Glossary

Artisanal fishery A community- or household-based fishery that is part of the local tradition and often uses traditional methods for capture. Artisanal fisheries differ from large-scale commercial fisheries in that the harvest levels are low with small amounts of capital invested and simple technology. They have small or no fishing vessels, operate from or close to shore, and harvest mainly for local trade and consumption. Often synonymous with small-scale fishery.

Commercial fishery A fishery where harvest enters a market-based system to be traded or sold. It can be economically valued more easily and is often part of a value-added supply chain.

Environmental flows The water quantity, quality, and flow regime required to sustain freshwater and estuarine ecosystem integrity and derived social benefits. Also known as e-flows.

Flow regime The temporal changes of flow within a river or stream, including the predicted pattern for low and high flows as well as the magnitude, duration, and rate of change of water levels. Factors that influence a flow regime are rain, snow melt, watershed size, geology, land and water use, and vegetation type.

Freshwater biodiversity The variety and variability among living organisms found in and around freshwater ecosystems, measured within and among species, and within ecosystems.

Inland fishery A fishery operating in inland waters for food, income, or recreation which may or may not involve harvest.
Inland waters Land-locked waters, including lakes, ponds, rivers, streams, creeks, springs, canals, reservoirs, and wetlands.
Recreational fishery A fishery where the principal motivation is recreation, tourism, or sport (i.e., competition). It may or may not involve harvest.
Small-scale fishery A fishery with simple technology. Typically, harvest is locally traded and consumed. Often synonymous with artisanal fishery.
Subsistence fishery A fishery where harvest is consumed by fishers, their families, or shared with others without formally entering a market or commercial economy. Often found in communities that rely on fish as their main source of nutrition; almost exclusively small-scale and artisanal.
Water quality A measure of the chemical, physical, and biological condition of water, usually with respect to a particular use.
Water quantity A measure of the amount of water in a system, typically expressed in terms of total yield and flow regime (pattern) over a specified amount of time.

Introduction

Inland fishes and freshwater biodiversity are all around us. The vast majority (87.5%) of human populations live within 3 km of a river (Kummu et al., 2011); yet, the societal value of inland fishes and aquatic biodiversity is often neglected. Perhaps this is because inland fishes and freshwater biodiversity are 'out of sight, out of mind,' just below the water's surface. Or perhaps, because inland waters have been so integrally tied to the rise of human civilizations, the societal value of resources within or supported by these systems is taken for granted. This neglect cannot discount the significant contributions these services provide (Table 1). Inland waters are home to more than 50% of all fish species (>18,000 species), more than 25% of all vertebrate species (Fricke et al., 2020). Inland fisheries employ approximately 60 million people as fishers and in post-processing jobs (over 50% are women; FAO, 2018). More than 90% of inland capture harvest is for human consumption and 43% comes from low-income food-deficit countries, where fish provide vital micronutrients and animal protein to communities that have few alternative sources (Funge-Smith, 2018). Inland fisheries have an estimated economic value of up to USD 122 billion, which is compounded when the value is weighted by the local gross domestic product (Funge-Smith, 2018).

This chapter seeks to explicitly acknowledge the immense societal value of inland fishes through examination of the human benefits of conservation and sustainable management of inland fishes and their ecosystems. These benefits can be broadly categorized into nine societal services: 1. Livelihoods and subsistence income; 2. Commercial income; 3. Food and nutrition; 4. Recreational services; 5. Cultural services; 6. Educational and scientific opportunities within fisheries; 7. Biodiversity and ecosystem function; 8. Regulation and indicator of freshwater quality; and 9. Regulation of freshwater quantity and natural flow regimes (Fig. 1). Around the globe, these services vary in their relative importance to different communities (Fig. 2). For instance, inland fisheries provide critical contributions to food security and nutrition in certain regions and recreational opportunities in others.

The natural environments that support these services are under extreme threat. Freshwater ecosystems are considered the most endangered in the world (Tickner et al., 2020 and references therein). Of the 29,500 freshwater dependent species so far assessed for the International Union for Conservation of Nature (IUCN) Red List, 27% are threatened with extinction. Freshwater species display very high levels of endemism, meaning they are often only found in one location, which may increase their risk of extinction (Collen et al., 2014). Major threats include: habitat degradation, flow modification, water pollution, overexploitation, invasive species, disease, hydropower development, and climate change (for more comprehensive discussions, see Dudgeon et al., 2006; Reid et al., 2018). While most of these drivers are external to inland fishes and freshwater biodiversity, tensions among societal services can also arise and threaten derived benefits, as different stakeholder groups prioritize different services. Typical key stakeholders in inland waters include recreational and commercial fishers, consumers of freshwater fish, community members who utilize freshwater

Table 1 Selected statistics on global inland fisheries and biodiversity summarized from Funge-Smith (2018), Funge-Smith and Bennett (2019), FAO (2020), and Fricke et al. (2020).

