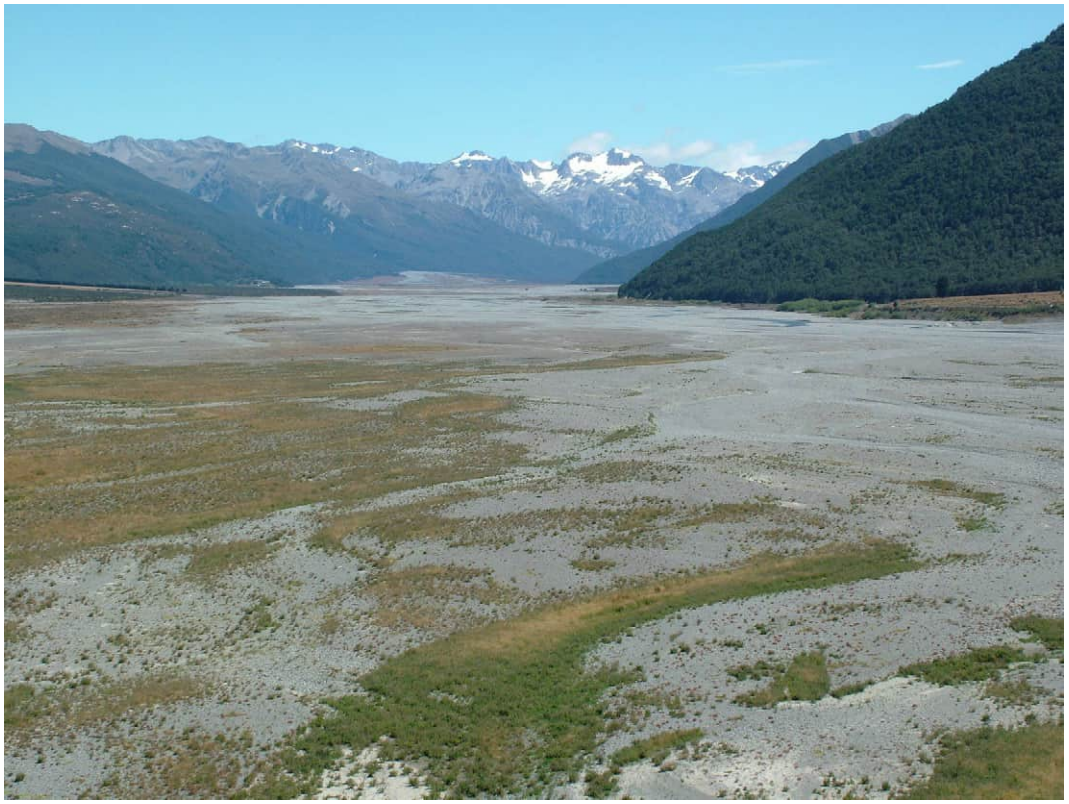

Fig. 26 The upper reach of the Waimakariri River near Arthur pass is typical of the braided rivers in the Southern Alps of New Zealand. (Photo: N. Müller).

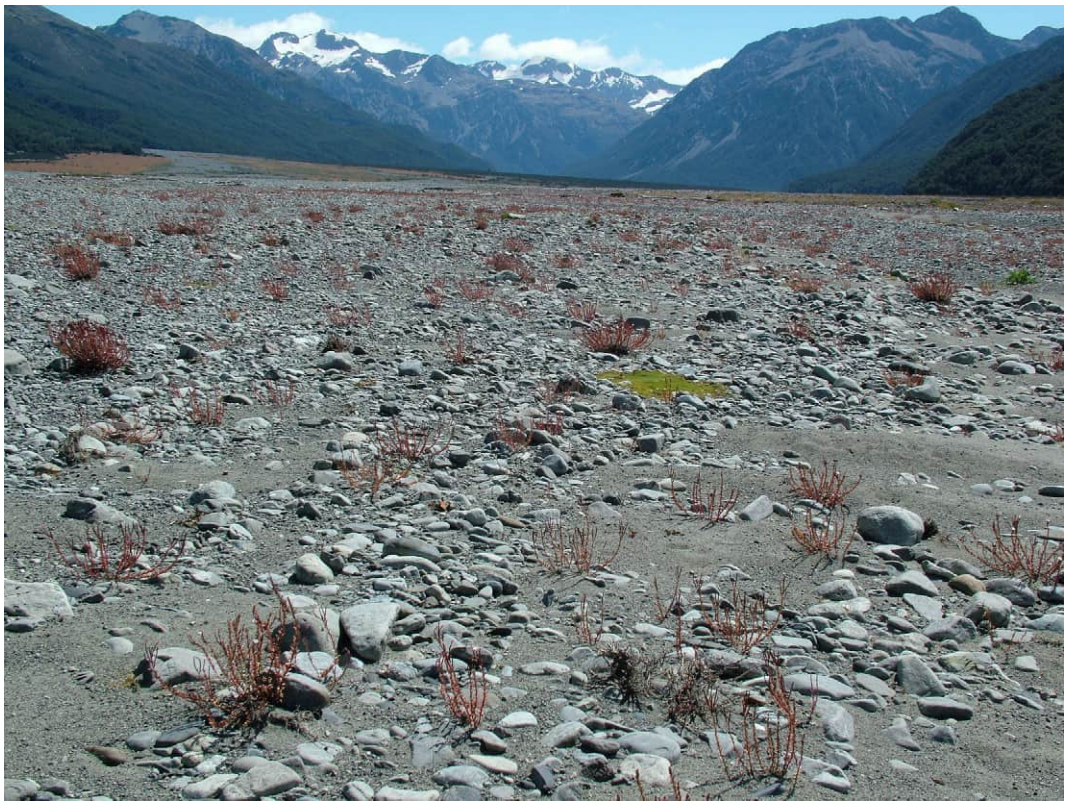

Fig. 27 In the headwater and upper reaches of rivers from the Southern Alps of New Zealand, native and endemic species (here, *Epilobium melanocaulon*) are typical for the pioneer phase. (Photo: N. Müller).

Fig. 28 Along the lower reaches of some New Zealand rivers, invasive non-native species (here *Cytisus scoparius* and *Lupinus polyphyllus* flowering) are dominating from the pioneer to the early successional ecologic phase. (Photo: N. Müller).

'pioneer phase' to the 'early successional ecologic phase' include the European grasses, *Agrostis capillaris*, *A. stolonifera*, *Anthoxanthum odoratum*, *Holcus lanatus*, *Festuca rubra* and *Dactylis glomerata*, the European herbs, *Crepis capillaris*, *Hypochaeris radicata*, *Lotus corniculatus*, *Plantago lanceolata*, *Trifolium repens*, *T. arvense*, *Rumex acetosella*, and *Sedum acre*, and the North American forbs, *Lupinus arboreus* and *L. polyphyllus* (Fig. 28). Widespread invasive shrubs include *Cytisus scoparius*, *Rosa rubiginosa*, *Salix* x *fragilis*, and *Ulex europaeus*—all originating from Europe (Müller et al., 2017; Williams and Wiser, 2004; Woolmore, 2011).

Southern Andes, Patagonia

The Andes in South America are considered as the Patagonian Andes (no. 228) (Fig. 2) south of Rio Bio Bio in Chile and Rio Colorado in Argentina. By moving from North to the South, climate changes from moderate to boreal arctic. Further, the Andes act as barrier for precipitation originating from the Pacific Ocean and consequently the Argentinean regions are much drier than those in Chile (Fig. 29). The tree line in the south is very low at about 400 to 600 m a.s.l., and rises in the north to about 1.000 to 1.700 m. Currently, glaciers cover almost 11% of the mountain range and in the last glacial maximum almost 75% was glaciated. The largest rivers are the Colorado, Negro, Chubut and Santa Cruz Rivers.

In Patagonia, the riparian zones are characterized by relatively low plant species richness as well as many other Patagonian ecosystems (Kellman, 1970). This is likely a result of the glaciation history (Mendelova et al., 2017), isolated location and restricted landmass of the Southern hemisphere, which limited colonization from other regions. The few specialized species of the floodplains (Lewerentz et al., 2019) are also distributed in areas with frequent and intense disturbance regimes like landslides and volcanic lahars. These areas of huge sediment loads are common in the vicinity of areas with volcanic activity (Iroumé et al., 2020) or glacial lake outburst floods (Ulloa et al., 2020).

The open gravel and sand bars provide the 'pioneer phase' of the gravel-bed rivers of Patagonia and are characterized by native pioneer plants such as *Agrostis inconspicua*, *Juncus scheuchzerioides*, *Gunnera magellanica* and *Acaena magellanica*, as well as non-native species such as *Plantago lanceolata*, *Prunella vulgaris*, *Trifolium repens*, *Holcus lanatus*, *Hypochaeris radicata* and *Agrostis stolonifera* (Fig. 30). In addition, there are native shrubs such as *Gaultheria mucronata*, *Berberis microphylla* and *Discaria chacaye*, while *Baccharis obovata* may be the most abundant. These species establish sporadic stands in the highly disturbed 'pioneer phase' along the active channel and form patchy to closed shrub layers in the later 'bio-geomorphological phase'. The taller native shrubs, *Escalonia virgata*, *Fuchsia magellanica* and *Berberis empetrifolia* and the non-native evergreen bamboo *Chusquea culeou*, are typical for the 'early

Fig. 29 The catchment area of the Rio Blanco is mainly located in the Parque Pumalín nature reserve near Chaitén, Chile and is characterized by an extensive and largely natural forest landscape. (Photo: G. Egger).

Fig. 30 Pioneer phase with buzzy burr (*Acaena magellanica*) at Rio de los Ñadis, Chile. (Photo: G. Egger).

successional ecologic phase' of the regional riparian forests (Harmel, 2020). The only willow species of the natural flora is *Salix humboldtiana*, which occurs sporadically in the floodplains of northern part of Patagonia (southern limit 38^{0} S).

In general, in the 'ecologic phase' for these riparian communities the shrubs display higher species diversity while there are fewer tree species. The trees are commonly represented by the deciduous *Nothofagus antarctica* in the south and evergreen *Nothofagus dombeyi* in the north and/or rainier climate zones. While *N. antarctica* stands are rare, these do occur both as early successional stands on open gravel bars and as mature forests in the inactive floodplain zones. Evergreen tree species usually predominate in the 'late successional ecologic phase' of the riparian forests. They are often associated with further characteristic trees of Valdivian temperate rain forests, including *Luma apiculata and Podocarpus nubigenus,* and of deciduous forests of the temperate zone in Chile, such as

Fig. 31 Species-rich floodplain forest (late successional ecologic phase) along the River Palena, Chile. (Photo: G. Egger).

Nothofagus pumilio, *N. betuloides*, *Pilgerodendron uviferum* (Gut, 2008; Vidal et al., 2011) and occasionally, *Amomyrtus luma* and *Embothrium coccineum* (Harmel, 2020) (Fig. 31). In contrast to the pioneer woody plants from the genera *Salix* and *Populus*, these species hardly germinate on the open gravel and sandy areas of the active channel, but establish on morphologically more stable substrates of the biogeomorphic and ecologic succession stages (Lewerentz et al., 2019).

Perhaps the most noteworthy aspect of Patagonian floodplains and riparian zones is the high abundance and sometimes complete dominance by alien plant species. Besides a potential vacant ecologic niche due to the lack of fast-growing early successional woody species and woodland phase, the invasion is facilitated by river regulation, road construction, a legacy of landscape scale wildfires, and clearing by logging and ranching activities. In this context, it is important to recognize the massive spread of the North American *Lupinus polyphyllus* in the 'pioneer phase' (Meier et al., 2013) and the European *S. fragilis* in the 'biogeomorphic' and 'early successional ecologic phase' (Harmel, 2020; Lewerentz et al., 2019; Fig. 32). In addition, a variety of alien woody species are common, including *Elaeagnus angustifolia*, *Rosa rubiginosa*, and *Cytisus scoparius* (Weber, 2017).

Conclusion and synthesis

The species composition of the riparian vegetation of gravel-bed rivers is differentiated according to the global floral regions. Thus, the global research indicates that only a few naturally occurring species or even only a few genera are more common at several reference mountain regions (see Table 1).

The majority of the investigated mountain regions with a high proportion of braided rivers are located in the boreal zone of the Northern Hemisphere such as the investigated mountain ranges of Alaskan Taiga, the Canadian Rocky Mountains, and the northeast Siberian Mountain ranges of the Russian Taiga (Maier et al., 2022). These boreal to sub-Arctic regions share common characteristics in climate and vegetation. Thus, the biogeomorphic phase is similarly occupied by a number of widespread, floodplain-typical ecologic pioneer tree and shrub species of the related genera *Salix* and *Populus* (Karrenberg et al., 2002). Further, native representatives of the genera *Myricaria* (Alps, Central Asia) and *Tamarix* (Central Asia) are also typical for the northern hemisphere. These species are characterized by prolific production of small, light seeds that are dispersed over wide areas by wind and water, the processes of anemochory and hydrochory, respectively. The obligate or facultative riparian plants also often display effective vegetative or clonal reproduction through root suckers or stump shoots. With typically vigorous growth, these ecological specialists are well adapted to the strong hydro-morphodynamics of the gravel-bed rivers.

Poplars (*Populus* spp.), willows (*Salix* spp.) and tamarisks (*Myricaria* spp., *Tamarix* spp.) are naturally absent along the braided river corridors of the Southern Hemisphere, where there are fewer woody pioneer species restricted to the riparian ecosystems or floodplain zones (Meier et al., 2013). This results in open niches that are available for colonization by the introduced Northern Hemisphere pioneer shrubs and trees, especially along the lower reaches of gravel-bed river corridors where agricultural and urban areas are increasing. This has resulted in severe invasions and serious alterations to the native biodiversity, as documented for the braided river corridors of the Southern Andes in Patagonia and for the Southern Alps in New Zealand (Budde et al., 2011; Caruso et al., 2013; Lewerentz et al., 2019; Harmel, 2020).

In contrast to the braided river corridors of the temperate zones, the Alps, Southern Andes and Rocky Mountains, the dominant tree species in established forests of the late successional ecologic phase differ in the Arctic zones, the Alaskan and Russian Taiga. In the Arctic taiga, conifers (*Picea* in North America or *Larix* in Eastern Russia/Siberia) that are adapted to the long, very cold winter months and very short vegetation period dominate the late successional ecologic phase. In contrast, in the temperate zones, flood-tolerant deciduous trees prevail, often from the genera *Quercus, Ulmus* or *Fraxinus* (Pfadenhauer and Klötzli, 2014).

An unusual case of the Arctic boreal zone is displayed with the very young riparian ecosystems of the glacier forelands of the Arctic tundra below the extensively glaciated mountains of Vatnjajökull (Iceland). Iceland was almost completely covered by ice during the last ice age (Hallsdóttir, 1995) and today there are very few endemic plant species. This is explained by a continuous long-distance influx of seeds and clonal vegetative fragments by ocean currents, winds or birds following the Holocene and even earlier (Rundgren and Ingólfsson, 1999). At present, most of the glacier forelands of the Arctic tundra are covered by young successional stages. Also, there are no native conifer trees in Iceland, which contrasts with comparable climatic areas within the boreal zones in Alaska, Canada and Russia. These trees of the late successional phase did not survive the ice ages in Iceland, and due to the isolated island location have not immigrated until recently (Hallsdóttir, 1995).

The continental floodplains of the inland rivers in Central Asia contrast to the riparian forests of the boreal and Arctic zones. In Central Asia, the early successional riparian forests of the ecologic phase tend to develop within a narrow corridor along the river channels and are often threatened by anthropogenic activities. Closed canopy, late successional riparian forests are mostly absent due to the arid climate.

The wadis of the Middle East represent very distinctive gravel-bed river corridors. Accompanying the hot and dry climates, the active channels are often intermittent and are predominantly characterized by sparse phreatophytic floodplain vegetation such as *Nerium* spp. and *Rhazya stricta* along with a number of species of the genus *Tamarix*.

It is notable that almost no endemic species occur in the river corridors of the reference regions in the Northern Hemisphere. The reason for this may be that the reference regions with a high proportion of braided rivers are mainly found in young (tectonic uplift) mountains and in most cases were covered by glaciers during the last glacial maximum. As a consequence, the time was too short and the environmental conditions too variable for the development of endemic species over the recent geological eras.

In contrast, the braided river corridors of the Southern Alps in New Zealand show a different pattern, with a flora dominated by endemic species in all succession phases. Most of those characteristic endemic species are woody plants, as reported by McGlone et al. (2001). These patterns originate in the long history of geographical and evolutionary isolation (McGlone et al., 2001).

Due to the biogeographic isolation by the surrounding oceans and the dry steppe to desert ecoregions in the east and north, the region of the Patagonian Andes is also characterized by a high proportion of endemic species (Rozzi et al., 2012). The endemic, riparian *Nothofagus* species also form the world's southernmost forests (Rozzi et al., 2012).

In addition to these riparian patterns, as revealed in Table 1, the majority of the selected characteristic plant species are not limited to floodplains, but are also present in adjacent, upland ecosystems. The plants are well-adapted to the local temperature regimes and display plant adaptations to the dynamic site conditions along the braided channels of the gravel-bed rivers. These life history requirements and ecophysiological adaptations also allow establishment in other regional sites with similar physical characteristics, such as with the rocky and stony habitats in the mountain regions, or in other disturbance-prone locations such as avalanche paths (Williams and Wiser, 2004).

Glossary

Aquatic An aquatic organism lives in the water. If it is semi-aquatic or amphibious it can tolerate both a terrestrial and aquatic environment and inhabits the water only partially (Fig. 1).

Ecosystem services This term comprises different kinds of direct or indirect benefits people obtain from ecosystems such as provisioning services (e.g., natural resources, energy production), regulating services (e.g., climate, hydrology, erosion), supporting services (e.g., nutrient and biogeochemical cycles, soil formation, habitat provision) and cultural services (e.g., heritage, education, science, ecotourism).

Hydrophytes Plants which have vegetative parts submerged or floating at the water surface, but not emerging into the air, and which survive unfavorable seasons as submerged buds attached to the parent plant or lying free on the substrate. This excludes emergent herbaceous plants and woody species.

Macrophytes Aquatic macrophytes are plants that grow in water, in soil covered by water, or in soil that is usually saturated with water.

Neophytes Non-native plant species which has been introduced in recent history to a geographical region.
Sessile A sessile organism cannot move, it is permanently attached to a solid surface, such as the soil.
Submergence Complete submergence means that the whole plant is below the water line. Totally submerged plants have no direct contact with atmospheric oxygen, and sunlight is weak or extinguished.
Terrestrial A terrestrial organism lives only on land and not in water.
Waterlogging When the soil and root system is filled with water, plants are waterlogged. They may even have a part of their stems or crowns submerged, but much of the shoot remains above the water line. This way, the transpiring organs—the leaves—still have direct contact with atmospheric oxygen and sunlight.
Wetland Wetlands occur at the interface between aquatic and terrestrial environments and may be continental or coastal, natural or artificial, permanently or periodically inundated by shallow water or consist of waterlogged soils. Their waters may be fresh, or highly or mildly saline. Wetlands are home to specific plant and animal communities adapted to their hydrological dynamics.

Introduction

Inland waters are colonized by all sorts of plants which occur in all regions of the globe, from the hottest desert oases with temperatures that can reach 58 °C, to the coldest regions like parts of Antarctica without ice (Sculthorpe, 1985). They grow below or

Fig. 1 The strong roots of a tree that grows on solid rock in the middle of a small river bed (Brague river, Southern France; photo © Pia Parolin).

Fig. 2 Temperate riverside forest (Brague river, Southern France; photo © Pia Parolin).

above the water surface, may have roots in the submerged ground or may float, ranging from minuscular algae to huge trees (Fig. 2). Some wetland plants are specialized in life between a flooded and a dry period, others live constantly in the water.

All life forms, from small buoying macrophytes over long herbs, endless vines to huge woody stems can be found. They all have in common that, from a terrestrial life, the evolution led to adaptations for life in an aquatic environment with high tolerance to flooding or even submergence.

The aim of this chapter is to give an overview of what life of wetland plants is all about, show an overview of their most important adaptations and ecology and indicate which are critical constraints they face.

What is a wetland plant?

Wetland plants occur in or near lakes or rivers. Here, we deal with freshwater environments, and with plants which are flooded for some hours or days or even weeks and months. Some can cope with prolonged waterlogging over several years, and some can even withstand total submergence for several weeks. Others are totally dependent on a submerged life, but here we focus on those that grow at the interface between water and air and must cope with a flooded and a dry period. Algae, mosses and lichens have a huge diversity in wetlands, but our focus is on flowering plants which are highly evolved, i.e., grasses, shrubs, trees and vines.

There is a gradual transition from terrestrial to aquatic conditions and it is impossible to establish sharp distinctions between swamp-forests and forests on dry land. It is a continuum, with boundary zones at the limit between marshes and terrestrial habitats. Depending on flooding depth, plants may be floating or growing in soil which is covered by water. As a result of excessive water content of the soil, they are subjected to periodic deficiencies in oxygen supply to their roots.

Higher aquatic plants are basically terrestrial organisms which evolved back to a life in water. Some can merely withstand a flash flood; others maintain an active physiological rhythm despite the constraints that flooding brings. Their differing tolerance to water in the root zone is linked to specialized morphological structures and all kinds of adaptations which allow them to cope with flooding. Without specific adaptations, higher plants cannot grow in wetlands.

Flooding constraints

Flood effects have manifold implications for sessile organisms such as plants.

(a) High mechanical stress: the dynamics, current and erosion of the river system cause mechanical damage to plants and can inhibit the establishment of seedlings.
(b) Inhibition of gas exchange and photosynthesis due to water and hypoxia. Gas is less present in water than in air. The diffusion coefficient of oxygen in the water is much lower than in the atmosphere. Therefore, as soon as water covers the soil, hypoxic conditions appear in the rhizosphere. Decomposition and high sedimentation rates further increase the lack of oxygen for the roots, which in order to function properly, need gas exchange and the presence of oxygen for respiration.
(c) Soil flooding lowers the redox potential and leads to the formation of trace gases (N_2O and CH_4) as well as to the formation of phytotoxic compounds (Mn^{+2}, Fe^{+2}, H_2S). Increased solubility of mineral substances and drastic changes in nutrient bioavailability are linked to flooding and may cause problems for plant ecophysiology.
(d) High sedimentation rates in rivers cause mud layers on leaf surfaces and impair leaf photosynthesis under water by turbidity and deposition of sediment layers on leaf surfaces. Sedimentation may also bury roots near the soil surface (Wittmann and Parolin, 2005).
(e) Changes in water levels may occur very fast and do not leave time to adapt with a quick physiological or anatomical response.
(f) Not enough, in the low water period drought may severely affect plants which are highly specialized to withstand exceeding water quantities. Drought causes particularly heavy stress for wetland plants.

Waterlogging vs. submergence

The level of flooding matters: for plants it makes a huge difference whether the whole plant is submerged and no gas exchange is possible at all, or whether parts of the roots and stem are waterlogged but the leaves are at least partly above the water surface (Fig. 3). Flooding height therefore has a key role and determines the species composition along a flooding gradient.

Another key factor is the predictability of flooding. If flooding occurs at a regular and thus predictable rhythm, a bit like a cold winter season in the temperate regions, then the plants can develop specific adaptations which allow them to survive the flooded period.

As an example, in Central Amazonia the river levels rise as much as 9 m where forests grow. This has an extreme impact on all organisms living there. But since the periodicity is strictly rhythmic and repeated—we speak of a monomodal flood pulse—every year at the same time (Junk et al., 1989), flooding does not kill the plants but enhances the development of diversity and species richness. Slight differences in height and duration of floods occur in different years, but—at least prior to climate change (Barichivich et al., 2018)—the living conditions are regular and predictable. Floods and droughts still occur in the time of the year, but due to global climate change, the amplitude of the flood pulse changed, mainly due to the increasing frequency and magnitude of severe flood events.

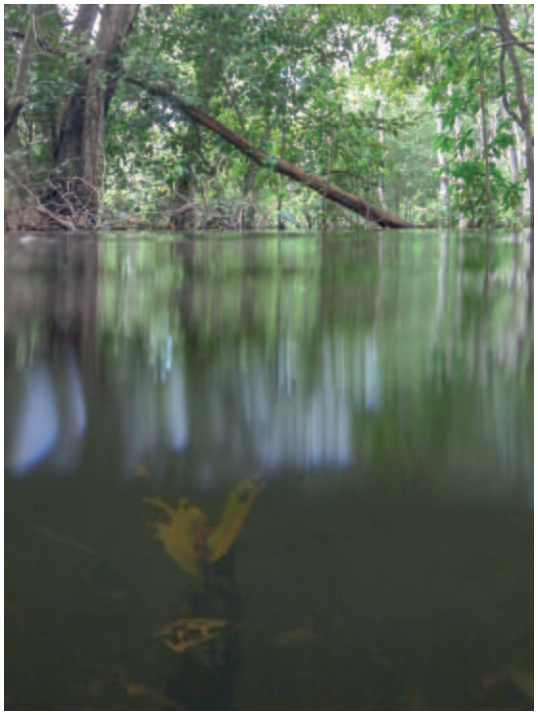

Fig. 3 Floodplain forest (Pantanal near Cuiabá, Brazil; photo © Pia Parolin).

In contrast, in temperate European floodplains such as those of the river Rhine, the periods of high water and flooding are short and unpredictable, which makes them much more difficult to withstand. Even so, trees that may survive flooded periods of up to 300 days per year, such as *Salix alba*, do also occur here.

Central Amazonia has some of the most extreme flooding conditions for plants and yet the floodplains are colonized by highly diverse forests (Fig. 4). Under these extreme conditions the natural limit for tree growth is where the annual flooding does not

Fig. 4 Central Amazonian black water floodplain forest near the Anavilhanas archipelago, Brazil (photo © Pia Parolin).

exceed 8 m of height. In the vicinity of Manaus, this corresponds to a flooded or submerged period of 300 days per year. The regularity of the flood pulse and mostly absence of salt and fires there allow for a highly diverse ecosystem. However, during extremely low water levels and dry periods, fire becomes an important problem for plant establishment and growth.

Tropical or temperate, does it make a difference?

The timing of flooding plays a crucial role. If a plant is dormant and without leaves, e.g., in a temperate winter, flooding of the roots is not deleterious to the whole plant. Physiological activities are downregulated.

However, if flooding occurs in a period when the plants grow—in a temperate summer, or in a tropical environment with high temperatures all year round, then flooding poses serious constraints.

Therefore, even in tropical environments trees may interrupt or lower their metabolism to survive with a decreased growth rate. The unfavorable growth conditions with inhibited water and nutrient absorption are tolerated until the plant takes on growing again, which is possible due to specific adaptations. In environments with a periodical regular flooding, trees may therefore form clear annual growth rings, superficially similar to those we find in temperate trees.

Concepts and their meaning for plant life

Flood pulse concept

The flood pulse concept (FPC; Junk et al., 1989) states that the regular alternation between a flooded and a non-flooded period is the driving force in a floodplain system. Where the periodic inundation and the dry phase occur at predictable intervals and alternate in foreseeable patterns, the plants and animals are able to adapt and follow the all-determining hydric rhythm. This concept is an integrative approach for studying highly diverse and complex ecological processes in floodplains.

Intermediate disturbance hypothesis

The "intermediate disturbance hypothesis" (Connell, 1978) states that disturbance may be a driving force for diversity. If we consider the high dynamics of an inland water system and flooding as a disturbance, in many ecosystems this disturbance will be an intermediate force which increases habitat diversity by erosion and sedimentation, or simply due to hydraulic stress. Flooding with freshwater represents a stressor which imposes only a low level of restrictions on the life of plants. This way, these forces lead to higher plant diversity.

The point of non-return hypothesis

The "point of non-return hypothesis" (Wittmann et al., 2010) states that part of the species adapted to the flood pulse may result from ecotypes originating from the pool of upland species associated with small streams, which gradually develop adaptations along the drainage systems. This allows them to tolerate gradually higher, prolonged, and predictable floods, as they migrate from small bodies of water to the large rivers. Finally, they acquire adaptations that no longer allow them to compete and colonize environments without large flood pulses. This hypothesis is valid for tropical regions with longstanding stable hydrological conditions, such as the Amazon, where plants adapted to regular flood pulses over evolutionary time scales.

Classification

All major groups of plants are represented in wetlands. They belong to families which are exclusively aquatic or to families with aquatic, palustric and/or terrestrial representatives (Junk, 2021).

Several classification systems exist for higher plants growing in wetlands. Here, we present one that Brazilian scientists elaborated for large floodplains. It splits the higher plants growing in wetlands into plants which grow in permanently terrestrial macrohabitats and into hydrophytes (according to the definition of wetland delimitation, Junk et al., 2014).

Those growing in permanently terrestrial environments include herbaceous and woody plants without specific adaptations to wet conditions which would harm them. Hydrophytes on the other hand are truly adapted and range from herbaceous free-floating or rooted species to woody species (Fig. 5).

Some herbaceous hydrophytes grow mainly during the aquatic phase (aquatic macrophytes *sensu strictu*), whereas others grow during the terrestrial phase. Among the former, the aquatic macrophytes *sensu strictu*, there are rooted herbaceous plants which can be emergent (e.g., *Typha, Echinochloa, Cyperus*), have floating leaves (e.g., *Nymphaea, Victoria*) or be submersed (e.g., *Utricularia foliosa, Cabomba*) (Figs. 6 and 7).

Free floating plants also include species which are almost fully emergent (e.g., *Eichhornia azurea*—Fig. 8, *Pistia stratiotes*) or where only the leaves float on the surface (e.g., *Lemna, Spirodela, Azolla, Limnobium*) or which are fully submersed (e.g., *Ceratophyllum, Wolffiella*).

Finally, woody plants are categorized depending on the influence of the flooding water (Fig. 9). Some can grow where the soils are permanently saturated with water or covered by a sheet of shallow water. Others grow in areas subjected to frequent predictable flood pulses of short duration. And yet others, namely riparian forests, grow in areas subjected to frequent unpredictable flood pulses of short duration or to predictable flood pulses of long duration. Interestingly, the absence of woody species in some habitats of savanna floodplains is not because of excess of water but because of drought stress during the dry period.

Ecology

Adaptations

Plant life is not possible without adaptations to the specific constraints imposed by waterlogging and submergence (Hook, 1984). The adaptations are manifold, and different plant species may have evolved different amounts and combinations of responses (Goncalves et al., 2021; Householder et al., 2021). Many responses may have developed several times in certain orders, families, or genera. These enable them to colonize specific habitats within the wetlands, with more or less flooding durations and height.

Specific adaptations at the leaf level include anatomical and morphological structures which allow the leaves to perform photosynthetic activity. Xeromorphic leaves which are thicker than usual are an adaptation against lack of water. This is caused by the inhibited root function. Even if a plant is standing in the water, it can suffer from a shortage of water because the roots are less functional. Where flooding is very intense, plants may respond with leaf shedding and a reduction of their metabolism. Others are able to maintain their leaves below water for many weeks (Fig. 10).

At the stem level, typical adaptations include periodical growth reductions of stem increment, stem water storage, internal oxygen transport and pressure ventilation. Adventitious roots and hypertrophied lenticels are morpho-anatomical structures which are mainly formed by the stem.

The roots are adapted in that they can form lysigenous and shizogenous aerenchyma and produce increased intercellular spaces for gas diffusion. Suberization is frequently encountered as well as structures promoting the diffusion of oxygen and anaerobic metabolism. Roots are also able to switch to anaerobic metabolism (Fig. 11).

Water is an important means of dispersal in wetlands (Van der Pijl, 1982). Therefore, in many wetland species the peak of fruiting occurs at high water (Fig. 12). This way, the fruits or seeds drop into the water and are dispersed by hydrochory (Van der Pijl, 1982) or by fish (Goulding, 1983; Horn et al., 2011).

While in the majority of land plants seeds lose their viability if submerged, in wetlands many fruits and seeds float or sink and remain viable (Sculthorpe, 1985). Whether they float or sink, in general they do not germinate until the flood recedes and the conditions are favorable for seedling growth.

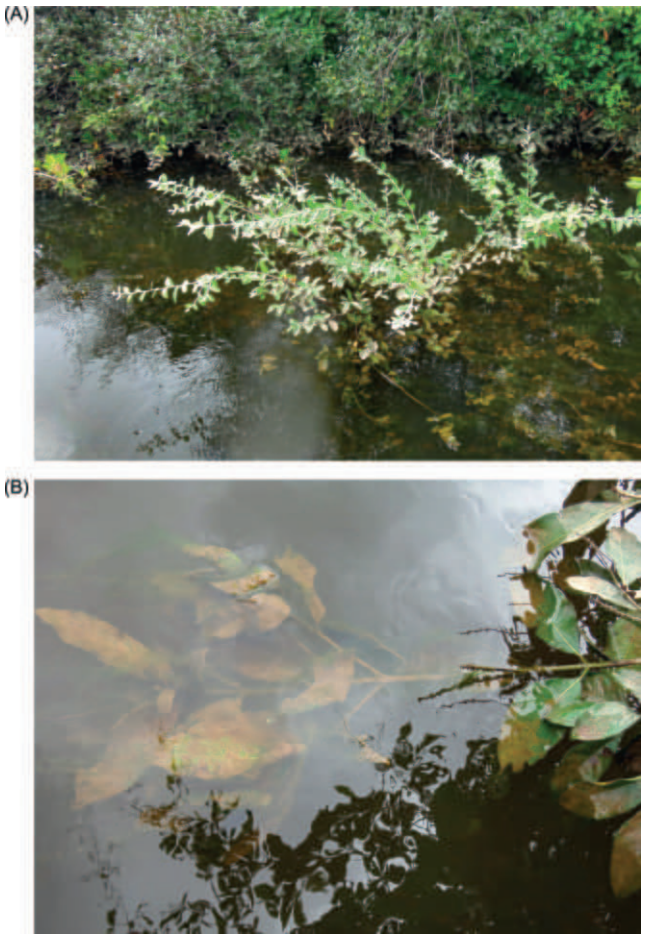

Fig. 10 Waterlogged shrubs (left) with submerged leaves (right) (Pantanal near Cuiabá, Brazil; photos © Pia Parolin).

Fig. 11 Aerial roots—pneumatophores—of the palm tree *Mauritia flexuosa* (Amazon river near Belém, Brazil; photo © Pia Parolin).

Fig. 12 Waterlogged tree flowering at high water, in the Amazon floodplains (photo © Pia Parolin).

As an example, in the swamps of the southern United States trees like *Taxodium distichum*, *Nyssa aquatica*, and *Nyssa sylvatica* do not germinate under water. The natural regeneration is limited to dry periods, when the soil surface is exposed (Hook, 1984). A fine-tuned mechanism of dormancy enables the diaspores to start germinating immediately after the retreat of the flood. As long as the seeds are in the water, they remain dormant and viable. Especially where the dry phase is very short, rapid and exactly timed seed germination is essential for the establishment and survival of the seedlings.

The diaspores—the units of dispersal of a plant—have adaptations to improve floatation, e.g., spongy tissues and air-filled spaces. Once the flooded period is over, germination starts. In a few cases, seeds may initiate germination while still floating. The emergence of a radicle was observed in the seeds of several tree species from Amazonia (Fig. 13). This is seen as a strategy to gain competitive advantages and may have ecological significance in specific environments (DuBarry, 1963; Oliveira-Wittmann et al., 2007).

The newly established seedlings will soon be exposed to the next flooded period. Therefore, in wetlands the species are highly adapted also in terms of tolerance of submergence and dormancy of the very young plants. They are too small to maintain a part of their stem and leaves above the water surface. But they will not succumb to submergence and withstand exceeding water levels (Fig. 14).

The combination of adaptations results in well-diversified species pools. Different tolerances to flooding result from specific structures of roots, stems and leaves. This leads to species-specific distributions and to zonations along the flood gradient (Fig. 15).

On the high levels in the flooding gradient, many adaptations are directed towards "escaping" submersion (Parolin, 2002). Since the water levels usually do not cover the whole plant, the responses are targeted towards obtaining oxygen and gas exchange. An increased stem and twig growth can be observed in the seedlings of many species. This rapid growth enables the protrusion of leaves above the water surface (Parolin, 2009).

Fig. 13 Seeds which germinated while floating on the Amazon river (near Belém, Brazil; photos © Pia Parolin).

Fig. 14 Sapling growing on a low level in the floodplain: when the water rises, it will most likely be fully submerged. This small plant can be several years old, it withstands prolonged submergence (photo © Pia Parolin).

Fig. 15 Natural distribution and zonation of plants in a forested wetland with rooted and floating macrophytes and grasses, a woody pioneer vegetation belt and the floodplain forest adjacent to upland forest (photo © Pia Parolin).

On very low levels in the flooding gradient, where a regularly recurring water column will be too high for this strategy, adaptations are more directed towards "tolerating" submersion. This includes that many species will lower their metabolism, have starch reserves and some are postulated to have photosynthetic activity under water.

Diversity

Despite the big changes of hydric conditions, a high diversity of species, life forms, adaptations are typical for plants in inland waters. The high diversity may be explained by several factors. Apparently, the stressors like flooding, submergence or drought only have a limited negative influence on plant growth. Favorable factors like stable temperature, light, water, nutrient supply, especially in tropical environments, and a high predictability of the flooded period enhance the evolution of adaptations.

Among the wetland plants there are specialists and generalists. In Amazonia, *Eschweilera tenuifolia* is an example for a specialist tree, extremely flooding tolerant and growing only on the lowest positions in the flooding gradient. It tolerates several years of uninterrupted waterlogging and is so specialized that it does not grow on other sites. On the other hand, the Kapok tree (*Ceiba pentandra*) is a generalist which occurs on the whole flooding gradient and also on the non-flooded uplands, and even on different continents.

One reason for the high diversity of species in Amazonia is the high age of the system. Changes of paleoclimatic conditions also caused changes of the vegetation (Prance, 1973; Ab'Saber, 1982; Haffer and Prance, 2001), but in Amazonia the river beds and their floodplains were always present and thus Amazonian floodplains are probably very old systems (Irion et al., 1997; Colinvaux et al., 2001) which may have represented refuges for the plants during drier periods, such as the ice-ages.

Interactions

Ecology is all about interactions. In wetlands, all the interactions that occur in uplands are also present, but additionally, the hydric element is present in a specific and dominant way. Food webs include plants and animals that live in the water, and which interact in very specific and close relationships. Animals feed along the edges of the water, or inside the wetlands, and they migrate between uplands and floodplains (Fig. 16). This way, there is connectivity of nutrients and species between uplands and wetlands. Overall, inland waters can be considered as highly complex and intertwined ecosystems.

Many fish species and aquatic mammals, birds and amphibians, need the plants for their development. Several animals reproduce in the dense stands of aquatic macrophytes or in trees of the flooded forests. These are the nurseries for the next generation, they provide shelter and food.

Also, the people who settle on the river or lake margins take profit of the sediment inputs and the nutritional values provided by the flooded ecosystems. The wetlands are therefore of fundamental importance for the local human river populations.

Utility of wetland plants

Plants of inland waters provide ecosystem services for the whole biological system and the human population. They provide all the services which plants as the main producers in the food chains supply, i.e., related to gas exchange and water cycles, cleaning the air and filtering, regulating diseases, pests, and climate. However, plants in inland waters have additional tasks which they naturally fulfil.

Fig. 16 Capuchin monkey feeding in the Amazon floodplains at high water (photo © Pia Parolin).

Sediment retention

Plants may be very efficient for sediment retention and thus enhance the natural nutrient input provided by the floods (Fig. 17). This way, biogeochemical cycles and food chains are strongly influenced by the plants which grow in the inland waters. Plants in inland waters provide regulating services which help to control floods and create environments which can act as sponges in the case of exceptional floods. Plants prevent riverbanks from erosion, and their roots may dispose deeper soil horizons to weathering by creating connectivity.

Human nutrition

Plants provide nourishment for all organisms linked to the inland waters. Animals feed on floating plant parts, or on fruits and seeds that fall into the water.

Many plant species of inland waters are of fundamental importance in the diet of the local human populations. Rice, taro, and other plants which need to grow in water assure the survival of millions of people worldwide (Fig. 18). Palm trees and local plants which are less known across the globe provide important quantities of fruits which are directly consumed or sold on the local markets. Macrophytes supply fodder for cattle and buffaloes.

Other uses

Wetland plants supply materials which the people need to construct their houses, boats, furniture, tools, and much more. Palm leaves are used for the roofs, local water resistant wood is employed for everything needed in the houses. Large perennial reed grasses (e.g., *Phragmites*) are used to cover the roofs of many houses in Germany.

Many tree species are important for timber and are thus traded on the markets. Plants supply fuel, fibers and medicines. Many diseases are linked to standing water and the presence and filtering activities of plants can decrease illnesses through a natural equilibrium of natural food webs.

The traits and morphology of wetland plants do not necessarily make the difference here, but the mere presence of specific plants in places where people tend to settle due to the need for constant water resources makes them highly valuable in inland waters. The nutrients in the alluvial soils spurred the colonization of wetlands by humans, as can be found on the Rhine, the Nile, the Amazon and many more rivers.

Fig. 17 Sediments are retained by the plant roots but also eroded by the river currents, making most wetlands highly dynamic ecosystems (Amazon river near Manaus; photo © Pia Parolin).

Fig. 18 Taro plantation in the Hanalei Valley on Kauai, Hawaii (photo © Pia Parolin).

The vegetation on the banks of rivers and interfluvial wetlands in the Amazon is currently recognized as landscapes managed by indigenous populations from the pre-Columbian period to the present day. However, knowledge about this sustainable use and management is gradually being lost by the increasing rural exodus leading to the forgetting of traditional knowledge (Ferreira et al., 2019). Less and less people know about the values of single plant species, be it for human nutrition, medication or related to complex food webs (Fig. 19).

Major problems of wetland plants

Contrary to upland ecosystems, in inland waters many plant species face problems which occur only under the influence of flooding and in linkage with wetlands.

Fig. 19 Local use of açai palms (Amazon river near Belém, Brazil; photo © Pia Parolin).

Problems for the plants in inland waters

Pollution

Problems for the plants include water pollution, e.g., through gold mining or oil search, the presence of herbicides or over-fertilization. Some species, like *Eichhornia crassipes*, have a high tolerance to pollutants and are used to clean polluted inland waters. However, the biomass accumulated by the species will retain the pollutants and may become a problem if well designed removal strategies and disposal are not used.

Alteration of hydric cycles

Altered hydric cycles arise with artificial water regulations where dams or river rectifications have been built. Dams and hydropower stations are being built all over, and their influence on the inland water networks is mostly disastrous. Changes which are linked to the presence of dams include the emergence of different flooding periodicities, which lead to disruptions of interactions and the asynchronicity of the plant life cycles and even change in species composition. Large-scale deforestation in catchment of rivers leads to changes in hydrological cycles and also alters hydrochemical parameters. In rectified rivers, such as all over Europe and N-America, many habitats along the river channels and wetlands were lost, and the concentration of hydraulic energy along a linear river channel increased bed erosion and consequently led to lowered groundwater levels. The results were fragmented river wetlands with reduced habitat and plant diversity, as well as the introduction of non-native invasive species (neophytes), which in turn endanger local species pools.

Changes of precipitation

Climatic changes lead to changed precipitations at a local and global level. Thus, the natural patterns of floods and droughts are undermined. Increased length and height of flooding has strong impacts on plant survival. Increased or less frequent floods and droughts can have devastating effects on plant life and species composition. Disruptions of networks and asynchronicity of life cycles are a consequence.

Fires following exceptional droughts are emerging ecological constraints. Since wetland plants of most inland water systems are usually not subjected nor adapted to fires, they may become a major concern in wetlands under climatic change scenarios.

Problems caused by the plants in inland waters

Plants also provoke problems. They can be invasive or simply grow too much once the natural equilibria are broken.

Invasive species

Many plants are invasive around the globe, and wetland species are particularly efficient as invaders. Wetland plants have been carried around voluntarily for ornamental purposes, or involuntarily with globalization. Fragmented (i.e., rectified, dammed) wetlands are most vulnerable to invasive species. Once arrived in a new ecosystem, some species are very efficient in forming monospecific stands because they have nearly unlimited resources in several wetlands: water and nutrients are often present in high quantities. And many wetland plant species appear to be good generalists which can easily cope with different inland waters. The only limiting factors are temperature and salinity.

Excessive biomass production

The very fast growth of floating macrophytes is a major problem in many circumstances. Once the natural network and equilibrium is broken, fast-growing plants will dominate an ecosystem. This often is counterproductive to what the human population needs, not to speak of the naturally occurring plants and animals.

Fast growth of few species fills the water surfaces and inhibits oxygen and light to penetrate the water. The large amount of biomass leads to increased decomposition and low oxygen rates in the water. This heavily affects fish and all other organisms.

Fast growing invasive species like the Amazonian water hyacinth (*Eichhornia crassipes*, Figure 20) currently occur in almost all freshwater lakes around the tropical regions of the globe and outcompete the local vegetation. Huge mats of floating plants choke waterways and the turbines of hydroelectric installations. This is an immense problem worldwide.

Conclusion/synthesis

This chapter shows that several adaptations and specific ecological features allow different wetland plants to grow under certain circumstances which otherwise are lethal for plants. They have different capacities to tolerate flooding or submergence, and to cope with the harsh conditions of standing water or strong currents. These not only determine their distribution, but also make them survivors in an otherwise often hostile environment.

Floodplain management should be based on conceptional considerations in order to avoid negative side effects as much as possible (Junk and Wantzen, 2004). The FPC predicts exchange of nutrients and energy between the aquatic and terrestrial phases. Human use of terrestrial resources will affect aquatic resources and vice versa. These impacts have to be considered when developing management concepts.

Wetland plants fulfil key roles for ecosystem services of inland waters. Their presence guarantees stability, favorable environments for the reproduction of several animal species including fish, crabs, molluscs, mammals and many more. Additional studies are needed to improve our knowledge about their optimal use and sustainable management, for regeneration projects of secondary forests and the rehabilitation of wetlands around the globe (Fig. 21).

We have to spread the understanding of inland water ecosystems which are a natural capital. Valuing the privilege of diversity instead of compromising the well-being of nature and humans is fundamental. And we must pay attention that diversity does not only mean a high number of species, but it also includes diversity of genetics, of adaptations, of macrohabitats, of social and cultural richness.

Knowledge gaps

- We need to understand adaptations and tolerance of aquatic plants: We only have a superficial knowledge of the ecophysiology of most species, and thus it is difficult to understand the reasons for their distribution in macrohabitats.
- There is a lack of basic knowledge for management, restoration, and replanting plans, for sustainable use and conservation of wetlands.

Fig. 20 Invasive *Eichhornia crassipes* in the city of Antananarivo, Madagascar (photo © Pia Parolin).

Fig. 21 Converted wetlands in Madagascar with varied agriculture (left), and rice cultivation (right) (photos © Pia Parolin).

- We need to better understand the role of salt and fire, two strong factors which more and more often appear in inland water ecosystems.
- Our understanding of food webs and interactions of animal species and plant species in different inland water ecosystems has to be enhanced.
- We need to better understand the spread of invasive species and how to control or use them if it applies.
- We need more research in order to understand the complexity and the interdependence of many processes. Research has to be focused on questions about recent, past and future climatic impacts, the importance of landscape connectivity and dynamics of flooding on biodiversity and biogeochemical cycles and how to include the results of floodplain research into sustainable management strategies (Junk and Wantzen, 2004).

Glossary

Bioindicator Biological processes, species or communities that are used to assess the quality of the environment and its evolution over time.
Ecohydrology Interdisciplinary scientific field studying the interactions between water and ecological systems.
Functional feeding groups Classification of the trophic role of macroinvertebrates in hydrosystems based on mouthpart morphology, feeding behavior and stomach/stable isotope analysis.
Hyporheic/hypolacustric interstitial Transitional habitat of stream or lake sediment which is influenced by both, shallow groundwater and surface water.
Neobiota Animal plant and microbiota species that colonize areas where they did not occur previously, mostly due to human intervention (e.g., transport, release).
Nerites Common name for the family Neritidae, small to medium-sized freshwater and saltwater snails, which have a characteristic gill and operculum.
Patch dynamics Differential distribution of benthos due to temporal changes of their habitats.
Reciprocal subsidies Flow of matter and energy between ecosystems (here: at the aquatic-terrestrial interface).
Voltinism Number of generations per year (for insects).

Introduction

In aquatic ecosystems, the community of organisms living at the bottom is called benthic, and its habitat, benthos. The expression "benthic invertebrates" includes a very heterogeneous group both in terms of their species composition and their contributions to ecosystem processes. Their size can vary tremendously from single-celled protists to large crayfish or mussels weighing more than 1 kg, but the size of most species ranges from less than one to a few millimeters. The distinction between micro- and macro-zoobenthos is often defined by the catchiness of 500 μm-mesh size nets, however, early larval instars and many tropical insect larvae commonly attributed to "macro" zoobenthos would slip through this mesh.

Despite their relatively small body size, benthic invertebrates can travel far distances, either by flying themselves (the dragonfly *Pantala flavescens* is known to make migrations of several hundred kilometers), or by using other animals as means of transport. For example, water mites and gordiid worms use winged aquatic insects as aircraft, unionid mussel larvae stick to migratory fish. Others use the water flow to become dispersed. Some nereid snails, shrimps and crabs have marine ancestors and need to reproduce in the sea, and later their offspring migrates back into the coastal rivers (Blanco and Scatena, 2006). Some benthic invertebrates are even of clinical importance, as they can be vectors of water-borne diseases such as malaria, West Nile virus, dengue fever dispersed by midges, onchocerciasis by black flies, or schistosomiasis by snails (not discussed here).

With the exception of few purely marine or terrestrial groups, all known invertebrate taxa can be found in inland waters, including 13 orders of insects (larval midges of the dipteran family Chironomidae being the most common), sponges, mollusks, crustaceans and worms from different groups (mostly nematodes and oligochaetes). Due to their enormous diversity, the taxonomic composition of the communities cannot be dealt with here, and only in few long-term studies, the cumulative species curves have reached a saturation point, e.g., in the Breitenbach study (Wagner et al., 2011). A detailed description of the morphology of many species (especially insect larvae) is yet missing, and the life cycle, habitats and diets of their different life stages are only known from few species.

Considering the functional diversity even within a single species, combined with a high local species diversity due to the patchy distribution (especially in running waters, microhabitat-specific communities vary on few centimeters distance) and the temporal (annual, multi-annual) variability of species, one can imagine the enormous importance of benthic invertebrates in the flow of matter within, across and between inland water ecosystems. Invasive, filter-feeding mussels may literally clean out planktonic algae and bacteria from lakes and rivers and switch the pathways of biotic carbon flow from the planktonic to the benthic food web (Karatayev et al., 2005). Some species act as environmental engineers by changing the physical habitat structure. Many benthic invertebrates are very sensitive concerning environmental quality, making them excellent bioindicators for the chemical and physical quality of the ecosystems they live in Pander and Geist (2013).

This chapter synthesizes classical and current knowledge on freshwater benthic assemblages, with the following main topics: (i) technical aspects of field sampling, (ii) the general environmental (abiotic and biotic) controls over community structure and ecological concepts, (iii) functional ecology and ecological concepts, (iv) types of habitat and their respective communities and adaptive strategies (streams, rivers, floodplains and lakes, the hyporheic/hypolacustric zone, and extreme habitats), and (v) management and conservation aspects. Finally, it also warns about the dramatic biodiversity decline of this group of animals, which is so little known that many species disappear without ever being known to science.

Methods for the study of benthic communities in continental waters

Aquatic habitats and their specific invertebrate associations are very diverse. A wide range of literature references covers sampling methods and analysis of benthic macroinvertebrates. Environmental assessment monitoring is extensively addressed in the classic texts of Hynes (1960, 1970), Bartram and Balance (1996), or the frequently used protocols of the United States Environmental Protection Agency (USEPA, 2016) and the European Water Framework Directive (Hering et al., 2003). Global harmonization of bioindication methods is urgently needed (Buss et al., 2014). European and North-American textbooks such as Tachet et al. (2010), Thorp and Rogers (2015), or Merritt et al. (2019), provide keys for the identification of benthic biota including an extensive list of sampling equipment. For tropical aquatic biota, methods have been reviewed by Wantzen and Rueda-Delgado (2009) and local identification guides are given, e.g., by Yule and Yong (2004) for South-East Asia, and Domínguez and Fernández (2009), Damborenea et al. (2020), or the ABLA book series for Latin America (Adis et al., 2006–2009).

Prior to sampling, the distribution and coverage of the habitats should be known, and the strategies for sample storage and analysis, as well as the identification and data and sample management need to be set up. Stratified random sampling allows to compare individual microhabitat types in streams (Hauer and Lamberti, 1996) or depth zones in lakes. The sampling gear needs to be selected according to the substrate type, current and target organisms (Table 1; Fig. 1).

Sampling, even for conservation purposes, always represents an impact on the ecosystem and needs to be well planned, including the request of permits. Special care has to be taken concerning rare and protected species, e.g., unionid mussels, dragonflies or crayfish. All sampling material including boots needs to be cleaned, dried and possibly sterilized in order to avoid the transfer of invasive species or diseases such as the crayfish plague (*Aphanomyces astaci*) between sampling sites. The timing of the sampling needs to be adapted to the life cycle of the organisms and to hydrological variations. Recently flooded riverbanks, sediments freshly deposited after storms, or sites where a mass emergence of adult, winged aquatic insects has just taken place before sampling are not representative. Eggs and smaller instars of invertebrates are hardly visible and can rarely be identified by morphological characteristics. More and more, environmental DNA and metabarcoding are used for identification (Deiner and Altermatt, 2014) and bioindication (Hering et al., 2018), revealing however only the presence/absence of species (including rare, cryptic, or yet undetected invasive species). Whenever possible, living animals should be observed in their natural habitat (or when freshly sampled) to understand their species traits. Living samples need to be aerated and cooled and quickly analyzed to prevent predation or decay. Therefore, most studies are based on animals that were killed and analyzed in the laboratory. Conservation of specimens lacking an exoskeleton needs specific treatment, most arthropods and shell-bearing mollusks are generally preserved in alcohol.

The term “benthic invertebrates” usually describes animals living on and in the uppermost layers of the sediments, however, if present, animals plant parts protruding into the water (macrophytes, floating roots, wooden logs) should also be sampled with specific gears (i.e., nets that can be closed around the plant parts before lifting it to the surface). For the sampling of macroinvertebrates in streams, Surber with defined sampling areas or D-type nets are classical devices, which use the water current to catch animals from the stirred substrate. Some taxa, especially mayflies (Leptophlebiidae, Oligoneuridae) may sense nets and escape (Bretschko, 1990). In stagnant waters, Surber samplers can be coupled with air-lift current from SCUBA equipment (Baumgaertner et al., 2008). Small species (microbenthos) can be removed from substrate surfaces with scrubs or ultrasonic devices. If they occur in fine sediments, these can be sampled with corers or suction pumps. Fine to medium-sized sediments in lakes and rivers can be

sampled with Ekman-type dredges or freeze-coring (Weigelhofer and Waringer, 2003). Emergence traps capture adult aquatic insects and deliver information about life-cycle duration (voltinism), they need to be regularly controlled to avoid predation by spiders (Freitag, 2004; Malison et al., 2010) (Fig. 2). Large mussels can be identified in situ using optical devices ("aquascopes", Prié et al., 2017). Standardized artificial substrates for colonization (Rosenberg and Resh, 1982) deliver an excellent baseline to compare faunal assemblages between different sites for biomonitoring; however, they are selective and not representative for the entire habitat diversity of a site.

In addition to sampling animals, key environmental parameters always need to be registered in the study of benthos. In faunistic studies, at least sample rarefaction tests, alpha and beta biodiversity analyses, and NMDS (Nonmetric MultiDimensional Scaling) inform about community composition and species distribution, multivariate analyses such as PCA and DCA (Principal and Detrended Component Analyses) help to interpret the influence of diverse environmental parameters on the distribution and composition of the species.

Abiotic and biotic controls over benthic assemblage structure

Among the most fascinating features in the study of benthic invertebrates are their spatial distribution and their species composition (Fig. 3). Both in rivers and lakes, specific assemblages can be found in specific zones of the respective ecosystem, with surprisingly similar patterns in different regions of the world, although they show biome-specific trends (Feio et al., 2018). These patterns are the result of a large number of biotic and abiotic conditions, which can be described in hierarchical scales (O'Neill et al., 1989) or as landscape filters (Poff, 1997). Next to general key controls of biodiversity such as evolution time and geographical dispersal potential, the structure of benthic communities is controlled in first place by hydraulics (Statzner et al., 1988). Water movement and the availability of the original bedrock material determine the physical habitat structure, with coarser sediments in wave impact zones of lakes and the mountainous sections of rivers and streams, and fine sand and silt in the depositional zones of both, lotic and lentic ecosystems. Coarser and medium-sized sediment particles provide surfaces to which larger invertebrate species may cling, and their larger porosity allows oxygenation of deeper zones that can be colonized by metazoans. On the other hand, fine sediments can be mobilized at lower flow velocity or wave impact, and their oxygen concentration quickly decreases with depth due to reduced exchange with the open water. Water movement also transports food particles and increases the oxygen solution at the water surface. This results in a fine-tuned distribution of benthic invertebrates, e.g., multi-species caddisfly larvae assemblages with different mesh sizes along the outlet of lakes.

In running water systems, life-cycle length of the organisms is coupled with the probable mobility of the sediments, resulting in habitats preferable for r- or K-strategists (Resh et al., 1988). This phenomenon results in a generally higher biodiversity, abundance and biomass of macro-zoobenthic species in gravellish substrata (Hynes, 1970; Allan et al., 2020) compared with lower values in fine substrata of lakes and the lower sections of rivers (but small specialist species may occur in high abundances, Wantzen et al., 2014). The introduction of solid substrates on soft lake sediments (e.g., shells from invasive mussels) may completely change the community structure (Werner and Rothhaupt, 2007). Tree logs may also interfere with soft-bottom habitats and create abundant,

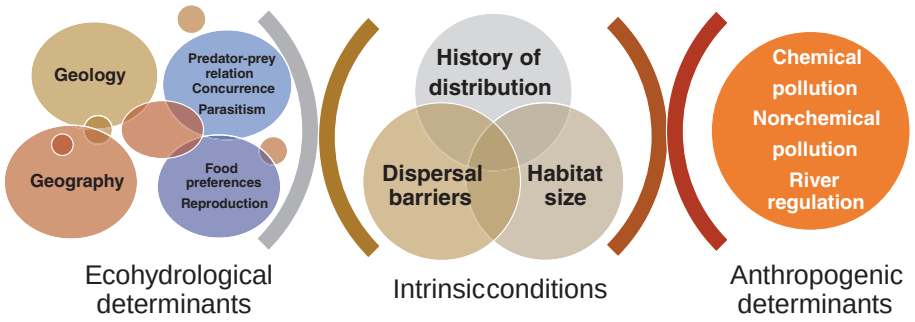

Fig. 3 Factors explaining the occurrence of benthic communities in inland waters. Modified from Braukmann, 1992.

Fig. 4 Tipuliid larvae (Diptera) dispose of a spiracular disc found on the end of the abdomen which is surrounded by hydrophobic lobes, which allow them to breathe atmospheric oxygen while the animal dwells in oxygen-poor environments. Photo: M. Schmidt, Mexico, with permission.

species-rich "biotic hot spots" in rivers and lakes (Wantzen and Junk, 2006). Moreover, flow and flood phenomena permanently modify this primary pattern in natural hydrosystems by erosion, transport and deposition of sediments, but also by expanding and reducing the wetted part of the floodplains, and by changing the relative contribution of water of different origins (surface, ground, and rain water). This results in a permanently changing spatial-temporal mosaic of differently old physical habitats, especially in river systems (Pringle et al., 1988; Ward, 1989; Junk and Wantzen, 2006; Tockner et al., 2010), but to some degree also in lakes (Wantzen et al., 2008).

Physical and chemical water quality (temperature, oxygen concentration, pH, dissolved salts and nutrients) exert the next level of control in the community composition, as they represent physiological limits for the survival of aquatic species. Diffusion speed of gases in water is 200 times slower than in air, and the amount of oxygen that can be solved in water decreases fast as temperature rises, therefore, many aquatic metazoans are limited by oxygen supply. Especially in fine, organic sediments, only the uppermost layer is oxidized, and only specialists pumping fresh water into the tubes they colonize by body movements ("bioturbation") may go deeper than that.

Benthic invertebrates have developed an impressive variability of respiratory organs. For small and flat animals (e.g., flatworms), the body surface may suffice for gas exchange. All aquatic insects and spiders have evolved from terrestrial ancestors, and some have maintained an air-filled, tracheal respiratory system. Some species directly breathe air at the water surface but their mobility is limited by the length of their respiratory organs, e.g., tipulids (Fig. 4). Water beetles and bugs (Heteroptera) carry tiny air bubbles under water or have developed a fixed-volume plastron for the exchange of gaseous oxygen (in the plastron and tracheae) and dissolved oxygen (in the water and in their body liquids). Other taxa have developed all kinds of internal (e.g., Odonata: Anisoptera) and external gills (e.g., Ephemeroptera, Trichoptera, Plecoptera). Some oligochaetes and chironomid larvae produce hemoglobin to survive in low-oxygen environments. Underwater respiration is connected to osmotic exchange with the water, which can become a physiological problem, if the water was much saltier or much less salty than the body liquid (see below: extreme habitats). Therefore, adaptive traits of respiration and osmoregulation are generally combined (Griffith, 2017).

Indirectly, the nutrient content triggering plant growth (and subsequent heterotrophic processes) also restricts the oxygen concentration, resulting in the absence of sensitive species in nutrient-rich waters. Most mollusks and crustaceans need calcium carbonate to produce their shells, therefore, their occurrence is restricted to waters with sufficiently high calcium content. In Amazonia, the apple snail *Pomacea papyracea* circumvents this problem by having a calcium-free shell of pure periostracum. Changes in the pH of the water (acidification as a consequence of air pollution) and/or presence of divalent heavy metal ions may severely interfere with shell growth (Boon et al., 2019).

Predator-prey relationships and competition are further, biotic, levels of control on the benthic biocoenosis. Their body size makes invertebrates a perfect prey for fish, which has cascading effects also on invertebrate predators (Diehl, 1992). Similar to planktonic invertebrates that can chemically sense the presence of predators and perform diel vertical movements in lakes, benthic invertebrates also adapt their daily behavioral patterns to reduce predation. In many lakes, mysid shrimps and phantom midge larvae (genus *Chaoborus*, Gosselin and Hare, 2003) switch between a nocturnal planktonic and a daytime benthic life. Displacement between microhabitats and drift behavior for dispersal in streams represent high predation risk for invertebrates. Ramírez and Pringle (2001) could show that above waterfalls that limit the access of predators, drift showed a diffuse pattern, but it was concentrated at the dusk and dawn periods (when fish cannot sense their prey) when vertebrate or crayfish predators were present below the waterfalls. Many other benthic invertebrates avoid fish predation by resting underneath stones at daytime and feeding at night (e.g., grazers, Fig. 5).

Fig. 5 Larvae of the cosmopolitan caddisfly family Helicopsychidae produce cases that look like snail shells. During daytime, they hide below stones, at night they graze algal films on stones. Photo: Karl M. Wantzen, Mexico, 2018.

Functional ecology of benthic invertebrates and ecological concepts

Benthic invertebrates play an important role in the dynamics of organic matter and nutrient processing of aquatic ecosystems, their floodplains and neighboring terrestrial ecosystems (Covich et al., 1999). Due to their body size, they can convey organic carbon from the microbial loop (i.e., the energy flow between bacteria, fungi, viruses and protists) and/or primary producers (algae, macrophytes, terrestrial plant debris) to larger invertebrate or vertebrate predators. They thereby connect the benthic with the pelagic food webs, the lentic (still-water) to the lotic (running water) foodwebs, or even the aquatic and terrestrial foodwebs. Emerging adult insects (e.g., adult mayflies, caddis flies, chironomids) or stranded aquatic invertebrates become a cornucopia for terrestrial spiders, beetles, birds and bats, whereas the feces or corpses of the latter become consumed by aquatic invertebrates. This phenomenon is known as "reciprocal subsidies" between foodwebs (Nakano and Murakami, 2001; Dahlin et al., 2021). Foodweb interactions do not occur in continuous processes, but rather in locally and temporally restricted "biotic hot spots and hot moments," e.g., when migratory, Polymitarcidae mayflies carry one ton of carbon upstream the Orinoco river (Wantzen and Junk, 2006), or when the fastest growing, last larval instars of the shredding caddisfly *Chaetopteryx villosa* litterally clean out leaf litter in temperate streams and even feed on terrestrial vegetation (Wantzen and Wagner, 2006). These phenomena may remain unperceived due to too long observation intervals.

During their life cycle, benthic invertebrates can act on different trophic levels. Net-spinning caddis flies, for example, feed on tiny organic particles during their early instars, are predators in larger larval stages, and winged adults may feed on nectar (or do not feed at all). Water mites are micropredators, then parasites on aquatic insects (Smith et al., 2010). Despite a high degree of specialization, omnivory is widely distributed, especially if high-energy food sources (e.g., pollen on water surfaces, honeydew from aphids) are shortly available. For benthic invertebrates, the classification in feeding guilds is commonly named "functional feeding groups" (FFGs, Merritt et al., 2019). The FFGs are the result of the morphological analysis of mouth parts and observation of feeding behavior, stomach content analyses or stable isotope analyses. The major functional feeding groups are (1) scrapers/grazers which consume algae and biofilms; (2) shredders, which consume leaf litter or other Coarse Particulate Organic Matter (CPOM), including wood; (3) gatherer-collectors, which collect Fine Particulate Organic Matter (FPOM) from the stream bottom; (4) filterer-collectors, which collect FPOM from the water column using a variety of filters; and (5) predators, which feed on other consumers. Sub-groups exist i.e., for the predators (e.g., engulfers, piercers). Identifying the composition and proportion of functional feeding groups may indicate the functioning and integrity of the ecosystem (Thorp and Rogers, 2015). FFGs can be combined with other characteristics such as mobility type (crawlers, clingers, swimmers, etc.), life span and reproduction type and period to sets of species traits, which allow a detailed functional analysis of the community and its sensitivity to environmental impacts (e.g., Hershkovitz et al., 2015).

In a general theory, the headwater zones of streams receive fresh leaf litter (CPOM), so that shredders prevail there, grazers prefer the intermediate stream parts where sunlight provides benthic algal growth, while gatherer and filterer-collectors increasingly dominate in the lower river sections that receive the CPOM, which has been comminuted to FPOM and where the residence time of the water is long enough to support the development of riverine plankton. This functional ecosystem model, known as the "River Continuum Concept" (Vannote et al., 1980), has dominated benthological research for decades, however it has overlooked important aspects, such as the primary production of and trophic interactions with floodplains, which may have a greater importance for the foodwebs than the food sources in the river main channel itself (Flood Pulse Concept, Junk et al., 1989; Junk and Wantzen, 2004), that headwater streams may depend on primary production rather than allochthonous litter input (Lau et al., 2009) and that leaf litter decomposition is subject to a number of geographical parameters, including the chemical quality of leaves (Graça et al., 2015; Rueda-Delgado et al., 2006). Moreover, the classical structural sequence of rivers from coarse-grained headwaters

to fine-grained lower sections (and their respective faunal assemblages) may be interrupted by natural or man-made structures (Serial Discontinuity Concept, Ward and Stanford, 1983). In synthesis (see, e.g., Thorp, 2009), the local hydromorphological and geochemical environmental conditions are decisive for the ecosystem functions in rivers. Functional concepts in lakes have a stronger focus on planktonic foodwebs, however, the importance of benthic assemblages (especially the benthic-pelagic coupling, see Karatayev et al., 2005) and flood effects (Wantzen et al., 2008) are increasingly acknowledged.

Specific benthic assemblages

Low to medium-order streams

In headwaters, aquatic and terrestrial ecosystems have a large contact zone. Hydrographs reflect the contributions of permanent groundwater inflow (with low temperatures allowing the presence of stenothermous species) and the flashy variations due to precipitation (flushing terrestrial organic matter into the stream). Densely arranged sediment patches of fine and coarse, mineral and organic particles allow the coexistence of highly diverse assemblages even in narrow stream sections (Pringle et al., 1988). Gravel and sand often form a "pool-and-riffle" structure that serves as a trap for FPOM and attracts gatherer-collectors, while shredders focus on debris dams. Many species show adaptations to the swift current, such as flattened body architecture, or an arrangement of external gills that avoids turbulences below the body (many may fly larvae). Biofilms reduce the adhesion to stones so that animals using suckers (e.g., Diptera: Blephariceridae) are only found in the uppermost stream sections where frequent spates remove slippery surfaces. Simuliid larvae clean surfaces, then glue a cushion of silk to cling themselves with their abdominal claws at the edges of boulders located in the current, where they filter particles with their antennae.

Habitat patches are quite dynamic, as frequent spates redefine the physical habitat structure (Matthaei et al., 1999). Life cycles of the invertebrates are generally short, often with highly polyvoltine species in the Tropics (possibly, an adaptation to the frequent sediment disturbance after rainstorms) and 1–2 year-long cycles in the temperate zones. Only few microhabitats in headwaters provide sufficiently stable conditions for the survival of long-living species such as true river mussels (Unionoida). In boreal streams, pearl mussels (*Margaritifera margaritifera*) belong to the longest-living animals on earth, attaining more than 200 years (Ziuganov et al., 2000). Along with the "EPT taxa" (Ephemeroptera: mayflies, Plecoptera: stoneflies, Trichoptera: caddisflies), they belong to the most pollution-sensitive taxonomic groups. If fish are absent, large invertebrate predators (decapods and larvae of stoneflies, dragonflies, dobsonflies) are the top predators. Many invertebrates drift down the stream to escape predation for dispersal, so that emerged adult aquatic insects fly against the air current above the waterline to compensate for this movement. In temperate zones, adult gammarids (amphipod crustaceans) migrate towards the springs that provide a thermal shelter. The terrestrial vegetation structure is very important for adult insects as mating sites.

Foodwebs are largely based on the diverse terrestrial inputs (leaf litter, but also fruits, flowers, terrestrial invertebrates) providing food sources for detritivorous or scavenging invertebrates (Graça et al., 2015; Wantzen and Wagner, 2006) but also on primary production by algae (Lau et al., 2009). In the middle to lower section of streams (or in wide high-mountain valleys), the stream bed widens and meanders or broadens, so that the bottom sediments are fully exposed to sunlight, and benthic green algae can develop well. Exclosure experiments with under-water electric fences (Pringle et al., 1999) show that grazing invertebrates (Fig. 5) remove the non-filamentous algae at night time, so that they are a rare sight in unpolluted streams.

Main channels of rivers

Downstream fining of sediments defines the physical habitat structure and—along with water quality—the benthic assemblages in larger rivers. The continuous gradient from coarse to fine substrata, known from textbooks, however, is often interrupted by inflowing streams or river sections crossing rocky outcrops that may "rejuvenate" both, sediment and community structure (see "Serial Discontinuity Concept" above). Some typical "rhithral" (stream) species may therefore occur locally in the "potamal" (river) sections of larger rivers, provided that the temperature and water quality requirements are met. Gravellish river sections, river banks and especially the channels connecting rivers to floodplain lakes, provide habitats for an abundant and diverse fauna, especially filter feeders and grazers that may use the organic particles brought by the water movement. On the other hand, mobile (often sandy) bed sediments, as they occur in the central channel strip of the lower section of rivers, are among the least densely colonized freshwater habitats (Marchese et al., 2005). In underwater sand dunes the fauna is often composed of Oligochaetes and other, worm-shaped taxa, which respond to the instability of the substrate, the quality of the water, and the organic matter accumulated on the bottom of these channels (see review in Wantzen et al., 2014).

Lakes and river floodplains

In lakes, the above-mentioned habitat dynamics are much slower, however, the relationships between substrate structure and faunal assemblages are similar to those of rivers. Lakes generally have a clear sequence of habitat zones, beginning with a fluctuating upper littoral zone inhabited by an invertebrate community of terrestrial and aquatic origin (Scheifhacken et al., 2007), a permanently wetted, lower littoral zone with different types of substrata and plant communities, and a profundal zone, which accumulates fine sediments and FPOM. The landscape topography is decisive for the lake morphology and the relative extension of the depth zones. In shallow lakes, light and wind-driven currents can influence even the deepest zones (Brauns et al., 2007).

While the wave actions in the upper littoral may provide comparable habitat conditions as the rhithral zones of streams (with some overlapping species), the community of the profundal zone of lakes is quite monotonous, adapted to the low oxygen concentrations typical of the bottom of these systems (O'Sullivan and Reynolds, 2004). In the macrophyte-covered lower littoral of lakes and in slow-flowing lowland rivers, the "true" benthic community (mostly nematodes, oligochaetes, chironomids) is usually less diverse than that associated with macrophytes. The latter include herbivores such as the aquatic butterfly *Acentria ephemerella* (Gross et al., 2002) but also many snail and caddis fly species. Macrophytes may play an important role as shelter against predators (Thomaz and Cunha, 2010; Hesselschwerdt and Wantzen, 2018).

Both in the upper littoral of lakes and in the floodplains of large rivers, water level fluctuations change life conditions in the sediments near or above the waterline (O'Leary and Wantzen, 2012). In this "Aquatic-Terrestrial Transition Zone", aquatic organisms need specific adaptations to survive drought (in some regions, even frost) and predation by terrestrial predators. These adaptations include resistant propagules such as eggs, diapausing life stages (e.g., *gemmulae* of freshwater sponges) or the migration into moister zones (see Wantzen et al., 2016 for a review).

The interstitial pore spaces in sediments of rivers (hyporheos) and lakes (hypolacustric zone)

The hyporheic interstitial zone is a specific ecotone between the shallow benthic zone and groundwater, colonized by specific epibenthic invertebrates (Brunke and Gonser, 1999; Thorp et al., 2006) and stygobionts (groundwater species, Danielopol and Griebler, 2008). Originally described for small streams (Orghidan, 1959; Schwoerbel, 1961), it is now known that coarse sediments of large rivers (Malard et al., 2002) and even lakes (O'Leary and Wantzen, 2012) have similar structures. Eggs, larvulae, larvae of aquatic insects and early instars of mollusks and crustaceans are often overlooked in benthos studies because they spend a part of their life hidden in the sediments. Interstitial invertebrates are either pre-adapted to live in the narrow pore-space by an elongate, worm-like shape and small size, or they display morphological adaptations (stretched body form in water mites, Schwoerbel, 1961) or the reduction of pigments and eyes (e.g., the amphipod genus *Niphargus*). This ecotone may extend far beyond the visible stream banks (Stanford and Ward, 1988) and the subterranean fauna of tributaries may expand into the interstitial of the main river. Presence of stygal species in the benthos of rivers can be seen as an indicator for groundwater upwelling. In spite of its great importance as habitat of all kinds of invertebrates and vertebrates (e.g., juvenile salmon and lampreys), the interstitial zone is still understudied (Marmonier et al., 2012), specifically in the Tropics.

Benthic invertebrates of extreme habitats

Benthic invertebrates are found in all types of water bodies, even tiny water bodies such as tree holes become colonized, and specialist species even survive in the digestive liquids of flesh-eating pitcher plants (Williams, 2000). In continental hypersaline habitats, they have to cope with salt concentrations up to tenfold that of the sea. Their fauna is often depauperate, however, it can be quite distinctive (Dejoux, 1993). Brine shrimps (*Artemia* spp.) have a remarkable osmoregulation and produce encysted eggs when the salt concentrations exceed their physiological limits (Gajardo and Beardmore, 2012). Survival in extremely ion-poor waters (conductivity $<<10$ µS/cm) also causes osmotic problems that is overcome by some species living in leaf packs or even inside fallen leaves (e.g., the chironomid genus *Stenochironomus*, Wantzen and Wagner, 2006). Drought resistance is known from many species (Williams, 2000; Wantzen et al., 2016). Dormant eggs of diverse notostracan crustaceans (e.g., the tadpole shrimp *Triops* sp.) can survive many years in dry sediments and hatched animals profit by the absence of fish predators in recently developed ponds.

Management and conservation of benthic biodiversity

Benthic invertebrate communities face classic problems related to water pollution and habitat loss, however, new threats arise (Reid et al., 2019). They all have in common that adaptive species traits that successfully evolved over millions of years are becoming obsolete due to the artificialization of the environment by humans. Light pollution, for example, attracts adult aquatic insects during their mating flights so that they end up at lamp posts rather than to reproduce and supplement terrestrial food webs (Perkin et al., 2014). Another new problem for the benthos is the effect of abundant plastic particles that are dispersed and maintained for decades in inland waters (Blettler et al., 2018) and affect the biodiversity and the functioning of aquatic communities (Redondo-Hasselerharm et al., 2018). Endocrine disruptors (hormone-like, artificial substances released to the environment) may have significant effects on the reproduction and the ontogeny of benthic invertebrates (Oehlmann et al., 2006). Inadequate agriculture and illegal gold mining release enormous amounts of sediments and toxic substances that have deleterious effects on benthic and fish communities in streams (Wantzen and Mol, 2013). More and more streams switch from perennial to intermittent discharge due to climate change, lacking conservation of headwaters, damming and water abstraction. This impoverishes the stream fauna (Larned et al., 2010). Due to river engineering (especially for navigation), the central channel strip of rivers is frequently dredged, and the habitats of the river banks have been transformed into concrete channel walls or rip-rap, which are less diverse but offer habitat for invasive species. Large benthic invertebrate species, such as the Giant River Pearl Mussel (*Pseudunio auricularius*, syn. *Margaritifera auricularia*) or the large potamal mayfly species have gone extinct in most of Europe and hardly return despite restoration efforts (Wantzen et al., 2014; Prié et al., 2017). Restoration efforts need to focus on the elimination of the known causes of species decline and on the reintroduction of a natural flow and sediment regime. Re-established floods below an alpine reservoir have successfully restored habitats for sensitive stonefly species (Jakob et al., 2004).

Modern river works connecting formerly separate river basins, increased shipping, sport fishing and the pet trade overcome biogeographic barriers and introduce new species around the world. Many benthic species have become invasive species. They affect ecosystem functioning and biodiversity but also human health, well-being and economy. Biofouling by byssus-fixed mussels such as *Dreissena* in North America (Hebert et al., 1989) and Europe (Bij de Vaate et al., 2002), or *Limnoperna* in Latin America (Darrigran, 2002) cause high economic costs associated with clogging strategic infrastructures such as aqueducts, pipelines or turbines. These and other filter-feeders like *Corbicula* mussels outcompete the native mussel fauna (Ferreira-Rodríguez et al., 2018; Karatayev et al., 2010). Golden snails (*Pomacea* sp.) are pests for rice culture in SE Asia. Invasive crustaceans are competitors, predators and disease vectors at the same time (Lodge et al., 2000). Diverse invasive species may facilitate each other, causing an "invasive meltdown" (Ricciardi, 2001). Global warming can break down thermal barriers of invaders in cooler regions (Hesselschwerdt and Wantzen, 2018). In all these cases, the structure and functioning of ecosystems become permanently disturbed. Once established, the control of invasive species is hardly possible. Locally, small barriers hinder upstream migration of invasive decapods and protect native decapods from crayfish disease. Species monitoring including eDNA analyses are needed to prioritize efforts to avoid the further establishment of these species, including the rigorous cleaning of sport boats (and angling devices) before transporting them to another water body, and the avoidance of canal constructions that connect distinct hydrographic basins.

Conclusions

Acting on many different trophic levels, benthic invertebrates hold a key position in all aquatic ecosystems. Their fascinating taxonomic, physiological and functional diversity has allowed them to colonize practically all types of habitats in inland water ecosystems. Detailed studies on their specific species traits allow us to use them as bioindicators for environmental impacts but also for the success of restoration projects, but there is a distinct bias concerning studies in the Global North and the Global South. More specifically, it is necessary to achieve a continuum from biodiversity analysis (along with environmental parameters and species traits), via the bioassessment of the environmental integrity of the ecosystems, to socio-ecological decision support for implementing adequate management/restoration actions and their subsequent effect monitoring. In this sense, it is urgent to join efforts and resources to create joint transnational and interdisciplinary programs that facilitate the exchange of taxonomic, biological and ecological knowledge and technical support to acknowledge the global value and better protect this wonderful world of aquatic biota.

Knowledge gaps

- Combined ecological and taxonomic studies, especially in the Tropics, linking genetic barcoding and morphology with species trait analysis and bioindicator value attribution.
- More detailed studies on "biotic hot spots and hot moments" (long-term, high-frequency studies).
- Effects of drought, microplastics, endocrine disruptors, and other novel threats (Reid et al., 2019).
- Effects of neobiota, including their role as vectors for diseases for other invertebrates (especially mussels and crayfish).

Glossary

Allochthonous sources Externally produced, such as organic material from riparian forests.
Allopatry Originating in, or occupying, different geographical areas.
Autochthonous sources Internally produced, such as algae and aquatic plants.
Clade A group of species that are more closely related to one another phylogenetically than to other species, which represent a single branch of the Tree of Life composed of an ancestral species and all of its descendants.
Diversity Differences between species, or more inclusive (i.e. higher or supra-specific) taxa.
Floodplain Area of land adjacent to a stream or river which experiences flooding during periods of high discharge.
River capture A geomorphological process by which the flow of a river or stream is diverted from one outlet to another.
Speciation The evolutionary process by which populations evolve to become distinct species.
Species A fundamental unit of biodiversity, biogeography, evolution and ecology. Definition of species depending on species concept (e.g. the biological species concept or the genealogical species concept).
Sympatry Occupying the same or overlapping geographic areas.
Taxon (taxa, pl) A named group of organisms in biological systematics.
Variation Differences within a species, with trait values usually characterized by a normal frequency distribution.
Vicariance Speciation that occurs when biological populations become geographically isolated.

Introduction

Freshwaters are among the most biologically diverse habitats on Earth, with more than 140,000 species of macroscopic fungi, plants and animals representing about 12% of all described species on earth (Reid et al., 2019). Freshwater rivers, lakes, and wetlands include about 18,000 fish species, with hundreds of new species described each year (Fricke et al., 2020). Yet all of these distinct evolutionary lineages are compressed into a habitat less than 0.5% the total continental surface area, and only about 0.3% the volume of the hydrosphere (Shiklomanov, 1998; Lundberg et al., 2000).

These myriad species exhibit a bewildering range of physiological, morphological and behavioral adaptations, which allow them to inhabit almost all continental aquatic environments. Fish thrive in alpine lakes above 4000 m elevation, cascades and rapids of torrential mountain rivers, benthos of deep river channels (to >100 m deep) in meandering lowland rivers, seasonally desiccated swamps and ephemeral desert pools, karstic caverns and subterranean aquifers, moist forest leaf litter, and coastal estuaries, mudflats, and mangroves swamps. Riverine fishes in particular constitute the great majority of the species and exhibit the greatest range of functional adaptations.

Freshwater ecosystems and their biodiversity are increasingly threatened by human activities, including habitat alteration, water pollution, overfishing, exotic species introduction, river diversions, fragmentation and flow regulation, expansion of agricultural and urban landscapes, rising sea levels and altered precipitation regimes (Dudgeon, 2019; IPBES, 2019). For freshwater fish, the rate

of their decline is closely associated with the extent of riverine diversions and wetland loss (Albert et al., 2021). Freshwater vertebrates, especially fishes and amphibians, are currently the most threatened groups of vertebrates on our planet (Reid et al., 2019).

This chapter provides a brief overview of freshwater fish diversity, summarizes the main patterns and processes in freshwater fish ecology and evolution, and highlights role of aquatic-terrestrial linkages in maintaining healthy fish populations and diversity. The last section describes the main threats to the persistence of freshwater fish diversity in the 21st century.

Freshwater fish

Surprisingly, not all the fishes encountered in freshwaters are obligate freshwater species. Many freshwater fishes are **diadromous**, meaning they migrate between freshwater, defined as <500 ppm dissolved salts, and seawater to feed or reproduce. These migrations occur on time scales ranging from daily to annually or longer, and over distances ranging from a few meters to thousands of kilometers. The Bull shark (*Carcharhinus leucas*) for example, is mainly a marine species, but commonly enters freshwater rivers around the world, having been caught up the Amazon river as far as Iquitos (Peru), about 5000 km upstream from the Atlantic Ocean. Others fish groups, like salmons (Salmonidae) and sturgeons (Acipenseridae) are **anadromous**, hatching in freshwater but spending most of their lives feeding at sea before returning to their home rivers to spawn. Yet others fish groups like the true eels (Anguilidae) are **catadromous**, spawning in the sea but spending much of their lives in freshwater lakes and rivers.

To distinguish among species with varying affinities to continental waters, freshwater fishes worldwide may be classified into three categories based on their physiological tolerances to saltwater (Myers, 1949). **Primary** freshwater fishes are strictly confined to freshwater, and have little or no tolerance to salty or brackish waters. As a result, marine water is an important barrier to dispersal in primary freshwater fishes. **Secondary** freshwater fishes have somewhat greater tolerance to brackish waters, but normally occur in inland continental aquatic systems rather than coastal waters or the open sea. Secondary freshwater fishes are capable of occasionally crossing narrow marine barriers. **Peripheral** freshwater fishes are members of otherwise marine groups and exhibit high salt tolerance. Such fishes are more or less permanent residents in freshwater or spent part of their life cycle in freshwater and another part in marine habitats.

These different tolerances to saltwater strongly affect fish biogeographic distributions and evolutionary histories. For example, repeated sea-level fluctuations associated with global climate (i.e. ice age) cycles during the Pliocene (c. 5.3–2.6 Ma) and Pleistocene (2.6–0.01 Ma) resulted in multiple episodes of marine transgressions and regressions, alternately inundating and exposing low-lying coastal plains and the lower reaches of rivers around the world. Rising seas result in the geographic isolation of river mouths among coastal drainages, creating vicariance events for primary freshwater fish species, while representing semipermeable filter barriers for secondary and peripheral freshwater fishes (Leprieur et al., 2011; Abreu et al., 2020).

Differences in salt tolerance also help illuminate the origins of insular freshwater faunas. Continental islands like Trinidad or Britain, with a geological history of being connected to an adjacent landmass, usually share primary freshwater fishes with the mainland. Oceanic islands however, like Iceland or Hawaii which have never been connected to a continent, have no native primary freshwater fishes. The fish species of oceanic islands are usually secondary or peripheral species.

Global patterns in freshwater fish diversity

Freshwater fish diversity is highest in large tropical river and lake basins, such as the Amazon, Congo and Mekong, and large ancient lakes such as those in the Rift Valley of East Africa (Fig. 1). Islands commonly have lower freshwater fish diversity than continental areas of the same size, and a lower percentage of primary freshwater fishes (see "Freshwater fish" section). At the intercontinental scale, variability of riverine fish species richness has been related to three main factors: the total amount of aquatic habitat, spatial heterogeneity of aquatic habitats, and the stability of aquatic environments over evolutionary time scales. These factors are interrelated, and their relative contribution in a specific region is difficult to assess.

Habitat volume. The effects of river basin size and total amount of aquatic habitat is known as the species-discharge relationship (McGarvey and Terra, 2016; Rolls et al., 2018). Large river basins generally hold more species than smaller ones. All else being equal, larger drainage basins contain larger fish populations than smaller ones, which decreases the probability of an extinction after catastrophic disturbance events. Furthermore, larger river basins generally also have greater habitat diversity, and thus more potential niches that can be exploited, compared to smaller rivers.

Habitat heterogeneity. The number of fish species is positively correlated with measures of habitat variability and its spatial turnover (Heino, 2011; Dias et al., 2014; Craig et al., 2020). One main reason for the remarkable species richness in freshwaters is the heterogeneous distribution of freshwater habitats across biogeographic space and through evolutionary time (Albert et al., 2018). The unique geographic conditions of riverine and lacustrine environments allows fish populations many opportunities to disperse, thereby lowering their extinction risk (Miller and Román-Palacios, 2019), and to become geographically disconnected, thereby increasing the chance of speciation (Carrete Vega and Wiens, 2012; Bloom et al., 2013). By contrast, most marine environments are highly connected, and rates of lineage accumulation are generally lower in oceanic groups of organisms (Miller, 2020; Rabosky, 2020).

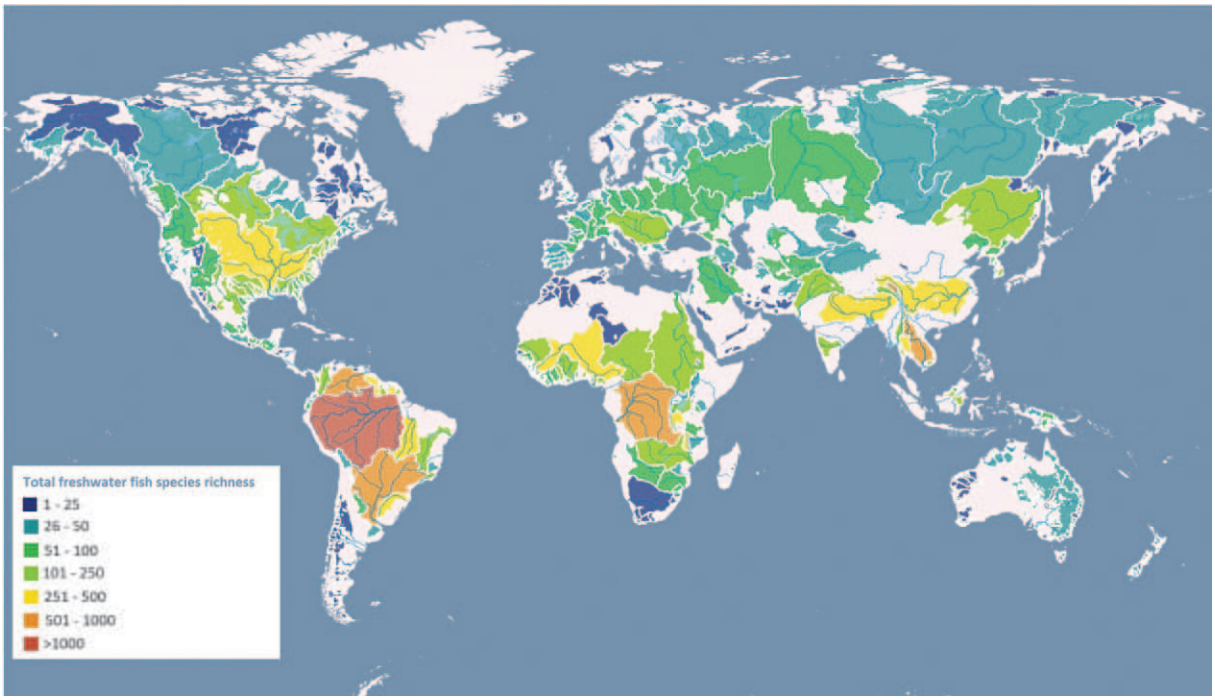

Fig. 1 Global freshwater fish richness patterns (rivers basins as spatial units). Map from Tedesco PA, Jézéquel C, and Oberdorff T (2013) *Global Freshwater Fish Species Richness*; accessed through the Global Freshwater Biodiversity Atlas (http://data.freshwaterbiodiversity.eu) on July 2020.

Habitat persistence and biome stability. Differences in species richness may also reflect the degree to which rivers have been recolonized since the last major climatic or tectonic disturbance event, and thus degree to which the ecosystems have reached an equilibrium level of species richness (Rabosky, 2009). Temperate and boreal rivers tend to have fewer species than tropical rivers of the same size, which can be understood in part by the more severe impacts of glacial intervals over the last 2.5 million years. Many rivers at high latitudes did not exist during the last glacial maximum (~20,000 years ago) and exhibit a relatively low diversity as they are still being colonized (Knouft and Page, 2003). By contrast, the large tropical river basins with the highest species richness have been the location of evolutionary diversification over millions of years (Oberdorff et al., 2019).

Freshwater fish biogeography

Biogeographical realms

Freshwater faunas of the world have been divided into seven main biogeographic realms based on similarities in species composition (Leroy et al., 2019). Each realm embraces a major continental landmass and is separated from the other realms by prominent dispersal barriers like oceans, mountain ranges, and deserts. The freshwater fishes realms are: (1) Neartic, including North America and Mexico north of the Isthmus of Tehuantepec; (2) Neotropical, including southern Central America and South America; (3) Palearctic, including Europe, and southwestern, northern, and northeastern Asia; (4) African or Ethiopian; (5) Sino-Oriental, including the Indian subcontinent, China, Southeast Asia and Sundaland; (6) Australian, including Australia, New Guinea and New Zealand; and the (7) Madagascan realm. Fig. 2 gives recent estimates of the freshwater fish diversity in each of these realms (Madagascar included in African realm here) and the distribution of species over the 15 fish orders that represent most of this diversity.

For freshwater fishes, each of the zoological realms may be further subdivided into freshwater ecoregions (Abell et al., 2008), whose boundaries generally, but not always, correspond with those of watersheds (i.e. drainage basins or catchments). Within an ecoregion there may be a turnover of species, such as when moving upstream or downstream within a river system (see "Within river patterns: From headwater to estuary" section), but taken as a whole, the ichthyofauna of a freshwater ecoregion has a distinct assemblage of species, although commonly overlapping with those of neighboring ecoregions. Interactive maps of these freshwater ecoregions, including descriptions of habitats and fishes, can be found on the webpage of the Freshwater Ecoregions of the World (https://www.feow.org/). Information and maps of the distributions of all freshwater fish families can be found in Berra (2007).

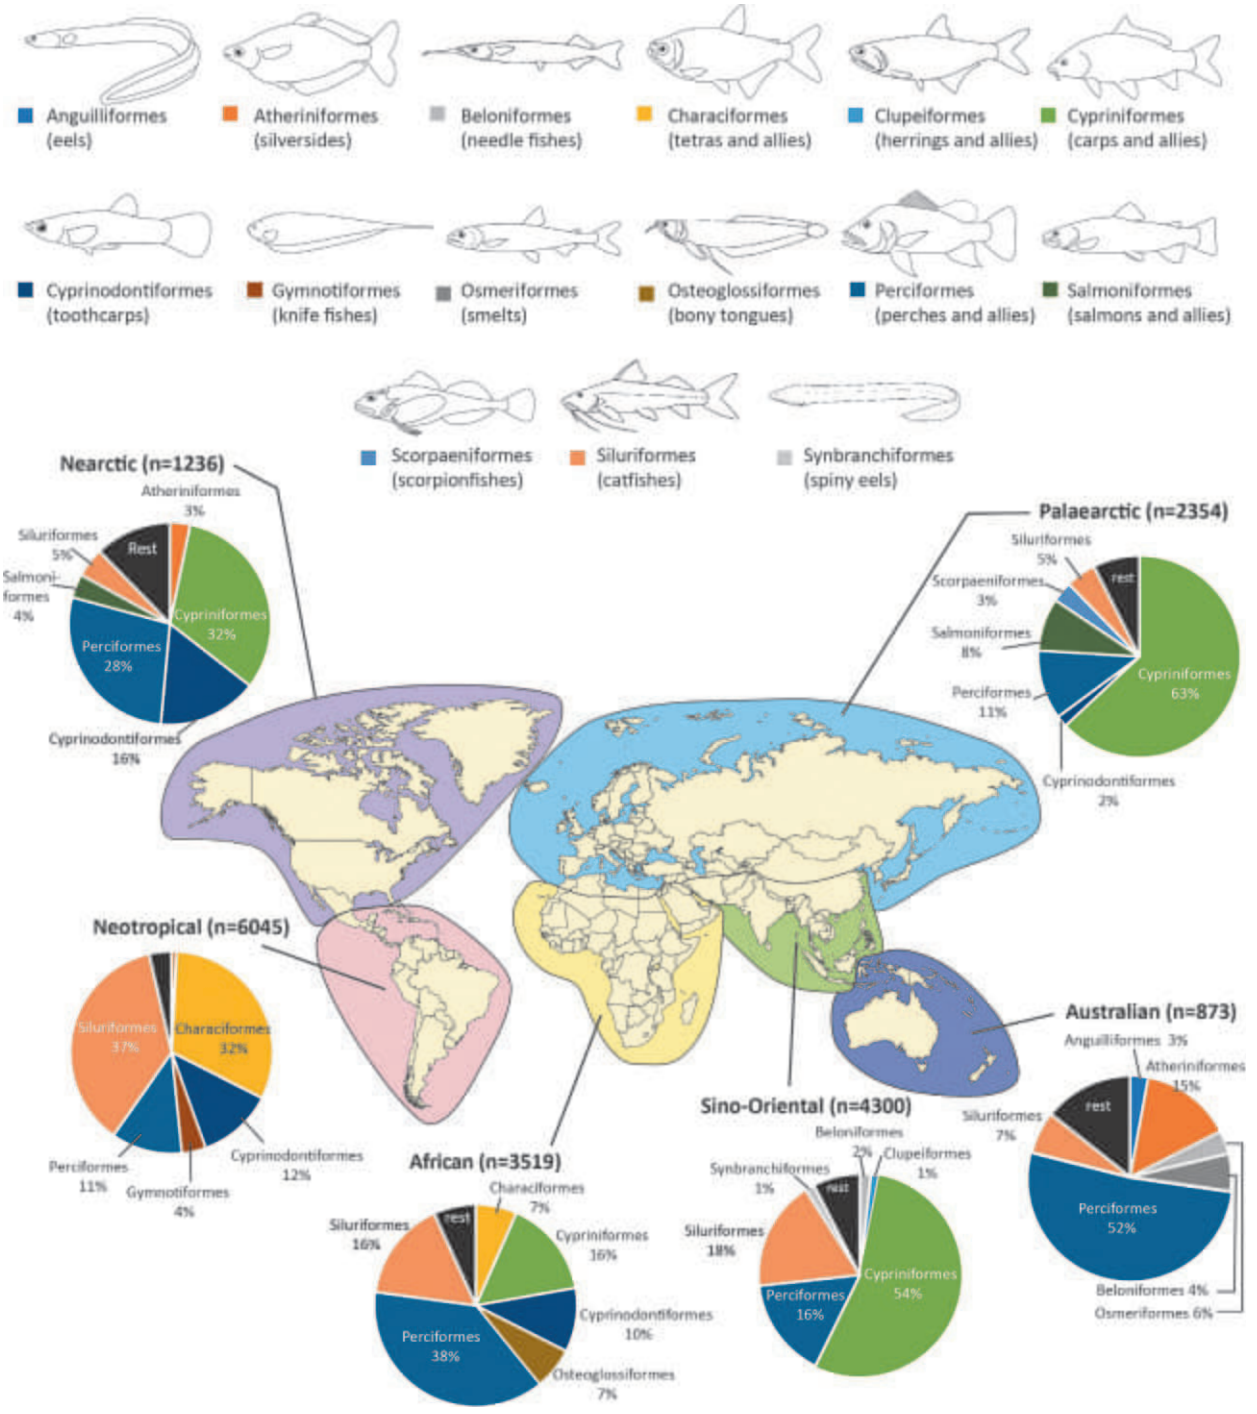

Fig. 2 Zoogeographical realms and the taxonomic composition of freshwater fish species. Number of species (*n*) in each realm and the contribution (as a percentage of the total diversity in each realm) of the six most dominant fish orders. Pie charts based on >15,000 freshwater fish species. Data from fishbase.org, accessed November 2019.

Dominant freshwater taxa

The reasons why certain fish orders dominate in some parts of the world and are absent in others (Fig. 2) is rooted in Earth's geological history and the breakup of the supercontinent Pangea (c. 250–100 Ma). The distinctiveness of continental fish faunas roughly reflects the amount of time that the organisms on those landmasses have been isolated from one another. Continents that have relatively high similarity, at least at a higher taxonomic level, were connected during the more recent parts of their geological histories. The very distinct floras and faunas of the Australian realm, on the other hand, reflect their long geographic isolation from any of the other major land masses. At lower taxonomic levels, distributional patterns of genera and species are further determined by interactions between (a)biotic conditions and species' functional traits (allowing them to thrive in some habitats, but not in others), as well as species' dispersal capacities (see "Taxonomic and functional disparities" section).

Remarkably, around 85% of the total global freshwater fish diversity belongs to just five taxonomic orders. Given their dominance, these groups are briefly described below.

Characiformes (tetras and relatives) are known from more than 2000 species, including tetras and piranhas. All are primary freshwater species. As a group, characiforms occur in tropical freshwater in Africa, Central and South America, with one species (*Astyanax mexicanus*) extending to the Texas border. Characiformes usually have an adipose fin, well-developed teeth in their oral jaws, a scaled body, and lack barbels. Most species grow to a relatively small adult body size (<5 cm SL), but some (e.g. *Hydrocynus goliath* in Africa and *Salminus franciscanus* in South America) can reach up to 1.3 m.

Cypriniformes (carps and relatives) are known from more than 4600 species, including goldfish, common carp, minnows and loaches. All are primary freshwater species, with the greatest diversity found in south-eastern Asia, and the group is absent from Australia and South America. Cypriniforms are characterized by a protrusible jaw in most species, having only a dorsal fin on their back (no adipose fin), and lacking teeth on the oral jaws, but possessing unique tooth plates in their throat (the pharyngeal jaws).

NOAA, obtained through Wikimedia Commons.

Cyprinodontiformes (toothcarps) are known from more than 1400 species, including guppies, mollies, swordtails and killifishes. They are secondary freshwater species, found mostly in freshwater and coastal marine areas, especially marshes, on all continents except Australia and Antarctica. Most species are small to medium-sized fish, with small mouths, large eyes, a single dorsal fin, a rounded or truncate caudal fin, a lateral line with pores on the head and pitted scales on the body, and pectoral fins usually set low on the body. Many species are livebearers (viviparous or ovoviviparous).

Perciformes (perches and relatives) are known from more than 10,000 species, both marine and freshwater species. Freshwater species include cichlids, freshwater sunfishes (centrarchids), and perches and North American darters (percids). They are secondary freshwater species found on all continents (except Antarctica) and in all oceans. Most, but not all species have spines present in the dorsal and anal fins, thoracic pelvic fins with one spine and five rays, ctenoid scales, two dorsal fins and no adipose fin.

Siluriformes (catfishes) are known from about 4000 species. Most catfishes are primary freshwater species, with two families of predominantly marine species. They occur on all continents except Antarctica, and are easily recognized by having up to four pairs of barbels around the mouth, lacking teeth, usually having an adipose fin, spine-like rays at the anterior dorsal and pectoral fins, and the body naked or covered by bony plates. Catfishes have an electroreceptive sense, and most species are nocturnal.

Within river patterns: From headwater to estuary

Despite idiosyncratic differences in taxonomic composition and evolutionary history of regional ichthyofaunas, many aspects of fish assemblage structure change predictably from headwaters to river mouth, a phenomenon known as the River Continuum Concept (Vannote et al., 1980; Fig. 3). Changes in river basin geomorphology and hydrology along the course of rivers reflect processes governing current speed, sediment load and organic matter decomposition, and allochthonous versus autochthonous production (Leopold, 1994). The taxonomic composition, phenotypic characters, and community structure of freshwater fishes in all regions of the world is strongly affected by longitudinal fluvial gradients (Matthews, 2012; Lujan et al., 2013).

Headwater streams are usually narrow and, when originating below the tree line, often over-shaded by marginal vegetation. Headwater streams generally also have cooler water temperature, because of the high elevation and the rapid flow rate down steep terrains. Consequently, in situ productivity is low and food chains relatively simple and short, depending strongly on allochthonous

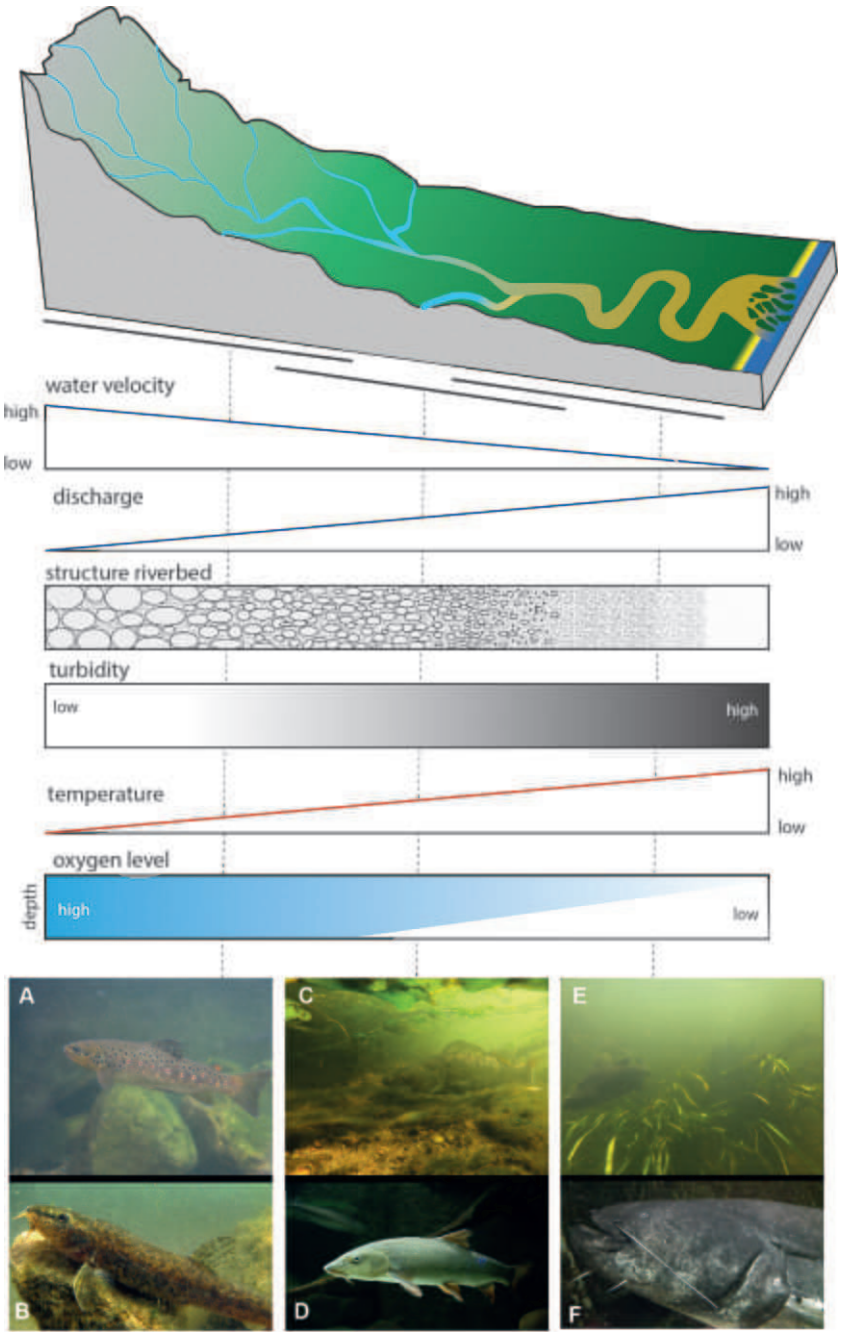

Fig. 3 Most rivers have a clear turn-over of fish assemblages (and dominant species) from headwaters to delta, reflecting changes in the physical environment as shown in a generalized form here. Some headwaters may originate in the lower sections of rivers (e.g. small forest creeks) and will not show pronounced changes in some of the physical properties illustrated here (e.g. temperature and structure of the riverbed). Some examples of indicator species for different river sections from the Rhine basin: (A) brown trout (*Salmo trutta*), (B) stone loach (*Barbatula barbatula*), (C) zander (*Sander lucioperca*), (D) common barbel (*Barbus barbus*), (E) common bream (*Abramis brama*), and (F) wels catfish (*Silurus glanis*).

inputs from terrestrial photosynthesis. In headwaters that lie above the tree line the predominant fishes are small-bodied algae-grazers.

Mountain-dwelling fishes usually exhibit morphological and ecophysiological specializations that facilitate life in high-elevation and torrential waters; i.e. rheophily. Rheophilic fish species commonly possess streamlined bodies or morphological structures that allow them to cling to bottom substrate, such as fin hooks, and mouths or fins shaped to form a sucker disk (Lujan and Conway, 2015). As headwaters are usually oxygen rich water, headwater specialist fishes have low tolerance to low oxygen levels such as can be found in lower sections of river.

Mountain and hill-stream fishes have evolved multiple times independently in each of the world's major mountainous regions (Albert et al., 2018). North American groups include the rainbow trout and relatives (*Oncorhynchus* with 10 species) in the mountains of western North America, and minnows and shiners (*Cyprinella* and *Notropis* with 64 species), and North American darters (*Etheostoma* and *Percina* with 132 species) in uplands of eastern North America. South American groups include the characiforms *Creagrutus* with at least 75 species and *Parodon* with 15 species, the catfishes *Astroblepus* with at least 80 species, *Chaetostoma* with at least 48 species, and *Trichomycterus* with at least 49 mountain species, and the killifishes *Orestias* with 45 species.

Eurasian groups include the snow minnows (Schizothoracinae) with at least 76 species in the Himalayas-Tibet region, the hillstream loaches (Balitoridae) with at least 102 species in the mountains of south and southeast Asia and Sundaland, the catfish families Akysidae with 57 known species and Sisoridae with at least 292 species. African mountain fishes include the cyprinid *Luciobarbus* with 38 species and the catfish family Amphiliidae with at least 102 species. There is also a curious group of fishes in their own family, Galaxiidae, with about 66 species that exhibit a circum-Antarctic distribution in high-altitude rivers of southern New Zealand, Australia, Africa and South America.

Middle sections have warmer water than headwaters and more autochthonous production (e.g. by algae) because of the nutrients that come down from headwater streams and because of increased light availability as rivers widen. Water flow is slower and food chains begin to lengthen. In West- and Central Europe, common fish species in middle sections are those of the genus *Barbus* (Fig. 3D), which depend on gravel beds for spawning.

Toward the mouth of the river, conditions start to resemble a slowly moving lake. Energy availability from both allochthonous and autochthonous production is high, as is energy input and dissolved organic matter from upstream reaches, leading to an increase of detritus- and plankton feeding species and mud as feeding ground. Turbidity is commonly also high and species that find food visually decrease in abundance. Oxygen levels are usually much lower compared to headwaters because of the combination of higher water temperature, lower flow rate and high decomposition of organic material. Brackish water, or occasional brackish conditions, in the lowest reaches of rivers can limit the occurrence of primary freshwater fishes, but fish diversity can be high due to the presence of secondary and peripheral freshwater fishes (see "Freshwater fish" section).

There may be many fish species that do not clearly conform to the river continuum concept, roaming from headwater to delta, but large rivers usually have a clear turn-over of fish assemblages along their course, at least among the species that dominate.

Importance of river floodplains for riverine fish diversity and abundance

Although the River Continuum Concept provides an important holistic view of river systems, it initially did not consider the role that lateral floodplains play in supporting aquatic productivity. Possibly, the importance of floodplains for fish was long misunderstood because nearly all large rivers in the temperate region were already heavily modified landscapes prior to scientific study (Opperman et al., 2017). It is now broadly recognized however that floodplains play a crucial role for fish abundance and diversity, with many studies across the world showing direct relationships between fish production and the extent of floodplain inundation (e.g. Welcomme, 1979; Risotto and Turner, 1985; Beechie et al., 1994; Agostinho et al., 2004; Pander et al., 2015). Consequently, the river continuum concept has been extended with the flood pulse concept (Junk et al., 1989), recognizing that floodplains are intimately connected to rivers (Fig. 4).

Floodplains are inundated seasonally (predictably) in most river systems, but irregularly (unpredictable) in others. The predictably, seasonality and duration of the flooding determine the extent to which fish fauna in a river system depend on, and have developed specific adaptations for, exploiting floodplains (King et al., 2003). When flooding is predictable (e.g. annual) and duration relatively long (e.g. several months), many fish will show adaptations to exploit the abundant food resources on floodplains and will use the floodplains as spawning and nursery areas. This is the case in most large tropical rivers, such as large parts of the Amazon, Congo and Mekong. Here, the flooding season usually represents the time of plenty during which fish built up fat reserves and use floodplains for spawning and rearing (e.g. van der Sleen and Albert, 2017). Predation rates are commonly low during the flooding season as fish are dispersed over large and vegetated areas. In the Amazon basin, the flooding period also coincides with the peak of the fruiting seasons of riparian trees. Many fish species feed on floodplain tree seeds and fruits, which form important nutritional items (e.g. Goulding, 1980; Fig. 4). In return, fish can be important (upstream) dispersal agents of tree seeds, a process known as ichthyochory. Access to this seasonal bonanza can be limited by extreme and persistent hypoxia in tropical floodplains, caused by decomposition of forest litter during the flood season. Fishes that exploit tropical floodplains therefore commonly possess a combination of morphological, physiological and behavioral adaptation for hypoxia.

The dry season can represent the opposite case, when fishes are restricted to the main river channels or oxbow lakes on the floodplain, food availability is low, and many fish species use fat reserves, built up during the floods, to survive. Predation rate and mortality can be very high during the dry season. These pronounced seasonal changes in food availability and predation risk may be an important mechanism for maintaining high levels of riverine fish diversity in tropical rivers (Lowe-McConnell, 1987). During the

Fig. 4 Example of floodplain forests (flooded forests) in the Amazon basin (middle Rio Negro, Brazil), during the low-water season (A; October to April in this part of the basin) and high-water season (B, May to September). Fishes and trees; a few examples of fish utilizing floodplains at high- and low latitudes: (C) a small pike (*Esox lucius*) hiding in the branches of a submerged willow tree, the Netherlands. (D) Common carp (*Cyprinus carpio*) spawn in areas of submerged vegetation in floodplains and lakes (photo from the Meuse basin, Belgium). Carp reproduction success is restricted to years when water levels start rising in May and when high temperatures and flooding of terrestrial vegetation last for a long period during May and June. (E) *Brycon hilarii* and *Piaractus mesopotaminus* swimming through an open area in the middle of submerged floodplain forest, Paraguay river, Brazil. (F) *Brycon pesu* in a submerged floodplain forest in the lower Tapajos River, Amazon basin, Brazil. Species of *Brycon*, *Piaractus* and carps are known to disperse seeds of floodplain plants, a process known as ichthyochory.

flooding season, food is abundant in such quantities that fish are not competing with each other, sharing the available resources. Any competitive advantage, and disproportional increases in population size, will be unset during the low water season, when predators likely prey on the more abundant species, and switch to other prey species with decreased abundance. As such, high predation during the low-water season may prevent any given species from becoming dominant and outcompeting others.

In temperate regions, water temperature will co-determine how much fishes can exploit floodplains. If floodplains are inundated in winter, fish may not be able to utilize the floods because of low metabolic rates and/or because of low primary productivity on the floodplains during winter. Fish in temperate region will therefore benefit most strongly from flooding in spring or summer. If that is the case, floodplains can be highly favorable habitats for juvenile fish, because of the slower water speed, usually warmer water (due to reduced flow rates), high food availability and low predation risk.

When flooding is unpredictable in timing and/or duration fish communities will lack specific adaptations for using floodplains. Nonetheless, fish will still benefit from the allochthonous energy input and use the floodplains more opportunistically. The importance of floodplain habitats for fish is difficult to overstate. Unfortunately, natural floodplains continue to be among the fastest disappearing habitats in the world.

Taxonomic diversity of freshwater fish

At a macroevolutionary scale, the species richness of a clade, such as a fish family or genus, is a balance between rates of speciation that increase diversity, and extinction, that reduce diversity. Rates of speciation in fishes have been hypothesized to be higher in lacustrine than riverine habitats (see "Lacustrine species flocks" section; Miller, 2020). Yet most freshwater fish diversity is thought to have arisen by allopatric speciation within the dendritic spatial geometry of continental river systems (Albert et al., 2011b, 2017; Miller, 2020). River basins have a much larger total habitat footprint than lakes, are often much older, and have a more complex history of rearrangements due to river capture and sea-level changes (Albert and Crampton, 2010; Albert et al., 2018).

Taxonomic and functional disparities

Diversity measures for freshwater fishes vary strongly among taxonomic groups. This may relate partly to the amount of research effort that has been dedicated to particular fish groups, but it is undeniable that diversity is not distributed equally across branches of the phylogeny of fishes (Alfaro et al., 2009). Among fishes, some higher taxa (e.g. families or genera) are exceptionally diverse, with hundreds of species exhibiting a wide range of functional traits, while others are represented by just one or a few species and little functional diversity. In fact, most of the higher taxa in fish, as in most groups of organisms, are species poor, while most species are members are a few species-rich groups (Albert et al., 2011a; Worm and Tittensor, 2018).

Many reasons have been proposed to explain these taxonomic and functional disparities. Some explanations focus on the role of so-called "key innovations," novel evolutionary traits that either spur speciation or reduce extinction (Seehausen, 2006; Siqueira et al., 2020). These traits can include any aspect of an organism's phenotype that allow many closely-related species to co-exist together in sympatry, including for example: small adult body size (Albert and Johnson, 2012), chromosomal and genomic reorganization (Volff, 2005), developmental canalization and modularity (Larouche et al., 2018), ecological specialization (Seehausen and Wagner, 2014), and specialized sexual communication systems (Crampton and Albert, 2006; Arnegard et al., 2010).

In addition, speciation rates can also relate to traits that impede dispersal, such as **philopatry** or the absence of dispersal-specialized developmental stages (Likens et al., 2009). For example, the loricariid catfishes (family Loricariidae) from South America attain relatively small adult body sizes and most species are highly territorial. As a consequence, the dispersal capacity of most loricariid species is low, which increases the chances for geographic isolation and speciation. Indeed, over 1000 loricariid species are known. In contrast, only 114 species are known in another catfish family occurring on the same continent, the Pimelodidae, which consists of large-bodied migratory catfishes, many of which are widely distributed. Reduced dispersal capacity has been suggested as an important factor underlying species richness in many fish families.

Other explanations for differential diversification focus on properties of the external environment, including the contributing roles of ecological opportunity (Roxo et al., 2017), total amount of evolutionary time and ecological incumbency (Albert et al., 2011a), and the vagaries of random diversification (Albert et al., 2020). Most higher taxa of freshwater fishes originated tens of millions of years ago, in the Late Cretaceous (c. 100–66 Ma) or Paleogene (c. 66–23 Ma). For example, the bowfin or choupique (*Amia calva*) of eastern temperate North America is the sole surviving lineage of the Amiiformes, a group that was once diverse and geographically widespread across much of the world during the Mesozoic period (250–66 Ma; Long, 1995; Arratia, 2013). Indeed, almost all of the early branches of bony fishes (Osteichthyes) are relicts of groups that were formerly diverse and widespread, and which only survive in the modern world with a few species in isolated freshwaters.

Regardless of the causes, the wide distribution of evolutionary ages among fish clades indicates that the formation of the modern biodiversity arose from interactions of landscape and biotic processes over an immense time span.

Lacustrine species flocks

Some fish groups exhibit a tremendous capacity to diversify rapidly. This capacity is well-illustrated by the phenomenon of "lacustrine species flocks," the accumulation of many closely-related species within the circumscribed area of a large lake basin (Echelle and Kornfield, 1984). Such rapid accumulations of many closely-related species, often differing from one another in traits related to feeding and habitat, have long been thought to represent classic examples of Darwin's hypothesis for the origin of species by means of natural selection (Goldschmidt, 1998; Foote, 2018; Richards et al., 2018).

Species flocks of lake-dwelling fishes have been described on all continents except Antarctica, concentrated in regions that were previously defaunated due to climatic or tectonic events (ice ages, vulcanism), or otherwise lacking an incumbent fauna of primary freshwater fishes (Cavin, 2017). Some of the more well-studied fish lacustrine species flocks include the cottoid sculpins of Lake Baikal, Russia (with 22 spp. in two genera), *Orestias* killifishes of the Lake Titicaca basin in the Andes of Bolivia and Peru (with 23 spp.), *Coregonus* ciscos or whitefish salmonids of the Great Lakes of North America (with 8 spp.), cypriniform barbs of Lake Tana,

Ethiopia (*Labeobarbus* 27 spp.) and Lake Lanao, Philippines (*Barbodes* 18 spp.), and Sailfin silversides (*Telmatherina* 10 spp.) in the Malili Lake system of Sulawesi, Indonesia.

Certainly the most spectacular of all of the fish species flocks are those of the haplochromine cichlids in the Great Lakes of the East African Rift Valley. These haplochromines have radiated into more than 3000 distinct phenotypes, each representing a putative species lineage, in only a few millions of years or less. Lake Victoria, with a flock of 500 morphotypes, is thought to have been a dry lake-bed perhaps as little as 14,000 years ago (Meier et al., 2017). There are also at least 241 cichlids representing several different clades in Lake Tanganyika (age 9–12 Ma) and about 400 species representing other additional clades in Lake Malawi (age 4.5–8.5 Ma). There are also well-studied cichlid species flocks in smaller lakes in volcanic calderas, for example in Cameroon (West Africa) and Nicaragua (Central America).

Cichlid fishes differentiated most rapidly in aspect of their head and mouth shape, structure of the teeth in the oral and pharyngeal jaws, and color patterns based on pigment cells called chromatophores. All these tissues are derived developmentally from a unique and exceptionally plastic vertebrate cell type called the neural crest (Bronner and LeDouarin, 2012; Powder and Albertson, 2016). These traits, associated primarily with feeding and sexual behaviors, allow species to occupy a wide variety of ecological roles in lacustrine ecosystems.

Species flocks have attracted much attention in the hope they would illustrate conditions in which adaptive divergence based on ecological specialization results in speciation. Yet in most cases where detailed population genetic and phylogenetic studies have been performed, the species that constitute a lake fauna have not been found to be monophyletic. Rather the species flock has been found to have accumulated through multiple rounds of dispersal and subsequent speciation, in and among the lake and tributary rivers of the regional watershed (Turgeon and Bernatchez, 2003; Lüssen et al., 2003; Martin et al., 2015). Many of the classic examples of sympatric speciation in lakes have been shown to involve complex histories of gene flow and dispersal into and out of the lake (Kontula et al., 2003; Fruciano et al., 2016; see review by Stroud and Losos, 2016). Lacustrine species flocks in general represent cases in which both ecological and geographic factors conspired to generate rapid adaptive diversification.

Threats to freshwater fish diversity

There are hardly any large rivers systems left on our planet in which fish do not face a multitude of threats (e.g. Dudgeon, 2019; Reid et al., 2019). Severe and persistent pollution continues to be a major problem in many rivers and includes pesticides and fertilizers running off from agricultural land, mercury from gold mining in headwaters, microplastics, and pollutants that affect the sex ratio in fish populations. Loss, or severe reduction, of river connectivity is another major threat. The construction of large hydrological dams for power plants is a growing concern for fish diversity in many tropical rivers (Winemiller et al., 2016). Hydropower dams modify habitat conditions in large areas upriver and down-river of the dam, retain sediments and nutrients in the reservoirs, and block fish migration routes. Fish passages (i.e. fish ladders) are often insufficient to fully mitigate the loss of connectivity and obstructions to fish migration routes (Brink et al., 2018).

Dams and other water diversion structures also strongly modifying the natural flood regime downriver (Timpe and Kaplan, 2017). These structures change the annual flood pulse to become highly intermittent, with important consequences for fish populations that depend on predictable access to floodplains for food, reproduction and rearing. In addition, floodplains have been severely modified throughout most of the world due to drainage and land-use change (e.g. deforestation for agriculture). In some parts of the world, the introduction of non-native (i.e. exotic) species is another major issue, causing (local) extinction of native species. The introduction of the Nile Perch (*Lates niloticus*) in Lake Victoria is a much studied example of the dramatic effects that alien species can have on an entire ecosystem (e.g. Goldschmidt, 1998). For other species, persistent overfishing led to the disappearance of larger individuals, with ramifications for the important ecological and demographic roles that larger individuals can play. On top of all this, climate change is becoming an increasing stress factor in many freshwater ecosystems, affecting species through warming water temperatures, shifting streamflow regimes, increasing extreme (e.g. flooding and drought) events, and facilitating species invasions.

Freshwater ecosystems and their associated riparian habitats are among the most biologically diverse on Earth, and have inestimable economic and cultural values. Yet human impacts to lakes, rivers, streams, wetlands and groundwater are dramatically reducing biodiversity and robbing critical natural resources and services from current and future generations. Freshwater biodiversity is declining rapidly on every continent and in every major river basin on Earth, and this degradation is occurring more rapidly than in terrestrial ecosystems (Albert et al., 2021). The abundances of freshwater fish populations have become dramatically reduced since 2000, at local scales in both temperate (Freyhof and Brooks, 2017) and tropical (Cohen et al., 2016; Pelicice et al., 2017) latitudes, and in different climate zones (Ngor et al., 2018). From 1970 to 2012 populations of freshwater fishes have declined by 88%, with mega-fishes (>30 kg) undergoing the largest declines (–94%, Carrizo et al., 2017; He et al., 2019).

Many freshwater fish have narrow distributional ranges or have small population sizes, making them intrinsically rare and sensitive to local disturbances. Data suggest that up to 40% the freshwater fishes in Europe and North America are at risk or already lost (Maitland, 1995; Jelks et al., 2008). Globally, it is estimated that 20% of all freshwater species have become extinct or face extinction in the decades to come, and this percentage will likely continue to increase in the future. The Yangtze basin is among the most impacted of any large river on Earth, with the recent extinction of the Yangtze paddlefish *Psephurus gladius* (Zhang et al., 2009). The Yangtze paddlefish was the last surviving species of a lineage that originated in the super-greenhouse world of the Mesozoic, with fossils from the Upper Cretaceous about 75 million years ago.

Effective management of freshwater resources and ecosystems must be ranked among humanity's highest priorities. The remedies - restrictions to the construction of dams, pollution control, restoration of wetlands areas, limits on harvests of vulnerable species, and restrictions on the translocation of non-native species—are well known, but modification and degradation of river systems still outpaces initiatives to mitigate the threats to freshwater diversity in most parts of the world. Freshwater faunas worldwide are imperiled and the future looks bleak for many freshwater fish species. Coordinated actions are urgently needed at the local, regional and international levels, in order to conserve freshwater habitats and species that have taken millions of years to evolve.

Glossary

Adaptation Heritable trait that fits an individual to its conditions of existence, leading to similarity among organisms that have similar lifestyles.
Amniotic egg Type of egg in which the embryo develops inside a protective membrane called amnion.
Anthropogenic impact Impact directly or indirectly caused by humans. Anthropogenic impacts in the environment include habitat degradation and climate change.
Body plan General morphological structure each organism assumes as it develops.
Cryptic diversity Defined as the occurrence of two or more distinct species erroneously classified as one species, often made up of morphologically similar but genetically distinct taxa and largely affected by biodiversity shortfalls and sampling gaps.
Embryonic development Process by which the embryo is formed and developed.
"Herps" or Herpetofauna Reptiles and amphibians of a particular region, habitat, or geological period. This is an artificial classification convenient for research purposes but does not reflect evolutionary relationships among these groups of vertebrates.
IUCN Red List The International Union for Conservation of Nature (IUCN) Red List of Threatened Species (also known as the IUCN Red List or Red Data List), is the world's most comprehensive inventory of the global conservation status of species.
Non-avian reptiles Cladistic term referring to all representatives of the class Reptilia, excluding birds (Aves).
Osmotic stress Physiological dysfunction caused by a sudden change in the concentration of solute around a cell, which causes a rapid change in the movement of water through its cell membrane.
Riparian environment Interface between land and a river or stream. Its geographical extension differs depending on the type of organism considered.
Semi-aquatic Organism that spends part of its life in an aquatic environment.

Introduction

Amphibians (frogs, salamanders and caecilians) and reptiles such as squamates (amphisbaenians, lizards and snakes), chelonians (turtles and tortoises) and crocodilians (alligators, caimans, crocodiles and gharials) have traditionally been recognized as "herpetofauna." Although such classification may be convenient for research purposes, it does not reflect evolutionary relationships among these animals, because amphibians and reptiles are distantly related in biological evolution. Furthermore, even though birds are closely related to crocodilians, they are not traditionally considered to be reptiles. Finally, the evolutionary origin of chelonians has been historically uncertain (Pyron et al., 2013; Shaffer et al., 2017; Zheng and Wiens, 2016).

Although all "herps" share the characteristic of being ectothermic animals, having body temperatures mainly varying according to the environmental conditions, they have a critical difference that influences their level of dependence to water: the amniotic egg. Amphibians lack an amniotic membrane during embryonic development, which imposes an aquatic phase at least during part of their development. However, many lineages conquered certain independence from water through development of the embryo on humid terrestrial habitats, or inside body pouches. Conversely, reptiles are amniotes, and their embryonic development is completed under protective membranes inside the egg. The origin of the amniotic egg, approximately 300 million years ago, was an important step in the evolution of vertebrates that allowed diversification of species without an aquatic larval stage (Pough et al., 2003).

More than 8500 amphibian and reptile species (43.4% of global diversity; Frost, 2020; Uetz et al., 2020) live in wetlands around the world, and therefore those ecosystems are extremely important for herpetofauna conservation (Junk and da Silva, 1997). While some species rarely leave permanent wetlands during their lifetimes, others temporarily occupy ephemeral swamps or seasonally flooded forests and grasslands, or just use wetlands as dispersal routes. Regardless of the time spent in wetlands, these ecosystems provide the resources necessary for herpetofauna to thrive. For instance, wetlands are bridges connecting terrestrial and aquatic habitats (Junk et al., 1989), so amphibians with aquatic larvae can complete the life cycle within these habitats, and reptiles can move freely between land and water to perform vital activities such as eating, thermoregulating and fleeing predators.

In this chapter, we introduce wetland amphibians and reptiles to the reader. We show some of their ecological and morphological adaptations that enable life at different degrees of association to these environments and discuss the overall threat status and challenges to promote species conservation. Finally, we argue on the importance of protecting these species-rich and threatened ecosystems. We based our species diversity and conservation assessments on the International Union for Conservation of Nature (IUCN) Red List. We further use more refined group-specific assessments when available for turtles (Rhodin et al., 2018) and for lizards and snakes (Meiri, 2018; Uetz et al., 2020).

Amazing forms, incredible diversity and conservation challenges

Amphibians

The term "amphibian" derives from the ancient Greek meaning "two kinds of life," and is allusive to the use of both terrestrial and aquatic environments. Modern amphibians (subclass Lissamphibia) are a monophyletic group comprising all frogs, toads, salamanders, newts, and caecilians, which are generally thought to be closely tied to wetlands because of general characteristics such as unshelled eggs (Fig. 1A) and permeable skin (Fig. 1B). Even though a few from the ca. 8300 species known to date (Frost, 2020) are able to tolerate high levels of salinity, amphibians have no marine representatives. The high rate of species discovery and the lack of knowledge on details about their natural history precludes us from obtaining an accurate estimate of the magnitude of the use of inland waters by amphibians. However, it was estimated that about three quarters of the extant amphibian species have a close relationship to freshwater environments at least during some part of their life cycles, usually during their larval, tadpole stage (Vences and Köhler, 2008).

Amphibian species can be categorized in four main groups depending on their relationship with water environments (Vences and Köhler, 2008): (a) aquatic: with at least part of their life cycle in or on the water; (b) water dependent: which do not live directly in the water but closely depend on it for resources such as habitat or food; (c) water related: aquatic plus water dependent species; and (d) non-water related: which are neither aquatic nor water dependent. The overwhelming majority of known amphibians are aquatic organisms that depend on water environments for egg deposition and tadpole development. However, just a few species can be considered water related (strictly aquatic) since most of them do not necessarily depend on water bodies during the post-metamorphic stage, which is rarely fully aquatic. Extreme association with aquatic environments occurs in some groups of caecilians (Fig. 1C) and salamanders, whose species usually share dorsolaterally flattened tails and large fins that facilitate swimming. As for anurans, two frog families can illustrate both extremes of the water dependency gradient: all species on the Pipidae family are closely tied to freshwater environments, as their entire life cycle occurs inside water (Fig. 1D). Members of this family show remarkable adaptations such as vocalization, mating, and egg deposition entirely underwater. Adults also show morphological traits such as presence of a lateral-line system for detection of movement and pressure gradients in the surrounding water and interdigital membranes for swimming. Conversely, Craugastoridae is a speciose non-water related family comprising terrestrial frogs whose males vocalize from territories established on the forest floor. Egg clutches are usually deposited in the soil under fallen leaves and depend on environmental humidity. Development to metamorphosis occurs within terrestrial eggs with the absence of an aquatic, free-living tadpole stage.

At a community level, the affinity with wetlands strongly influences the formation of amphibian assemblages. For example, distance from streams is the main factor influencing the occurrence and abundance of aquatic-breeding species in Amazonian forests (Menin et al., 2011). As a consequence, the distributions of amphibian species with aquatic reproduction are more related to environmental variables, whereas species with terrestrial reproduction show strong spatial patterns (Landeiro et al., 2014). Fine-scale distributional patterns of aquatic-breeding species such as *Atelopus hoogmoedi* and *Scinax ruberoculatus* are affected by subtle changes in limnological variables such as water pH and pond availability (Ferrão et al., 2018; Jorge et al., 2016). This reinforces the notion that aquatic-breeding amphibians are highly sensitive to environmental heterogeneity and must be regarded as powerful and reliable indicators of habitat alteration.

With regard to the conservation of amphibians in wetlands, hunting and illegal trade are worrying but represent relatively lesser threats when compared to emerging climate changes and diseases, as well as habitat degradation and loss (IUCN, 2020). For

Strong shell to avoid the predation by caimans (*Peltocephalus dumerilianus*; Podocnemididae; Ph: FV); K. Terrestrial species are able to swim considerably well (*Chelonoidis denticulatus;* Testudinidae; Ph: Thais Morcatty); **Crocodilians**: L. Laterally compressed tail (*Paleosuchus trigonatus*; Alligatoridae; Ph: William E. Magnusson); M. Flexible trunk (*Paleosuchus palpebrosus*; Alligatoridae; Ph: Boris Marioni); N. Four-chambered heart that allows complete submersion for long periods (*P. palpebrosus*; Alligatoridae; Ph: FV).

example, the waterborne disease-causing fungus *Batrachochytrium* sp. is linked to declines of hundreds of amphibian species around the world such as anurans with aquatic larvae and salamanders, and aquatic hosts are more exposed to disease during their ontogeny than species with terrestrial reproduction (Mesquita et al., 2017). Another key amphibian life-history aspect is breeding migration of individuals between suitable aquatic and terrestrial habitats, and disconnection between these systems negatively affects the richness of species with aquatic larvae (Becker et al., 2007). Although research has been carried out since amphibian declines were first detected in the 1990s, apart from some specific examples, little empirical progress on their conservation has been made (Grant et al., 2019), and currently amphibians constitute the tetrapod group most threatened with extinction (IUCN, 2020). Consequently, the viability of their populations in the Anthropocene depends on actions aiming to the integrity of aquatic environments, as well as their proper connectivity to suitable land, thus permitting the amphibious way of life of these highly sensitive organisms.

Lizards

Various squamate groups that began to diversify about 200 million years ago are collectively known as "lizards." Most of the extant lizards share a characteristic standard body plan, which also corresponds to the body plan of their extinct relatives and the first amniotes (Pough et al., 2003). Such a generalized body allows these highly adaptable vertebrates to explore the environment in a very efficient way, leading to high species diversity, currently occupying most of the distinct ecosystems on Earth (Pough et al., 2003). Throughout evolutionary history, lizards also diversified into alternative body plans, well adapted to different dietary preferences and habitats. One of the best known evolutionary changes in this group is the reduction or loss of limbs associated with body elongation (Wiens et al., 2006). This "serpentiform body plan" increases the efficiency in burrowing or crawling lifestyles and independently occurred several times during the evolution of fossorial, arboreal and terrestrial animals (Caldwell, 2003). Extreme examples of these changes in lizard evolutionary history include highly specialized groups, such as the diggers amphisbaenians and the hyperdiverse snakes (focus of the next section).

As a result of the evolutionary novelty provided by the amniotic egg, lizards have widely diversified at the terrestrial interface and strictly aquatic species are currently unknown (Bauer and Jackman, 2008). However, the spatial occurrence of lizards across the landscapes are largely controlled by humidity and temperature gradients, both in global and local scales (Bauer and Jackman, 2008; Faria et al., 2019). This is because species have largely variable requirements regarding optimal activity temperatures and resistance to dehydration (Diele-Viegas et al., 2018; Leal et al., 2002). Most lizard species periodically exploit the inland riparian environments, but for at least 132 species, those habitats are strictly necessary for their occurrence and survival, in such a way they can be considered as semi-aquatic (count updated from Bauer and Jackman, 2008; Meiri, 2018). The relative proportion of the global diversity of this lizard functional group varies widely. Diversification of semi-aquatic species are especially notable in the rainforests of the Americas and Southeast Asia (de Ávila-Pires, 1995; Bauer and Jackman, 2008; Vidan et al., 2019; Fig. 2). Most of these semi-aquatic lizards live at the terrestrial interface, but some are arboreal, commonly found perched above water, and especially diverse in the stratified forest environments around the globe (Meiri, 2018; Vidan et al., 2019; Fig. 2). Conversely, semi-aquatic lizards are not diverse in the other main tropical region (Afrotropical), and are absent in the Palearctic (Bauer and Jackman, 2008; Vidan et al., 2019; Fig. 2).

Lizards with higher levels of water dependence may present remarkable ecological and morphological adaptations that facilitate their life in this environment (Bauer and Jackman, 2008), especially regarding the improvement of swimming capacity. They often possess laterally flattened paddle-like compressed tails, with crests or fins, especially useful in aquatic environments as propellers and rudders (Bauer and Jackman, 2008; Uzzell, 1966; Fig. 1E). Many species also swim by undulating the body, and they usually share keeled scales, enlarged tubercles or crests, that increase the propulsive surface (Uzzell, 1966; Vitt and Ávila-Pires, 1998). The growing evidence on the evolutionary relationships among species has shown that such unique characteristics linked to this lifestyle (known as "caiman-like" morphology) have evolved independently in lizards not directly related (Marques-Souza et al., 2018).

Some lizards living in aquatic environments also use water bodies as antipredator escape routes and have longer hind limbs, occasionally complemented with lateral extensions of the fingers, allowing support and resistance in rapid bipedal runs over the water (Bauer and Jackman, 2008; Leal et al., 2002). Similarly, semi-aquatic Amazonian lizards sleep over water bodies, and when disturbed, promptly jump into them and escape using the same strategy (de Ávila-Pires, 1995; Bauer and Jackman, 2008). Semi-aquatic anoles are also able to dive when disturbed and stay several minutes underwater, possibly breathing using air pockets like scuba tanks (Swierk, 2019). There are also some dietary specializations considering the species most linked to wetlands, which actively forage submerged and feed on aquatic organisms as arthropods, snails and fishes (de Ávila-Pires, 1995; Bauer and Jackman, 2008; Leal et al., 2002; Martins, 2006; Fig. 1F). In Amazonian seasonally flooded forests, lizards explore the terrain and resources in synchronicity with flooding events (de Ávila-Pires, 1995; Martins, 2006; Mesquita et al., 2006), even leading to the prevalence of species with seasonal reproductive cycles with small clutch sizes in these environments (de Ávila-Pires, 1995; Dixon and Soini, 1986; Mesquita et al., 2006). However, it is interesting to note that despite these similarities among some subsets of species, the semi-aquatic lifestyle is not necessarily accompanied by general syndromes of morphological homogeneities in the lizards' body plan (Leal et al., 2002). This may be a result of the fact that semi-aquatic lizards exploit the riparian environments in a very heterogeneous way (Leal et al., 2002).

As a consequence of this greater dependence on wetlands for semi-aquatic lizards, and the great sensitivity of these environments to natural or human-induced changes, many species of this functional group are currently considered threatened (IUCN, 2020). In fact, considering only semi-aquatic lizards that until publication of this book had their conservation status properly evaluated, 17% are included in one of the extinction threat categories (IUCN, 2020; Fig. 2). The main threats to these organisms include changes in the dynamics of aquatic ecosystems and deforestation, and some larger species are hunted by humans for skin trade or to

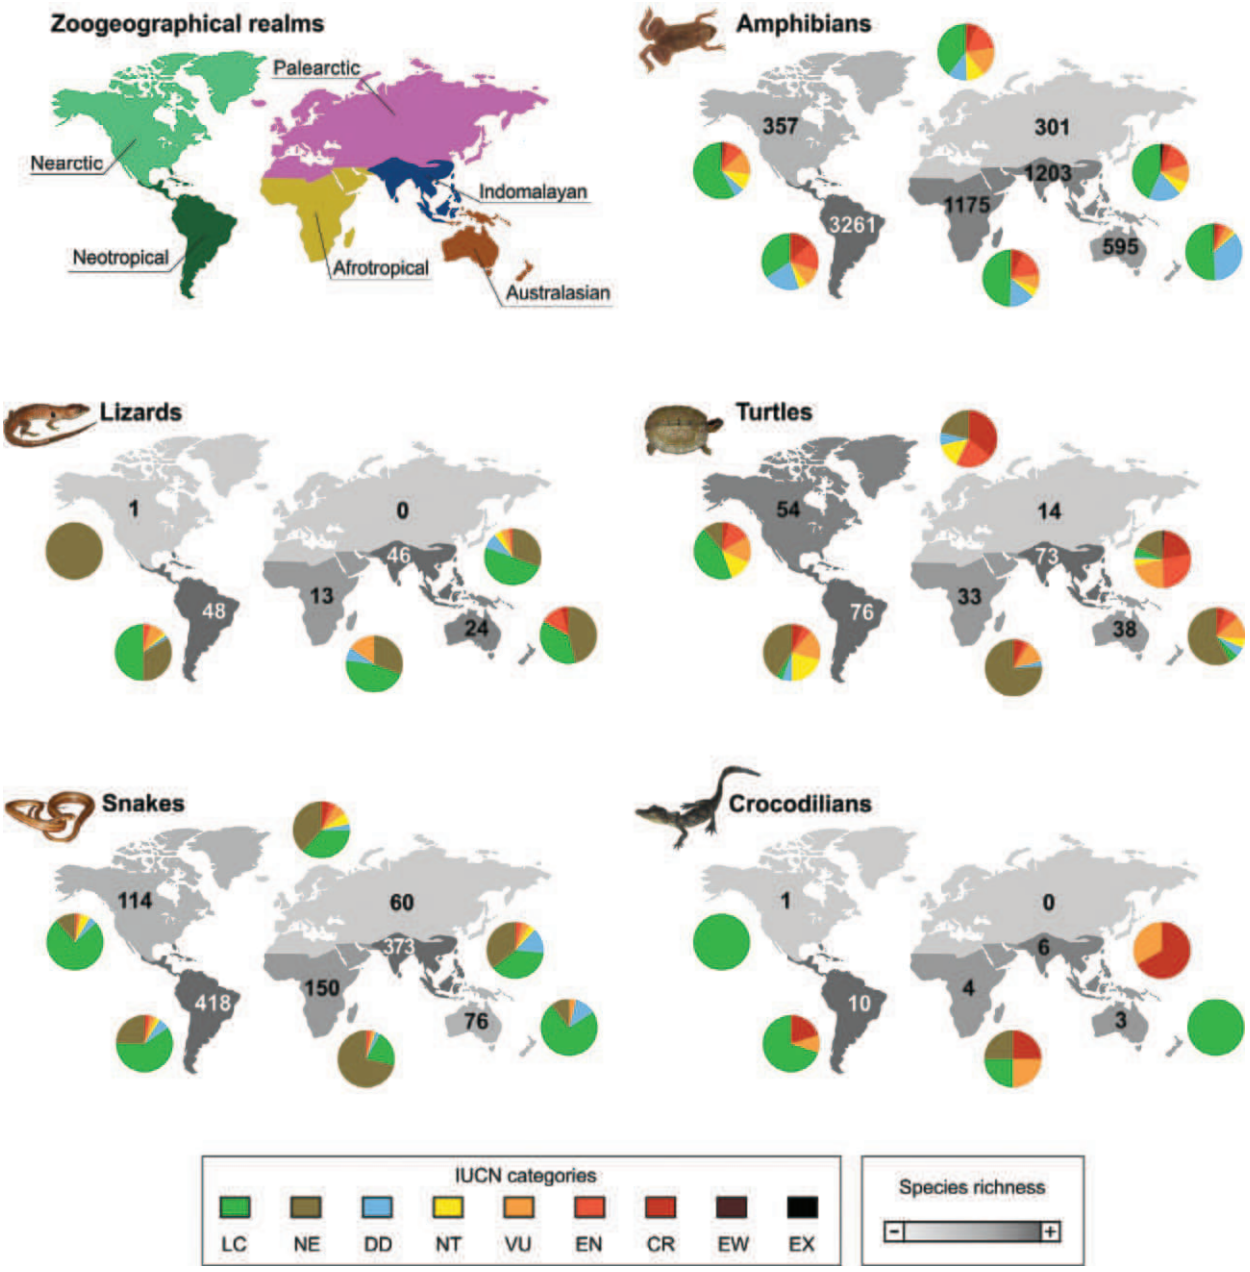

Fig. 2 Patterns of global diversity and conservation status of wetland amphibians and reptiles based on IUCN Red List assessments. Species lists are based on IUCN, with updates from Meiri (2018; lizards) and Uetz et al. (2020; snakes, crocodilians, turtles). Earth's land surface is divided in zoogeographical realms according to the IUCN classification (Oceanian and Antarctic realms omitted), with their respective species richness. IUCN categories are presented in relative percentages in pie charts using distinct colors: (LC) least concern; (NE) not evaluated; (DD) data deficient; (NT) near threatened; (VU) vulnerable; (EN) endangered; (CR) critically endangered; (EW) extinct in the wild; (EX) extinct.

be eaten (Bauer and Jackman, 2008). Although no climate-change vulnerability risk assessment has been conducted specifically for semi-aquatic lizard species, the group as a whole is considered under high extinction risk to global warming (Sinervo et al., 2010; Urban, 2015), and the wetland lizard fauna should be no exception.

Snakes

Snakes are limbless squamates closely related to lizards, which have been successful in colonizing almost the entire planet, thanks to their ability to occupy different habitats within ecosystems (O'Shea, 2018). While some species rarely emerge from underground holes, leave the water or descend from the canopy, others frequently cross through different habitats. Scientists may find clues about the habitat type more frequently used by a snake through its morphology (Cadle and Greene, 1993; Guyer and Donnelly, 1990).

Like many other animals, snakes that spend most of their time in the water often have eyes and nostrils in the upper region of the head, as this should generate some adaptive advantage to see and breathe in the water surface while avoiding overexposing the body (Fig. 1G). These snakes are commonly considered to be strictly aquatic, although the proportional area of wetlands they use may depend on their body size. Large aquatic snakes usually have a great dispersal capacity, so they are expected to explore large proportions of wetlands, or even use these environments as dispersal routes to reach adjacent habitats. For example, the giant South American Anaconda *Eunectes murinus* and the Australian Water Python *Liasis fuscus* can cross multiple wetlands connected by streams, lakes, or even dry lands (Pizzatto et al., 2009; Rivas et al., 2007). On the other hand, the smaller water snake *Nerodia sipedon sipedon* from North America rarely moves away from a single wetland. Interestingly, its closely related *Nerodia erythrogaster neglecta* has a greater ability to move across connected wetlands, even though it is not much larger than *N. s. sipedon* (Roe et al., 2003, 2004).

Snakes with similar body sizes have distinct abilities to cross wetlands, so body size is not the only factor determining the use of wetlands by snakes, but there are other factors likely to be related to local environmental conditions. Such conditions usually vary seasonally in response to climate, and snakes occupying wetlands must be prepared for changes in habitat quality (Roe et al., 2004; Seigel et al., 1995). Like all non-avian reptiles, snakes are ectotherms, and therefore have survival and reproduction largely affected by temperature. This is particularly critical in wetlands because heat is lost more quickly in the water. The temperature ranges at which a snake can maintain optimal physical and physiological activities vary widely among species, but if the tolerated water temperature range is relatively narrow for a species, it must have limited ability to cross wetlands during a cold winter (Roe et al., 2004). In addition, periods of high drought may lead to osmotic and heat stress, temporary scarcity of prey such as frogs and birds, and high exposure to predators. Therefore, during cold or dry seasons, snakes may aestivate, maintaining basal metabolic levels (just enough not to die), or they may migrate to less hostile habitats and return when conditions are more suitable (Vogrinc et al., 2018; Willson et al., 2006).

Instinctively, one could think that most snakes in wetlands are aquatic, which may be eventually true in some regions. However, a random sample of 130 species that occupy wetlands around the world reveals that most species are traditionally classified as terrestrial (Fig. 3) by the herpetological literature (see O'Shea, 2018). This classification is based on the fact that these species do not have eyes and nostrils in the upper region of the head and are more frequently found outside water. However, this does not mean that these snakes are unable to swim or move over the vegetation covering wetlands. One of the main reasons why non-aquatic snakes occupy wetlands is that these habitats are usually rich in prey such as fish and frogs (Fig. 1H). Additionally, hunting a snake in aquatic environments requires skills that are not common to most snake predators. Therefore, occupying wetlands simultaneously provides a source of food and protection for snakes (Roe et al., 2004). A good example is the semi-arboreal *Thamnodynastes lanei* (Dipsadidae), which is rarely found in the forests of eastern Amazonia, but it is the most frequently species found in the grasses covering wetlands. The diet of this species is mainly based on frogs, and its thin and light-brown colored body makes it very well camouflaged in the grass (Fig. 1I).

Investigating wetlands locally may reveal that snakes use these habitats at different levels of specificity. While some species may never leave a wetland in their lifetime, others migrate to adjacent habitats when conditions become inadequate at some time of the year, or even use wetlands only as temporary hunting sites or dispersal routes. The combination of species with different levels of specificity in the use of wetlands makes the snake diversity in these environments unique, which has led snake scientists to consider wetlands as ecologically distinct from adjacent habitats (de Fraga et al., 2011). This is relevant for conservation programs and policies, because differences in snake diversity between wetlands and adjacent habitats suggest that regional habitats are biologically complementary to each other. Therefore, wetlands should be protected at ecosystem level, although most conservation-status assessments have been conducted at species level. Looking at a comprehensive sample of 1191 snake species that occupy wetlands, most do not appear to be threatened according to the IUCN criteria (Fig. 2). However, a considerable percentage of these species (32.5%) have never been rigorously evaluated, especially in the Afrotropical realm, which is alarming in relation to the anthropogenic impacts that have affected the snake diversity of wetlands. Contamination of water and soil by heavy metals, pesticides and other pollutants is perhaps the greatest source of threat to wetlands, and there are studies showing that snakes absorb these pollutants in worrying concentrations (Campbell and Campbell, 2001; Hopkins et al., 2009). Considering that snakes are prey to a wide variety of mammals and avians, snakes contaminated by pollutants potentially harm the entire wetland ecosystem functioning.

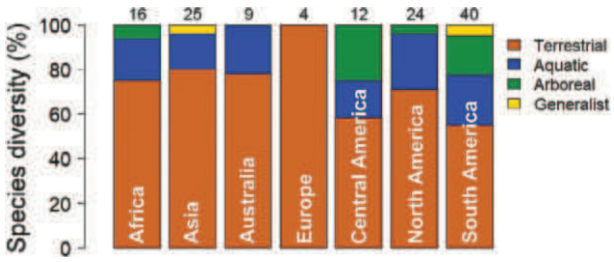

Fig. 3 Proportional species diversity of a random sample of 130 species that occupy wetlands in different regions of the world, classified by the most frequently used habitat type. The numbers above the columns indicate the number of species analyzed in each region.

Turtles

Turtles are one of the most distinctive animals on Earth that have essentially kept the same body plan for at least 220 million years (Stanford et al., 2020). The shell is their main characteristic (Lovich et al., 2018). Their lineage had millions of years of evolving adaptations that contributed to the success of this group in several ecosystems (terrestrial, freshwater, and marine). Turtles have developed morphological, ecological, and behavioral specializations that allowed them to feed and reproduce in different habitats (Moll and Moll, 2004).

Turtles show morphological adaptations to live in freshwater habitats that allow them to walk on the bottom, swim and dive. Their limbs have interdigital membranes that enable them to move in the water, and some species are able to travel long distances. Another adaptation that enhances a turtle's swimming ability is its streamlined shell (Renous et al., 2008). The shells of freshwater turtles are softer and flatter than those of terrestrial turtles, a trait that improves their hydrodynamics by decreasing drag. Also, the neck of freshwater turtles is fused to the body by a thick connective tissue, an adaptation that contributes to their ability to swim.

Wetland turtle species comprise specialized and generalized lineages whose behavior is adapted to spatial and temporal ecosystem fluctuations (Moll and Moll, 2004). Most species are influenced by the annual variation of the hydrological cycle in the various river systems where they occur, changing their densities and abundances in the geographic space accordingly. These cycles are coupled with natural flood and drought drainage regimes that alter the availability of environments used for feeding and reproduction (Bury, 1979; Junk and de Mello, 1990; Junk et al., 1989).

The Podocnemididae family in the Amazon is a good example of a lineage adapted to the hydrological cycles. All *Podocnemis* species have their feeding and reproductive cycles adapted to the dynamics of the river systems. During the annual flooding season, they stay in feeding areas, composed mostly of flooded forests, and when the water level drops, they migrate to large river waterbeds for nesting. *Podocnemis expansa*, the largest species of the genus, shows strong and extremely expanded hind limbs with well-developed interconnections between digits, that enable their migration for hundreds of kilometers (Vogt et al., 2015). Unlike other members of the genus, *Podocnemis unifilis* is a habitat generalist and has the ability to nest in different types of substrate to avoid predation; this plasticity may result in greater resilience of the populations to the ongoing climate change (Erickson et al., 2020). Another shared trait among *Podocnemis* species is the feeding behavior called neustophagia that occurs when the turtle opens its jaws slightly near the surface level to ingest food particles (Rhodin et al., 1981). On the other hand, some members of the group are less associated with deeper water levels and occur mostly in lakes and flooded forests. For instance, *Peltocephalus dumerilianus* (Fig. 1J) shell and limbs are not very well suited for swimming, but they allow an underwater walk in shallow waters in search of seeds, fruits, fish, and mollusks that are captured and chewed by strong beak and jaws. However, there are hungry predators wandering around, and it is interesting to note that the shell of *Peltocephalus dumerilianus* is strong enough to avoid predation by caimans (Vogt, 2008).

Some Chelidae species, such as *Phrynops geoffroanus*, *Mesoclemmys gibba*, and *Chelus fimbriatus*, nest at the beginning of the dry season, when it is easier to access the riverbanks (Ferrara et al., 2017). Hatchlings start to be ready at the beginning of the rainy season, when the availability of large water bodies and resources increase, and predation is reduced, since predators such as fish and caimans are more scattered in the landscape.

Among terrestrial species, *Chelonoidis denticulatus* (Fig. 1K) deserves mention for some behavioral adaptations to seasonally flooded habitats in the Amazon. Some populations that dwell in *várzea* forests and white-water rivers are able to swim considerably well, crossing rivers and large water bodies during the flooded season. Local people say that they are able to wander in the bottom of rivers for a few hours, and usually rest on floating tree trunks and branches. Unfortunately, under these circumstances they become more vulnerable to poaching (Morcatty and Valsecchi, 2015).

Presently, there are 360 chelonian species and about 80% dwell in freshwater ecosystems. A large proportion of these species (46%) are threatened at some degree, especially due to illegal consumption of their eggs and meat, and their cultural use in traditional medicine (Rhodin et al., 2018). Unfortunately, in the Amazon basin, this scenario is not different. One of the most remarkable Amazonian species, *P. expansa*, has a long history of exploitation. Turtles have been used for at least 200 years to produce oil and butter, and these unsustainable practices have resulted in depleted populations across the species range (Forero-Medina et al., 2019).

Podocnemis expansa is classified by the IUCN Tortoise and Freshwater Turtle Specialist Group (TFTSG) as a Critically Endangered species (Rhodin et al., 2018). However, a recent study indicates that although some populations are slightly declining, most populations are stable or increasing their numbers and *P. expansa* has been classified as Near Threatened in Brazil (Vogt et al., 2015). Nevertheless, as the cultural heritage in the Amazon basin values the turtles throughout the region, there is a widespread demand for meat and eggs. In 2017, Brazil took the first steps towards the turtle management with the creation of legal conditions that allow turtle community-based management initiatives for two of the most important species, *P. expansa* and *P. unifilis*. This step is very important for turtle conservation in Brazil, since it would be unfeasible to conserve species excluding the people that depend on the resource to survive. These initiatives can embrace sustainable practices if supported by useful information and technical support.

Crocodilians

Crocodilians (crocodiles, alligators, caimans and gharials) belong to a very ancient group that diversified little since they appeared some 250 million years ago (Brazaitis and Watanabe, 2011). Although earliest crocodilians were terrestrial and their original body plan evolved for life on land (Parrish, 1987), the evolution of a body plan much more efficient for swimming with a laterally

compressed tail (Fig. 1L) and a flexible trunk (Fig. 1M) facilitated aquatic lifestyles. Additionally, one of the most interesting adaptations that allowed crocodilians to fully explore aquatic environments is their four-chambered heart that allows submergence for long periods of time (reviewed in Grigg and Kirshner, 2015; Fig. 1N).

Today, all extant crocodilian species are semi-aquatic reptiles that thrive in freshwater habitats such as marshes, swamps, rivers, lakes, ponds, creeks, floodplains, artificial canals and agricultural lands throughout the tropics, subtropics, and some temperate regions (Grigg and Kirshner, 2015). Some species may even occupy estuaries and near-shore marine habitats (Nifong and Silliman, 2013; Rosenblatt and Heithaus, 2011). Some evidence suggests that habitat selects for different crocodilian species rather than the species selecting different habitats and many life history features such as reproduction, habitat use, feeding, genetic flow and social interactions have been shaped by the surrounding environment (reviewed in Somaweera et al., 2019).

In general, most crocodilians are habitat generalists. Some species such as the American alligator (*Alligator mississippiensis*) may occupy both coastal and inland habitats (Wilkinson, 1984). The freshwater crocodile (*Crocodylus johnstoni*) from northern Australia thrives in almost all freshwater habitats, including small and sometimes ephemeral headwater streams, and the downstream tidal reaches of large rivers (Webb et al., 1983). However, in places like the Amazon basin, four crocodilian species occupy the same geographical area with overlapping distributions, but avoid interspecific competition by occupying specific habitats and partitioning food resources (Villamarín et al., 2011, 2017). There, the black caiman (*Melanosuchus niger*) occurs predominantly in seasonally inundated floodplains, whereas the spectacled caiman (*Caiman crocodilus*) and the Cuvier's dwarf caiman (*Paleosuchus palpebrosus*; Fig. 1N) are somewhat more generalist occupying both floodplains and forest streams. Finally, the cryptic Schneider's dwarf caiman (*Paleosuchus trigonatus*; Fig. 1L) occupies almost exclusively non-flooded forest streams (Magnusson, 1985). Thus, even within the same landscape some crocodilian species may occupy wetland habitats more frequently than others. In fact, only *P. trigonatus* and the African dwarf crocodile *Osteolaemus* spp. inhabit almost exclusively small streams in closed canopy rainforests (Magnusson and Lima, 1991), whereas the great majority of crocodilian species inhabit -and modify- to some extent wetland habitats worldwide.

Crocodilians are known to physically alter the environments they inhabit and have been referred to as ecosystem engineers, especially in relation to the alteration of plant communities and the creation of different microhabitats (reviewed in Somaweera et al., 2020). It is not surprising then that crocodilians exert an important role in the modification of wetland habitats. Many species excavate and take refuge in holes, burrows and tunnels or create depressions along their regular pathways where water may store (Magnusson and Taylor, 1982). Also, the construction of mound nests implies the removal of vegetal material which can result in physical habitat modifications at specific locations (Campos, 1993; Hall and Johnson, 1987). Thus, crocodilians impose considerable physical modifications and may even influence landscape-level topography.

As large-bodied predators with the ability to feed at different trophic levels, crocodilians would potentially play a key role in food webs in the environments where they inhabit. However, a recent thorough review on this topic failed to find compelling evidence on this and suggests that there is uncertainty about whether crocodilians play a key role in ecosystems (Somaweera et al., 2020). Regardless of the documented scientific evidence, crocodilians are arguably an important group of semi-aquatic predators and declining populations of many species during most part of the 20th century brought extreme concern to environmentalists and the scientific community.

Until the late 1970s, uncontrolled commercial hunting of crocodilian species led to dire population declines worldwide. Crocodilian skins have been used mainly for the manufacture of exotic leather products and not long ago, most species were considered threatened by extinction. However, over the last 50 years, hunting restrictions and incentives for sustainable management both at national and international levels have been issued and many of the once-overexploited species have been successfully recovering (Thorbjarnarson, 1999).

These protective measures were put in place at the right time and no crocodilian species has become extinct as a result of overhunting. In fact, in places where habitat loss is not a serious problem, controls over illegal commercial hunting has led to population recovery of most species. Today, 52% of assessed species experience a low risk of extinction (Fig. 2). Nevertheless, in some places habitat loss has been a further contributing factor, and allied to commercial hunting or the culling of unwanted individuals, habitat degradation has led to critical situations for species especially in the Indomalayan biogeographical realm (Ross, 1998). Thus, allied to hunting restrictions and incentives for sustainable management, the protection of wetlands is an essential further measure to guarantee the conservation of crocodilian populations.

Conclusion/synthesis

Amphibians and reptiles are conveniently known as "herpetofauna" for research purposes, although they are not closely related in biological evolution. The main difference between amphibians and reptiles is the amniotic egg. The lack of this feature determines the dependence of amphibians to water (or environmental humidity) at least during part of their development. On the other hand, protective membranes in the egg provide reptiles more independence from water. In any case, numerous "herps" have evolved remarkable ecological and morphological adaptations to thrive in aquatic environments for at least some part of their lives.

Worldwide, around 43.4% (8500 species) of the global diversity of amphibians and reptiles thrive in wetlands and thus, the conservation of these threatened ecosystems is vital for these species. Although some of the threats currently faced by these animals are specific for certain groups, such as a waterborne disease-causing fungus affecting amphibians, broad patterns on the conservation status suggest that a great part of the world's wetland herpetofauna depends on habitat integrity and availability.

Knowledge gaps

- Updated assessments of conservation status for all amphibian and reptile species, refined according to taxonomic updates.
- Accurate estimates of species richness considering cryptic diversity and sampling gaps.
- Data on basic natural history aspects such as habitat use, reproductive mode and feeding habits for both described and undescribed taxa.
- Factors regulating species densities (number of individuals per area) and diversity estimates (numbers of species and differences in species composition among sites) in wetlands.
- Empirical assessment of the ecosystem importance of amphibian and reptile species.
- Impacts of climate change on the maintenance and viability of wetland herpetofauna.

Wetland Ecosystem Services

Christian Damm, Department of Wetland Ecology, Institute of Geography and Geoecology, Karlsruhe Institute of Technology, Rastatt, Germany

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Wolfgang Junk and Florian Wittmann.

Glossary

Benefit Ecosystem benefits are material things (like timber) and services (like flood protection or water purification) that have value to human society.
Ecosystem Services (ESS) The benefits human populations derive, directly or indirectly, from ecosystem functions.
Function Ecosystem functions are the capacity of natural processes and components to provide goods and services that satisfy human needs, directly or indirectly. Whereas this definition focusses on the outcome, some authors define functions restricting it to the internal functioning of ecosystems and thus use it similar to the term 'process' (see above).
Goods Any material, mostly tangible product of an ecosystem that is or can be used by humans, thus serving a human demand and usually having an economic price.
Natural Capital The natural environment's limited living and non-living resources (like organisms, minerals, fossil fuels, air, water) and its functions and processes to persist (e.g. weathering, the water cycle, evolution, nutrient cycling, recruitment, and ecological interactions).
Process Ecosystem processes are the complex interactions (events, reactions or operations) among biotic and abiotic elements of ecosystems. The term is often synonymously used with "ecosystem function."
Valuation Attributing a value to an ecosystem service, which is needed to assess its benefits and thus be able to decide any action and compare the importance of different ecosystem services. It can be monetary (like the €-market value of fish) or non-monetary (like saved lives due to flood protection or spiritual and cultural values).

Introduction

Wetlands are among the most important natural features for humanity (Russi et al., 2013). The particular importance of wetlands for humanity arises from an extraordinarily large number of 'ecosystem services' (ESS) which they provide (Costanza et al., 1997; MEA, 2005b; De Groot et al., 2006, 2018; Mitsch and Gosselink, 2015). For thousands of years human existence has depended on natural resources tied to the existence of water (Hook, 1993; Finlayson, 2014). Human biology and culture rely on natural processes, functions and goods which are intricately connected to the presence of water. Coastal and inland waters and especially the (semi-)terrestrial environments adjacent and hydrologically connected to them have and still are providing the foundation of man's existence and the development of human civilization.

The multitude of benefits which man derives from wetlands is based on their particular position within the landscape at the land-water interface "as recipients, conduits, sources, and sinks of biotic and abiotic resources" (Clarkson et al., 2013). Wetlands receive, accumulate, store and convey water, sediments, nutrients and propagules from their catchment. These processes provide the basis for a great structural and functional variability: water is diverted from flood peaks, stored, purified and released, its energy creates morphological structures providing habitat, sediments are retained and soils are building up, nutrients are processed, pollutants neutralized and biomass is produced to name just a few of the processes, structures and functions which wetlands provide. Many of these natural functions are highly beneficial to human existence and have long been directly or indirectly used by man. Concepts and language to adequately evaluate and discuss these services, however, are relatively recent. The term 'natural capital' has been coined by E.F. Schumacher (1973) and was taken up by economists and ecologists alike (e.g. Costanza and Daly, 1992; Mace, 2019). Westman (1977) investigated the value of what he called "nature's services" as an objective basis for decision making when weighing the benefits of undeveloped nature against the benefits of resource development and consumption with subsequent damage to ecosystems. The term "ecosystem services" is attributed to Ehrlich and Ehrlich (1981) who used it in their elaboration on species extinction and biodiversity loss. The concept of ecosystem services greatly advanced after the publications by Daily (1997) and Costanza et al. (1997), the latter providing a first global monetary assessment of 'nature's contribution to human welfare,' attaching concrete USD-figures to a large number of ecosystem services. This courageous and highly disputed attempt was nevertheless an 'eye-opener,' creating worldwide awareness for the enormous values provided to human society by natural ecosystems. The worldwide growing awareness for the limits of natural resources, their depletion by human overexploitation and the need to act in order to safeguard the life supporting functions greatly promoted the development of the ecosystem service approach in science and beyond. Living in a globalized economic world requires the inclusion of natural resource use into economic accounting, an important basis for decision making processes on all scales (De Groot et al. 2012). Therefore, the ecosystem service concept was and still is being developed with the idea of a common methodology for the valuation of natural assets that contribute to human well-being. Defining and delineating the structures, processes and goods generated by ecosystems and their interrelations was and still is a main task of this development, as well as creating a common language among ecologists, economists and decision makers in order to implement efficient and sustainable policies.

Intentions of the Ecosystem Service-Concept:
- Raising appreciation for nature's benefits to human welfare
- Create accountability for human's use of natural resources within our economic framework
- Support resource-conscious, sustainable decision making

Today the concept of ecosystem services, despite it's still unsolved details, has long been accepted beyond the scientific community, thus providing a conceptual link between ecology and economy as well as a tool for environmental accounting to support decisions concerning sustainable use of natural resources (Wallace, 2007; TEEB, 2010; Seppelt et al., 2011).

Definition of ecosystem services

The Millennium Ecosystem Assessment defines ecosystem services as "the benefits that people obtain from ecosystems" (MEA, 2005a,b). Daily (1997) defines them as "the conditions and processes through which natural ecosystems, and the species that make them up, sustain and fulfill human life." Similarly, the European TEEB-study (The Economics of Ecosystems and Biodiversity) views them as "the direct and indirect contributions of ecosystems to human well-being" (TEEB: Russi et al., 2013). Other analogous definitions exist (Boyd and Banzhaf, 2007), all commonly conveying the idea that ecosystem services are essential assets to human society and are thus socially valuable (Daily, 1997). Differences exist in ESS definitions regarding the treatment of natural structures, processes, functions, goods, benefits and services (Boyd and Banzhaf, 2007; Wallace, 2007; Fisher and Turner, 2008; TEEB, 2010). But how does an ecosystem generate a 'service' for humans to be used? The following cascading scheme shows the connection of the biophysical structure of ecosystems (e.g. a lake or river we see), their processes (e.g. primary production of growing plants), functions (e.g. production of biomass) and the final service provided (e.g. food). The final benefit for human wellbeing in this case is nutrition which can be translated into an economic value using common market prices for the goods or services provided (TEEB, 2010) (Fig. 1).

Classification of ecosystem services

The use of the ecosystem service concept in science, planning, politics and other fields requires a common understanding of terms and contents. Clear definitions, delineations and a consistent classification are required when ESS are to be quantified to allow for assessments, comparisons and trade-offs. Various systems have been proposed to classify Ecosystem Services. The UN-based Millennium Assessment (MEA 2005a), aiming at a global stock-taking of the consequences of ecosystem change to human

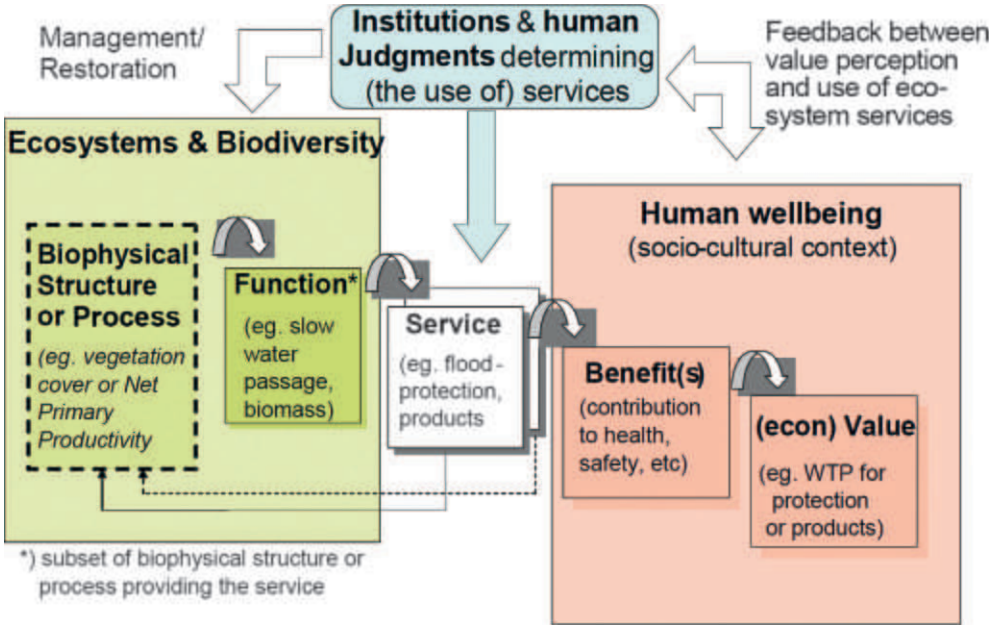

Fig. 1 Ecosystem Cascade-Model (TEEB, 2010). Adapted from Haines-Young R and Potschin M (2010) The links between biodiversity, ecosystem services and human well-being. In: Raffaelli, D. and C. Frid (Eds.): *Ecosystem Ecology: A New Synthesis. BES Ecological Reviews Series*, Cambridge University Press, Cambridge, ch 6, 31 pp and Maltby (ed.) (2009).

well-being, set a milestone in the application of the ecosystem service approach and proposed a most widely used classification. It differentiates four classes of services:

- *Provisioning services*: Material benefits (=goods) ecosystems provide like freshwater, food, raw material, medicinal resources, as well as cultivated plants and animals (genetic resources).
- *Regulating services*: The benefits obtained from natural processes which control the rates and states of physical and biotic systems like the regulation of climate, water flow, sediment flow, carbon sequestration, disease control and more.
- *Cultural services*: Non-material benefits ecosystems provide such as esthetic inspiration, cultural identity, sense of home, spiritual experience, science and education, physical and mental health are often related to the natural environment. Arts and design, tourism, recreation and many religious practices are also based on these services.
- *Supporting services*: The formation of fertile soil, the cycling of nutrients facilitated by microbial activity and the provision of habitat as living space for plants or animals as well as the dispersal of propagules like seeds are examples of '*supporting services*.' They relate to 'the underpinning natural structures and processes that ultimately give rise to final services' (Potschin and Haines-Young, 2016) thus are the basis of all ecosystems and their services.

Other classifications differ to a large or smaller degree from this categorization. Among the four classes given above the supporting services are the least accepted, mainly because they do not result in direct benefits to human welfare, but rather are basic ecosystem functions that support other ecosystem services which then generate the final uses for human society. E.g. the service to provide intact aquatic habitat for fish is not yet a use for humans, whereas the catching of a fish turns it into an economically important benefit as a 'final service.' Therefore, there is doubt about these 'intermediate services' as they are sometimes called as opposed to the final ecosystem services. Thus the 'Common International Classification of Ecosystem Services (CICES) e.g. originally excluded the supporting services from ecosystem services also in order to avoid inconsistencies (e.g. double counting) esp. in economic accounting of ESS (Potschin and Haines-Young, 2016; Haines-Young & Potschin 2018).

Numerous lists of ecosystem services have been published with smaller or larger differences in classification, delineation and number of ecosystem services. Being the most widely used ecosystem service classification, the Millennium Ecosystem Service Assessment provides the following list of Wetland Ecosystem Services (Table 1).

Other ecosystem components like abiotic energy (e.g. hydropower) and abiotic materials (e.g. sand, gravel, clay extraction) (van der Meulen et al., 2016) can be added to this list but again it is not undisputed whether they are "services" of an ecosystem or rather supporting functions (e.g. Haines-Young and Potschin, 2013).

Examples of wetland ecosystem services

So what is special about ESS of wetlands? Wetlands provide an extraordinarily large number of ecosystem services, with a higher cumulative value than most other ecosystems (Costanza et al., 2014; Russi et al., 2013). Some of them will be described briefly in the following section.

Table 1 Ecosystem Services provided by or derived from wetlands.

Services	*Comments and Examples*
Provisioning	
Food	production of fish, wild game, fruits, and grains
Fresh water	storage and retention of water for domestic, industrial, and agricultural use
Fiber and fuel	production of logs, fuelwood, peat, fodder
Biochemical	extraction of medicines and other materials from biota
Genetic materials	genes for resistance to plant pathogens, ornamental species, and so on
Regulating	
Climate regulation	source of and sink for greenhouse gases; influence local and regional temperature, precipitation, and other climatic processes
Water regulation (hydrological flows)	groundwater recharge/discharge
Water purification and waste treatment	retention, recovery, and removal of excess nutrients and other pollutants
Erosion regulation	retention of soils and sediments
Natural hazard regulation	flood control, storm protection
Pollination	habitat for pollinators
Cultural	
Spiritual and inspirational	source of inspiration; many religions attach spiritual and religious values to aspects of wetland ecosystems
Recreational	opportunities for recreational activities
Esthetic	many people find beauty or esthetic value in aspects of wetland ecosystems
Educational	opportunities for formal and informal education and training
Supporting	
Soil formation	sediment retention and accumulation of organic matter
Nutrient cycling	storage, recycling, processing, and acquisition of nutrients

Inland fisheries and aquaculture

The provision of food is one of the most easily understood ESS of wetlands. Fish, mussels and other aquatic organisms have always been an important resource to support human life. In 2017, 3.3 billion people received 20% of their average intake of animal protein from marine and freshwater fish. The global inland fishery capture in 2018 reported by FAO was 12 million tons which represents 12.6% of total global capture fishery production and excludes aquaculture which today accounts for half of the total global production. Asia contributes 66% to these figures with Africa adding another 25% (FAO, 2020). The reported global inland catch 2015 was estimated to be about USD 26 billion (Funge-Smith, 2018). These figures include FAO-reported capture only and are thus likely to be underestimated. Including this hidden component, as well as freshwater mollusks and crustaceans, the FAO estimated the total use value to be USD 43.5 billion (Funge-Smith, 2018). The non-market use value (NMUV) of the recreational fishing, 72% of which is estimated to stem from the US and Canada, is remarkably high. About 5.4% of global reported catch are attributed to recreational fishing. Increasing introduction and establishment of non-indigenous species to support recreational fishing has a considerable impact on ecosystem integrity. Whereas overexploitation of fish stocks is an increasing threat to marine systems, inland waters are more threatened by changes in species composition due to overexploitation, habitat change, pollution, non-native species introduction and interaction with hatchery-reared fish, the cumulative effect of which results in substantial losses of biodiversity and ecosystem services (Allan et al., 2005).

Inland fisheries globally provide an important source of protein to millions of people, particularly in low income countries (Fig. 2). At least 43% of the global inland capture comes from 50 low income nations with chronic food deficit problems (Funge-Smith, 2018). Inland fisheries are mostly rural and small-scale, large scale commercial inland fisheries being limited. Inland fisheries ecosystem service accounts for 2–6% of global agricultural workforce and thus contributes to poverty alleviation and nutrition security.

Raw biotic materials

Wetlands are among the most productive ecosystems in the world (Whittaker and Likens, 1973; Holland et al., 1990; Clarkson et al., 2013) comparable to rain forests and coral reefs (Dodds et al., 2019). They supply human societies with numerous natural materials, which are some of the most easily observed and direct ecosystem services (goods) that wetlands provide. In many parts of the world, wetlands do not only provide the most important food source, but rather provide building and fuel materials important to local economies, especially in poor countries (FAO, 2020). Floodplains in particular are highly productive sources for hardwood and softwood for timber as a building material, fuel for energy, and pulp for the production of paper, tissue and insulation materials. Similar uses can be applied to reeds, such as Common Reed (*Phragmites*) and papyrus (*Cyperus*) (Ye et al., 2016; Jones et al., 2018) cattail (*Typha*) and sugarcane. Energy crops for biogas production or direct combustion are an increasing

Fig. 2 Subsistence fishery is an important means to sustain livelihood in poor countries. Source: Wikimedia.org.

use of natural and artificial wetlands using woody species like Willow (*Salix*), Poplar (*Populus*), Alder (*Alnus*), Eucalyptus and non-woody species like the reeds already mentioned, Cattail (*Typha*), Rushes (*Scirpus*), Sedges (*Carex*) and many others. Another economically important wetland organic material is peat, which originates from organic debris (from sedges, rushes, mosses) accumulated under oxygen-deprived conditions over hundreds or thousands of years. Peat is commonly burned directly or used to generate electricity, to ameliorate soils (e.g. potting soil) and for other industrial uses. A large number of other uses of wetland species for direct consumption or as raw material for numerous uses exists.

Water related ecosystem services

Water is a principal feature of wetlands and is the basis for a number of provisioning and regulating ecosystem services.

Water for drinking and non-drinking purposes

The provision of water from wetlands for direct human consumption, to feed aquaculture, irrigate agriculture and other areas, for industrial utilization like cooling processes and other uses is a most obvious ecosystem service wetlands provide.

Water purification

Wetlands are embedded in the flows of global and local water cycles. They are a source of clean water – but also a sink and end point or transitional structure for polluted waters in the form of e.g. sewage, rainwater runoff loaded with sediments, fertilizers, agrochemicals and microplastic and pathogens from wastewater. They are often referred to as the 'earth's kidneys,' because they receive water and waste from both natural and human sources (Mitsch and Gosselink, 2015) and function as biologically active filters, absorbing pesticides and chemicals and removing harmful waste from water. Nevertheless it is important to note that the water purification function of wetlands is limited with overloads of nutrients and chemicals threatening the ecosystem's own integrity or e.g. providing additional risks for global warming (Verhoeven et al., 2006). With the global demand for clean water rising continuously, wetlands as water sources assume an increasingly important role for humanity.

Water purification in wetlands removes solid impurities, particulate or suspended matter as well as dissolved substances and enables access to cleaner water with reduced or even avoided costs for technical water purification, thus assuming substantial economic value. Water purification by wetlands can be described as the cumulative effect of three interrelated biogeochemical processes consists of

- Sediment retention, physically removing particulate or suspended matter e.g. from agricultural runoff (Venterink et al., 2006)
- Nutrient retention resulting in the removal of excess phosphorus and nitrogen (Fisher and Acreman, 2004), commonly associated with agricultural runoff and sewage effluents causing eutrophication, algal bloom with subsequent oxygen depletion and other negative impacts on ecosystems
- Reduction of contaminants by physical retention or active breakdown of harmful substances through microbial activity (detoxification)

Water purification occurs by more or less reversible absorption to superficial organic matter of plants or plant residue or on soil particles, with bacterial and fungal metabolic processes or detoxification. Aerobic and anaerobic processes in close proximity as well as a diversity of decomposers and decomposition processes in wetlands help to reduce the chemical load. High productivity and the built up of preserved organic matter (e.g. peat) can trap contaminants in wetlands (Mitsch and Gosselink, 2015). The quantification of the purification processes is difficult (Tockner et al., 1999).

As a "nature based solution," so called 'constructed wetlands' make use of the natural purification processes provided by vegetation, soils and microbes and are used in waste water treatment as a cost-efficient alternative or supplement to conventional technologies (Masi et al., 2017).

Water storage (surface and groundwater)

Within the global and local water cycle, wetlands have an important role in regulating water quantity in landscapes. Receiving discharge from their headwaters originating from rainfall or snowmelt, wetlands store water above ground in open waterbodies like lakes, ponds and rivers and temporarily on flooded areas. Below the soil surface, pore water (groundwater) in the saturated zone and soil moisture in the unsaturated zone contribute to water storage. Like natural tubs or sponges, wetlands take up water from their catchment area, fill their storage capacity and release it when incoming surplus falls below outgoing runoff. Thus changing discharges are buffered, prominently evidenced in the flattening of flood waves in rivers with intact lateral connectivity between river and floodplain. Water storage is essential for the development and maintenance of hydric soils, hydrophytic vegetation and their respective wildlife habitat. It supports the biogeochemical processes that occur in wetlands, such as the removal of nutrients and particulates, resulting in improved water quality. Water storage is the physical basis for other regulating ecosystem services like erosion control, flood retention, low water regulation, groundwater recharge and others.

Flood retention

Being based on wetland water storage, flood retention is commonly referred to as a separate ecosystem service, the final service or benefit being the reduced risk or avoided damage to human population and infrastructure caused by extreme flooding. When well connected to a rising river, wetlands enable excess water to spread out into the landscape, reducing its depth, its speed and causing a delayed discharge. More technically flood retention alters the form of a flood wave, reducing the flood peak, broadening the wave and slowing down its speed. The term flood retention mainly refers to the benefit of lowered risk of flooding, an effect that depending on the size of the wetland extends upstream and downstream. It helps to avoid damage caused by insufficient adaptation (e.g. unprotected settlements in a flood-prone area) or caused by failure of flood-protection infrastructure (e.g. dike breaching) or unusually high flood levels.

Low water regulation

Maintaining permanent surface waters during drought is another buffering function connected to water storage. The excess volume of water stored within the wetland is released slowly, supplying a base flow in outgoing water courses. Thus wetlands are of even increasing importance for water security and the maintenance of aquatic habitats in times of climate change with prolonged periods of drought and increasing flooding events.

Groundwater recharge

is another ecosystem service connected to water storage: water from periodic or permanent waterbodies like lakes or oversupplied, saturated soils permanently infiltrates into the ground supplying the groundwater reservoir (=aquifer). On the other hand, wetlands often have impermeable layers of sediment that also limit infiltration to ground water. The recharge function of a wetland is thus often limited to the edges, making wetlands with a relatively large perimeter/area ratio more important for this function (Mitsch and Gosselink, 2015). The quantification of groundwater recharge is quite difficult and not completely understood (Hunt et al., 1996). Nevertheless, the supply from wetlands for local and regional groundwater storage can be very important.

Erosion control

Erosion control and storm protection have so far mostly been investigated in marine and tidal wetlands but also present a highly valuable ESS in inland wetlands. Erosion control is provided by different processes that act on different spatial scales. At small spatial scales, the dense vegetative cover of wetlands on riverbanks, lake shores and runoff slopes builds an effective structure to prevent excessive erosion by the dissipation of wave and current energy. Furthermore, an interwoven layer of roots stabilizes the soil against erosion. Rough vegetation cover slows down water velocity and covers open soil, reducing the current's erosive force. This effect protects the wetland itself, stabilizes e.g. stream- and riverbanks, affects natural water course development and helps protect landscapes and man-made structures. At large spatial scale lateral connectivity reduces discharge and velocity which potentially reduces erosive effects on the river channel upstream and downstream.

Erosion control constitutes obvious benefits to human society and considerable economic value. The great potential of this ESS is depicted by the correction of the 1997-estimates of the monetary value of coastal wetlands by Costanza et al. who in 2014 ESS increased the value of tidal marshes and mangroves from 14,000 $/ha/year to 194,000 $/ha/year, largely influenced by new studies on storm protection, erosion control and waste treatment function of these systems (Costanza et al., 2014). In contrast to coastal

wetlands there is a lack of data on the monetary value of erosion control by inland wetlands (Russi et al., 2013). Nonetheless, given the large extent of floodplain wetlands along most rivers in the world, a considerable contribution of this ESS can be safely assumed.

Climate regulation: Climate mitigation

Natural wetlands are important climate stabilizers on a local and global scale (Neubauer & Verhoeven 2019), providing a regulating ecosystem service of increasing importance to human welfare. Cooling of local and regional climate results mainly from evapotranspiration, which is an energy consuming - thus cooling - process of wetland vegetation and other moist or wet land and water surfaces (Hesslerova et al., 2019). Urban regions in particular benefit greatly from this effect, being increasingly employed in the establishment of 'urban wetland parks.' The Ramsar Convention's "Urban Wetland Accreditation"-program encourages this trend to utilize ecosystem services for human welfare.

The large amounts of water in wetlands of the boreal climate zone have recently been considered important for climate regulation, absorbing solar energy in summer (cooling) and releasing it in winter (warming) regulating temperature on a regional scale (Wu et al., 2021). Besides temperature regulation, evapotranspiration sends vapor into the atmosphere, increasing humidity and even cloud formation which is easily observed in tropical rain forests. This affects precipitation and incoming radiation, thus temperature (Kleidon et al., 2000).

Climate regulation: Carbon sequestration

A separate climate regulating ESS of inland wetlands pertains to the plant-based reduction of atmospheric greenhouse gas (mostly carbon dioxide) into organic matter. The wet, waterlogged conditions of wetland soils slow down decomposition rates of decaying, carbon-rich plant litter which due to high biomass production results in large accumulation of organic matter, mostly as peat or other hydric soils with high carbon content (Mitsch and Gosselink, 2015). 20–30% of the estimated 1.5×10^{12} tons of global soil carbon are stored in wetlands which cover only 5–8% of earth's land surface (Nahlik and Fennessy, 2016). This process of incorporating atmospheric carbon into vegetation and a soil-bound long term storage is called carbon sequestration.

Rates of Wetland Carbon Accumulation per square meter and year (modified from Mitsch and Gosselink, 2015).

Northern peatlands	10–50 g-C m^{-2} $year^{-1}$
Temperate wetlands	140–504 g-C m^{-2} $year^{-1}$
(Sub-)Tropical freshwater wetlands	19–480 g-C m^{-2} $year^{-1}$

Estimates of Global Carbon Storage of Wetlands and other ecosystems (1 pg = 10^{15} g).

Wetlands	455–700
Tropical rain forest	450 (total released: 75)
Terrestrial ecosystems total	3000
Fossil fuels	5000–10,000 (total released: 375)
Oceans (0–75 m)	630
Oceans (>75 m)	38,000

(modified from Mitsch and Gosselink, 2015)

There is considerable concern about the decrease of carbon sequestration services, since human impact continues to destroy wetland area and degenerate its quality globally resulting in a reduced capacity to sequester carbon. Moreover, rising temperatures increase microbial biomass decomposition, releasing carbon dioxide from wetlands, thus turning them from a sink into a source of greenhouse gases. Furthermore, wetlands are known to emit methane, another and even more effective greenhouse gas, which could offset the positive climate function of wetland carbon sequestration. However, models suggest that the sequestration of intact wetlands will nevertheless continue to have a net positive effect on the reduction of greenhouse gases (Mitsch and Gosselink, 2015).

Habitat function and biodiversity

Any ecosystem service provided by organisms – the nutrient cycling realized by microorganisms, the growth of timber trees as well as the food provided by fish – requires in the first place the presence of a suitable living environment to exist. Quality habitat is needed for reproduction, growth and survival of individuals. Furthermore, an appropriate amount of space is needed to maintain populations, allowing for dispersal among patches that enable interaction and genetic exchange. Thus the ESS habitat provision is an underlying requirement supporting other ESS. This ecosystem service is dependent on habitat size (quantity) and its ecological intactness (quality). Reduction of both is endangering wetlands globally at an alarming pace (Ramsar, 2018).

Wetlands in particular provide a great diversity of habitats, based on their inherent combination of terrestrial and aquatic conditions, explicitly expressed in the term 'wet-land.' Wet and dry conditions can occur in close spatial proximity and are overlain by various patterns of temporal change in water level - or flooding regime. This temporal and spatial variability creates a diversity of sites with changing combinations of ecological conditions. In addition to high productivity it results in various species communities

and a high level of biodiversity locally as well as on a global scale (Bacon, 1997). Natural ecosystems have been called 'storehouses' of genetic information, their millions of species containing the information of environmental adaptations acquired over 3.5 billion years of evolution. To safeguard this genetic treasure, it is essential to maintain and restore the habitat of natural ecosystems (De Groot et al., 2002). The importance of the habitat function is also reflected in the disproportionately high percentage of endangered and threatened species: e.g. in the US, wetlands cover 3.5% of the land surface but 50% of threatened and endangered occur in this habitat (Mitsch and Gosselink, 2015) as well as about a third of all US-American plant species.

Cultural ESS

Swimming in a clear lake, canoeing through a jungle of reed, enjoying a hike in a bog, birdwatching in a marsh, learning about the water cycle on a small stream – what are all these activities worth? Wetlands provide many of these so called 'cultural ecosystem services.' They are sites of local identification and inspiration to indigenous and non-indigenous people, places of spiritual and religious significance. Their landscapes are appreciated for their special esthetic value that most of us can easily relate to. They are inspirational to artists, writers, painters and photographers. Swimming, boating, hiking, catch-and-release fishing, there are many kinds recreational uses of wetlands that many people appreciate and benefit from. Their complexity of structure and function makes wetlands excellent sites for research and a great place for environmental education. Thus wetlands provide a broad range of these 'non-consumptive use values' – uses that usually do not diminish the resource they are based on. Many of these cultural ecosystem services are not easily monetized. A number of indirect methods has nevertheless been developed to assign a monetary value to some of them like the willingness-to-pay method or travel cost analysis for recreational activities.

Outlook

The ecosystem service concept has experienced an exploding development over the past decades in policy and academics circles. The concept is increasingly being used to raise awareness for the growing impact of human activity on our life-sustaining resources from local to global scales. It has proven to be a practical tool for the assessment, comparison and valuation of the manifold goods and services nature provides to human well-being. Its capacity to communicate these benefits to citizens, experts and decision-makers alike provides a critical framework for wise use of natural resources. Wetlands in particular, whose ecosystem services continue to be negatively impacted by climate and land use change greatly benefit from the application of this concept.

Future efforts should communicate the inherent limitations of the approach as well as its well-proven opportunities to facilitate decisions regarding our shared natural capital and its management. Further efforts should focus on:

- increasing the practical application of the ESS-concept by providing user-oriented tools for ESS assessments (e.g. River Ecosystem Service Index RESI: http://www.resi-project.info)
- improving interdisciplinary and transnational cooperation by further harmonizing ESS definitions and classification
- studying the dynamics of trade-offs and off-site effects in ecosystem services
- the development of globally recognized methods and institutions for ESS valuation targeting at incentive policies supporting wise resource use (like REDD+ in forest management)

Restoring Riparian Peatlands for Inland Waters: A European Perspective

Dominik Zak[a,b], Astrid Ledet Maagaard[a], and Haojie Liu[c], [a]Department of Ecoscience, University of Aarhus, Silkeborg, Denmark; [b]Department of Ecohydrology and Biogeochemistry, Leibniz-Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany; [c]Faculty of Agricultural and Environmental Sciences, University of Rostock, Rostock, Germany

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Wolfgang Junk and Florian Wittmann.

Glossary

Drainage Peatland drainage for agricultural purposes uses surface ditches, subsurface permeable pipes, or both, to lower the groundwater depth. Excess water from the plant root zone and underlaying soil layers can enter the pipes through perforations and flow away from the field to a ditch or another outlet.

Eutrophication A process of increasing generation of biomass in lakes or other water bodies caused by increasing concentrations of plant nutrients such as phosphate and nitrate.

Fen A common peatland ecosystem that typically develops at groundwater discharge sites. Fens are usually dominated by sedges or occasionally by reedbeds, shrubs, and trees. While the groundwater flow path is often the main water source, the hydrology can be much more complex than the simple lateral groundwater flow.

Helophytes Plants adapted to live in aquatic environments. Important representatives in rewetted peatlands are reed communities, specifically *Typha latifolia* (cattail) and *Phragmites australis* (common reed).

Mineralization Conversion of organic compounds into inorganic compounds through various decomposition processes.

Peat (Also known as turf) consists of decomposed and humified plant litter. The organic matter content is defined to be at least 30% of dry matter (DM) but may also be higher than 90% of DM.

Peatland Terrestrial wetland ecosystems, also named "mires", where waterlogged soil conditions prevent full decomposition of plant material. The thickness of the peat layer is defined to be at least 0.3 m, but this strict definition does not apply in all European countries.

Restoration Management measures that aim to recover the original form and function of peatland habitats to favorable conservation status.

Rewetting Measures to raise water levels back to the soil surface to recover anaerobic soil conditions that are important for the growth of natural peatland vegetation while simultaneously halting carbon emissions from oxidation. Due to subsidence, rewetting of soils by closing pumping stations and/or drain systems might also cause inundation.

Topsoil removal Removal of the upper degraded peat layer can be a suitable measure to avoid mobilization of phosphorus and carbon after rewetting. At the same time, unwanted seed banks may be removed, improving the water flow through the soil matrix.

Introduction

Peatlands have long been regarded as wastelands, and for several hundred years they have been drained to attain economic value (Schoock, 1658). Surprisingly, many people today have never heard about peatlands; yet, some might be familiar with the famous bog body the "Tollund Man", found in a Danish peatland (https://search.creativecommons.org/search?q=Tollund%20Man), or

associate these wetland ecosystems with a scene from "Lord of the Rings" where the hobbit Frodo has to walk through the dead marshes (https://lotr.fandom.com/wiki/Dead_Marshes). However, the increasing ecological challenges that we are facing presently, such as deterioration of water bodies due to high nutrient inputs from agriculture, has made it evident that there is an urgent need of vital peatlands. The eutrophication of inland waters because of land management creates major environmental challenges, and even though fundamental ecological knowledge is increasing, these challenges are exacerbating. An important reason for this is the pressure on agricultural land to meet the food, energy, and water demands of the world's increasing population (WWAP, 2015; Scanlon et al., 2017). Despite attempts in recent decades to control excess fertilizer application (Lam et al., 2011), diffuse pollution of watercourses remains sufficiently large to counteract the fulfillment of the environmental goals of European legislation and national environmental programs (Land et al., 2016). Among the mitigation measures targeting diffuse pollution, the restoration of riparian peatlands has been suggested as a tool to mitigate the deterioration of watercourses by non-point pollution (Zak et al., 2010). Rewetting has been proposed as a valid strategy to restore the unique biodiversity of peatlands, and in recent years focus has increasingly been directed at the recreation of the carbon (C) and nutrient sink functions of peatlands in order to lessen both the impacts of climate change and the eutrophication of water bodies (Kimmel and Mander, 2010). This approach is consistent with Target 12 of the 4th Strategic Plan of the Ramsar Convention, which advocates the restoration of degraded wetlands prioritizing biodiversity conservation, disaster risk reduction, livelihoods, and climate change mitigation and adaptation (Resolution XII.11, 2015). However, eutrophic shallow lakes (water depth mostly <1 m) may be formed after the rewetting of former agricultural peatlands because of historical land use and soil subsidence (Fig. 1), leading to nutrient mobilization, elevated methane emissions, and slow development towards the desired target vegetation (Zak et al., 2018). This chapter will inform about the ecological importance of peatlands, their loss and restoration, the biogeochemical processes as drivers of elevated nutrient mobilization, and interventions to mitigate negative side effects after the rewetting of long-term drained peatlands.

Fig. 1 Peatlands are often neighbors to lakes or rivers. Natural peatlands, as shown in the upper image from NW Poland, are only rarely found nowadays in Central Europe since most have been drained for agricultural usage. After rewetting of long-term-drained peatlands, shallow lakes often form. The lower image shows a site at the River Peene Valley (NE Germany), which for many decades was used as grassland for cattle farming.

Ecological importance of peatlands

Peatlands cover about 4.4×10^6 km^2, which equates ca. 3% of the total global land area (Yu et al., 2010). The formation of peatlands across wide parts of Europe commenced at the end of the last glaciation about 14,000 years ago. Depending on hydro-geological conditions, peatlands may form with a thickness of 10 m and more. The growth rate of peatlands in northern Europe is estimated to 0.2–0.9 mm/year (Gorham, 1991; Pontevedra-Pombal et al., 2019) and is thus rather low compared to, for example, sediment growth rates (0.6–7.5 mm/year, Baud et al., 2021). A prerequisite for peat growth is permanent waterlogging of the complete peat body. Under these conditions, senescent plant tissues, mainly roots, will only be partly decomposed. Carbon and nutrients can be stored over several thousands of years in non-disturbed peatlands. The great peat thickness (up to several meters) as well as the high organic matter content ($\geq$30%) are the reasons why they store more than 20% of the global terrestrial soil C stock or 40–60% of the atmospheric CO_2 content. Therefore, the conservation and protection of peatlands have global importance in the current climate debate (Tanneberger et al., 2021a). Natural peatlands also provide important habitat functions for many highly adapted endangered plant and animal species (Lamers et al., 2015). Most peatlands (ca. 80%) are found in the temperate regions of the northern hemisphere and in the tropical regions of South Asia (Joosten and Clarke, 2002). In Europe, Finland has the highest proportion of peatlands, which cover 30% of the land area (Fig. 2). There is a large array of different peatland types, and their classification therefore differs nationally or even locally (Davis and Anderson, 2001). In the following, groundwater-charged peatlands (=fens) are considered; however, their separation from rainwater-fed bogs may prove difficult due to obscure hydrology or water budgets at certain sites. The proportion of fens has been estimated to around 40% of the global peatland area and more than half of Europe's peatland area (Joosten et al., 2017). Since fens often appear at the interface between upland areas and surface waters, such as lakes, rivers, or coastal waters, they are supposed to play a significant role, not only for regulating the water balance in the landscape but also for cleaning inflowing ground- or surface water for nutrients (Fig. 3). This double function once earned them the name "kidneys of the landscape" and the currently common term "wetland buffer zones" (Walton et al., 2020). Accordingly, these specific ecosystems may also be valuable for reaching the environmental goals of WFD and other directives. It is important to note that besides their large-scale impacts, the water surplus of peatland systems favors a specific microclimate with higher air humidity and lower temperatures than the surrounding areas, making these sites attractive niches for certain species (Helbig et al., 2020).

Large-scale peatland drainage for land use

European peatlands have been subjected to drainage for many centuries. In the 1960s, drainage was intensified to convert peatlands to grassland and land for other arable crop production (Fig. 4). In some places, drainage practices led to a lowering of the water table by more than 1 m causing loss of almost all ecological functions and degradation of the peat (Holden et al., 2004). Nowadays, the proportion of drained peatlands accounts for 15% on a global scale and about 50% in Europe; in some countries the total proportion is >90% (e.g., Denmark, Germany, Luxembourg, the Netherlands, and Portugal; Tanneberger et al., 2021b). The consequences of peatland drainage for peat properties, as well linked matter fluxes, are well documented and are briefly summarized below (Lamers et al., 2015; Liu et al., 2020):

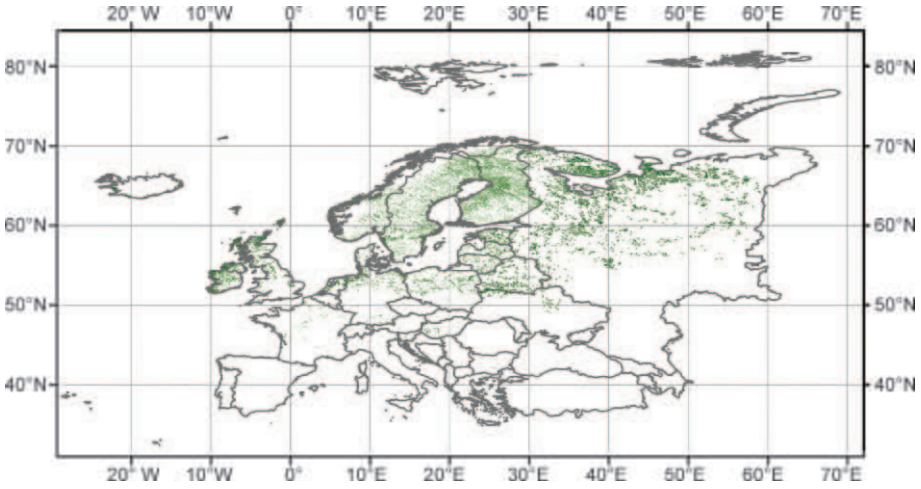

Fig. 2 Peatland map of Europe (Xu et al., 2018). The highest proportion of peatlands is found in the northern part of Europe, while the southern part is rather poor in peatlands.

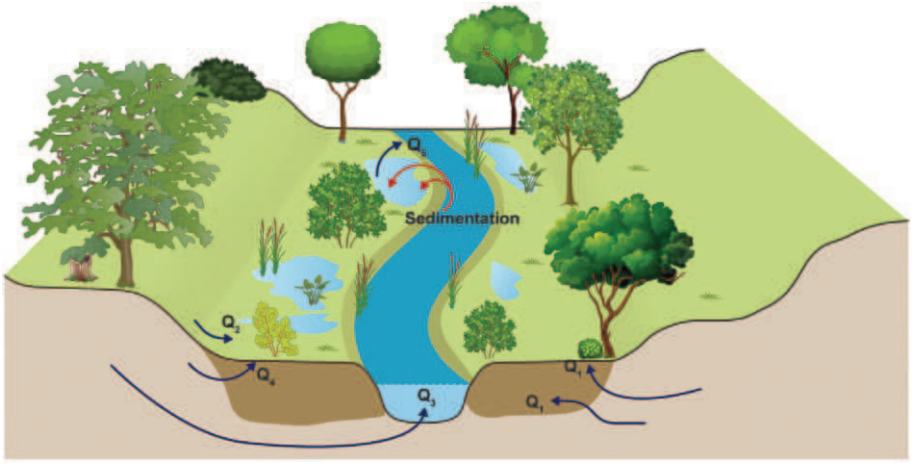

Fig. 3 Riparian peatlands as interface between mineral upland and watercourses retain water and nutrients from the catchment before the remaining water enters the downstream systems. Due to this double function, they are called the "kidneys of the landscape". Water flow paths occurring as sub-surface and surface flows (Q1–Q5, including flooding events) can be rather heterogeneous and variable in space and time, implying that the assessment of the nutrient filter function of riparian peatlands can be rather challenging (Walton et al., 2020).

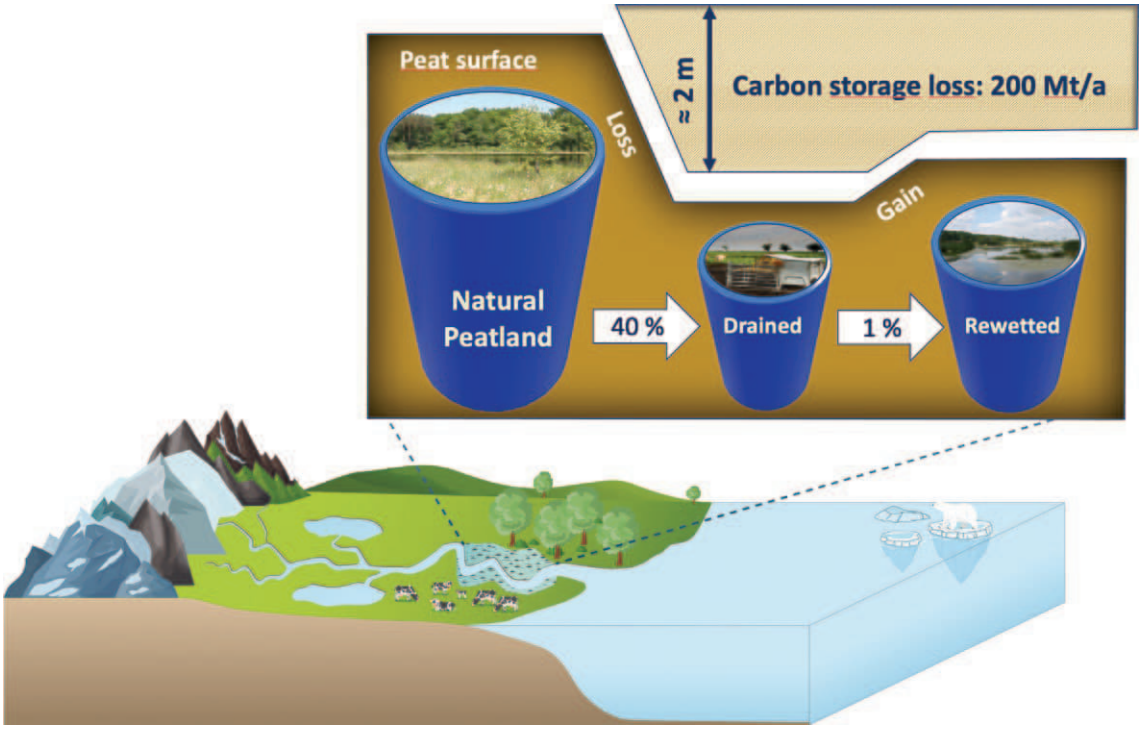

Fig. 4 Nowadays, a large proportion of European peatlands are drained—in some European countries more than 90%. Drained peatlands emit substantial amounts of carbon dioxide and have lost their important habitat function as well as their role as nutrient sinks and water storages. There is no information available about the global total carbon loss from drained peatlands but according to annual estimates the carbon loss in 2019 was about 200 Mt (Conchedda and Tubiello, 2020).

- Non-reversible loss of the oscillation capability and water storage capacity of drained soil layers due to peat mineralization, subsidence, and formation of highly decomposed peat characterized by high dry bulk densities, low water permeability, and hydro-phobicity.
- Elevated net emission of greenhouse gases (GHGs) such as carbon dioxide and partly of nitrous oxide with a high climate impact during wet-dry cycles. Drainage of peatlands has a significant effect on the anthropogenic release of GHGs, amounting to, for example, 4.5% even in industrial countries like Germany.
- Loading of downstream systems with nutrients due to both missing filter functions (bypass of ground water in ditches before it reaches the peat soils) and accelerated mineralization and release of nutrients accumulated over centuries in the peat matrix itself.

- Elevated washout of dissolved organic carbon from upper degraded peat layers during temporary rewetting after high precipitation or seasonal groundwater table increases.
- Acidification of low-carbonate soils by oxidation processes.
- Substantial loss or extinction of peatland-adapted flora and fauna, fragmentation, isolation, and thus endangerment of many species in the few remaining natural peatlands (genetic impoverishment).
- Increasing risk of peat fires as documented in the European part of Russia in 2010 and Indonesia in 2015.

Peatland rewetting to restore their ecosystem functioning

The UN Decade of Ecosystem Restoration starting just now is a critical period for meeting our commitments under the Paris Agreement regarding peat soils as well as for peatland science (Tanneberger et al., 2021a). During recent decades, substantial progress has been made in terms of analytical methods, linking of various research disciplines, and knowledge transfer, and at the same time awareness of the need to solve environmental problems and the challenges of global change has increased across all generations.

While it has been clearly demonstrated that it is better to protect and preserve existing peatlands in pre-disturbed conditions, restoration of damaged and severely degraded peatlands may still be a viable solution under certain circumstances. Good examples are available from all around the world of the restoration of peatlands to provide multi-functional benefits (Kimmel and Mander, 2010; Grand-Clement et al., 2013). Such benefits include recreation and amenity values, management and reduction of flood risks and storm surges, improvement of water quality, and the ever increasing need to store C and mitigate the impacts of climate change (Jabłońska et al., 2020). In Europe, the value of peatlands is acknowledged through a variety of policies such as the EU Biodiversity Strategy (European Commission, 2011), the Habitats Directive (European Union, 1992), the Water Framework Directive (European Union, 2000), and obligations under Resolution XII.11 of the Ramsar Convention on Wetlands (Resolution XII.11, 2015). However, peatland restoration is often opportunity driven and opportunities will vary. In the areas of Central and Eastern Europe where population densities and agricultural intensification rates are relatively low, opportunities arise to restore areas of former wetlands on sub-optimal farmland, such as in Northern Germany. However, in other areas of Europe, for example the United Kingdom and the Netherlands where the pressure on land is extreme due to high population densities and intensive agriculture, opportunities to restore wetlands are often smaller and piecemeal.

It should be noted that the term "restoration" has a rather broad definition in the literature and that it has provoked some controversy in different communities, mainly because the natural state might not be reached even after decades of land restoration. Thus, in the following, we apply the term "restoration" to all measures aiming to recover the ability of peat accumulation. This means that restored fens will act as long-term sinks for C and nutrients in the future again. Eventually, the resumption of this role would be just a question of time even without human intervention, but this contradicts common thinking that operates within legislative periods or project lengths of only a few years.

To recover the sink function of severely degraded peatlands, re-establishment of anoxic soil conditions is essential. This requires ground-water tables near the peat surface throughout the year (Evans et al., 2021). In the rewetting practice, such conditions can only be met if temporarily or permanently inundated conditions are established since (1) severely degraded fens have lost their capability to move the peat body up and down ("oscillation") to compensate for natural fluctuations of groundwater tables and (2) the peat surface level can vary by several decimeters over short distances, implying that water table depths will differ accordingly. Nowadays, it is well accepted that rewetting of degraded peatlands systems will not restore the hydrology to predominantly groundwater-percolated peatlands; rather it will create novel ecosystems (sensu Hobbs et al., 2009) fed by a mixture of groundwater, rainwater, and surface water (Wheeler and Proctor, 2000). High nutrient availability in the altered peat soils poses a risk of nutrient and C fluxes (as dissolved organic carbon, DOC) to surface waters post-rewetting (Zak et al., 2010). A long-term monitoring program in Denmark has emphasized that rewetted organic soils may act as P sources several years after restoration (Audet et al., 2020). The mobilization of nutrients and other substances due to changes in soil characteristics will be covered in the next section.

Biogeochemical controls of nutrient and carbon mobilization in rewetted peat soils

Overall, the processes and the driving factors controlling the mobilization of nutrients and C in inundated fens are well understood. Both seasonal and spatial aspects as well as the time of rewetting must be considered (Zak et al., 2010). For recently rewetted fens, the highest mobilization of matter is found in the highly degraded peat at the soil surface, while the underlaying less decomposed peat can be widely ignored for matter mobilization (Zak and Gelbrecht, 2007). However, after a few years, newly inundated fens can be found with a several centimeter-thick detritus mud layer that stores C and nutrients similar to those quantities reported for other wetland types (Cabezas et al., 2014). However, the muddy substrate becomes a hot spot of methane and phosphorus mobilization (Zak et al., 2018). This layer is mainly formed by dead plant litter. The litter breakdown at the end of the growing season is here termed the 'hot period' of matter mobilization, as also found for other freshwater ecosystems (Webster and Benfield, 1986). Litter decomposition by microorganisms is a key biogeochemical process that regulates nutrients and the C cycling in peatlands. Decomposing litter consists of a set of biopolymers like carbohydrates, lignin, and protein, which vary in stability and hence are

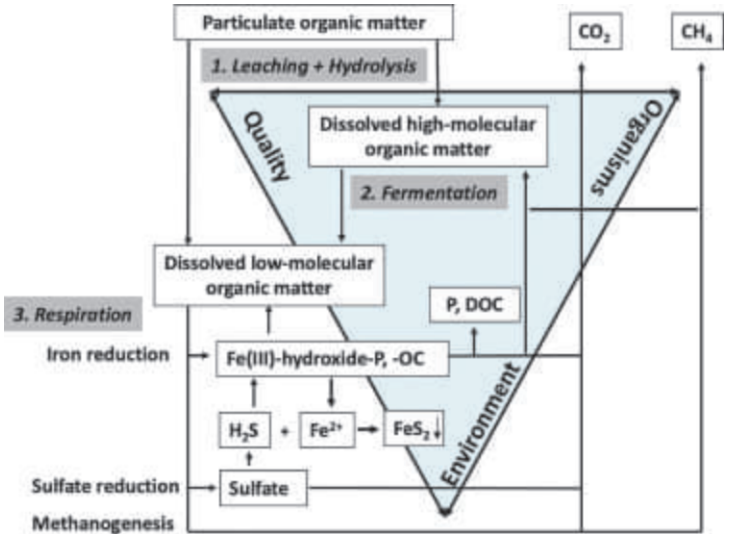

Fig. 5 The decomposition of particulate organic matter (e.g., plant litter) and the associated nutrient and carbon fluxes follow a distinct sequence that is controlled by the quality of organic matter, environmental conditions, and the presence or activity of certain water and soil organisms.

decomposed at different rates (Berg and McClaugherty, 2003). There is a distinct sequence of processes driving the recycling of nutrients and C from primary production back to the environment (Fig. 5). First, there is the "leaching stage" together with hydrolytic cleavage that occur after the die back of plants, causing high losses of plant nutrient stock (Aerts and De Caluwe, 1997), hydrolysable polyphenols, and other organic substances with low-molecular weight such as carbohydrates and amino acids (Maie et al., 2006). The second stage involves slow decomposition of submerged and settled plant litter at low-oxygen or even anaerobic conditions (Asaeda et al., 2002). Besides microbial-mediated redox-processes, like iron or sulfate reduction, abiotic processes such as ion-exchange reactions between the solid and aqueous phases, as well as mineral formation or dissolution, can have a significant impact on matter mobilization (Beltman et al., 2000; Zak et al., 2010). As for other systems, the interaction between different spheres -the atmosphere, the hydrosphere, and the pedosphere—must be considered to understand the turnover of matter and the associated fluxes. The interactions determining the growth of plants and microorganisms exert an important feedback on the interactions between the spheres and processes. The major challenge is the potentially high spatial and temporal variability of certain factors such as soil properties, hydrology, or microbiological control of the rates of the different biogeochemical processes and their complex interactions, creating high uncertainty of model predictions. The role of macroinvertebrates and higher levels of organisms is not well investigated in fens despite their potentially strong impact, as documented for other freshwater ecosystems (e.g., Webster and Benfield, 1986).

Phosphorus mobilization

Oxidation of peat during long-term drainage has been observed to lead to a substantial loss of organic C and, therefore, to an enrichment of phosphorus (P), iron (Fe), and aluminium (Al) with decreasing molar ratios of C:P and C:N in the upper soil layers (Zeitz and Velty, 2002). In addition, subsequent peat subsidence and peat compaction have been demonstrated to lower the porosity and increase the dry bulk density of the peat (Liu and Lennartz, 2019). Concurrently with this, refractory organic-bound P is transformed into more labile and mobile inorganic P forms (Fig. 6). Such P forms are inter alia sorped onto redox-sensitive Fe(III) hydroxides, formed by oxidation of Fe sulfides, or onto other reactive surfaces from metal oxides (Litaor et al., 2004). The sum of these processes explains the elevated P mobilization potential of highly decomposed peat compared to slightly decomposed peat in deeper undrained soil layers of drained fens and/or natural fens (Zak and Gelbrecht, 2007). Correspondingly, net P mobilization in inundated degraded peat soils has been found to be significantly higher than in less decomposed peat soils (Zak et al., 2010), even when determining the rates under water-stagnant conditions. In peat cores from different degraded fen peatlands (Zak et al., 2010), the level of P mobilization rates, i.e., the release from peat to soil water, was 0.1–52.3 mg P m^{-2} d^{-1}, and the rates were significantly correlated with in-situ P concentrations that ranged between 0.4 and 15.3 mg L^{-1}. This finding was rather unexpected. Apart from P mobilization, two other processes control P concentrations in peat soils—P uptake by plants or microorganisms and P resorption, which vary in importance according to the particular fen sites (Fig. 6). It is interesting to note that "internal P mobilization" (Smolders et al., 2006) and the corresponding P concentrations may vary by two orders of magnitude in rewetted fens; this has been explained by different soil properties, mainly the amount of P bound to redox-sensitive compounds and Fe/P ratios in peat (Zak et al., 2010). Overall, oxygen-free conditions were found to promote the reductive solution of redox-sensitive P compounds (Lamers et al., 2002). The dissolution of Fe(III)-P-binding forms can be caused either directly by microbially mediated iron

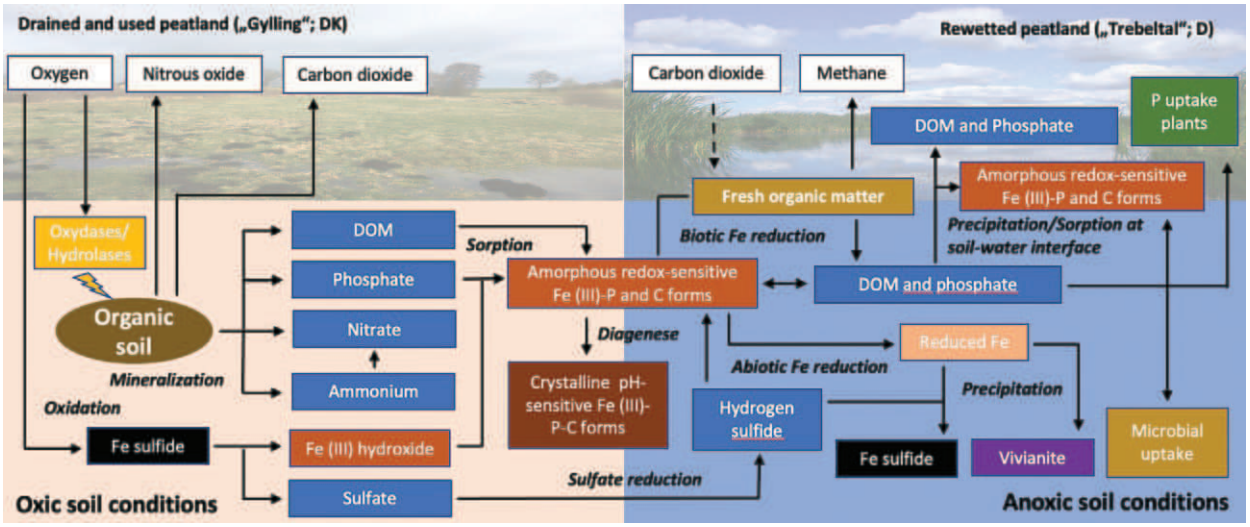

Fig. 6 The lowering of water tables by drainage measures results in peat mineralization and enhanced nutrient and carbon fluxes (left image). After rewetting, enhanced mobilization of phosphorus might occur due to biotic and abiotic process but mobilized phosphorus might also be recaptured by formation of phosphorus minerals or nutrient uptake by plants (right image).

reduction or indirectly by hydrosulfides formed during sulfate reduction (Fig. 6). Besides inorganic P forms, it has been estimated that the release of organic P from degraded peat due to ongoing decomposition of organic matter might account for at least 15% of total P release (Zak et al., 2010). Interestingly, despite comparatively high concentrations of dissolved organic matter (>100 mg DOC L^{-1}), only a low proportion of dissolved organic P was found in degraded peat soils, usually less than 5% of dissolved P, in a study by Zak et al. (2014). Microorganisms mediating organic matter decomposition and associated redox processes are extensively investigated in other systems, but only few studies on inundated peatlands have been conducted to unravel species distributions and abundances depending on varying soil conditions (Weil et al., 2020; Zak et al., 2015). A major part of dissolved P can be taken up by growing plants. Thus, the level of P uptake by dominant plants like *T. latifolia* and *P. australis* was found to be as high as P mobilization rates in degraded peat, ranging between 1.1 and 3.0 g m^{-2} during 150 days of the growing season, in a study by Zak et al. (2014). Likewise, P uptake by an increasing microbial biomass might partly buffer the high P mobilization in inundated peatlands; however, the quantitative importance of this process is not yet clear. As for plant uptake, microbial storage of P can be only short-term depending on seasonal changes in soil conditions (Turner and Haygarth, 2001). Lower acidic to circum-neutral soil pH conditions (3–7) support P sorption due to a positively charged surface of iron compounds. A positively charged surface can also be achieved under more alkaline conditions (pH >7) since calcium (Ca) occurs as a bivalent cation acting as "bridging ion" for P sorption (Bruland and Richardson, 2006). To sum up, peat soils enriched with metals like Fe, Al, and Ca compared to P will be characterized by lower net P mobilization than soils having lower metal/P ratios or lower P-binding capacities, respectively.

Nitrogen and dissolved organic matter mobilization

Processes and factors controlling the mobilization of P in inundated fens are tightly linked with nitrogen (N) and C mobilization, but the quantitative importance of some of the identical processes and above all the associated flux paths may differ substantially. Thus, gaseous fluxes account for a significant part of the N and C cycling but can be ignored for P since the volatile substance phosphine can be formed only at a very low redox potential and other conditions (Fu and Zhang, 2020) that are probably not fulfilled in inundated fens. Likewise, contrary to P, both C and N contents become lower during long-term drainage of peat, again because nitrate or carbonates other than phosphate can be easily leached from the soil matrix at fluctuating groundwater levels and water runoff (Gosch et al., 2019). Only ammonium and some dissolved organic matter fractions (some containing N) have a somewhat higher binding affinity to the soil matrix and can therefore accumulate. Binding partners can likewise be redox-sensitive iron-hydroxides or redox-stable aluminium compounds (Riedel et al., 2013).

Dissolved N occurs mainly in reduced form as both ammonium and dissolved organic N (DON) contrary to P, which is mainly present in its oxidized form as phosphate. Higher nitrate concentrations are only found in the surface water of inundated fens (Kieckbusch and Schrautzer, 2007). In contrast, nitrate concentrations are mostly lower than 0.01 mg N L^{-1} in soil water (Zak et al., 2014). Already during the first weeks of rewetting, nitrate becomes depleted by microbial heterotrophic respiration and biomass assimilation or oxidizes reduced iron or sulfur compounds (Burgin and Hamilton, 2007). In rewetting experiments with different degraded peat soils, it was found that ammonium concentrations rose immediately after rewetting, mainly in the highly decomposed peat but to some extent also in the underlying less decomposed peat (Zak and Gelbrecht, 2007). However, ammonium release rates were found to be almost 100-times higher in highly decomposed peat cores from degraded fens than in less decomposed peat samples from near-natural fens in an investigation by Zak et al. (2010). It is assumed that this ammonium

mainly derives from mineralization of organic matter accumulated in the peat matrix during the drainage phase; however, ongoing mineralization of organic matter in anaerobic peat soils cannot be excluded (Cabezas et al., 2012). After rewetting, washout of ammonium occurs either due to ion-exchange reactions or simply due to the establishment of a new chemical equilibrium between the aqueous and the solid phase. Average concentrations of ammonium in soil water of inundated peat soils can reach levels exceeding 10 mg N L^{-1}, which is two orders of magnitudes higher than in near-natural fens. Likewise, elevated DON concentrations up to almost 30 mg N L^{-1} were recorded over 5 years in the surface water outlet of an inundated rewetted peatland (Kieckbusch and Schrautzer, 2007).

During the last three decades, DOC concentrations have nearly doubled in many inland waters of Central Europe and North America (Monteith et al., 2007). This phenomenon has been proposed to be caused by a decrease of atmospheric sulfate deposition and the large-scale drainage and agricultural use of riparian peatlands (Worrall and Burt, 2007). The common dry-wet cycles in drained peatlands potentially causing high DOC pulses into adjacent surface waters are of critical importance (Brothers et al., 2014). There is some evidence that also the rewetting of degraded fen peatlands might be responsible for enhanced DOC export to lakes and streams in the long term. DOC concentrations of pore water near the soil surface were found to be higher than 200 mg L^{-1}, i.e. up to 10-fold higher in peatlands rewetted for more than 10 years compared to natural peatlands (<50 mg L^{-1}) in a study by Zak et al. (2010). A comparison of experimental net release rates of DOC, carbon dioxide, and methane suggested that DOC export may be an important pathway of carbon loss (Zak et al., 2018). However, other investigations strongly indicate that DOC is retained at the oxygenated soil surface, as corroborated by low in-situ DOC surface water concentrations found in inundated peatlands (Riedel et al., 2013). Interestingly, higher nitrate concentrations in rewetting water lowered the level of DOC mobilization (Cabezas et al., 2013). Overall, it can be expected that only a minor part of the DOC released within the peat soil will be exported to adjacent water courses, but the amount is probably still higher compared to natural peatlands.

Restoration measures moderating adverse effects of peatland rewetting

In recent decades, our understanding of biogeochemical processes in rewetted formerly degraded peatlands has increased substantially. Additional experience from the monitoring of peatland restoration projects has enabled us to establish some robust scientific principles for understanding the implications of actions and for optimizing restoration measures. Still, avoidance of predictable undesired side effects after rewetting of fens can require very cost-intensive operations (Fig. 7). Accordingly, some may argue that we should just follow "the beaver strategy" where large, drained areas are flooded and beaver introduced without preliminary research, without any technical debate, and without asking the landowners. However, beaver, once a cute, respected animal, has become increasingly unpopular among the land users, and also the conservation movement are skeptical towards the beaver strategy as the

Fig. 7 Rewetting of peatlands is often linked with further management such as water table control, topsoil removal, or plant harvesting using either special harvesters or water buffalos in order to (i) improve the restoration outcome, (ii) reduce high nutrient and carbon fluxes after rewetting of long-term drained peatlands, and (iii) gain an income to reduce restoration costs.

flooding has impacted the few remaining intact peatland habitats. The new knowledge we have may to some extent be theoretical but may nevertheless support water authorities, landscape managers, and decision-makers in making sound environmental choices. Eventually, other practical aspects such as economic and social issues, which may vary strongly even at local scale, and which restoration measures to implement must be considered when developing overall realistic management plans (Lamers et al., 2015).

Water management

The water regime has been shown to be the main driver of nutrient mobilization and GHG exchange in peatlands (Evans et al., 2021) and in many other wetland types as well (Kim et al., 2012). Previously, in the restoration of peatlands, adjustment of water tables to the surface or just below has been suggested to prevent, as far as possible, inundated conditions (Joosten et al., 2012). In fact, the highest mobilization of P and methane has been found at high water tables under inundated conditions (Tiemeyer et al., 2020). Therefore, more naturally fluctuating water levels have been recommended in order to improve the ecological quality of wetlands (Lucassen et al., 2005) as well as to avoid flooding of soils with high total P content and low Fe:P ratios (Cusell et al., 2013). Accordingly, it is not the water table that is the primary driver of the mobilization of matter, but other factors like soil properties and the quality of the rewetting water also determine the level of mobilization rates (Zak et al., 2010; Forsmann and Kjaergaard, 2014). Eventually, adjustment of the water table in a degraded peatland is a theoretical approach. Even seasonal changes of water tables might be partly buffered by maintaining the existing drainage infrastructure with pumps and weirs. A pronounced microtopography of long-term drained areas inevitably results in the formation of shallow lakes with water depths varying spatially from a few centimeters to several decimeters, even across short distances, which renders a uniform water depth unfeasible. If technical and financial means are available to manage the inflow and outflow of water to and from rewetted fens, surface water tables should preferably be kept at levels as low as possible to promote recolonization of peat-forming plants. A low water table favors certain species of sedges and brown mosses that are not able to grow under water or float as some sphagnum species in flooded bogs (Visser et al., 2000). Otherwise, submerged macrophytes with a high methane production potential like *Ceratophyllum demersum* might colonize and become dominant over time in open water bodies of inundated fens (Zak et al., 2015). Finally, it remains questionable if inflow of surface water from adjacent rivers should be avoided or if outflow of surface water from peatland should be minimized. If inundated peatlands are already affected by internal eutrophication, inflow of nutrient-enriched river water will support the sedimentation of particulate P compounds (Walton et al., 2020). However, in places where adjacent water courses are vulnerable to slightly increasing nutrient concentrations, maintenance of existing dams is recommended to reduce the water outflow from the peatland. In practice, pipes with non-return valves have proved useful for this purpose, although there is a risk that the valves may be blocked.

Removal of highly degraded peat prior to rewetting

Where peatlands have undergone extensive degradation over time, especially due to intensive drainage and agricultural use, it is usually not sufficient to simply rewet them to restore low DOC concentrations, low CH_4 emission, and oligotrophic-mesotrophic conditions during the first stage of their post-restorative development (1–100 years) (Pouliot et al., 2011). Removal of upper degraded peat soils, often less than 30 cm, before rewetting will minimize the nutrient availability for plants and also promote recolonization of plants adapted to more nutrient-poor conditions (Emsens et al., 2015). This so-called topsoil removal could potentially lower substantially the biomass production. Additionally, the chemical composition of plant material might change towards a more refractory character; this, however, needs further investigation. Topsoil removal might also force the development of even deeper shallow lakes upon rewetting. However, depending on the peatland topography and the restoration measures applied, rewetting does not necessarily lead to the formation of shallow lakes, as has been previously demonstrated (Zak et al., 2017). Brown moss-low sedge communities and low-nutrient conditions can develop within a few years following rewetting. Therefore, prior to undertaking topsoil removal, an evaluation of the restoration objectives and the potential risk of elevated fluxes of matter is recommended. This should include analysis of the state of the soil degradation, the hydrology, and the topography of the system (Zak et al., 2018). If water-saturated conditions in the top peat layer cannot be guaranteed, then the creation of bare substrate might delay the recolonization of peat-forming vegetation because of heat stress on the bare peat surface or enhanced germination of ruderal and competitive species (Klimkowska et al., 2007). An option to mitigate this problem might be mulching with straw material or combining this with the introduction of seeds to accelerate the re-establishment of fen communities (Klimkowska et al., 2007). However, both approaches may fail if the appropriate hydrological conditions are not established. Topsoil removal can be a rather expensive measure, and its carbon footprint needs to be carefully assessed, particularly if the objective of the peatland restoration is to mitigate climate change. The degraded surface peat might be a suitable material for some horticultural purposes and thus hold a commercial potential, and it may be a preferable source rather than extraction of peat from intact peatlands (Klimkowska et al., 2010). Such a commercial use may partly offset the high removal costs. The total carbon footprint needs to be evaluated for the cases when removed peat is used to dam the ditches or improve the surrounding mineral soils for agriculture. For this purpose, an estimation is needed of the mineralization rate of the remaining organic carbon under oxic conditions compared to the GHG potential of methane emission if the degraded peat layer is not removed. Finally, consideration should also be given to whether the C in the peat can be sequestered under oxic conditions, for example by hydrothermal carbonization technologies, i.e., biochar production.

Plant harvesting and removal

Rewetting of drained fen peatlands induces the establishment of tall, graminoid wetland plants (helophytisation) like *P. australis* and *T. latifolia* and these may become the dominant vegetation for several years to decades (Baumane et al., 2021; Kreyling et al., 2021). Due to high nutrient availability, these plants form dense stands with a high biomass, which results in rapid export of nutrients from the soil water (Zak et al., 2014). Harvesting of plant biomass in rewetted peatlands is thus an additional effective method of permanently removing N and P from the soil-water nutrient cycles. Harvested plant material needs to be removed; otherwise, a major part of the plant nutrients will be released during leaching (Zak et al., 2014). Nitrogen availability is initially growth limiting, but due to high levels of atmospheric N deposition common for intensively used agricultural landscapes and high P plant uptake and removal rates, P will eventually become limiting. Therefore, regular harvesting of plant biomass can be considered a longer-term method of restoring peatlands with high soil P, peatlands that exhibit a continual loss of phosphate, or in catchments with high P inputs from agriculture. As biomass harvesting can deplete the soil P pool, it can be an effective method for a return to nutrient-poor conditions. Harvesting can oppose to topsoil removal be considered a long-term mitigation method and requires special harvesting techniques (Fig. 7). Over time, harvesting will aid the re-establishment of plant assemblages better adapted to nutrient-poor conditions, such as bryophytes in fen communities. The various harvesting options show that apart from pollution management, N and P are potential resources to be restored for circular economy value chains such as for energy, construction, and fodder (Ziegler, 2019).

Conclusions and synthesis

There is clearly a need for strengthening the links between the restoration of ecological and biogeochemical functions of peatlands and the wider benefits that may thus be provided to society. Efforts are required to raise the awareness of the linkages between the restoration of severely degraded peatland systems and international commitments, such as the Nationally Determined Contributions under the Paris Climate Change Agreement or the Sustainable Development Goals (SDGs), especially those related to Goal 6 Clean Water and Sanitation, which calls for the protection and restoration of water-related ecosystems, including wetlands and lakes. Policymakers need to understand how peatland restoration can make a significant contribution to global initiatives; however, peatland scientists need to ensure that their knowledge is translated into a language that is understood within broader policy forums. In the long term, rewetted fens have the potential to fulfil multiple restoration goals, including those targeting climate, water, and species protection. Ultimately, the restoration of peatlands is a matter of societal choice, and it is essential that society understands the potential benefits that such restorations can bring to ensure that informed and intelligent choices are made.

Knowledge gaps

The current knowledge gaps concern:

- nutrient balances in both drained, natural, and rewetted peatlands.
- importance of hydrology, specifically of water fluxes and change of hydro-physical peat properties over time of rewetting.
- formation of P minerals like vivianite as stable P sinks changes in DOC quality and the export over time in rewetted fens.
- importance of nutrient status on recolonization with specific peat-forming plant species.
- new peat formation and the role of macrozoobenthos in nutrient recycling.
- long-term effects of harvesting management or topsoil removal on certain soil nutrient fractions like organic bound N and P, including legacy P and plant litter quality.
- pre- and post-rewetting microbial abundances along with changes in CH_4 emissions, plant communities, and peat geochemistry to better assess carbon and nutrient cycling over rewetting time.

Important case studies

Site name	*Country*	*Coordinates*	*Topic/Concept*	*Key reference*
River Peene Valley (riparian fen peatlands, both natural, drained, and rewetted)	Germany	53.8502° N; 13.6959° E	Restoration of ecosystem functioning of peatlands	Kreyling et al. (2021)
River Odense Valley (rewetted riparian peatlands and floodplains)	Denmark	55.3297° N; 10.3267° E	Restoration of ecosystem functioning of peatlands	Baumane et al. (2021)
Narew floodplains (riparian fen peatlands, sedge, and reed beds)	Poland	52.7558° N; 21.2154° E	Cost-benefit analysis of peatland restoration	Jabłońska et al. (2020)

Worldwide Wetland Loss and Conservation of Biodiversity and Ecosystem Services

Beth A Middleton, U.S. Geological Survey, Wetland and Aquatic Research Center, Lafayette, LA, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Wolfgang Junk and Florian Wittmann.

Glossary

Assisted migration Intentional transfer of a species beyond its current distribution, especially to move the species to a suitable habitat formerly outside of its range.
Dams (for hydroelectric, water storage) An obstruction impeding the downstream flow of water. Dams are often constructed by humans to generate electricity or store water for urban, agriculture, or industrial development.
Down-cutting Lowering of channel elevation due to hydrologic alteration of a river by damming or straightening.
Dredging Excavation to deepen a channel, typically to improve navigation or increase water flow.
Groundwater abstraction Extraction of water from subsurface layers or aquifers for urban, agriculture or industrial development.
Land drainage Dewatering of a wetland via ditches, tiles or other means for the purpose of urban, agriculture, or industrial development.
Land filling Artificially increasing the elevation of a low-lying area.
Land-use/climate change interaction The combined effects of both land-use and climate change on biota and their environment.
Levee An obstruction built for the purpose of preventing water flow from the channel or other parts of the watershed, which dewaters or impounds parts of a floodplain.
Protected area A legally protected tract of land, which is managed to conserve long-term ecosystem and cultural services (following Dudley, 2008).
Return water Water that is released after usage, often to a water body that is not its original water source.
Sea level rise Increase in elevation of sea water, which contributes to salinity intrusion in coastal wetlands.
Water diversion The redirection of water flow usually from one river to another, sometimes for the purpose of increasing sediment or freshwater supply to a damaged floodplain.

Introduction

This article will review global and regional trends in wetland loss and conservation, with the goal of evaluating best strategies for conservation and management to address future challenges to these important ecosystems.

Main topics/concepts

Global and regional trends of wetland loss

Humans have altered wetlands since ancient times, especially to store water by building dams and levees on floodplains. Wetlands also are dried through ditching, tiling and filling, and subsequently used for agricultural, forestry, urban or industrial development (Table 1) (Smith, 1971; Middleton, 1999). Levees and sea walls have been constructed to protect farms, industries and cities from flooding along rivers and coasts (Table 1). For example, levees were constructed along the Mississippi River after destructive

Table 1 Causes of wetland loss in world inland wetlands.

Human-related impacts	*Impact*	*Additional Citations*
Land drainage for agriculture, forestry, industry, urban development, mosquito control	Drying of wetland by ditching, tiles, pumping, and/or modification of landform by bulldozing	Middleton (1999)
Land filling, excavation or sediment addition for raising elevation of wetland for agriculture aquaculture, forestry, industry, waste disposal, urban development	Drying of localized portion of wetland, especially to create elevated mounds in forestry, or excavation of wetland for aquaculture or rice paddies	Dong et al. (2020)
Construction of levees (i.e., dikes, berms, bundhs, seawall) e.g., coastal and inland river flood and storm protection	Drying of wetland on one side, impoundment of water on the other side of levee; lack of flood pulsing	Junk et al. (1989)
Water diversion for agriculture, industry, urban usage	Water reduction and/or seasonally inappropriate water levels in the affected area	Middleton and Souter (2016)
Groundwater abstraction for agriculture, industry, or urban usage	Regional aquifer depletion; especially damaging to spring seepage wetlands	Middleton (1999)
Water return from usage (e.g., irrigation return water, sewer release, heavy metal, nutrients and other pollution	Water increase and discharge with agriculture, industrial and urban runoff	Dong et al. (2020)
Dredging for navigation	Deepening of channel and filling of wetlands	Middleton (1999)
Mining of peat, or underlying strata (e.g., gravel, sand)	Open water creation, vegetation change	Middleton (1999)
Logging or plant harvest	Vegetation loss	Middleton (1999)
Fire	While lightning strike fires are a natural process, fire can create holes in hydrologically-altered peatland	Middleton (1999)
Sediment diversion or application	Added sediment raises elevation of wetland	Craft et al. (2002)
Subsidence	Earthquakes, extraction of groundwater, oil, gas, minerals	Dokka (2006)
Sea level rise	Melting of ice caps and glaciers	Middleton and Souter (2016)
Drought	Natural drought cycles, but vegetation death exacerbated by water abstraction in waterways and any increase in salinity in arid inland wetlands	Middleton and Souter (2016)
Hurricanes and storms	Natural process, with suspected increases in occurrence due to climate change	Middleton and Souter (2016)
Down-cutting	River entrainment and other land-use changes	Middleton (1999)
Dams for hydroelectric and other purposes	Causes loss of vegetation upstream due to impoundment, and drying with seasonally unnatural water release downstream	Middleton (1999)
Land-use change/climate change interaction	Effects of land-use alteration may worsen if climate change drought/flooding/sea level rise/storm activity become more intense	Sirami et al. (2017)

flooding in 1927–1928 (Newling, 1990). Particularly near urban areas, wetlands are altered for mosquito control by ditching, tiling, pumping, vegetation management and pesticide spraying (Table 1) (Middleton, 1999).

These and other direct drivers of wetland loss and change have altered global wetlands (Table 1) including land drainage and filling; levee construction; channel deepening for floodplain dewatering and development (ag, urban, industrial); excavation for aquaculture and rice farming; navigation channel dredging, straightening, and stream channel entrainment; below-dam channel down-cutting and floodplain dewatering; above-dam impoundment; freshwater extraction from impoundments with polluted water return (agricultural, urban, industrial); mining of peat and underlying strata; oil and gas exploration; subsidence; and vegetation harvesting including logging (Middleton, 1999; Ramsar Convention on Wetlands, 2018). Climate change could interact with these land-use drivers to exacerbate the negative effects of drought, fire, hurricane intensity, and sea level rise (Middleton and Souter, 2016).

The alteration of wetlands can result in their ultimate destruction; estimates of global wetland loss following transformations by humans are as high as 87% of the Earth's total original wetlands (Fig. 1) (Davidson, 2014). On the average, region-wide wetland loss is 53.5% since 1700 (Davidson, 2014) (Table 2), with average loss higher in inland vs coastal wetlands (average loss = 60.8% vs. 46.4%, respectively). Regional wetland loss has been disproportionately greater in Europe and North America than elsewhere (Table 2) (Hu et al., 2017).

Without wetland alteration by humans, the world would have as much as 29.83 million km^2 of wetland area based on remote sensing coupled with the Precipitation Topographic Wetness Index, which assesses wetland status using global water table, topography, precipitation and basin boundary distributions (Hu et al., 2017). Using this approach, estimates of global wetland loss are 1.53–14.86 million km^2 (Table 1) or 33% of the original wetlands (Table 2) (Hu et al., 2017). While there is not a strong consensus among studies on the overall loss of world wetlands, these widely varying estimates are no doubt due to differences in methodology (Table 2). Geographical estimates of wetland loss might be improved by adding analyses of flood frequency based on water gauge information and local knowledge, but such an approach might still miss smaller wetlands below the detection size of the remote sensing technique (Allen, 2016).

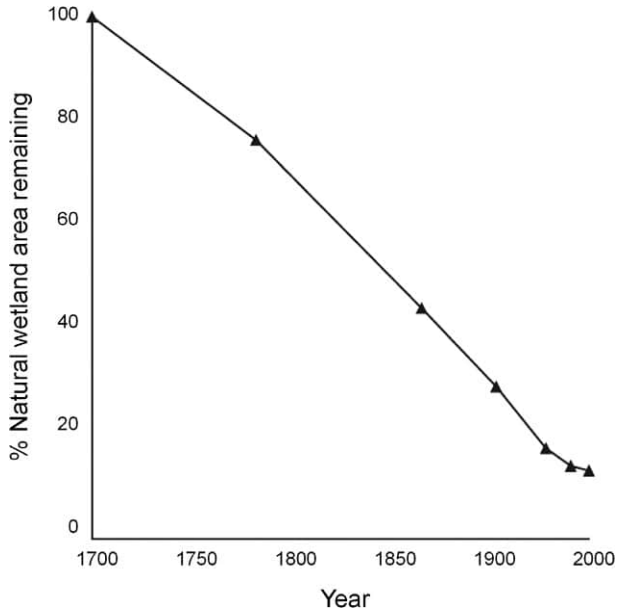

Fig. 1 Natural wetland loss from 1700 to 2000 based on rates of wetland loss based on published reports. From Davidson NC (2014) *How Much Wetland had the World Lost? How Much Wetland had the World Lost?*, with permission.

Table 2 Estimates of percentage area loss of wetlands on various continents.

Continent	*OECD (1996)*	*Davidson (2014)*	*Hu et al. (2017)*
Time period	Until 1985	Long term average	Until 2009
World	50%	54–57%	33%
Asia	27%	45%	27%
Africa	2%	4%	16%
Europe	56–65%	56%	45%
North America	–	56%	8%
South America	6%	–	32%
Oceania	–	44%	18%

From Hu S, Niu Z, Chen Y, Lifeng L and Zhang H (2017) Global wetlands: Potential distribution, wetland loss, and status. *Science of the Total Environment* **586**: 319–327.

Overall, wetland ecosystem types account for more than 6% of the land area on earth with varied percentages of wetland landmass remaining in some regions including South America (20%), North America and Russia (10% each), China and Africa (7% each), Europe (5%), as well as Australia, tropical Asia, and subtropical Asia (3% each) (Junk et al., 2013). In Brazil and other South American countries, wetlands may account for as much as 20% of the country's total land area. Following conservation efforts after the 1980s, loss in North America and Europe has slowed, but has remained high in Asia (Hu et al., 2017).

While the Ramsar Convention on Wetlands has designated 2410 wetland protected areas by Ramsar Convention on Wetlands (2020), it is unclear if the Ramsar Convention on Wetlands has stemmed the rate of regional wetland loss (Davidson, 2014) (Fig. 1; Table 3). For example, most countries in South America have been slow to define, delineate and classify wetlands, so that threats to Ramsar sites continue (Wittmann et al., 2015).

Currently, 89% of the world's wetlands are not protected (Reiss et al., 2017). Based on the Wetland Extent Trends Index, wetlands excluding man-made ones declined by 30% between 1970 and 2008 including 50% in Europe and 17% in Oceania (Dixon et al., 2016). Extensive areas of freshwater and coastal wetlands have been lost in the last 50 years in China (23.0% and 51.2%, respectively) (An et al., 2019). In North America, wetland loss has decreased substantially in recent years so that the current rate of loss is roughly equal to the amount of gain via restoration and creation (0.06% per year) (Kolka et al., 2018).

Wetland conservation

Natural area protection is an important approach in the conservation of wetlands, which included land designation by local, state, or federal entities, NGOs (e.g., Nature Conservancy), and the Ramsar Convention on Wetlands. Designated protected areas (irrespective of wetlands) cover 12.7% of lands, and have lower levels of human disturbance and habitat loss than surrounding areas (Geldmann et al., 2013). While protected area designation has been effective at preventing habitat loss, the practice has been less effective for preventing species decline (Geldmann et al., 2013). Even so, 89% of the world's inland wetlands are not in a

Table 3 Area and number of Ramsar sites by region.

Region	*Site number*	*Area (km^2)*
North America	185	227,002.8
Europe (excluding Russia)	936	153,981.9
Russia	35	103,237.7
China	37	31,685.4
South America	95	290,704.0
Africa (excluding islands)	277	823,967.0
Tropical Asia	163	97,476.3
Australia	64	75,101.8

From Junk W An J, Finlayson S et al. (2013) Current state of knowledge regarding the world's wetlands and their future under global climate change: A synthesis. *Aquatic Science* **75**: 151–167, based on Ramsar; http://www.ramsar.org/cda/en/ramsar-documentslist/main/ramsar/1-31-218_4000_0.

protected area status (Reiss et al., 2017). A high level of protection is important for wetlands given their importance in providing critical habitats for biota, and human services.

There are many inventories that describe regional wetland protection status and distribution around the world. Some of the best descriptions of wetland type, distribution and status come from the United States (U.S.) Fish and Wildlife Service wetland inventory, the Canadian wetland inventory, the Australian Wetland Database and Directory of Important Wetlands in Australia, and from European efforts including Annex I of the Habitats Directive [92/43/EC], the Manual of European Union Habitats-EU-27 (Reiss et al., 2017). Description, classification and status of various Brazilian wetland types are included in this volume (Junk, 2021). Ramsar protected wetlands are listed in reports and websites and represent worldwide cooperation to protect wetlands (Junk et al., 2013) (Table 3).

Protected area status does not always mean that a wetland is completely without land-use pressures. The Ramsar Convention reports that after designation, human influence may remain in wetlands particularly in Europe, Central America and Asia, with the lowest human pressure in designated wetlands in Oceania and North America (Ramsar Convention on Wetlands, 2014; Reiss et al., 2017). While the U.S. has fewer Ramsar-designated wetlands than some other regions, unlike some other countries, many U.S. wetlands are protected by federal, state, local and NGO designation (Beilfus, 2012).

Of the various wetland types, rivers and associated floodplains generally have the highest level of protection. Nevertheless, 70% of the world's river reaches have no protection in the upstream portion of their watersheds (Abell et al., 2017). While the Convention on Biological Diversity has targeted a 17% protection level for inland waters, only 11% of the world's rivers have integrated protection for the entire upstream to downstream river system (Abell et al., 2017).

The integrated protection of the entire river and its floodplain is important for many reasons. Downstream conservation threats often need to be remediated in the headwaters, and cannot be effectively addressed in only downstream reaches (Vörösmarty et al., 2010). In fact, an emphasis on downstream freshwater resources for humans could facilitate freshwater flow from upland wetlands and be a useful concept in floodplain conservation (Harrison et al., 2016), particularly from the perspective of maintaining biotic refugia during drought (Hamilton et al., 2005). Certain types of special river designation can provide such protection e.g. the U.S. National Wild and Scenic River Act of Oct 2, 1968. This act designates particularly remarkable rivers for their value (e.g., scenic, recreational, geological, biotic, cultural) and preserves them in a free-flowing state (United States Fish and Wildlife Service (USFWS), 2020).

Non-riverine peatlands have fewer national level designations to protect them; however, knowledge is emerging that peatlands and other wetlands store carbon that can be of value in reducing greenhouse gases in the atmosphere (Moomaw et al., 2018). Peat is conserved via carbon-based peat initiatives (REDD+, Green Climate Fund), and recognition of wetland carbon storage lends an important argument for conserving wetlands on public lands, particularly in peatlands (Richardson et al., 2014; Roucoux et al., 2017; Middleton, 2020).

Synthesis: Future conservation, management and emerging perspectives

This article has examined global and regional trends in wetland loss and conservation, and opened the conversation on future challenges in the protection of these ecosystems. Of particular concern for the future is the potential of ecosystem damage from the combined action of land-use and climate change (Sirami et al., 2017). Particularly in wetland protected areas, a number of strategies to counteract these threats may be useful.

Remediation of damage caused by land-use alteration can help wetland species and ecosystems maintain themselves. For example, freshwater remediation of hydrologically-altered floodplains can help species and ecosystems maintain themselves during drought, especially in salt-affected tidal freshwater wetlands (Souter et al., 2014; Middleton and Souter, 2016). Alternatively, during severe drought or dewatering of a wetland, refugia for aquatic species might be protected from development in permanently wet or low-lying areas (Table 4) (Middleton, 2009; Davis et al., 2013). In particular, seed banks may harbor species (Middleton, 1998), so that stream corridor vegetation may be regenerated after drought (Baron et al., 2002; Middleton and Souter, 2016).

A few landscape-level approaches have emerged including the idea of assisted migration, which is the intentional transfer of a species to a suitable habitat outside of its current range. While assisted migration is controversial, the procedure may be a way of

Table 4 Example protected areas designated for the conservation of wetland resources, with the year of first national level designation given (n.d. = not designated) (Ramsar Convention on Wetlands, 2020 and other sources).

Location	*Year*	*Resource*	*Area size (km^2)*	*Wetland type*	*Conservation threats*	*Designation status*

reducing species extinction in a future with climate and/or land-use change (McLachlan et al., 2007). Wetland reserve design could be enhanced to support maximum biodiversity and ecosystem services with respect to connectivity, elevation variability, longitudinal and latitudinal floodplain connectivity, interconnection of the freshwater-terrestrial landscapes at different timescales, and the free flow of water to groundwater-fed wetlands (Reiss et al., 2017). Also, the intensity of local management (e.g., burning, cutting) might be reduced or softened during periods of stress to avoid damaging vegetation and ecosystem services (e.g., drought) (Middleton et al., 2017).

Conclusion/synthesis

This article reviews trends in global and regional wetland loss and conservation, and strategies for future conservation and management from the perspective of climate and land-use changes. Wetland loss assessments are not uniformly in agreement with estimates of global wetland loss, which are as high as 87% since 1700 CE as based on reports (Davidson, 2014), or as low as 33% as based on remote sensing (Hu et al., 2017). Estimates of wetland loss might be improved by refining both remote and local assessment techniques.

Conservation is essential given the biological importance of wetlands as critical habitats for biota and human services. Given the potential of the interaction of land-use and climate change to cause stress in wetland protected areas (Sirami et al., 2017), a number of management actions could improve the situation. These actions include the reversal of certain land-use changes through freshwater remediation of hydrologically-altered floodplains, improved wetland reserve design, assisted migration, and the softening of burning/cutting regimes during drought.

Knowledge gaps

- What is the minimum flow of freshwater that can maintain vegetation and ecosystem function during drought, especially in various types of hydrologically-altered wetlands?
- After human usage, can return water abstracted from ground and surface water be delivered to hydrologically-altered wetlands in a fashion that maintains ecosystem function?
- How important is the interaction of land-use and climate change in various world wetland types and situations?
- Are extreme environments the main extinction factor of wetland species i.e., do species become extinct during extreme drought or burning episodes?

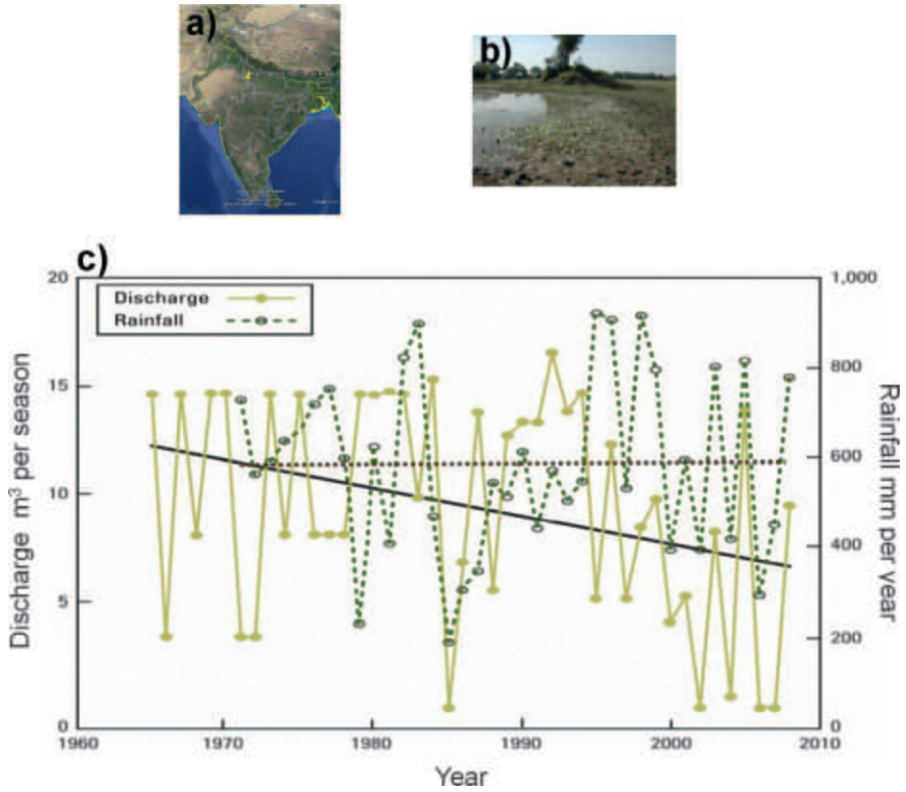

Fig. 2 (A) Location of the Keoladeo National Park, Bharatpur, Rajasthan along the Banganga River. (B) Increasing water extraction for development occurred in the 1990s. By the late 1990s, floating beds of aquatic species were mostly absent but reemerged in wet depressions after a large monsoon in 2009. An interbasin water transfer re-flooded the park for a period of time after 2010. (C) Precipitation (mm) and water discharge from the Ajunbund to the Keoladeo National Park, 1965 to 2008 (Middleton, 2009).

Important case studies (where appropriate)

Case Study: Keoladeo National Park, Rajasthan, India

Subtropical monsoonal wetlands in northern India (Fig. 2A) flood seasonally following the monsoon, and then dry down slowly during the winter season (October-March). In the Keoladeo National Park, during the flooded season, floating grasses such as *Paspalum distichum* floated in the water column, and then died back during the summer season drawdown (Fig. 1B; ~March-June). Aquatic plant regeneration is driven by seed banks during sporadic rains in (July–September) (Fig. 2B; Middleton, 1999). The Keoladeo National Park is a historic overwintering ground for waterfowl of the Asian flyway, and is of critical value for humans as well as biodiversity (Middleton, 1999).

Water diversion for agricultural irrigation and urban expansion along the Gambhir and Banganga Rivers affected the water supply to the Keoladeo National Park in the early 1990s (Fig. 2C; Middleton, 2009). Before the 1990s, water was discharged from the river into the park from Ajunbund from September through February. By 2009 following dewatering, the floating marshes of grasses had mostly disappeared in this protected area. The wetland vegetation partially returned following the monsoon of 2008, following an interbasin water transfer from another river after 2010. Certain aquatic plants reappeared in wet depressions of the flooded wetlands during 2008–09, most likely regenerating from the seed banks (Middleton, 1998, 2009). The national park demonstrates that certain types of wetland vegetation have some resilience to dewatering after hydrological alteration because some plant species are stored in the seed bank and can regenerate when water becomes available (Middleton, 2009).

Wetlands Under Global Change

Eric J Ward, U.S. Geological Survey, Wetland and Aquatic Research Center, Lafayette, LA, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Wolfgang Junk and Florian Wittmann.

Glossary

'Blue' carbon Carbon sequestered by coastal ecosystems, including coastal wetlands. As opposed to 'green' carbon of terrestrial systems or 'teal' carbon sequestered by inland waters and associated ecosystems.

'Teal' carbon Carbon sequestered by inland waters and wetland ecosystems. As opposed to 'green' carbon of terrestrial systems or 'blue' carbon sequestered by coastal ecosystems.

C_3 plant C_3 plants are plants which utilize a metabolic pathway where the initial product of carbon dioxide assimilation is 3-phosphoglycerate. C_3 carbon fixation is the most common metabolic pathway for photosynthesis in modern plant species.

C_4 plant C_4 are plants which utilize a metabolic pathway where the initial product of carbon dioxide assimilation is four carbon oxaloacetic acid. C_4 carbon assimilation is an adaptation of the ancestral C_3 carbon assimilation pathway that reduces energy loss to photorespiration and water loss via transpiration.

Eutrophication Excessive concentration of nutrients in a body of water, often associated with human activities higher in the watershed, such as land clearing or fertilization. Eutrophication may result in large increases in phytoplankton populations (i.e., 'algal blooms').

Evapotranspiration Water transferred from an ecosystem to the atmosphere via evaporation from surfaces and transpiration of plants.

Invasive species A species that creates negative environmental, ecological or economic impacts through overpopulation. Invasive species are often introduced or exotic, though native species may be deemed invasive due to overpopulation as a result of human activities through alteration of environments, food webs or introduction of exotic genotypes.

Monoclonal stand A patch of vegetation occupied by a single genotype of a plant species, usually spread through vegetative reproduction, such as root or rhizome networks.

Particulates Microscopic particles of solids or liquids suspended in the air, also known as aerosol particles. Depending on size, some particulates may be injurious to human health, increasing risks of cancer, heart attacks and respiratory disease.

Peatland An ecosystem characterized by soil composed largely of partially decomposed organic matter. Different types of peatlands include bogs, fens, mires, muskegs and pocosins.

Radiative forcing A change in the Earth system energy balance, often in reference to a human impact to an ecosystem, such as wetland conversion or restoration. For detailed definitions and discussion regarding application to ecosystem processes, see Neubauer (2021).

Volatile organic compound An organic compound that has high vapor pressure at room temperature, low boiling point and high number of molecules in surrounding air (or volatility). Many volatile organic compounds can have negative human health and environmental effects, such as promoting the formation of tropospheric ozone and smog.

Introduction

Wetlands are among the ecosystem types most threatened by global change (Erwin, 2009), including both climate change and other anthropogenic factors such as sea level rise, urban development, deforestation, agricultural land use, drainage, levees, tidal flow restrictions, pollution, eutrophication, and fires. Wetlands also have a disproportionate influence on the global carbon cycle, containing approximately 20–30% of soil carbon despite accounting for only 6–8% of land area (Mitsch et al., 2013). Historically, wetlands have often been viewed as unproductive lands and were targets for drainage and conversion to other land uses (Kolka et al., 2018). For example, within the 48 conterminous states of the U.S. (CONUS), an estimated 53% of wetlands were drained or converted from 1790 to 1980 (Dahl, 1990). From 1990 to 2009, overall losses of wetland area in CONUS were not significantly different from zero; however, certain wetland types continued to be lost, particularly coastal saltwater wetlands (Dahl, 2011).

Indeed, wetland conversion and loss remain issues of global importance. Global losses of some coastal wetland types, such as salt marshes and mangroves, may be as high as 2% or 3% per year (Pendleton et al. 2012), though considerable disagreement exists about those rates and if they have changed in recent years (Feller et al., 2017). Considerable concern remains about coastal ecosystem losses, along with their potential for 'blue' carbon sequestration and storage (e.g., Windham-Myers et al., 2018), a term coined in contrast to the 'green' carbon accounted for in terrestrial ecosystems. Other authors have pointed to the importance of 'teal' carbon found in inland wetland systems and the relative lack of data concerning their global rate of loss (Nahlik and Fennessy, 2016; Middleton, 2020). While forecasting the impact of global change on any ecosystem is a complex problem, wetlands are particularly difficult due to their nature as biogeochemical hotspots that are variable in space and time. As it may be unclear whether wetlands should be treated as primarily terrestrial or aquatic due to their position at the terrestrial-aquatic interface, they have been historically neglected in global Earth system models (Bailey et al., 2017). This promises to be an area of active research in the coming decades.

In this chapter, we focus on the major global change factors affecting wetlands and the responses of different wetland types to those global change factors. We will not explicitly address the question of wetland impacts on Earth system processes and global climate. While some have argued that the climate impact of restoring some wetland ecosystems may be neutral or increase global temperature in the short term, due to relative contributions of CO_2 uptake and emissions of other greenhouse gases such as CH_4 (Bridgham et al., 2006), others have argued that most inland and coastal wetland restorations have a present net cooling effect (i.e., a negative radiative forcing) that is more readily apparent on longer time frames (Mitsch et al., 2013; Taillardat et al., 2020). The exact accounting of radiative forcing, greenhouse gas emissions and carbon sequestration is complex and dependent on both the timeframe and modeling approach used in such analyses; it is not a simple property of a given ecosystem (Neubauer, 2021). What is generally undisputed in scholarly literature is that the historical conversion of wetlands to other land uses-such as crops, production forestry, pastures and urban/suburban areas-have had the largest effects on global climate and that such transitions continue to release large amounts of greenhouse gases to the atmosphere when they occur.

Global change factors

The term 'global change' refers to many factors both inclusive of and extending beyond the usual definitions of 'climate change.' "Global change research" as defined by the U.S. National Academies of Sciences, Engineering, and Medicine (2017) is the "study, monitoring, assessment, prediction, and information management activities to describe and understand the interactive physical, chemical, and biological processes that regulate the total Earth system; the unique environment that the Earth provides for life; changes that are occurring in the Earth system; and the manner in which such system, environment, and changes are influenced by human actions." Thus, if we discuss global change affecting wetlands, we must include a wide array of factors. These include, but are not limited to:

Climate Change: Anthropogenic emissions of greenhouse gases, primarily CO_2 has been the major driver of widespread warming of the global climate and related changes to local climates, which have been documented since the 1950s (IPCC, 2013). Changes in the long-term distribution of global temperatures, humidity and precipitation could affect all types of wetlands. Climate not only regulates the supply of water to wetlands via precipitation and snow melt, but also the losses of water from the landscape via evapotranspiration to the atmosphere. The frequency and intensity of storm events play an important role in ecosystem disturbance regimes, especially in coastal areas. Climate change is also a major factor in fire risk for wetland ecosystems (Turetsky et al., 2015). Another consideration sometimes overlooked is that the CO_2 concentration of the atmosphere directly impacts ecosystems. As CO_2 is a substrate for photosynthesis by plants, it may be expected that increasing atmospheric CO_2 will impact plant productivity and growth directly, as opposed to indirectly through changing climate. Special attention is given to this question in the section *'Direct effects of CO_2 on wetland ecosystems'* below.

Hydrological Alterations: Human activities have had dramatic impacts on the hydrology of many areas, impacting the quantity, quality and timing of water flowing into and out of wetlands. Historically, wetland drainage often preceded conversion to other land uses, such as agriculture or production forestry, though other reasons, such as reducing the spread of malaria were used to promote wetland drainage (McCorvie and Lant, 1993). River dikes and levees reduce sediment and freshwater delivery to floodplains and alluvial deltas outside the levee system, while concentrating flow and increasing water depth between levees. Sea dikes, canals and spoil banks can greatly alter the delivery of sediments and saltwater to coastal saline wetlands (Day et al., 2008). Urbanization, with its concomitant increases in impermeable surface, storm drainage and reduction in organic inputs, can have large impacts on wetlands, even when they are not drained or converted directly (Faulkner, 2004; Lee et al., 2006).

Sea Level Rise: Sea level rise (SLR) can be measured either eustatically (relative to the center of the earth; ESLR) or relative to local land surfaces (RSLR). Tide gauge data suggest that ESLR is over 200 mm since 1880, while satellite data gives an ESLR rate on the order of 80 mm from 1995 to 2015 (Rovere et al., 2016). Wetlands, however, respond to RSLR, not ESLR directly. Other factors may contribute to make RSLR either greater or less than ESLR in a given area, such as tectonic activity, geological subsidence, subsurface fluid extraction, and sediment compaction (Day et al., 2008; Törnqvist et al., 2008; Giambastiani et al., 2020; Herrera-García et al., 2021). Sea level rise impacts are not limited to coastal saline wetlands. Indeed, RSLR impacts are expected to extend many kilometers inland along waterways to affect tidal freshwater wetlands (Doyle et al., 2010; Krauss et al., 2018) (Fig. 1).

Nutrient Loading and Pollutants: Runoff water from human-dominated landscapes such as urban and agricultural areas may carry chemicals that function as either toxic pollutants or nutrients. Through fertilization and the cultivation of crops, humans have

Fig. 1 A wetland forest impacted by sea level rise and increasing salinity in North Carolina. Such forests are often termed 'ghost forests' due to their prevalence of dead tree stems. Courtesy Melinda Martinez.

increased the bioavailability of many nutrients to ecosystems, which flow into adjacent natural areas including wetlands. Human activities now make bioavailable to terrestrial and wetland ecosystems more nitrogen, which is of the most essential nutrients to plant growth, than all natural processes combined (Vitousek et al., 1997). While nutrients are critical to plant growth and other ecosystem functions, an excess of nutrients in wetlands can lead to eutrophication of adjacent aquatic systems. Eutrophication may cause algal blooms, which can cause aquatic die-offs due to limited light penetration to littoral plants, changes in pH and subsequent depletion of dissolved oxygen when algae decompose (Chislock et al., 2013). Some algal blooms are categorized as harmful algal blooms (HABs), associated with release of noxious toxins that degrade water quality, pose risks to human health, and induce die offs of both aquatic and terrestrial animals. Impacts to commercially important fisheries are immediate, but effects may extend to terrestrial species that use such water supplies. Indeed, livestock losses were linked to HABs as early as the late 19th century (Francis, 1878).

Nutrient loading also impacts wetlands themselves, changing community structure of plant species and sometimes reducing overall biodiversity (e.g., Drexler and Bedford, 2002). While wetlands at the terrestrial-aquatic interface can be useful in removing nutrients and reducing aquatic eutrophication, loss of biodiversity, greenhouse gas emissions (e.g., nitrous oxide release from denitrification of nutrient inflows) and shifts in microbial and plant communities may all lead to undesirable changes in wetland structure and function (Verhoeven et al., 2006; Faulkner, 2004). Similar to nutrients, wetlands can serve an important function in the retention of potentially harmful pollutants such as lead, chromium, copper, nickel, and zinc, which could damage adjacent aquatic ecosystems and drinking water supplies. However, these same pollutants may damage wetland ecosystems themselves, including animal populations such as amphibians and migratory birds that depend on such ecosystems (Faulkner, 2004).

Biological Invasion: Wetlands are prone to invasive species, especially when disturbed by human activities such as hydrological alteration, nutrient loading and introduction of non-native species and genotypes (Bansal et al., 2019; Ciotir et al., 2013; Zedler and Kercher, 2004). Indeed, the number of highly invasive plants in wetlands worldwide seems disproportionate to their coverage on the landscape, perhaps due to their interconnectedness and position at the terrestrial-aquatic interface (Zedler and Kercher, 2004). Many invasive plants in wetlands are large-bodied, plants that produce large amounts of leaf litter in monoclonal stands. The removal of not just aboveground living biomass, but also belowground biomass and leaf litter may be necessary to restore lost biodiversity in invaded ecosystems in such situations (Lishawa et al., 2019). Invasive species not only can out-compete native species, but may alter nutrient cycling, microtopography, ecosystem structure, soil microbiomes and ecosystem food webs (Ehrenfeld, 2003; Windham and Meyerson, 2003; Zedler and Kercher, 2004). Invasive species in wetlands also include a variety of animals, including gastropods, insects, fish, reptiles, birds and amphibians, but the full impact of them is rarely fully understood (Swarth and Kiviat, 2009). The control of invasive animals that inhabit wetlands and adjacent waters has been the target of large public expenditures, ranging up to hundreds of millions of dollars in the U.S. for certain species (Jenkins, 2013).

Interactions among factors: Importantly, global change factors do not act in isolation. Ecosystem resilience to one type of change may be affected by the impacts of another global change factor (Day et al., 2008). For example, land-use conversions upslope may

limit migration of coastal ecosystems in response to sea-level rise (Borchert et al., 2018). Hydrological changes are almost invariably accompanied by changes in nutrient inputs in both coastal and inland systems (Day et al., 2008; Faulkner, 2004). Because of their hydrological connections and placement at the terrestrial-aquatic interface, the conservation of wetlands involves accounting for uncertainties related to interacting stressors, which has led some to advocate for a 'safe operating space' concept in their management (Green et al., 2017).

Wetlands responses to global change

Direct effects of CO_2 on wetland ecosystems

The long-term effects of elevated atmospheric CO_2 on ecosystem productivity of biomass and biomass allocation patterns remain research areas of great uncertainty. However, we do now have the benefit of a handful of long-term elevated CO_2 experiments in otherwise intact ecosystems or agroecosystems using free-air carbon dioxide enrichment (FACE) technology. A review of 15 such FACE studies suggests that indeed carbon uptake in C_3 plants is enhanced under elevated [CO_2], despite a mean decrease of ~10% in photosynthetic capacity (Leakey et al., 2009). This carbon uptake usually is accompanied by a decline in leaf and canopy-scale water use, as well as an increase in nitrogen-use efficiency. However, it is important to note that these effects are not equal in all ecosystems or agroecosystems. In particular, this same review found that productivity enhancement in C_4 plants only occurs under drought. It is unclear if the general response trends among plants holds true for wetland plants, but it does provide a good basis for testable hypotheses in wetland studies.

The longest running elevated CO_2 field study in an otherwise intact ecosystem employs open-top chamber technology rather than FACE and is located in a *Scirpus olneyi* tidal marsh in the Chesapeake Bay (Rasse et al., 2005). This experiment indicates that long-term gains in productivity are possible in such systems but interacting factors such as rising salinity could dampen these enhancements, as may species composition shifts associated with nutrient loading that favor C4 forbs over C3 graminoids (Langely and Megonigal, 2010). Thus, while there may be productivity gains in some systems associated directly with elevated atmospheric CO_2 concentrations, we cannot expect such responses to be universal in magnitude or direction across ecosystems, nor with other interacting global change factors. For example, freshwater marsh species germination and seedling growth responses to CO_2 are dependent on water level and salinity (Middleton and McKee, 2012).

Forest ecosystems may be of particular interest, due to their capacity for C storage in both the decadal scale as biomass and even longer timescales in the soil. Elevated CO_2 studies in wetland forests are limited, though notably a large-scale manipulation of whole ecosystem warming and elevated CO_2 is currently underway in a spruce-tamarack bog in northern Minnesota (Hanson et al., 2017). Initial results show little response to elevated CO_2 in overall carbon balance of the ecosystem (Hanson et al., 2020), though the response of individual species or groups, such as ericaceous shrubs (Ward et al., 2019) and conifers (Warren et al., 2021), have been noted. This suggests that the structure and composition of the ecosystem may respond directly to elevated CO_2 levels and these responses may interact with other drivers such as temperature, even if there is not an ecosystem level response in carbon exchange. Unfortunately, there are no studies using FACE technology in wetland forests, though the response of FACE studies in other forests may provide some guidance in what would be expected. Initial results from the first few years of operation suggested a very consistent (~23%) increase in biomass productivity across four forest FACE studies (Norby et al., 2005), but longer term results were dependent on nutrient status and species (McCarthy et al., 2010; Norby et al., 2010; Talhelm et al., 2014). In general, elevated CO_2 experiments in coniferous forests have suggested little to no impact on canopy scale water-use, whereas an effect is often observed in deciduous broadleaf forests (Medlyn et al., 2001; Leuzinger and Körner, 2007; De Kauwe et al., 2013; Hasper et al., 2016; Ward et al., 2018). Overall, it seems many types of plants react positively to elevated CO_2 concentrations, however, the exact impact on wetland ecosystem productivity and carbon assimilation depends on interactions among species (community shifts) and interactions of elevated CO_2 with other global change factors.

Global change responses of different wetland types

Wetlands can be categorized in various ways, but many begin with the hydrological, geographical or geological context of the wetland, such as the classifications of Cowardin et al. (1979), Brinson (1993), and the Ramsar Convention (Matthews, 1993). Of these the Ramsar classification scheme is the broadest, including marine, inland and man-made wetland ecosystems that may not meet all definitions of 'wetland' including coral reefs, rocky shores, salt pans, reservoirs, aquaculture ponds, lakes and rivers. The Cowardin et al. (1979) and Brinson (1993) classifications were made primarily with wetlands of the United States in mind and rely on substantial knowledge of a wetland to properly classify it, but these systems are applicable to a wide range of wetlands globally if such data are available. The Brinson classification scheme relies heavily on hydrogeomorphic setting and characteristics, with little reference to biota, though a category of peatlands was included that relies upon biogenic accretion of soil. Below we will refer mainly to categories from the Cowardin et al. (1979) system that relies on both hydrogeomorphic setting and biotic communities, because both of these may be important in the context of global change. A full accounting would be exceedingly long, but here we tackle some of the main contrasts between wetland types and what they mean for global change responses.

Riverine, estuarine, lacustrine, and palustrine wetlands: A common distinction made among wetlands is among major systems that describe their hydrologic, geomorphic, and biogeochemical setting or habitats (Cowardin et al., 1979). These include *riverine* (within a flowing water channel), *estuarine* (tidal habitats partially sheltered from open ocean), *lacustrine* (within a basin

characterized by open freshwater) and *palustrine* (freshwater wetlands without significant open water areas). Palustrine wetlands are often hardest to distinguish from the other systems and can border any of the other three, but are characterized by persistent vegetation, low salinity (<0.5 psu), shallow water depths and the lack of erosive action from open water. In such settings, global change may be expected to shift the transitions between different ecosystems. For example, rising sea levels and salinity intrusion may shift the boundaries between palustrine and estuarine systems, while human activity or climate change may change river flow, shifting boundaries of palustrine and riverine systems. Indeed, many or even most wetlands may transition to different ecosystems entirely in response to global change factors. Another way to view this is that ecosystems may 'migrate' as their respective communities respond to changes in hydrology, climate and other global change factors. Estuarine wetlands are expected to move landward and up slope, though their ability to do so may be severely limited by urbanization and flood control infrastructure in these areas (Enwright et al., 2016; Thorne et al., 2018). Sea level rise and salinity intrusion are likely to lead to migration of tidal riverine and adjacent palustrine systems upstream and upslope, but the degree to which this does and will occur remains uncertain (Ensign and Noe, 2018). Water levels in lacustrine and depressional palustrine systems may be impacted by changing water levels due to shifts in precipitation or evapotranspiration as a result of climate change. Some wetlands, such as peatlands, show a capacity to adjust to such water table changes (Bridgham et al., 2008), but again, the limits to such responses remain uncertain.

Dominant vegetation type: Another way of organizing wetlands is by dominant vegetation types and we may expect different types will respond to global change in different ways. The Cowardin et al. (1979) classification scheme defines these as vegetation 'classes' within the systems listed above. The most typical vegetation types in wetlands are forests, scrub/shrub and emergent marsh communities, though some would also include floating vegetation (rooted and unrooted), mudflats and shallow submerged vegetation in the general umbrella of wetlands, especially given that some vegetation is seasonally ephemeral, or shifts based on interannual variations in water availability. Some variation in response to global change factors may be assigned to these broad classes. For example, herbaceous vegetation may be more resilient than forest vegetation to disturbances such as storms, fires, floods, drought or sea-level rise; this may be due to differences in belowground or hydrological processes (Loiselle et al., 2021; Stagg et al., 2016; Zhang et al., 2019) as much as the differences in aboveground stature more obvious to a casual observer. As the range limits of one vegetation type may be set by one climatic factor while another by a different factor, it is important to not limit projections to a single factor or a single boundary. For example, future wetlands of the coast of the Gulf of Mexico are likely to change distribution in response to both less frequent freezing events leading to the expansion of mangroves in some areas, and increased aridity expanding the distribution of unvegetated mudflats and succulent marshes in others, both at the expense of emergent marshes (Osland et al., 2019). Trade-offs between succulent and emergent marshes in this last example also highlights the importance of studying differences within the major vegetation classes. Different species or communities within the forest, scrub/shrub and herbaceous classes may respond differently to global change factors, such as the differences in direct responses to CO_2 between conifer and broadleaved trees or C3 and C4 graminoids discussed in the section on elevated CO_2 impacts above.

Soil type and nutrient status Another set of divisions commonly made between wetlands is based on soil type and nutrient status. Mineral and organic soil wetlands are often considered separately, partly because of the large difference in carbon density of these types (Kolka et al., 2018; Nahlik and Fennessy, 2016). Historically, much of the conversion of wetlands to agriculture and commercial forestry has been in mineral soil wetlands, over 90% in Canada and the United States (Kolka et al., 2018); however, much of the remaining carbon stored in wetlands of this region is in organic soil. Quantifying the global extents of mineral versus organic soil wetlands is complicated by various definitions used to distinguish these types of wetlands and delineate wetlands from other ecosystems (Mitra et al., 2005). Within organic-soil wetlands (i.e., 'peatlands'), especially in boreal zones, differentiation is made between more acidic, nutrient-poor bogs that receive limited or no surface water inputs (i.e., 'ombrotrophic' peatlands) and fens, which receive surface water and nutrient inputs (i.e., 'minerotrophic' peatlands). However, global peatlands are diverse in structure and nutrient status, found in a variety of geomorphic contexts from alpine depressions to coastal lowland floodplains bordered by mangroves (Page and Baird, 2016). As peatlands generally form under high water table conditions that limit the incidence of fire, peatland drainage and drought can increase fire risk. These environments have important interactions that contribute to rapid carbon loss from increased fire risk (Turetsky et al., 2015; Page and Baird, 2016). Unlike vegetation fires typical in mineral soils, peatland fires smolder within the soil column and persist under low oxygen conditions, releasing a wide array of particulates and volatile organic compounds that lead to regional air quality problems (Page and Baird, 2016).

Boreal, temperate and tropical wetlands: Another major way of classifying wetlands is by climatic zones or biomes. While responses may vary somewhat by climate zone, it is important to emphasize that many of the same global change factors, such as hydrologic alteration, pollution, biological invasion, sea level rise and climate change, which must be considered across all climate zones (Mitsch and Hernandez, 2013). At the highest latitudes, it has long been recognized that a likely outcome of increasing global temperature is the expansion of some wetlands from permafrost melt and the loss of others due to increased evapotranspiration and geomorphological changes (Carpenter et al., 1992). Relative to wetlands in temperate and tropical regions, many northern peatlands remain relatively undisturbed. Because temperature changes are most pronounced at the highest latitudes, northern peatlands may face some of the largest impacts from climate change, and least in part because of the added impact of the accumulated impact of permafrost melting, fire and vegetation changes (Page and Baird, 2016). While climate change remains a factor to consider in temperate and tropical zones, anthropogenic land use change and hydrological alteration play a much larger role in these warmer climates. Historically, many peatlands were drained and converted to other uses in temperate regions of Europe and North America, much of which continues to be used for commercial forestry and agriculture (Kolka et al., 2018; Page and Baird, 2016). Peatland drainage for agriculture and commercial forestry use is also common in tropical areas, including at least 20% of lowland tropical peat forest in Indonesia and Malaysia (Miettinen et al., 2012). While wetland conversion for agriculture and tree

plantations in Southeast Asia is perhaps best documented in scholarly literature, it is an issue throughout the global tropics, including Amazonian várzea forests (Vijay et al., 2018) and African papyrus marshes (Saunders et al., 2012). One of the challenges of estimating global change impacts on tropical wetlands is that the basic extent of tropical wetlands is not well documented, but modeling based on hydrological and geomorphic factors suggest that extensive areas of peatlands in South America and Africa have not been mapped, much less studied in the context of global change (Gumbricht et al., 2017; Page and Baird, 2016).

Conclusions

Understanding wetland responses to global change is important to the human capacity to predict changes in future climate, as well as the cycling of carbon, water and nutrients in the Earth System. Wetlands not only store disproportionate amounts of carbon compared to other terrestrial ecosystems, but they lie at the terrestrial-aquatic interface crucial to understanding landscape and global scale biogeochemical cycles. While human management of wetland ecosystems is centuries or even millennia-old in many areas of the globe, current global change factors may present novel conditions such as permafrost thaw, elevated atmospheric CO_2, and sea level rise, which defy simple inference based on past experience. However, experiments addressing how global change factors effect wetland species and communities may provide some guidance in our predictions, such as experiments on direct plant responses to increases in atmospheric CO_2 and their interactions with other environmental factors such as temperature and hydrology. Responses of wetland ecosystems to global change factors are complex and may come down to subtleties between different dominant species found within the same vegetation classes. While the past decades have seen many important experimental and observational studies of wetland responses to such factors, large uncertainties remain.

Future research could be targeted to knowledge gaps in the diversity of wetlands outside of temperate (and some boreal) regions that are well studied, especially within tropical regions where even the basic extent of wetland ecosystems is not well documented. The interactive effects of multiple global change factors likewise form an area of interest to the global Earth system modeling community where knowledge gaps exist, especially in real-world management-relevant contexts. Wetlands are prime examples of ecosystems where not just conservation efforts, but also restoration efforts are often targeted, so practical approaches for such efforts in the context of global change factors is likely to be another area of active research in the coming decades.

Section Introduction: Groundwater sciences in Limnology

Christian Griebler[a] **and Grant C Hose**[b], [a]Department of Functional & Evolutionary Ecology, Division of Limnology, University of Vienna, Vienna, Austria; [b]Department of Biological Sciences, Macquarie University, Sydney, NSW, Australia

Groundwater is quantitatively the most important source of freshwater and sustains surface terrestrial and aquatic ecosystems and human beings across the globe. Groundwater has for millennia been used as a drinking water source, for recreation and therapy (e.g. thermal springs), as well as for irrigation. Scientific disciplines targeting abiotic aspects of groundwater (e.g. hydrology, hydrogeology, geology, geochemistry) have a long history. However, research on the biotic and ecological aspects of groundwater, particularly subterranean ecosystems started comparatively late, about 100 years ago, first looking into the biodiversity of fauna and later into microbial communities. By definition, groundwater of the terrestrial subsurface is inland water, making groundwater ecology a sub-discipline of limnology. Despite this, standard textbooks in limnology largely ignored groundwater and aquifers as limnic ecosystems (Welch, 1952; Ruttner, 1962; Lampert and Sommer, 2007; Schwoerbel, 1999; Wetzel, 2001). Only recently, limnology textbooks have paid attention to subsurface aquatic habitats (Schönborn, 2003; Schwoerbel and Brendelberger, 2013; Dodds and Whiles, 2020). There is a handful of books focusing on groundwater microbiology and biogeochemistry (e.g. Chapelle, 2000; Cullimore, 2007). The first book solely dedicated to groundwater ecology appeared in 1994 edited by Janine Gibert, Dan Danielopol, and Jack Stanford. This year (2022) a completely reworked 2nd edition will be released (Malard et al., 2022). While there are a few other books on groundwater fauna (Spandl, 1926; Chappuis, 1927; Botosaneanu, 1986) and subterranean ecosystems including caves (Vandel, 1965; Wilkens et al., 2000; Culver and Pipan, 2014), groundwater ecology textbooks have never been published, with the exception of the German textbook by Griebler and Mösslacher (2003).

The first edition of the 'Encyclopedia of Inland Waters' released in 2009 contained over 240 topic-related articles, of which less than ten dealt directly (Alley, 2009; LaBaugh, 2009; Pipan and Culver, 2009; Puri, 2009; Valett and Sheibley, 2009) or indirectly (De'camps et al., 2009; Glazier, 2009; Nimmo, 2009) with groundwater. In this 2nd edition, we have 26 chapters included in a groundwater-focused section, with content covering groundwater disciplines and habitats in an integrative and comprehensive manner.

The series of chapters starts with a review by Robert Reinecke on the global abundance and distribution of groundwater, pointing at the multiple factors that impact this valuable resource. The chapter discusses available data and identifies knowledge gaps and research needs in pursuit of exploring this hidden resource. The two chapters that follow introduce the typology of groundwater systems (Steffen Birk) and their hydrology (Andreas Hartmann). Besides the common hydro(geo)logical terminology, the chapters describe general aquifer properties including groundwater recharge, groundwater storage and groundwater discharge, and how these attributes vary with aquifer type and geology. Conceptual hydrogeological models are presented as valuable tools to combine the available information about these processes and their underlying physical structure into visual hypotheses of groundwater systems. Similar to the first edition, there is a chapter about the unsaturated (vadose) zones. This time, Christine Stumpp and Gerhard Kammerer complement the introduction into the hydrology of the subsurface. The chapter already hints at the importance of biological processes for seepage water quality as source of groundwater.

Grant Hose and coauthors introduce the different types of groundwater dependent ecosystems (GDEs) that occur across subsurface, terrestrial and aquatic realms. GDEs are natural systems that require access to groundwater to maintain their biodiversity and ecosystem processes. The limited knowledge of the degree and timing of groundwater dependency of most GDEs, and the pressures of climate change are challenges for the management and conservation of these valuable ecosystems. The discussion of GDEs is extended to the transition zones between surface and subsurface aquatic environments, which include the parafluvial-hyporheic zone. In consecutive chapters, Maurice Valett and Ann Marie Reinhold, and Ignacio Peralta-Maraver and Anne Robertson dig into groundwater-surface water (GW-SW) interactions within this interface between the surface water, the groundwater systems and the riparian habitats, which are characterized by the simultaneous occurrence of multiple physical, biological and chemical processes stimulated and originating from the three habitats. The interplay between sediment depth, redox potential and pore-space hydrodynamics determines both the shape and the size of the parafluvial-hyporheic biotope, the distribution of organisms within it, and the rate at which physical, biological and chemical processes occur. Without doubt, parafluvial-hyporheic zones are hot spots of biodiversity. A range of field methods to assess GW-SW interactions is introduced. Recent advances in computer modeling of stream systems allow the integration of ideas from hydrology, engineering, and ecology to increase understanding and predictive ability.

The next set of chapters introduces the smallest biological entities and organisms in groundwater ecosystems. Starting with natural groundwater viral communities, Schweichhart and coauthors for the first time compile existing knowledge on viruses in groundwater systems. Also for the first time, a chapter on fungal communities in groundwater ecosystems has been composed by Alice Retter and Ali Nawaz. Both chapters provide a condensed overview on the occurrence and potential roles of prokaryotic viruses

(phages) and fungi in groundwater ecosystems. While our knowledge of these fields is steadily growing, they are two topics that require much further research. These chapters provide a segue to those by Clemens Karwautz and Christian Griebler, as well as Martina Herrmann and Martin Taubert, which provide a comprehensive introduction into the microbial biodiversity in groundwater ecosystems and key processes as well as microbial drivers involved in biogeochemical cycling of carbon and nitrogen in aquifers. Microbial consortia in groundwater habitats ranging from shallow to deep environments, including karst and porous aquifers, as well as contaminated groundwater and drinking water are described in terms of their composition and functions. A focus is on processes of the nitrogen and carbon cycling in aquifers and its tight interconnection. Recent advances in "multi-omics" and isotope-based approaches are highlighted. With a specific focus on the ecology of microbial contaminant degradation in groundwater, Tillmann Lueders and András Táncsics point to the versatility of microbial communities to clean up organically polluted aquifers. Knowledge about opportunities and limitations of biodegradation can support societal efforts to protect and restore groundwater resources and habitats.

The following set of chapters is dedicated to groundwater habitats and their fauna. Starting with karstic systems, Tanja Pipan and Dave Culver introduce the epikarst, its hydrological functioning, physical structure, and organisms. Anton Brancelj and Fabio Stoch look deeper into karst systems, from epikarst to the vadose zone and from the epiphreatic to the phreatic zone of karstic cave systems. Key controls such as the local climate, particularly temperature, precipitation, and subsurface hydrology, along with vegetation are discussed. Living space and the amount of available organic material determine the community structure within a given karstic zone. The structure of stygofauna, both functional (body size, feeding habits) and compositional (species diversity), is closely related to the habitat structure and environmental conditions. Nataša Ravbar and Tanja Pipan further extend the characterization and classification of karst habitats including all types of karst groundwater dependent ecosystems (KGDEs) considering important driving processes and their vulnerability and opportunities for protection. Without doubt, KGDEs and their ecosystem services need greater understanding and improved predictions of how they will change and adapt under current pressures and global challenges, including climate, land use and societal changes. Due to their great importance for biodiversity, KGDEs are of considerable conservation value, and are crucial for the preservation of biota and for socio-economic development. A more general view on the diversity of groundwater fauna is provided by Florian Malard. Groundwater metazoans are typically hidden and still poorly known. In fact, they are an important, yet underestimated, contribution to global freshwater biodiversity. Documenting and understanding their compositional and functional diversity has revealed an enormous wealth of species new to science, but many parts of the world remain unexplored or poorly documented. Much of the progress achieved in understanding mechanisms shaping phenotypes, distribution patterns and organisms' function is yet to translate into policies that frame the management of groundwater ecosystems and protect the important services they deliver to humans.

Springs are another economically and ecologically important type of groundwater dependent ecosystem. Chapters by Marco Cantonati and Dudley Williams introduce into the typology of springs across disciplines and scales and highlight their unique properties and features. The chapter of Cantonati in addition offers an overview of the main groups of photoautotrophs in springs, while Williams does the same for invertebrates. Overall, broad and specific characteristics of spring communities, and the mechanisms of community assembly are examined together with the ecological controls that account for the differences observed between individual springs. The importance of springs in natural, global landscapes is emphasized alongside increasing anthropogenic pressures.

Trophic interactions and food web dynamics are covered in two further chapters. The first one by Schmidt and co-authors has a strong focus on interactions at the micro-scale, the playground of microbes in the pores of sediments. The authors outline how an increased understanding of micro-scale processes may lead to an improved appreciation of the range of ecosystems functions taking place at larger scales. An overview of existing concepts, methods, and findings is provided. Saccó and co-authors report the current knowledge of trophic dynamics in both aquatic and terrestrial subterranean communities including fauna. Substantial shortage of nutrients drives food web interactions and opportunities for adaptive opportunistic strategies in subterranean environments. Recent research contrasts the archetype of poorly structured food chains against convoluted mechanisms sustaining a range of biotic diversity and functional complexity. Novel analytical designs described in the chapter provide important new perspectives into the investigation of these key ecological dynamics.

The final set of chapters considers applied aspects of groundwater ecology. Robert Luetkemeier and colleagues start with an article on global anthropogenic pressures on groundwater. While groundwater is essential for drinking water supply, food production and ecosystem functioning, human-groundwater interactions often critically lead to overexploitation and quality degradation. In this chapter, the authors explore anthropogenic activities in the agricultural, domestic and industrial sectors and their direct consequences for quality and quantity of groundwater. In addition, indirect effects from anthropogenic activities in terms of the likely impacts of climate change on groundwater systems are considered. Two subsequent chapters report on drinking water production from groundwater and the aspects that need to be considered. Savio and co-authors give an overview of the available knowledge on the microbiology of karst aquifers, typical sources of microbiological pollution, and available management strategies for the protection of karst water resources used for drinking water production. In this context, a recently developed concept for the sustainable quality management of karst water resources based on a holistic analysis of fecal pollution and its sources is presented. While the chapter of Savio et al. focuses on karst systems, the chapter of Derx and colleagues deals with porous aquifers. In particular, they focus on river bank filtration for production of drinking water. The chapter summarizes the current approaches for evaluating pathogen fate and transport in the environment, their removal during subsurface transport in porous aquifers, and the protection needed to achieve safe drinking water. Modelling techniques for estimating the required pathogen reduction by riverbank filtration or subsequent disinfection steps are presented. The monitoring and modelling techniques include microbial source tracking, experimental tracer tests, analytical and numerical transport models and quantitative microbial risk assessment.

A case study by Erin Haacker summarizes the physical geography, hydrogeology, and management of the High Plains Aquifer, one of the most important aquifers in North America. The High Plains Aquifer is heavily utilized for irrigation of corn, soy, and cotton and is threatened by agricultural development, with much of the aquifer already depleted to the point of no longer

supporting efficient irrigation pumping. The remaining aquifer lifespan varies over space and is difficult to predict, with estimates ranging from less than a decade in some places, to several centuries in others.

Anne Jäger und Hans Jürgen Hahn provide a chapter on methods for sampling and monitoring groundwater fauna. Since groundwater ecosystems are among the least explored habitats in the world, it is timely that this chapter describes the methods, strategies, and challenges of accessing subterranean aquatic habitats. Common methods for collecting groundwater fauna are described including their accuracy and efficiency in collecting organisms, as well as to whether they allow for a representative, quantitative sampling of aquifers. Moreover, morphological and molecular approaches for species identification, and their use in biodiversity and community ecology research are discussed.

The section finishes with a chapter that summarizes important knowledge gaps, obstacles and research frontiers in groundwater microbial ecology. Griebler and colleagues compiled 10 hot topics that need consideration in future microbial ecological research. Among these are the quantitative assessment of the subsurface carbon cycle including the import and export of carbon, rates of organic matter transformation, and the role of chemoautotrophy. Furthermore, the link between microbial communities and their processes with the meio- and macrofauna is not understood at all, and groundwater fauna microbiome studies may constitute a promising starting point. Finally, ecological principles and laws determined for other terrestrial and aquatic ecosystems await testing to assess their validity in groundwater ecosystems.

In conclusion, the 26 groundwater-related chapters contained in the 2nd edition of the Encyclopedia of Inland Waters, provide readers with the most comprehensive compilation available to date. We hope that in a 3rd edition of the Encyclopedia of Inland Waters, this compilation will be further extended to include topics we could not envisage this time. The ecology of hot springs and the deep subsurface, a chapter on groundwater ecosystem services, and more case studies on the world's largest aquifers are examples. Nevertheless, we hope readers share our excitement about this groundwater section and make frequent use of the material in basic science, applied groundwater issues, and teaching.

Groundwater – Global Abundance and Distribution

Robert Reinecke, University Potsdam, Potsdam, Germany

This is an update of W.M. Alley, Ground Water, in Encyclopedia of Inland Waters, edited by Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00015-6

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Aquifer A layer of (ground-) water carrying permeable materials.
Baseflow Streamflow that is sustained by groundwater inflow.
Grid cell Discretization of the spatial domain of a model into parts.
Groundwater depletion A shortage of groundwater supply.
Groundwater Water that exists beneath the earth's surface in saturated zones.
GWAAEs Groundwater-associated aquatic ecosystems.
GWDTEs Groundwater-dependent terrestrial ecosystems.
Karst Rocks of particular material where percolating water widens cracks and fissures.
Land subsidence Lowering of the ground due to a lack of support (e.g., due to missing water).
Permeability Ability of porous material to let fluids pass through.
Stomata Pores in the epidermis of plants that control the rate of gas exchange.
Transboundary aquifers Aquifer systems that extend across political boundaries.
Water table Boundary between saturated and unsaturated zones underground.

Introduction

Groundwater is the source of about 40% of all human water abstractions (Döll et al., 2014). It supplies water for human consumption, irrigation, and various industrial purposes. It is also an essential source of water and habitat for freshwater biota in rivers, lakes, and wetlands. These different water bodies can be connected to what is known as an aquifer, a layer of (ground-) water carrying permeable materials that can be hundreds of meters deep and extend for hundreds of kilometers, acting as a steady water supply to surface water bodies even in periods without rain. These aquifers are replenished by groundwater recharge, a complex process driven by precipitation and various other factors.

Billions of people rely on groundwater as an accessible source for drinking water and irrigation, especially during droughts. The importance of groundwater will likely increase with climate change, as surface water availability is related to changing precipitation patterns (Taylor et al., 2013). For example, rain events that occur less often but with higher intensity may lead to flood events followed by periods of drought and vice versa. During both floods and droughts, groundwater can be a reliable source of clean water. However, increased demand may limit the availability of groundwater for humans and biota alike (Kløve et al., 2014).

This chapter provides an overview of the current state of knowledge on the global abundance and distribution of groundwater. It provides information about the global availability of groundwater and the multiple factors that impact this valuable resource (Section "Global water availability and the role of groundwater as an accessible source of clean water"). Existing knowledge gaps are discussed alongside current research in pursuit of exploring this hidden resource, for example, with the use of global groundwater models (Section "Simulation of global groundwater"). Further, current information on global surface water-groundwater interactions and global coastal groundwater availability is presented and discussed in the context of a changing climate (Section "The importance of groundwater in a changing climate").

Groundwater - a resource under threat

In the last century, the global population has quadrupled and altered terrestrial water fluxes, with a lasting impact (Wada et al., 2012). Dams and other river regulations have led to changed flow regimes affecting downstream users and freshwater biota (Biemans et al., 2011; Grill et al., 2014). In addition, the use of groundwater for irrigation has increased the amount of water transpired by plants. Eventually, water used for irrigation ends up as excess water in streams and finally the ocean. It is likely that this additional water is contributing to rising sea levels (Wada et al., 2012).

Groundwater, a reliable source of freshwater throughout the year, has been heavily affected by human abstractions. Groundwater pumping has lowered water tables and even led to groundwater depletion (a shortage of groundwater supply due to continuous overuse; Döll et al., 2014; Scanlon et al., 2012; Wada et al., 2012; Konikow, 2015). Subsequently, lower water tables cause reduced base flow (the share of streamflow sustained by groundwater) to rivers and wetlands, deteriorating water quality and freshwater ecosystems. Additional effects of groundwater abstraction are land subsidence (lowering of the ground due to a lack of water support), increased pumping costs (deeper wells require deeper drilling, stronger pumps, and therefore more energy) and seawater intrusion (lower groundwater levels might lead to seawater inflow; see "Coastal groundwater"; Bierkens and Wada, 2019; Gleeson et al., 2016).

Groundwater is a central resource for global food security and the health of freshwater ecosystems worldwide (Kløve et al., 2014). For example, depleted aquifers that are no longer able to supply water in ecologically and economically critical periods, e.g., by providing water to surface water bodies, are a persistent threat to ecosystems as well as to humans. This threat has already led to unprecedented actions by legislators; in California, for example, following recent massive droughts, the Sustainable Groundwater Management Act (SGMA) was implemented. SGMA enforces the development of groundwater sustainability plans for all over-drafted basins in the state. Importantly, overuse of groundwater is not a local but a global issue, as demonstrated by international programs such as UNESCO's program for International Shared Aquifer Resource Management (ISARM, http://isarm.org (last access: 22.05.21)) and the Transboundary Waters Assessment Program (TWAP, UNESCO-IHP, 2012). In a globally connected world, with trade and consumption affecting remote water resources, it is crucial to understand the distribution and availability of groundwater as one of the planet's most vital resources.

Despite the importance of groundwater, there is a fundamental lack of data that hinders the assessment of its global distribution, availability, and quality. While the strategic importance of groundwater for worldwide water and food security will likely increase with climate change, we still lack the necessary data (e.g., on hydrogeology, water levels) to thoroughly assess groundwater on a global scale, but also on continental and even local scales.

Global water availability and the role of groundwater as an accessible source of clean water

Groundwater represents 97% of the available freshwater globally (excluding inaccessible frozen water at the poles and bound in glaciers; Guppy et al., 2018). As highlighted earlier, groundwater is often used in an unsustainable way; hence, an estimated 20% of the world's aquifers are currently overexploited (Gleeson et al., 2012). Unsustainable groundwater use has led to the deterioration of groundwater quality, especially in coastal aquifers affected by seawater intrusion. In light of these developments, the following section discusses groundwater in the context of the United Nations' (UN) Sustainability Development Goals (SDGs) and is followed by a section that provides deeper insights into the Global distribution of groundwater. The replenishment of groundwater resources is shown in section "Groundwater recharge," while the connection to the world's oceans is discussed in section "Coastal groundwater." Section "Global groundwater abstractions" summarizes the current knowledge about global groundwater use, and Section "Observation of groundwater on large scales" discusses available global datasets.

The sustainable development goals (SDGs) and their link to groundwater

The UN SDGs are a collection of global goals that the member states set out to pursue by 2030. While they do not explicitly feature groundwater, their goals, such as ending poverty and hunger, protecting the planet, and targeting peace and prosperity for all, depend on groundwater. Groundwater is pivotal for sustaining industrial and agricultural development; its sustainable use determines the future of groundwater-dependent ecosystems, too (GWAAEs, GWDTEs). On the other hand, aquifers may extend across political boundaries, called transboundary aquifers, and are thus a potential source of conflict (Puri, 2009). Therefore, the challenge is balancing the needs of nature and humans (industries, agriculture, sanitation, drinking water) in the context of a limited and pivotal resource shared across political boundaries. For sustaining and creating a liveable and peaceful planet, groundwater is

an important piece of the puzzle that needs to be considered. The following summarizes the interlinkages between the SDGs and groundwater because of the importance of the SDGs as a global political framework that decision-makers and stakeholders widely recognize.

A special connection between groundwater and the SDGs exists with respect to the availability of clean water and sanitation for all people (SDG 6), responsible consumption and production (SDG 12), and climate action (SDG 13) (Guppy et al., 2018). However, a connection does not mean that the goals, or sub-goals, may only positively affect groundwater; some goals may even contradict each other. For example, the goal of ensuring safe access to drinking water (SDG 6.1) can be compromised if groundwater is overused or if the groundwater is unsafe to drink, e.g., due to fecal contamination from increased agricultural use of the area implemented in order to reach SDG 2 (zero hunger). Lesser but visible connections can be drawn between groundwater and the eradication of poverty (SDG 1), the goal of zero hunger (SDG 2), industry, innovation, and infrastructure (SDG 9), and life on land (SDG 15) (Guppy et al., 2018).

Global distribution of groundwater

Our knowledge about the global distribution of groundwater is highly uncertain, as we still lack global datasets that allow for a more precise assessment. Current assessments conclude that while surface water adds up to about 100,000 km^3, groundwater accounts for almost 25 million km^3 (Fig. 1). The majority of this water is ancient and has been recharged over millennia (Gleeson et al., 2016).

Multiple computer models (Reinecke et al., 2019b; Fan et al., 2013; deGraaf et al., 2015) have estimated the distribution of that volume by applying numerical approaches (see Section "Simulation of global groundwater") to compute a map of global groundwater levels (Fig. 1). The map shown in Fig. 1 is based on a quasi-equilibrium (also called steady state) representing what the depth to groundwater would look like if climate and groundwater-surface water interactions could balance out over millions of years without any changes or abstractions by humans. The figure clearly shows the impact of the topography, as groundwater naturally follows gravitational gradients to the lowest points.[1]

Irrespective of the assumptions of a steady state, all current estimates of the global distribution of groundwater are very uncertain, mainly due to (1) a lack of global hydrogeological data (see also Section "Observing groundwater from space – GRACE"), (2) uncertainties regarding the amount of groundwater recharge (Reinecke et al., 2021; Section "Groundwater recharge") and interactions between surface water and groundwater (Reinecke et al., 2019b; Section "Groundwater-surface water interactions"), (3) and a coarse spatial resolution of the models used. Added to this list is a general lack of understanding around certain groundwater processes themselves, even on smaller scales, such as the flow in karst (rocks of particular material where percolating water widens cracks and fissures), fractured aquifers, capillary rise, or permafrost, all of which are currently not represented in global models.

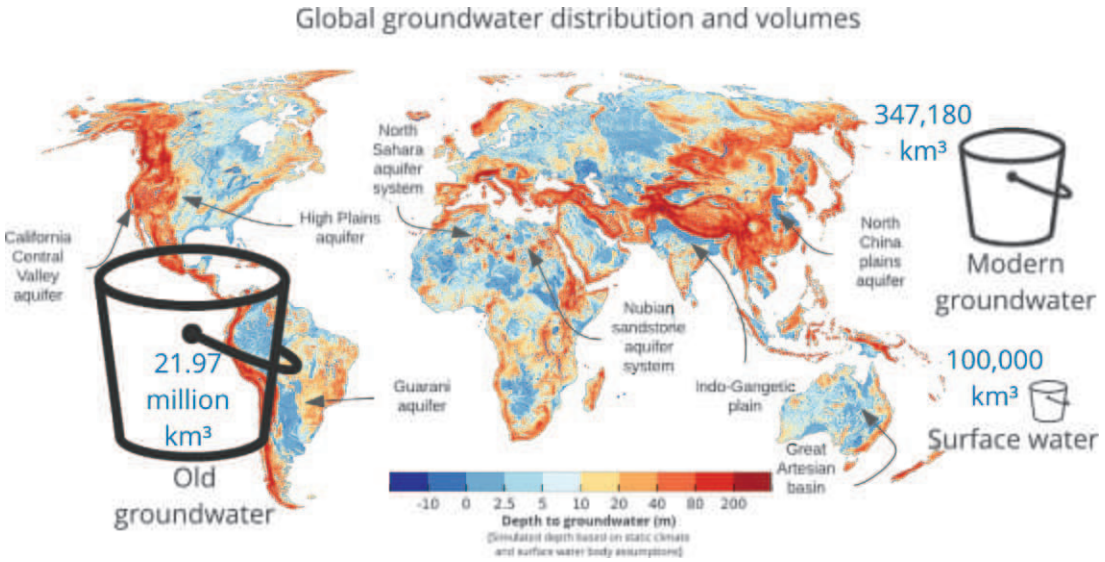

Fig. 1 Global groundwater abundance and distribution. Arrows mark the location of major aquifers. The depth to groundwater map is based on a steady-state simulation of Reinecke et al. (2019b). Volumes of groundwater and surface water are based on Gleeson et al. (2016), where modern groundwater is considered to be recharged over the past 50 years. Modified from Reinecke R, Foglia L, Mehl S; Trautmann T, Cáceres D, Döll P (2019b) Challenges in developing a global gradient-based groundwater model (G^{3}M v1.0) for the integration into a global hydrological model. *Geoscientific Model Development* 12(6): 2401–2418, https://doi.org/10.5194/gmd-12-2401-2019.

[1]Some of the blue areas in Fig. 1 are indeed much too wet for their location, e.g. the Sahara. These places exist due to the steady state assumption of that particular simulation, which also assumes the steadiness of wetlands in regions where they would typically only occur once every couple of years.

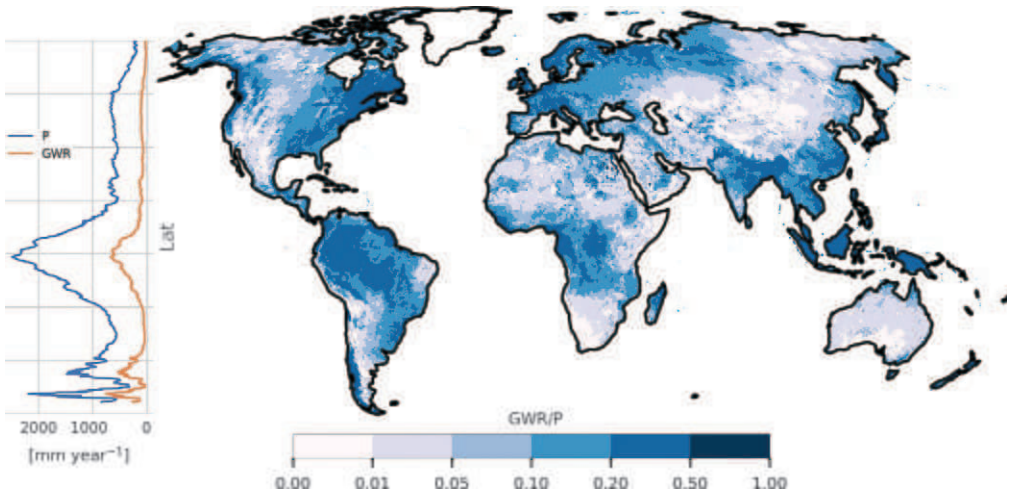

Fig. 2 Groundwater recharge ratio (diffuse groundwater recharge (GWR) relative to precipitation (P)) at preindustrial CO_2 concentrations based on an ensemble of eight global hydrological models (Reinecke et al., 2021).

Groundwater recharge

Aquifers are replenished by groundwater recharge, which can be conceptualized to occur mainly in two ways. (1) Diffuse recharge occurs over large areas as excess water from precipitation infiltrates into the soil and percolates downwards without being taken up by plant roots. (2) Focused recharge occurs when streams, rivers, and wetlands lose water to aquifers or when water flows through fractures, e.g., in karstic systems. This process is influenced by complex local conditions and is thus challenging to estimate for larger areas (Reinecke et al., 2021). Recharge is an important indicator for assessing the sustainable use of a groundwater body (Herbert and Döll, 2019). Only when less water is abstracted than replenished is sustainable use possible. Fig. 2 shows the global distribution of groundwater recharge according to an ensemble of eight global hydrological models. Diffuse recharge can account for up to 20% of the yearly precipitation in some regions.

Groundwater-surface water interactions

Groundwater and surface water bodies are connected. Continuous groundwater pumping can lead to declining river discharge (deGraaf et al., 2019) when groundwater flows recharge surface water. In the opposite direction, a large percentage of streams provide vital recharge to aquifers when the streambed is permeable enough (Jasechko et al., 2021; Reinecke et al., 2019b; Hare et al., 2021). However, due to a lack of global geological data, it is currently unclear how much water is transferred via that interface even though it is pivotal for understanding groundwater's global distribution and availability (Jasechko et al., 2021; Reinecke et al., 2019a).

Coastal groundwater

Particularly in coastal areas, people rely on groundwater as a source of drinking water. While groundwater is under pressure globally due to extensive water abstractions (e.g., Gleeson et al., 2012; Wada et al., 2010), proximity to coasts amplifies these pressures because of potential sea water intrusion (lowered groundwater levels and in addition higher sea levels may lead to reversed gradients and thus sea water flowing inland into the aquifer) that can endanger groundwater quality (van Camp et al., 2014). Future climate change and rising sea levels may additionally alter coastal groundwater dynamics (Befus et al., 2020) and thus threaten the water supply for a large percentage of the global population.

Global groundwater abstractions

In some places, groundwater has been accumulating over millennia and is only recharged slowly. When an aquifer is used unsustainably (abstraction exceeds recharge), it can be depleted, leading to dire consequences for humans and ecosystems. In Iran, for example, abstractions have already led to widespread groundwater depletion in around 77% of the land area (Ashraf et al., 2021). Globally, millions of wells could run dry if abstractions continue (Jasechko and Perrone, 2021). This is especially concerning, as the importance of groundwater for freshwater supply will likely increase with a changing climate (Taylor et al., 2013).

Reasons for continued abstractions are manifold; however, non-sustainable irrigation practices and the international food demand are likely the main drivers of this continuing trend (Dalin et al., 2017). These continuing abstractions may contribute to rising sea levels, as the ultimate sink for abstracted water is the ocean (Wada et al., 2012; Döll et al., 2014).

Observation of groundwater on large scales

Assessing the global abundance and distribution of groundwater is a challenge, as data sources are scarce. Three main reasons for this lack can be identified: (1) countries may not have the necessary resources to collect hydrogeological data and well observations on a large scale, (2) countries may not wish to make these data available to others, as it reveals insights about an increasingly strategic resource; this is exacerbated in regions with transboundary aquifers that provide conflict potential, (3) and compiling available data into global datasets is a challenging and time-consuming task. Even the global observations that have been published need to be regarded with care, as they are primarily available in regions where human influences on the natural system are most significant.

Observing groundwater from space – GRACE

The only current data source that is indeed a "global" dataset is the GRACE (Gravity Recovery and Climate Experiment; Table 1; NASA, 2007). The satellite mission started in 1997 and was succeeded by the GRACE-FO (Follow-On; NASA, 2018) in 2018. Two satellites measure gravitational anomalies that can be used to trace mass changes triggered by large-scale groundwater depletion. However, the spatial resolution of the data is very coarse (2°; about 222 km at the equator) and GRACE measures total variations in gravity, thus much pre-processing is necessary to assign gravity changes to a particular source in the water column, e.g., groundwater mass changes (Döll et al., 2014).

Table 1 Global datasets relevant to the distribution and availability of groundwater.

Name	*Data*	*Spatial extend/resolution*	*References*
GRACE	Gravity anomaly	Global, 2°–0.5° (depending on data product)	NASA (2007, 2018)
GLHYMPS	Permeability map	Global, variable resolution, 100 m depth	Gleeson et al. (2014)
GLHYMPS 2.0	Permeability map	Global, variable resolution, 100 m + depth to bedrock information	Huscroft et al. (2018)
WOKAM	Karst map	Global, variable resolution	Goldscheider et al. (2020)
GGIS	Groundwater levels	Global, point data	IGRAC (2004)
GEMStat	Groundwater quality data	Global, point data	ICWRGC (2014)
Groundwater Watch	Selected well data of the USGS	US, point data	USGS (2021)

Data centers and datasets

A key to assessing groundwater resources is adequate data on the subsurface permeability (the ability of porous material to let fluids pass through). Currently, only two global datasets, GLHYMPS (Gleeson et al., 2014) and its successor GLYMPS 2.0 (Huscroft et al., 2018), provide insights on the distribution of global permeability of the first 100 m vertically (Fig. 3; Table 1). Overall, the permeability from this dataset can be assumed to be underestimated (Reinecke et al., 2019a), and additional efforts are needed to improve the currently available data to allow for a more detailed representation of the hydrogeology, for example, its vertical heterogeneity.

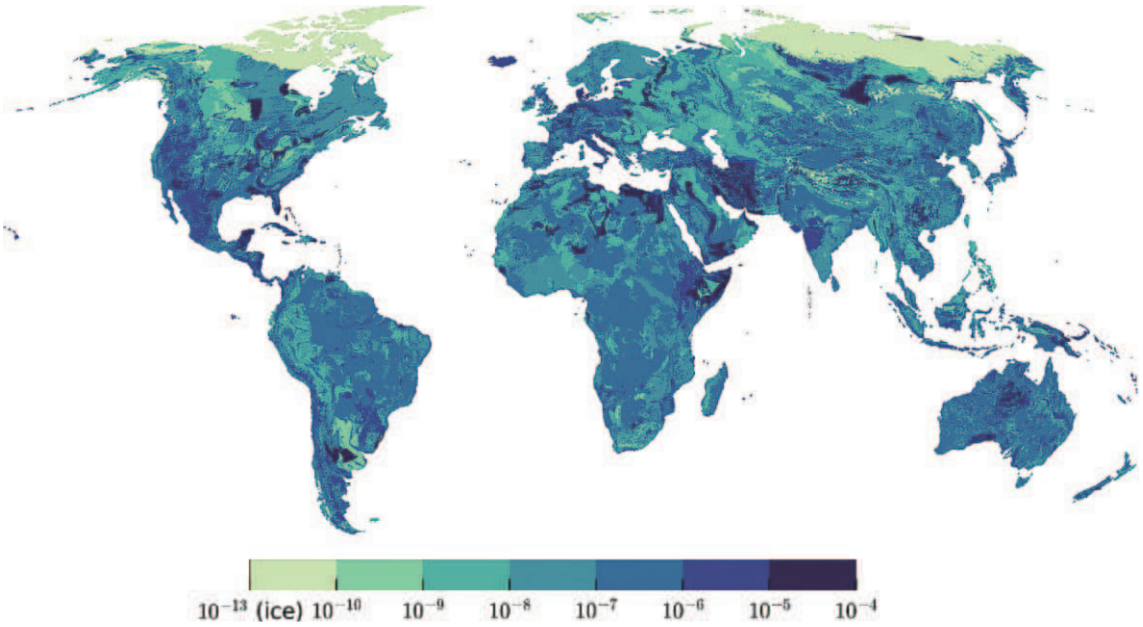

Fig. 3 Hydraulic conductivity [m s^{-1}] derived from Gleeson et al. (2014) scaled to 5 arc-minutes based on Fig. S3 from Reinecke et al. (2019b). Very low values in the northern hemisphere are due to permafrost conditions. From Reinecke R, Foglia L, Mehl S; Trautmann T, Cáceres D, Döll P (2019b) Challenges in developing a global gradient-based groundwater model (G^3M v1.0) for the integration into a global hydrological model. *Geoscientific Model Development* 12(6): 2401–2418, https://doi.org/10.5194/gmd-12-2401-2019.

A complimentary dataset is the World Karst Aquifer Map (WOKAM; Table 1; Goldscheider et al., 2020), showing the global distribution of karstifiable rocks (for example, carbonates and evaporites). Currently, no global modelling assessment includes this landscape characteristic, which is crucial for water availability in many regions of the world.

Global data on groundwater levels from well data can be retrieved from the supplemental material of Fan et al. (2013) and Jasechko and Perrone (2021); a unique dataset for the continental US is the Groundwater Watch data of the USGS (Table1; USGS, 2021).

An additional source for information is the UNESCO category 2 centers and their data center activities. IGRAC (International Groundwater Resources Assessment Centre) runs the openly accessible Global Groundwater Information System (GGIS; Table 1; IGRAC, 2004), an online platform that supports sharing of global groundwater data. Information about global groundwater quality data, on the other hand, can be found in the GEMStat database (Global Environment Monitoring System for Freshwater; Table 1; ICWRGC, 2014) hosted by the ICWRGC (International Centre for Water Resources and Global Change).

Data on groundwater recharge is still rare because estimates are very challenging to obtain and are often delineated from groundwater level changes. Two existing large-scale datasets are the global estimate of Mohan et al. (2018) and an Africa-wide dataset by MacDonald et al. (2021).

Simulation of global groundwater

In recent years, global groundwater models have emerged as a new modelling category, often coupled to existing global hydrological and land surface models to improve their representation of surface water-groundwater interactions and their simulation of evapotranspiration (Reinecke et al., 2019b; deGraaf et al., 2015; Fan et al., 2013). Still, these models are relatively new and present challenges for evaluation (Gleeson et al., 2021; Reinecke et al., 2020) due to their relatively coarse spatial resolution and the limited availability of hydrogeological data.

Fig. 4 shows both a conceptualization of reality (also called a perceptual model; Wagener et al., 2021) and a possible implementation in a global gradient-based groundwater model to convey the level of abstraction necessary for a global-scale

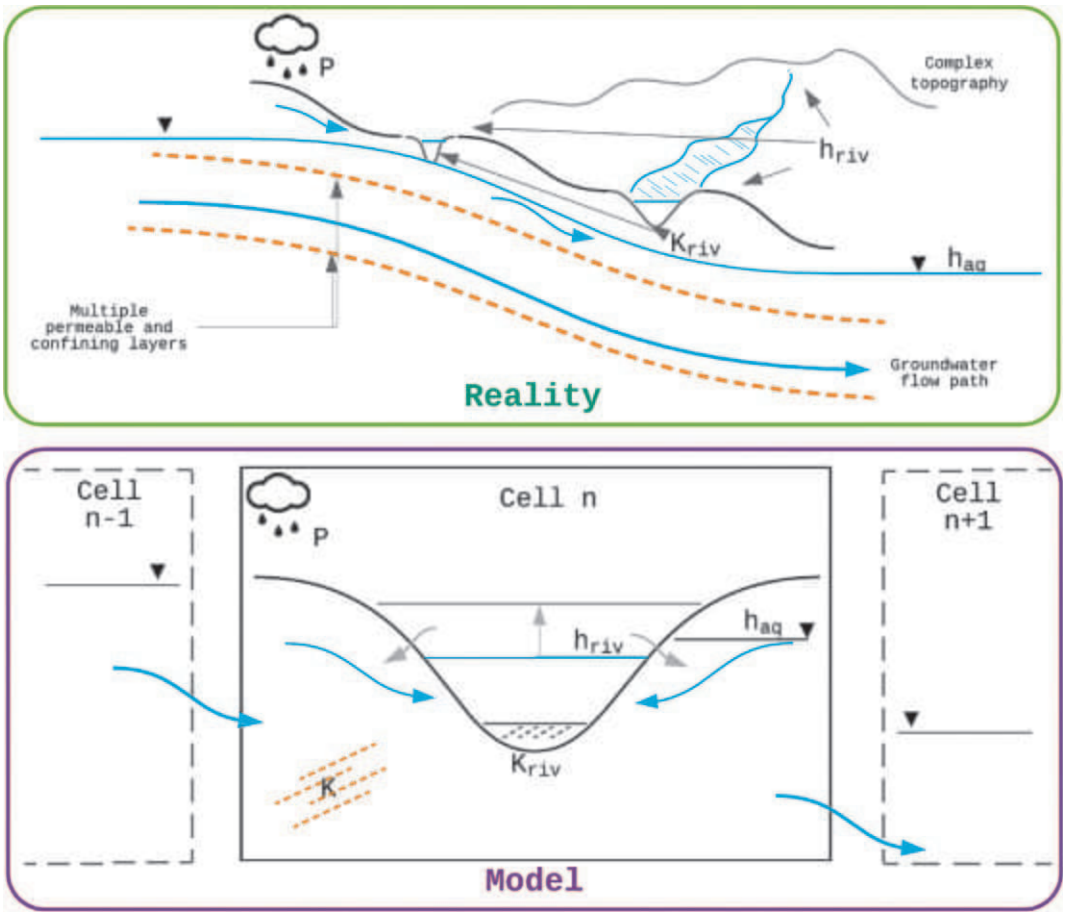

Fig. 4 Conceptual representation of reality (top) and simplified global gradient-based groundwater model representation (bottom). Blue lines in both boxes represent groundwater flow paths. Adapted with modifications from Reinecke R, Wachholz A, Mehl S, Foglia L, Niemann C, Döll P (2020) Importance of spatial resolution in global groundwater modeling. *Ground Water* 58(3): 363–376, doi: 10.1111/gwat.12996.

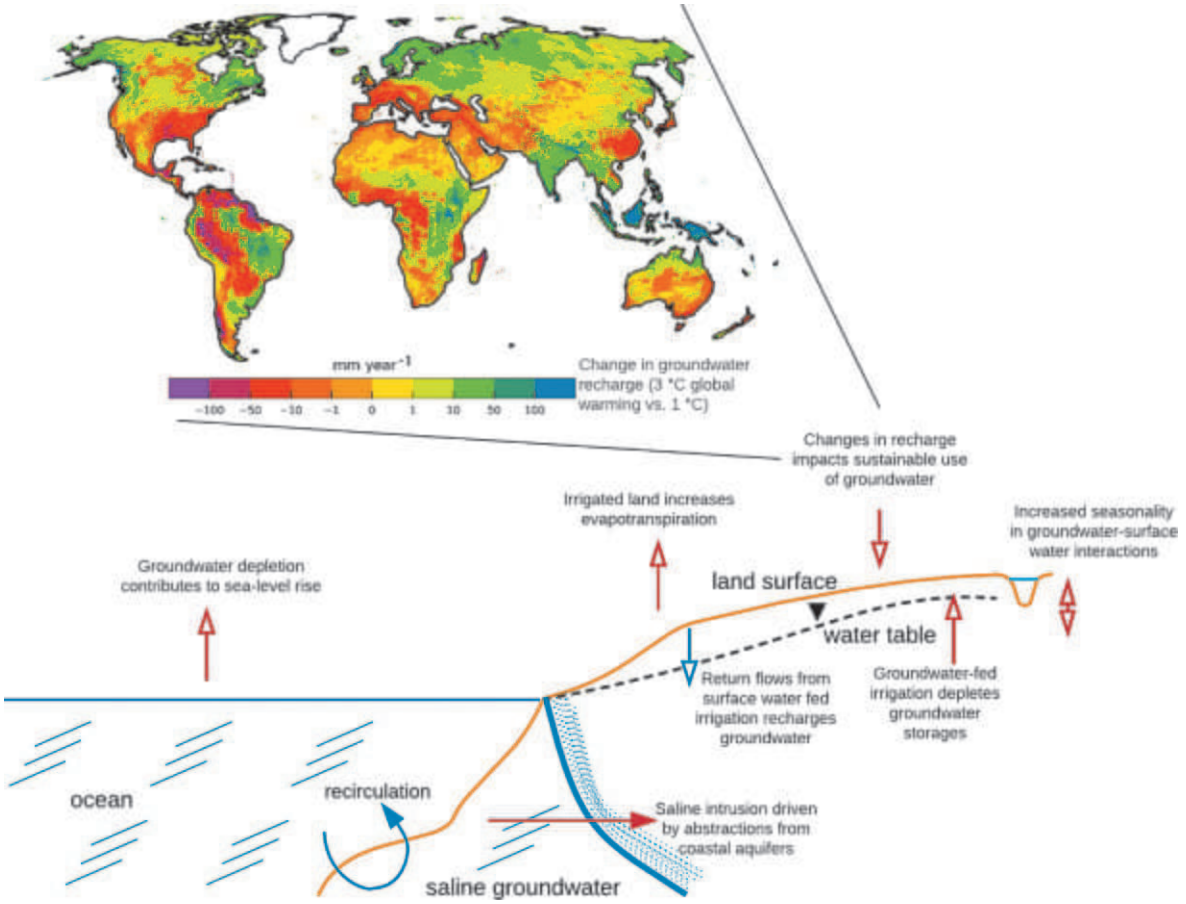

Fig. 5 Different impacts of climate change (red arrows) on groundwater based on Taylor et al. (2013). The map of simulated groundwater recharge changes is based on Reinecke et al. (2021). Modified from Reinecke R, Müller Schmied H, Trautmann T, Andersen LS, Burek P, Flörke, M, Gosling SN, Grillakis M, Hanasaki N, Koutroulis A, Pokhrel Y, Thiery W, Wada Y, Yusuke S, Döll P (2021). Uncertainty of simulated groundwater recharge at different global warming levels: a global-scale multi-model ensemble study. *Hydrology and Earth System Sciences* 25(2): 787–810, doi: 10.5194/hess-25-787-2021 and based on Taylor RG, Scanlon B, Döll P, Rodell M, van Beek R, Wada Y, Longuevergne L, Leblanc M, Famiglietti JS, Edmunds M, Konikow L, Green TR, Chen J, Taniguchi M, Bierkens MFP, MacDonald A, Fan Y, Maxwell RM, Yechieli Y, Gurdak, JJ, Allen, DM, Shamsudduha M, Hiscock K, Yeh, PJ-F, Holman I, Treidel H (2013) Ground water and climate change. *Nature Climate Change* 3(4): 322–329, doi: 10.1038/nclimate1744.

model. In reality, one might find multiple streams and rivers inside a 5 × 5 km area; however, these are often represented as only one major stream inside a model grid cell (models often discretize the spatial domain into parts, for example, 5 × 5 km lots, that are referred to as grid cells). This simplification might also be necessary for other parameters found in Fig. 5: the precipitation (P) and resulting recharge, the river height (h_{riv}), the conductance of the river (K_{riv}), the hydraulic head of the aquifer (h_{aq}), and the hydraulic conductivity (K). While it is clear that the reality is much more complex and one might, for example, find multiple layers of permeable and confining material that influence groundwater flow, global models are limited to simplified representations due to a lack of data and computational challenges (Reinecke et al., 2019b).

The importance of groundwater in a changing climate

The importance of groundwater for global water security will likely increase with the changing climate (Taylor et al., 2013). In a world with an increased frequency of extreme events like floods and droughts and a global shift in precipitation patterns, and thus also a changing availability of surface water, groundwater as a reliable resource will be vital for many communities. However, it is still unclear how the changing climate will impact groundwater availability and where sustainable use of this resource will be possible. Recent analyses suggest that even the slow-changing groundwater fluxes could adapt to the changing climate on human time scales (Cuthbert et al., 2019).

Groundwater is affected in multiple ways by climate change. Changes in precipitation may reduce groundwater recharge in parts of the world, while others may see increases in recharge (Map in Fig. 5). Additionally, a decrease in precipitation will likely also lead to increased groundwater pumping. However, it is difficult to determine whether increased pumping is only the result of decreases

in precipitation or surface water availability or simply a growing population. It is also unclear how rising CO_2 levels will affect plant water use and thus groundwater recharge: with rising CO_2, plants open their stomata less, which in turn reduces evapotranspiration and thus increases runoff; on the other hand, plants might grow better with increased CO_2, which will increase evapotranspiration (Reinecke et al., 2021).

Continuing or even increased abstractions from groundwater for irrigation will likely increase the contribution of groundwater depletion to rising sea levels (Wada et al., 2012; Fig. 5). If this water is taken from coastal aquifers, an increase in saline intrusion could result (Fig. 5). Additionally, the rising sea levels threaten these aquifers with saline intrusion through overwash (flow of seawater over the crest of a beach system; Befus et al., 2020). While the abstractions from groundwater deplete groundwater storage, they increase evapotranspiration (Fig. 5), and changes in precipitation patterns can change the interactions between surface water and groundwater bodies (Fig. 5).

Outlook

Groundwater is the largest available source of freshwater and is a key resource to ensure clean and available drinking water for humans and biota alike. While it is not explicitly mentioned in the UN's SDGs, it is a crucial resource for achieving them. Compared to surface water, groundwater by volume is 100 × larger, but its accessibility varies globally, and abstractions worldwide have led to widespread lowered water tables with dire consequences. Our knowledge about this hidden resource is still limited by data availability, mainly groundwater levels, and hydrogeology. While current modelling efforts provide initial insights into how groundwater is distributed globally and how it interacts with our other water resources, limited knowledge about processes like groundwater recharge call for further research. Especially since groundwater is such a vital resource when facing the challenges of a changing climate, knowledge about how it is affected and how it can be used sustainably on a global scale is imperative and of utmost relevance, especially in the context of transboundary aquifers. Currently, the global abundance and distribution of groundwater remain uncertain.

Knowledge gaps

- Global hydrogeology, especially vertical resolution
- Current and past distribution of groundwater (limited global data)
- Reliable estimates of groundwater recharge on large scales (challenging to measure and model)
- Large-scale understanding of groundwater-surface water interactions
- Long-term impacts of climate change on groundwater

Groundwater Systems—A Hydrogeological Typology

Steffen Birk, Institute of Earth Sciences, NAWI Graz Geocenter, University of Graz, Graz, Austria

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Aquifer Water-bearing units underground capable of yielding water to wells or springs.
Confined aquifer Aquifer where the groundwater is pressurized such that it rises above the bottom of an overlying confining unit when the aquifer is penetrated by a well.
Confining unit Geological units significantly less permeable than aquifers.
Consolidated rocks Rocks in which the individual minerals are firmly held together; includes sedimentary rocks where grains are cemented as well as igneous rocks (formed by crystallization from magma, e.g., basalt or granite) and metamorphic rocks (formed under high temperature and pressure, e.g., gneiss).
Groundwater Water occupying the pore spaces below the (subsurface) water table.
Piezometric surface Imaginary surface to which groundwater rises if a confined aquifer is penetrated by a well.
Primary porosity Pores created when the rock was originally formed.
Secondary porosity Porosity developed after the original formation of the rock; more narrowly defined, discontinuities (fractures) separating blocks of intact rock, which were created by mechanisms other than dissolution.
Tertiary porosity Conduit porosity developed where the dissolution of rock widened fractures.
Unconfined aquifer Aquifer where the water table is located within the water-bearing unit (water-table aquifer).
Unconsolidated rocks Sediments composed of loosely arranged particles or grains (not cemented).
Water table Surface where the water pressure is equal to the atmospheric pressure.

Introduction

Groundwater is a major water resource for the world population and sustains streams, lakes, and wetlands. Sustainable use and protection of groundwater must be based on a sound understanding of groundwater flow and storage. As part of the hydrological cycle, groundwater systems are dependent on hydrological processes controlling their recharge and discharge. Yet, regional and local assessments of groundwater systems also require knowledge of subsurface properties controlling groundwater flow and storage. The aim of this chapter is to introduce the basic terms and concepts needed to characterize and classify groundwater systems with regard to these hydrogeological properties and their effect on flow and storage.

The following section introduces basic definitions of different types of subsurface waters, in particular groundwater. Subsequently, different types of aquifers are distinguished based on the hydraulic conditions found in the subsurface. Then different types of porosity are considered, which correspond to a classification of aquifers based on the geological material. Building on this typology, aquifer properties controlling groundwater flow and storage are introduced and discussed with regard to the different aquifer types. Finally, chemical and thermal properties of groundwater and how they are interlinked with groundwater flow are discussed.

Basic definitions

After intense rainfall or snowmelt, the soil or rock at the ground surface may temporarily be saturated with water. Generally, however, the shallow subsurface contains both air and water and thus is termed the *unsaturated zone* (or vadose zone) (Fig. 1). Underneath the unsaturated zone follows the *saturated zone* (or phreatic zone), where all voids are filled with water. If observation wells are drilled into the saturated zone, the lower part of the well fills with water. The top of the water column in the well marks the *water table*. Water below the water table is termed *groundwater*. At the water table, the water pressure is equal to atmospheric pressure. Below the water table, the water pressure increases with increasing depth. Conversely, the pressure in the unsaturated zone is lower than atmospheric pressure. This is a result of the capillary forces within narrow pores spaces and leads to a *capillary fringe* where water is held above the water table.

Processes within the unsaturated zone and the capillary fringe, such as the infiltration and downward percolation of water, play an important role in replenishment of groundwater systems and in the fate of contaminants released at the ground surface or shallow subsurface. Yet, these processes are dealt with elsewhere. The remainder of this chapter focusses on the zone below the water table, i.e., groundwater.

Types of aquifers

Aquifers are water-bearing units capable of yielding water to wells or springs; the unsaturated zone of such a unit is understood as being part of the aquifer (Todd and Mays, 2005). Aquifers can be overlain or underlain by *confining units* that are significantly less permeable than the aquifer. Confining units can be further classified into aquicludes (containing but not transmitting water), aquifuges (neither containing nor transmitting water), and aquitards (transmitting less water than adjacent aquifers). Evidently, aquifer and confining unit are relative terms. A geological unit that yields only little water may be considered an aquifer if other units within the same region are even less productive, whereas the same geological unit may be classified as confining unit if overlain or underlain by rocks that yield more water. A quantitative measure of the capability to transmit water thus is needed and will be introduced in the section "Flow properties".

Based on the position of the water table different types of aquifers can be distinguished (Fig. 2). In an *unconfined aquifer* (or water-table aquifer) the water table is located within the water-bearing unit (upper aquifer in Fig. 2). This condition is often found where permeable rock crops out at the land surface. A *perched aquifer* is a special case of an unconfined aquifer that occurs if a local groundwater body develops on top of a discontinuous confining layer above the regionally extensive water table of a main groundwater body. Thus, the perched aquifer and the underlying groundwater body are separated by an unsaturated zone. The groundwater within a *confined aquifer* is pressurized such that it rises above the bottom of an overlying confining unit when the aquifer is penetrated by a well (lower aquifer in Fig. 2). The imaginary surface constructed from water levels of such wells is termed

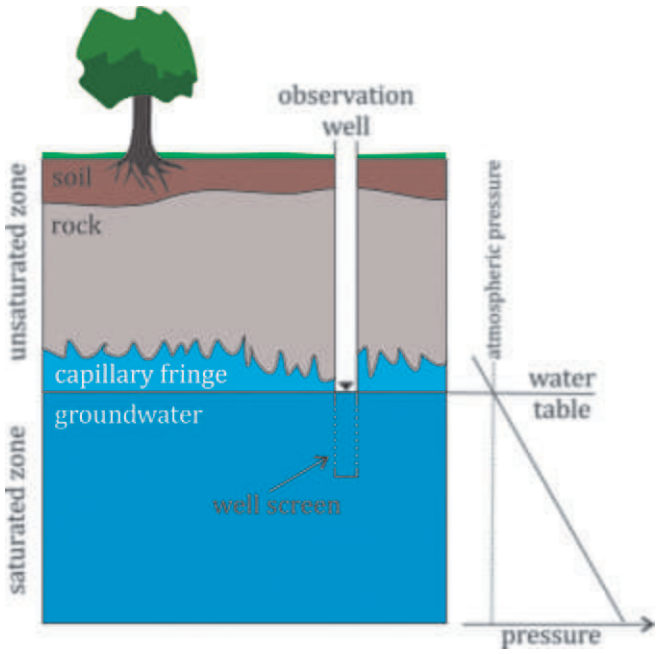

Fig. 1 Zonation of the subsurface and basic hydrogeological terms. Groundwater enters the well through the slotted part of the well casing termed well screen (dashed line). The water table observed in the well is marked by an inverted triangle.

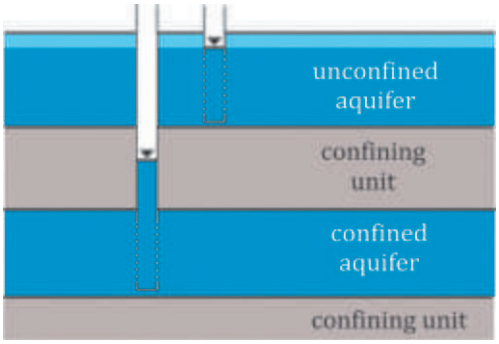

Fig. 2 Definition of unconfined and confined aquifers based on the relative position of the water table observed in the well.

piezometric surface (or potentiometric surface). If the pressure is sufficiently high to rise the water above ground level a flowing artesian well results. Confined or artesian aquifers may be found when a water-bearing unit crops out in a topographically elevated recharge area and dips into a basin where it is covered by a confining unit.

Distinguishing between unconfined and confined aquifers is important in several ways. From a practical point of view, it is vital to recognize confined conditions when drilling into the underground, as the rise of groundwater in the borehole might require technical measures that need to be planned in advance. Evidently, this particularly applies to artesian conditions where the water rises above ground level. Yet, also groundwater flow from a confined aquifer into an overlying unit generally results in undesired changes of hydraulic conditions and potentially adverse effects e.g., on water quality. A striking example is a case reported from Staufen, Germany, where confined groundwater had been allowed to rise in a borehole and caused swelling of the adjacent rock; the resulting uplift of the land surface caused severe damages to buildings (Sass and Burbaum, 2010). Confined and unconfined conditions also need to be distinguished from the more theoretical perspective of groundwater hydraulics. Although comprehensive treatment of groundwater hydraulics is beyond the scope of this chapter, fundamental differences in the storage properties of confined and unconfined aquifers are addressed below in the section "Storage properties".

Types of porosity

The occurrence of groundwater requires voids or pore spaces in the underground that can take up water. The percentage of pore spaces in a rock volume is termed (total) *porosity*. Different geological materials not only have different values of porosity; more importantly, also the size, shape, and connectivity of the pore spaces differ. The different nature of the pore spaces is closely related to their origin and thus to the type of geological material. Hence, hydrogeologists distinguish different types of porosity depending on when and how the pore spaces where formed.

Primary porosity denotes pores created when the rock was originally formed. This type of porosity is most relevant in unconsolidated sediments. Such sediments consist of grains that were transported and deposited by wind, water, or ice. The size distribution of these grains is one major factor controlling porosity. As a rule, total porosity is higher the smaller and the more uniform the grain sizes are (Fig. 3 and Table 1). Sediments transported by wind tend to be well sorted, i.e., display a narrow range of grain sizes. Since the transport and deposition of sediments by water is controlled by characteristic relationships between grain size and flow velocity, one may also expect sediments deposited in river channels and floodplains to be well sorted. However, flow velocities in such environments may vary considerably in space and time. Across the river valley, the grain size distribution of such sediments therefore may exhibit significant variability. Sediments deposited from ice generally are expected to be poorly sorted and thus may display a wide range of grain sizes. The shape and packing of the grains are further factors affecting the porosity of unconsolidated sediments. Compaction by overlying rock and cementation by chemical precipitates transforms the unconsolidated sediments to consolidated sedimentary rock. Primary porosity is reduced by this process of lithification, which is why secondary porosity gains importance in this type of rock.

Secondary porosity generally denotes porosity developed after the original formation of the rock and comprises all types of discontinuities separating intact blocks of consolidated rocks. We distinguish fracture porosity, which includes discontinuities formed by a variety of processes, such as lithostatic or fluid pressures, tectonic forces, and thermal effects, from conduit porosity, which develops where the dissolution of rock widens fractures (Fig. 4). Consequently, conduit porosity is sometimes referred to as *tertiary porosity* (Ford and Williams, 2007). Rocks that are sufficiently soluble to enable the development of conduit porosity are termed karst rocks and, in particular, include carbonate rocks (e.g., limestone) and evaporite rocks (e.g., gypsum). It is important to note that several types of porosity can occur simultaneously. For example, sedimentary rocks such as sandstone can be fractured but still may have significant primary porosity. Likewise, dissolution may create conduits in carbonate rocks, while the majority of fractures may be little affected by dissolution and primary porosity may exist as well.

It is common to name aquifers after the geological material or the type of porosity primarily enabling groundwater flow. Hence, permeable unconsolidated sediments, such as sand and gravel, where groundwater is transmitted through primary porosity, are

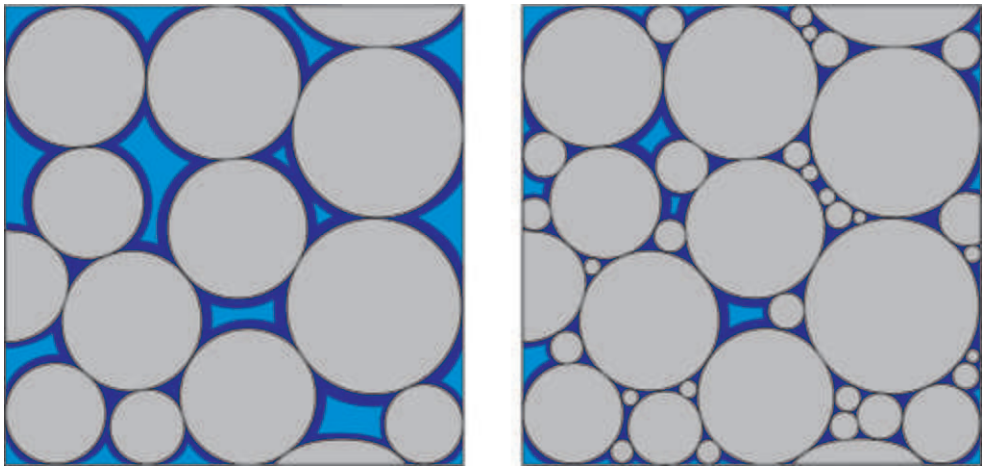

Fig. 3 Schematic sketch of the primary porosity (blue colors) of an unconsolidated sediment. The relatively coarse and well sorted sediment on the left has a higher total porosity than the poorly sorted sediment on the right, which contains fine grains filling spaces between the coarse grains. Dark blue color indicates immobile water surrounding the grains; only the light blue colored part of the pore space is available for groundwater flow (effective porosity).

Table 1 Approximate ranges of total porosity, effective porosity, and hydraulic conductivity for selected geological materials.

Geological material		*Total porosity*[a] *(%)*	*Effective porosity*[a] *(%)*	*Hydraulic conductivity*[b] *(m s^{-1})*
Unconsolidated rocks	Gravel	28–34	15–30	10^{-3}–1
	Sand	35–50	10–30	10^{-6}–10^{-2}
	Silty sand	33–40	8–12	10^{-7}–10^{-3}
	Silt	40–50	5–20	10^{-9}–10^{-5}
	Clay	40–60	1–5	10^{-13}–10^{-9}
Consolidated rocks	Karstified limestone	10–25	0.5–10	10^{-6}–10^{-2}
	Fractured basalt	5–30	2–10	10^{-7}–10^{-2}
	Sandstone	15–30	5–25	10^{-10}–10^{-6}
	Unfractured igneous or metamorphic rock	0–5	0–3	10^{-13}–10^{-10}

[a]From Singhal BBS and Gupta RP (2010) Applied Hydrogeology of Fractured Rocks (2nd edn.). Dordrecht: Springer; Hölting B and Coldewey WG (2019) *Hydrogeology*. Berlin: Springer for silty sand.
[b]From Freeze RA and Cherry JA (1979) *Groundwater*. Englewood Cliffs, NJ: Prentice-Hall.

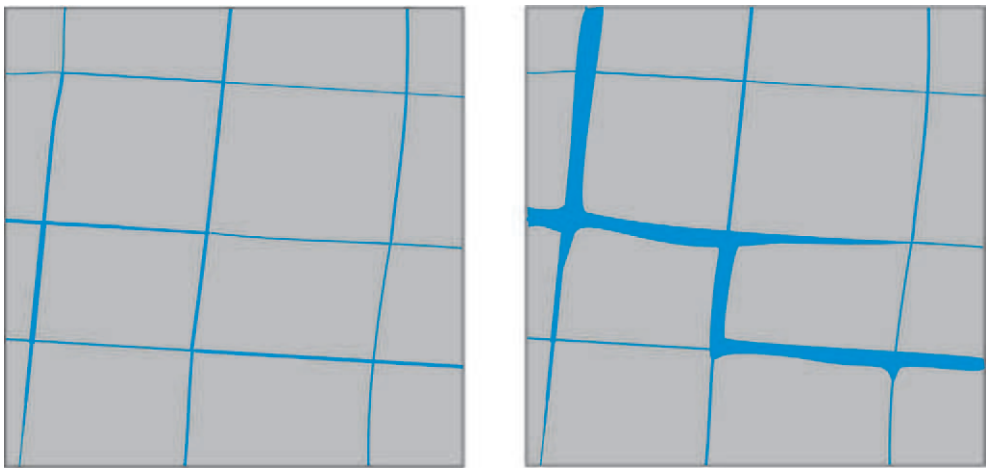

Fig. 4 Schematic sketch of fracture porosity resulting from discontinuities separating intact blocks of consolidated rocks (left). Conduit porosity develops where fractures are widened by dissolution of rock (right).

termed *unconsolidated aquifers* or *porous aquifers*. Correspondingly, the term *consolidated aquifer* refers to all types of permeable consolidated rocks. Commonly, these rocks are fractured and thus the aquifers are termed *fractured aquifers*. Some consolidated rocks, for example sandstone and basalt, the latter of which originates from volcanic lava flows, additionally may have primary porosity. Nevertheless, they usually will be classified as fractured aquifers, as flow typically occurs through open fractures rather than through the narrower pore spaces provided by the primary porosity. Similarly, solution conduits, which commonly have openings ranging from centimeters to meters, are expected to be more effective in conducting water than the pores or fractures of karst rocks. Aquifers where conduit porosity controls groundwater flow thus are termed *karst aquifers* or *karstified aquifers*.

The transmission of groundwater requires interconnected pore spaces of sufficient size to overcome adhesive forces attracting the water molecules to the mineral surfaces. The volume percentage of such pore spaces is termed *effective porosity*. The pore size in unconsolidated sediments tends to decrease with decreasing grain size. As a consequence, large parts of the pore space of fine-grained materials, such as clay or silt, is occupied with immobile water (Fig. 3). Hence, these materials have effective porosities considerably lower than their total porosity (Table 1). As a consequence, clay or silt are hardly capable of transmitting water and are classified as confining units rather than aquifers. Coarse materials such as sand and gravel, particularly if well sorted, tend to have high effective porosity that might come close to their total porosity (Table 1). Such materials represent aquifers, even though their total porosity generally is lower than that of fine-grained materials. The capability of rocks to transmit water thus appears to be related to their effective porosity rather than their total porosity. In this regard, the major difference between the two sediments sketched in Fig. 3 is not so much their different total porosity, but that the coarse and well sorted material has larger openings and thus higher effective porosity than the poorly sorted sediment. Yet, particularly some consolidated rocks may have low total porosity and consequently low effective porosity, but if few interconnected fractures or conduits have large openings these rocks are still able to transmit water. A more quantitative measure of aquifer permeability thus is needed and introduced below.

Flow properties

With some exceptions, such as flow through highly conductive conduits or flow in the vicinity of highly productive pumping wells, groundwater flow is very slow, in the order of meters per day or even well below that. Under such conditions, the *specific discharge q*, i.e., the volumetric rate of flow per unit area of flow cross section, is found to be proportional to the *hydraulic gradient i*, the slope of the water table (or piezometric surface). This is defined by Darcy's law (Darcy, 1856)

$$q = K\, i \tag{1}$$

where the proportionality constant K is termed *hydraulic conductivity*. Hydraulic conductivity estimates can be obtained by solving Darcy's law for K and inserting values of specific discharge and hydraulic gradient measured in lab or field experiments.

Hydrogeologist often treat hydraulic conductivity as if it were a property of the rock. Strictly, this is not correct, because K is also dependent on the density and viscosity of the fluid. Yet, in many groundwater systems the aforementioned fluid properties are spatially and temporally nearly constant, such that variations in K almost entirely result from differences in geological materials. Assuming constant fluid properties, values of K for different materials vary by many orders of magnitude (Table 1). Hydraulic conductivities of unconsolidated aquifers such as sand and gravel typically range from 10^{-5} to 10^{-2} m s^{-1}, though lower or higher values are possible. Values of confining units, e.g., composed of silty or clayey sediments, are orders of magnitude lower. Similarly, consolidated rocks exhibit a wide range of hydraulic conductivity depending on the characteristics of their fracture or conduit porosity.

Assessing the hydraulic conductivity of rocks is complicated by their *heterogeneity* and *anisotropy*. The grain size distribution of unconsolidated sediments and the frequency as well as the size of fractures or solution conduits of consolidated rocks commonly vary in space. This heterogeneity is displayed in the spatial distribution of hydraulic conductivity values. As a consequence, measurements of K at different locations may yield very different results even within the same geological setting. As a further consequence, hydraulic conductivities obtained by lab or field experiments depend on the scale of observation. This is most obvious for consolidated rocks with several types of porosity, such as sandstone or limestone. Lab measurements conducted at small samples of such rocks mainly provide information about the hydraulic conductivity associated with the primary porosity, whereas the effects of fracture or conduit porosity can only be observed at large spatial scales. In addition, sediment structures, fractures, and conduits may have preferential directions. This leads to a directional dependence, i.e., anisotropy, of hydraulic conductivity. As an example, the hydraulic conductivity of unconsolidated sediments composed of multiple layers generally is higher in the horizontal than in the vertical direction. Consolidated rocks tend to exhibit even higher anisotropy of hydraulic conductivity, because the mechanisms creating fractures and conduits often favor distinct directions.

Characterizing an aquifer's ability to transmit water is further complicated when groundwater flow is fast. Darcy's law holds only if inertial forces and turbulent friction can be neglected, which is not met if the flow velocity is too high. This is generally expected in karst aquifers, where velocities are often in the order of kilometers per day, and also occurs in other highly conductive aquifers close to productive pumping wells. The additional forces increase the flow resistance and cause deviation from the linear relationship between hydraulic gradient i and specific discharge q stated by Darcy's law. One approach to account for this effect is the non-linear flow equation proposed by Forchheimer (1901).

$$i = a\,q + b\,q^2 \tag{2}$$

where $a = 1/K$ is the reciprocal of hydraulic conductivity and the Forchheimer coefficient b an aquifer property controlling the non-linear deviation from Darcy's law. Estimates of b for various geological materials are provided by Zeng and Grigg (2006), Chin et al. (2009), and Sidiropoulou et al. (2009). Compared with hydraulic conductivity values of rocks, the non-linear flow properties of geological materials have been considerably less investigated though.

The ability of an aquifer to transmit water, characterized by its hydraulic conductivity K (and under the above specified conditions the Forchheimer coefficient b), is one important control on the interaction of groundwater systems with other components of the water cycle. A highly conductive aquifer is able to transmit the entire recharge under a hydraulic gradient much lower than the slope of the land surface (Fig. 5, left). In such recharge-controlled systems, the water table of the elevated areas is at great depth and thus disconnected from the hydrological processes at the land surface. In contrast, the transmission of groundwater through lowly conductive rocks involves steep hydraulic gradients such that the water tables of the elevated areas are shallow and thus interacting with the evapotranspiration and runoff processes at the land surface (Fig. 5, right). In such topographically-controlled systems, the potential recharge exceeds the rate at which groundwater can be laterally transmitted by the aquifer, i.e., recharge is rejected (Theis, 1940; Cuthbert et al., 2019).

Storage properties

In a hypothetical groundwater system where recharge and discharge are in balance, the stored water volume remains constant in time. However, natural or artificial fluctuations in recharge and discharge commonly cause temporal changes in the stored water volume. For example, consider the situation where pumping is started in an unconfined aquifer. As pumping starts, water is withdrawn from the wellbore, causing the water level in the pumping well to drop. Continued pumping then requires that groundwater flows from the aquifer towards the well. As a result, groundwater is drained from the aquifer storage and the water table in the vicinity of the pumping well starts to decline (Fig. 6, left). Hence, water withdrawal from the aquifer storage involves changes in water levels. To characterize this relationship quantitatively, we define the *storativity* (or storage coefficient) of an aquifer as the water volume released from storage per unit surface area per unit decline in water level.

In the above example of an unconfined aquifer, the water is released by gravity drainage from the aquifer storage. The water volume per rock volume released by gravity drainage is termed *specific yield*; it is equivalent to the storativity of the unconfined aquifer. Since some percentage of the water is retained as thin films surrounding grains or as capillary water in narrow pores, the specific yield is lower than the total porosity. The approximate ranges for effective porosity given in Table 1 also apply to specific yield (Singhal and Gupta, 2010). Thus, the specific yield of unconsolidated sand or gravel roughly ranges between 0.1 and 0.3, while values of fined-grained sediments are lower. Highly fractured, consolidated rocks may reach values similar to those of

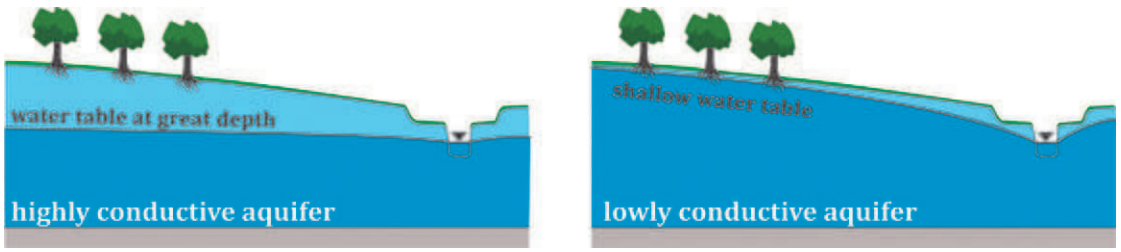

Fig. 5 The water table of a highly conductive aquifer (left) tends be at great depth below the land surface, whereas the transmission of groundwater through a lowly conductive rock requires a steep hydraulic gradient, thus leading to shallower water tables (right).

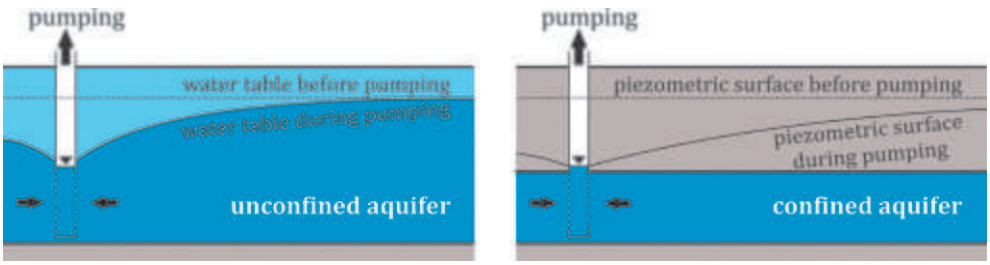

Fig. 6 Comparison of unconfined and confined aquifers when they are pumped. In the case of the unconfined aquifer (left) water is released by gravity drainage from the aquifer volume enclosed by the water tables before and during pumping. In contrast, the pore spaces of the confined aquifer (right) remain saturated during pumping; water is only released from the aquifer storage because the lowering of the piezometric surface corresponds to a reduction of pressure and thus leads to expansion of water and reduction of pore space.

coarse-grained unconsolidated rocks, but often the specific yield of consolidated aquifers is lower than that of unconsolidated aquifers.

Consider now a confined aquifer that is pumped (Fig. 6, right). As long as the aquifer is confined, the pore space remains saturated despite the lowering of the water level in the pumped well. Nevertheless, groundwater is released from the aquifer storage, because the decline of pressure, which corresponds to the lowering of the piezometric surface, results in an expansion of water and compression of the rock and thus the reduction of pore space due to the load of the overburden. The water volume that can be released by this mechanism and thus the storativity of confined aquifers can be estimated from the compressibilities of rock and water. The storativity of confined aquifers typically ranges in the order of 10^{-3} to 10^{-5}. This is much lower than typical values of specific yield and indicates that in unconfined aquifers the described effect of decompression generally is negligible compared with gravity drainage.

The greatly different values of storativity constitute an important difference between confined and unconfined aquifers. This can be understood by considering a pumping situation as described above (Fig. 6). Since the same decline in water level releases much less water per unit volume from a confined than from an unconfined aquifer, the confined aquifer requires a much larger aquifer volume to provide the same amount of water. As a consequence, after a given time the area affected by pumping will be larger for the confined than for the unconfined aquifer (assuming they have the same hydraulic conductivity). Similarly, disturbances by flood pulses or effects of droughts propagate faster (or over a greater distance in a given time) in a confined aquifer than in an unconfined aquifer of otherwise similar properties.

Chemical and thermal properties

Groundwater systems can also be characterized and classified based on their chemical and thermal properties. A comprehensive treatment of this topic is beyond the scope of this chapter. Yet, basic concepts and their interrelation with groundwater flow are briefly introduced below.

The water infiltrating into the soil after rainfall or snowmelt initially has a low solute concentration. As the water moves through the soil, it dissolves gases such as carbon dioxide and reacts with the soil organic matter and minerals. Thus, the water is already enriched in solutes when it reaches the water table. Depending on the geochemical conditions in the aquifer, the chemical composition of the groundwater further evolves through time.

The solute content of groundwaters reflects the processes involved in the hydrogeochemical evolution along the flow path. Thus, groundwaters can be classified into various types of hydrochemical facies based on the major ions they contain (Back, 1966). The cation facies can be characterized as calcium type, magnesium type, sodium and potassium type, or no dominant type; the anion facies can be classified as bicarbonate type, sulfate type, chloride type, or no dominant type (Fig. 7). The chemical composition of the geological material evidently is a major control on the hydrochemical facies. For example, limestone is composed of calcium carbonate and thus groundwater flowing through limestone that creates conduit porosity by dissolving the rock is expected to be of calcium-bicarbonate type. If water originating from limestone penetrates gypsum, which is composed of calcium sulfate, the increasing load of calcium leads to chemical precipitation of calcium carbonate and the hydrochemical facies changes towards calcium-sulfate type. Similar processes occur in other rocks such that the chemical composition evolves with increasing travel time and distance along the groundwater flow path. Generally, the content of dissolved solids increases with increasing distance and depth of the groundwater circulation, and the anionic facies is expected to change from bicarbonate to sulfate and chloride type, i.e., towards anions originating from highly soluble minerals (Tóth, 1999).

The chemical evolution of groundwaters is also influenced by thermal conditions within the aquifers, as changes in water temperature may disturb chemical equilibria and thus enable further dissolution or chemical precipitation of minerals. The surficial zone of the subsurface is influenced by seasonal temperature fluctuations, the amplitude of which decreases with depth (Anderson, 2005). At a depth of around 10–20 m below ground level, seasonal fluctuations are usually no longer observed (Todd and Mays, 2005), and thus the shallow groundwater exhibits temperatures close to the mean annual air temperature. In the geothermal zone that follows below, the temperature of the rock increases with depth according to the geothermal gradient (on average three Kelvin per 100 m). Since slowly circulating groundwater is in thermal equilibrium with the rock, the groundwater temperature increases with depth too. As a consequence, deep groundwater systems may exhibit high groundwater temperatures and thus constitute thermal water resources.

Changes in solution content and temperature involved in the deep circulation of groundwaters affect the density of the groundwater and thus potentially are able to induce density-driven flow processes. Moreover, the viscosity of water decreases with increasing temperature, which affects the hydraulic conductivity (see section "Flow properties"). Thus, potential changes in the density and viscosity of the water resulting from the chemical and thermal evolution along the flow path need to be considered in the assessment of deep groundwater systems. Similar effects can be found in coastal aquifers where freshwater and saltwater interact or in groundwater systems where thermal impacts resulting from human activities affect the density or viscosity of the water.

Conclusion

The hydrogeological typology of groundwater systems rests on two pillars, the distinction between unconfined and confined aquifers as well as the differentiation of porosity types. The first is defined by the position of the water table relative to the hydrogeological units; the second is determined by the characteristics of the geological material. The framework provided by this typology supports the understanding of aquifer properties governing flow and storage processes in groundwater systems. Groundwater systems can be further classified based on other aspects such as the chemical or thermal properties of the water. Possible interrelations between groundwater flow, chemistry and temperature need to be considered particularly in the hydrogeological assessment of deep groundwater systems, coastal aquifers, or settings affected by human impacts.

Knowledge gaps

- How to deal with scale effects resulting from the occurrence of several types of porosity in hydrogeological assessments of consolidated sedimentary rocks, for example, when measuring hydraulic conductivity values and when using these values in models predicting groundwater flow or the transport of heat or solutes.
- Properties of rocks controlling groundwater flow if inertial forces or turbulent friction cannot be neglected, particularly how properties of fracture or conduit porosity control groundwater flow dynamics and aquifer properties observed at large scale.
- Feedbacks between groundwater flow, chemical and thermal evolution of groundwater, and biological processes in different types of hydrogeological settings, including resulting changes in aquifer properties.

The Hydrology of Groundwater Systems - From Recharge to Discharge

Andreas Hartmann, Institute of Groundwater Management, Technical University of Dresden, Dresden, Germany

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Introduction

Groundwater is the world's largest source of non-frozen fresh water (Gleeson et al., 2016) providing approximately half of the earth's population with drinking water (Velis et al., 2017). Groundwater systems are important parts of the hydrological cycle comprising the subsurface water itself, the geologic media containing the water, flow boundaries, groundwater recharge, point/areas of groundwater discharge or groundwater removal like springs or wells (Alley et al., 2002).

Quantitative understanding of groundwater systems' functioning is relevant for a wide range of research fields (Fig. 1). For instance, sustainable management of groundwater use is only possible if groundwater recharge, storage, discharge, and the impact of groundwater removal through pumping are well understood. Likewise, proper understanding of hydrological systems, especially during dry periods, can only be obtained when the interactions of surface water and groundwater are considered. Many ecosystems, e.g. wetlands, are dependent on groundwater. Hence, assessment of their present and future health require understanding of groundwater availability and quality. On the other hand, groundwater systems in agricultural and industrial regions are often exposed to pollutants that reach the phreatic zone posing a threat to drinking water supply and groundwater dependent ecosystems. Consequently, the characterization and simulation of transport of and storage of pollutants in groundwater systems has become a growing field of research. Similarly, accounting for the interaction of groundwater with subsurface constructions such as tunnels, building foundations, or mining has received increased attention in civil and structural engineering.

Fig. 1 Areas of research that require quantitative understanding of groundwater systems.

Definitions and structure of groundwater systems

In order to understand and quantify groundwater systems processes, some important technical terms need to be introduced. Groundwater storages are often referred to by the term aquifer. An aquifer is rock or sediment in a formation, a group of formations, or a part of a formation that is water saturated and sufficiently permeable to transmit economic quantities of water to wells or springs. Aquifers can be local (within the limits of a topographic catchment) or regional (crossing the boundaries of topographic catchments (Fig. 2, modified from Jones et al., 2019). An aquitard, or confining unit, is a low-permeability unit that can store

groundwater and transmit it slowly from one aquifer to another. If completely impermeable, a geologic layer is called an aquiclude. The unsaturated zone, or vadose zone, is located between the land surface and the water table. Pores may contain some water but are not fully saturated. In the saturated zone, all pore space is filled with water at a pressure greater than the atmospheric. The water table of an aquifer is the level below which the material is saturated with water or, in other words, the boundary between fully-saturated and unsaturated pores. The vertical distance between the water table at the top and the aquitard or aquiclude at the bottom is often referred to by thickness of the aquifer. A well is defined as an excavation structure used to access groundwater stored in an aquifer. The water level measured in the well shows the hydraulic head of the groundwater (in the following referred to by "head" or "groundwater head") at this particular location.

Aquifers can be classified by their lithological setting. In a so-called unconfined aquifer when groundwater is in direct contact with the atmosphere through the pore spaces in the overlying rock or sediments. Its water table marks the upper surface of the groundwater. Within a confined aquifer, groundwater is overlain by an aquitard or aquiclude that limits upward movement of the groundwater. Its water table is at the same level as the lower boundary of the aquitard or aquiclude but its potentiometric surface, to which groundwater would rise in a pipe, is higher (Fig. 2). If groundwater would rise above the surface due to a confined aquifer setting, it would be referred to as "artesian." Locally limited aquicludes or aquitards within the unsaturated zone allow vertically percolating waters to also form perched aquifers that are at levels higher than the regional water table.

The water balance of an aquifer summarizes inflow, outflow and storage changes. It is defined by its inflows (groundwater recharge, lateral groundwater inflow), its outflows (groundwater discharge to springs or streams, pumping through wells, lateral groundwater outflows) and its change of storage. An aquifer is in a stationary state, when the inflow equals the outflow and the change of storage is zero. The components of the aquifer's water balance, from recharge to discharge and storage, will be described in the following sections.

Groundwater recharge

Groundwater recharge is defined in a general sense as the volume or process of downward flow of water reaching the water table, forming an addition to the groundwater reservoir (de Vries and Simmers, 2002). Water that contributes to groundwaters recharge originates from precipitation reaching the surface, rainfall or snow melt, that has infiltrated into the subsurface and that has percolated vertically through the unsaturated zone toward the water table. Three types of recharge can be distinguished (Fig. 3A): (1) Direct recharge that reaches the water table as a result of soil moisture excess and direct vertical percolation through the unsaturated zone, (2) indirect recharge that infiltrates and percolates through river beds or lakes, and (3) focused or localized recharge that results from local horizontal near(surface) concertation of infiltrating water, for instance through joints, depressions, sink holes or rivulets (not river beds or lakes). Global estimates of direct recharge range from very low annual volumes, e.g. in the deserts, to larger than 1000 mm per year in the tropics (Fig. 3A). In addition to direct recharge, focused or localized recharge have been shown to produce large volumes of groundwater recharge at very short time scales (Hartmann et al., 2015, 2017). For all three types of recharge, evapotranspiration will reduce the volumes that finally reach the groundwater. Evaporation and water uptake through roots substantially reduce the water volumes percolating downwards as direct recharge. Recharge can decrease even to zero

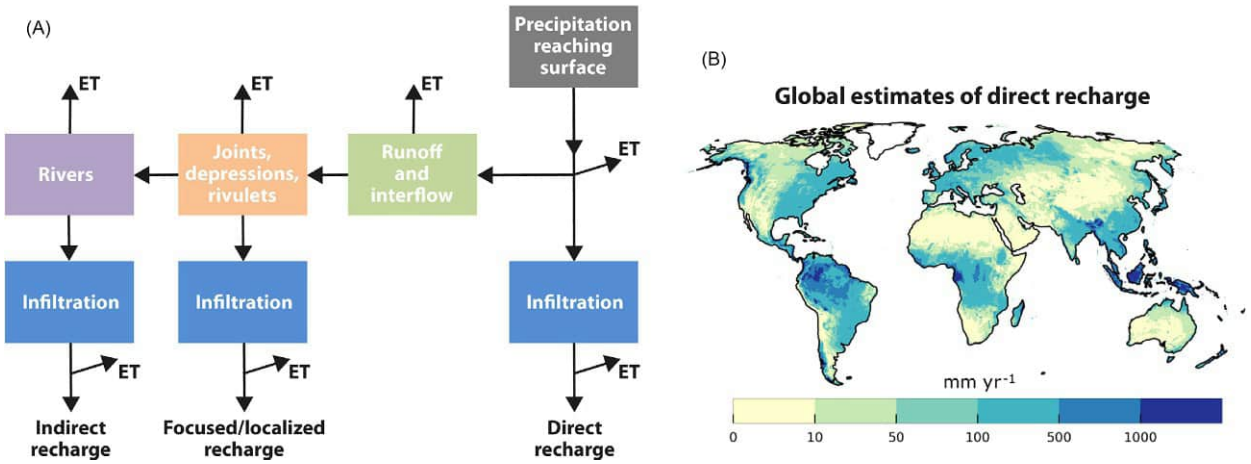

Fig. 3 (A) Mechanisms of groundwater recharge (Lerner, 1997; ET: evaportranspiration) and (B) global estimates of direct recharge under pre-industrial conditions (ensomble mean of eight global hydrological models Reinecke et al., 2021).

depending on the climate, season and vegetation (Jasechko, 2018). However, recharge can also make up >90% of infiltrating rainfall and snow at regions were soils are thin and temperatures are low, e.g. mountain areas (Chen et al., 2018).

Due to its occurrence in the subsurface, measurement of recharge is not straight forward. At well-defined catchments, where surface runoff and evapotranspiration can be estimated independently, long-term, average groundwater recharge can be obtained through the catchment's water balance. Water table observations at locations with negligible influence of lateral groundwater contributions, e.g. close to a groundwater divide, allow the assessment of groundwater recharge through water table fluctuations over time (Crosbie et al., 2005). Direct measurement of vertical percolation, as a proxy of groundwater recharge, is possible with so-called lysimeters that measure the water balance components of isolated and undisturbed soil monoliths. Baseflow analyses of discharge observations, modeling and, especially in arid regions, environmental tracer techniques also allow indirect assessment of groundwater recharge (Scanlon et al., 2002).

Groundwater storage

Groundwater is stored in the voids between the solid matrix of the subsurface. The space available for groundwater is described by the porosity of the aquifer material. It develops either when a rock or sediments are formed (primary porosity) or when fractures or weathering create additional voids after original formation of the rock or sediments (secondary porosity). Sometimes the term 'tertiary porosity' is used to describe voids formed by chemical weathering alone, e.g. karstification (Ford and Williams, 2007). Aquifers that store groundwater mostly in unconsolidated material are classified as unconsolidated aquifers; aquifers that mostly use their secondary porosity to store groundwater are classified as consolidated rock aquifers (sedimentary rock, metamorphic rock, or igneous rock, see Fig. 4, modified from Winter, 2001). Two metrics to quantify porosity exist, total porosity and effective porosity both of them quantifying the ratio of pore space against total volume of voids and solids. While the total porosity describes the entire pore space including voids that are sealed from their surroundings, the effective porosity describes only the part of the pore space that is penetrable by water. Consequently, the effective porosity is the more important measure when it comes to groundwater flow and storage. It ranges from values <1% (e.g., crystalline rock) up to 25% or larger (e.g., gravel).

However, when an unconfined aquifer is pumped, not all water that is stored in the effective pore space will be drained. Due to capillary forces and adhesion, part of it will be retained in the pore space. The other part, i.e. the volume of groundwater that can be drained by gravity, is called specific yield. Similar to the porosity, it is defined as the volume of drainable water per total volume of voids and solids. It ranges from 0% (clay) to >20% (gravel). When a confined aquifer is pumped, no drainage of pore space takes place but still water is released. This water is originating from decompression of the aquifer that results in expansion of the water itself and compaction of the effective pore space. How much water can be released per meter of aquifer thickness is quantified through the specific storage. It usually ranges from 0.1–1% m^{-1}. Both specific yield and specific storage (times the aquifer thickness) combine to the storativity of an aquifer but due to the huge differences in amount by orders of magnitude, the specific storage can be neglected when considering unconfined aquifers, while the specific yield of a confined aquifer is zero by definition.

Groundwater flow and discharge

Groundwater flow within an aquifer depends on the "slope of the aquifer", i.e. the difference of groundwater heads over a distance, the inverse of resistance to flow within the aquifer material, and the cross-sectional area (Fig. 5). The first who experimentally

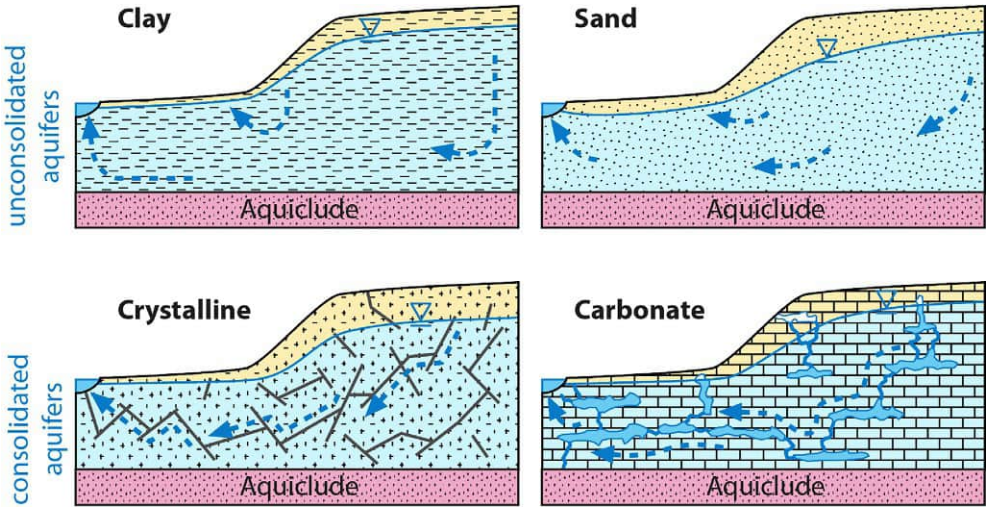

Fig. 4 Different rock types. Modified from Winter TC (2001) The concept of hydrologic landscapes. *Journal of the American Water Resources Association* 37: 335–349, doi:10.1111/j.1752-1688.2001.tb00973.x.

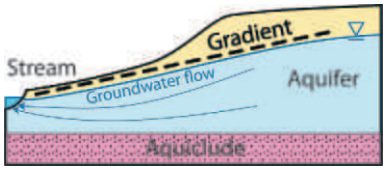

Fig. 5 Groundwater discharge to the stream following the gradient of the water table.

described the relationship between groundwater flow and the three variables mentioned was Henry Darcy in 1856. Using a saturated pipe filled with unconsolidated material, a pre-defined cross-sectional area, and by setting up a constant head difference between inlet and outlet of the pipe, he could show that groundwater flow is linearly correlated with the head difference, the cross-sectional area, the reciprocal of the flow distance and a linearity constant that was defined as the hydraulic conductivity. Darcy's equation is defined as

$$Q = A \cdot k_h \left(\frac{dh}{dx}\right) \tag{1}$$

$$q = k_h \left(\frac{dh}{dx}\right) \tag{2}$$

Where A [m^2] is the cross-sectional area, k_h [m/s] the hydraulic conductivity of the aquifer, and dh/dt [–] represents the change of groundwater head dh [m] over a distance dx [m]. Since this first experiment, Darcy's equation has been used to quantify volumetric groundwater flow or specific groundwater flow (normalized by the cross-sectional area) in a wide range of hydrogeological applications. But it was also shown that there are limits of its application for very low head gradients where electrostatic forces hold the water as well as with very high head gradients where groundwater flow becomes turbulent (e.g. in karstic caves or enlarged fractures).

Values of the hydraulic conductivity depend on the aquifer type (rock/unconsolidated), and span over more than 10 orders of magnitude, from 10^{-13} m/s for unfractured crystalline rock until 10^{-2} m/s for gravel or karst aquifers (Freeze and Cherry, 1979). The hydraulic conductivity results from the properties of the fluid, e.g. water, and the surrounding material, e.g. unconsolidated gravel. Cancelling out the properties of the fluid (specific weight and dynamic viscosity), the permeability of the aquifer material can be obtained (Hubbert, 1956), which can be combined with any other fluid that can move through the material (e.g. oil or contaminants in the fluid phase).

Despite the simplified example of a groundwater system in Fig. 2, real aquifer systems usually show a lot of heterogeneity at different scales. Due to the history of deposition, sand and gravel aquifers may expose strong changes of effective porosities and hydraulic conductivities within the scale of a few centimeters. At the range of some meters of depth, unconsolidated sediments may be followed by fractured crystalline rock or weathered carbonate rock (karst). If the saturated zone of an aquifer comprises such heterogeneities, it is necessary to weigh the hydraulic conductivities of the different layers by their thickness to obtain the effective hydraulic conductivity of the aquifer. If hydraulic conductivities differ for different directions, the aquifer is anisotropic; if they are the same, it is isotropic. For groundwater development by wells, the horizontal hydraulic conductivity and the aquifer thickness

(Fig. 2) are critical properties as they define how much water can be pumped without emptying the well. They are summarized in the transmissivity of the aquifer, which is defined by the effective hydraulic conductivity over all horizontal layers times the aquifer thickness.

The velocity of flow through an aquifer v [m/s] can be derived by dividing the specific groundwater flow (Eq. 1) by the effective porosity (therefore $v \geq q$). Because of wide ranges of v, hydraulic conductivities, and aquifer sizes (up to several Mio. km^2; Richts et al., 2011), groundwater travel times can range from several hours, e.g. in a karstic setting, to millennia or longer (Sprenger et al., 2019). As a consequence, changes of groundwater flow and discharge following changes of boundary conditions, e.g. reduced recharge volumes due to changing climate, may therefore occur with a substantial delay (Cuthbert et al., 2019).

Conceptual models of groundwater systems

A hydrogeological conceptual model synthesizes our understanding of a groundwater system. It includes information about geology and lithology, level and gradient of the potentiometric surface, the type of aquifer (e.g. confined or unconfined), groundwater recharge and discharge areas, and the direction(s) and scale of groundwater flow. It therefore summarizes all available information about the aquifer characteristics introduced in the preceding sections. Following Enemark et al. (2019), the components of a conceptual model consist of (a) a conceptual process structure, (b) a conceptual physical structure, and (c) a spatial variability structure (Fig. 6). The process structure defines the occurring groundwater recharge (Section "Groundwater recharge") and groundwater discharge processes (Section "Groundwater flow and discharge") and the locations where they are taking place. The conceptual physical structure defines the location and geometry of the aquifers, aquitards and aquicludes (Section "Definitions and structure of groundwater systems"), the aquifer types (Section "Groundwater recharge"), and the general boundaries of the groundwater system. The spatial variability structure defines how aquifer properties, such as hydraulic conductivities, specific storage, specific yield or effective porosity, vary in space and directions therefore describing the degree of heterogeneity and anisotropy of the aquifer system (Sections "Groundwater storage" and "Groundwater flow and discharge").