Catch	
Total annual catch	12.0 million tonnes (12.5% of total global capture fishery production)
Proportion for human consumption	>90% of total inland fishery capture harvest
Harvest from Low-Income Food-Deficit countries	>43% of total inland fishery capture harvest
Economic value	
Estimated economic value (including non-market use value)	USD 108 billion – USD 122 billion
Employment	
Estimated number of fishers	16.8 million – 20.7 million
Estimated number of fishing post-processing jobs	8 million – 38 million
Percent of women in fishing the workforce	>50%
Biodiversity	
Number of inland fish species	>18,000 (>50% of all fish species; >25% of all vertebrate species)

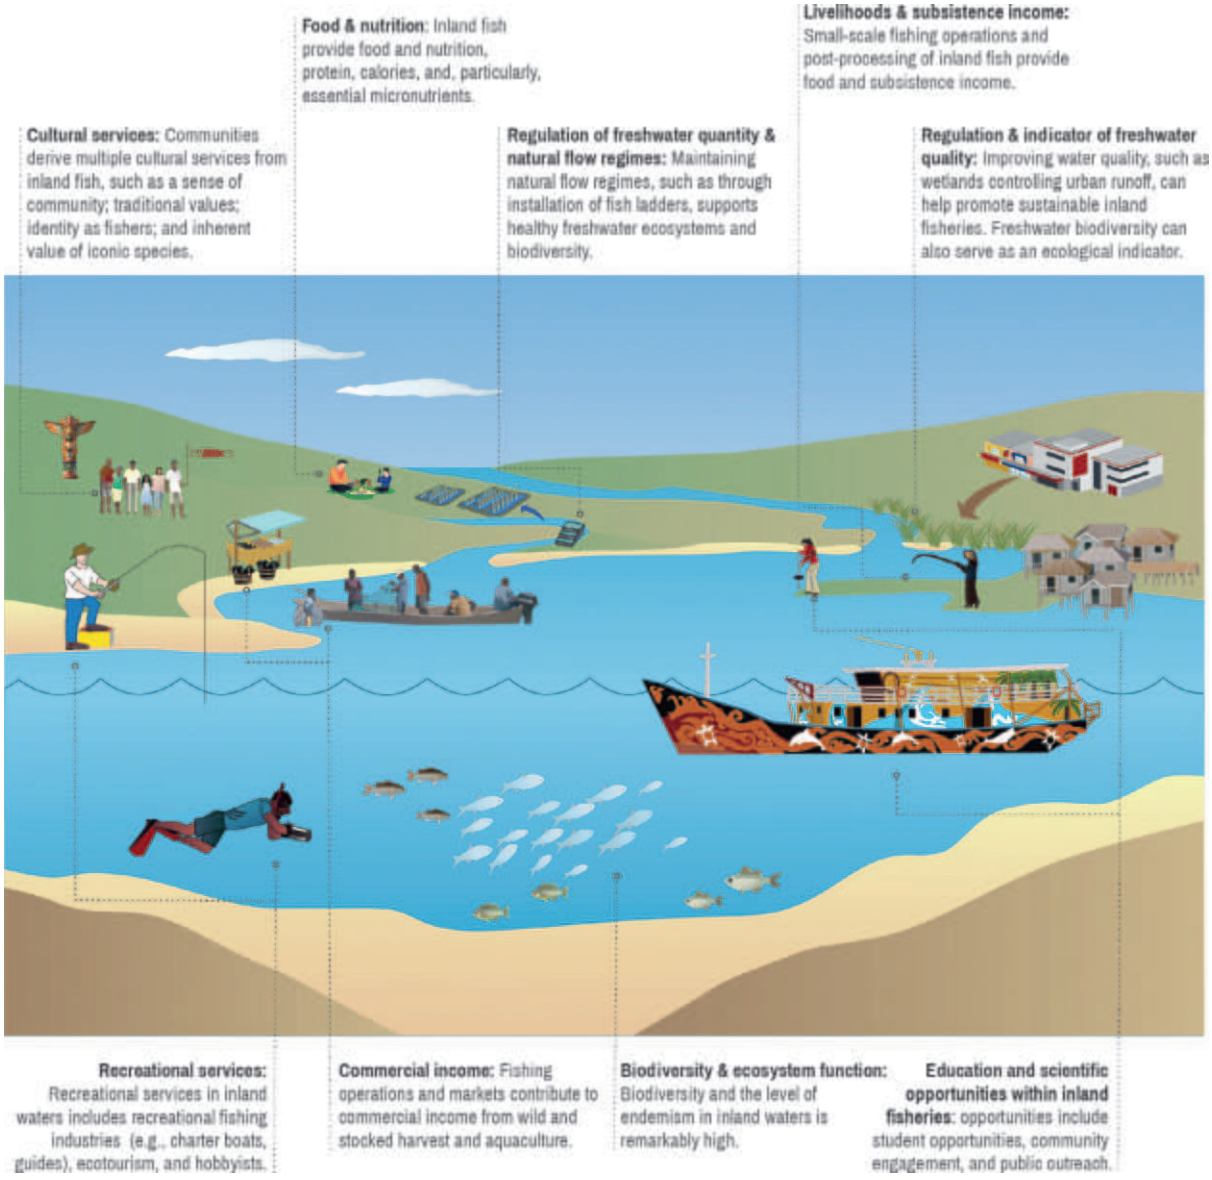

Fig. 1 Inland fishery services across a hypothetical landscape: livelihoods and subsistence income; commercial income; food and nutrition; recreational services; cultural services; educational and scientific opportunities within fisheries; biodiversity and ecosystem function; regulation and indicator of freshwater quality; and regulation of freshwater quantity and natural flow regimes.

resources for consumption and recreation, and stakeholders with wider interests, including regulatory agencies that require efficient methods for assessing aquatic environments. Services gained from maintaining fish in inland waters, for example, can conflict with the benefits of harvesting fish from those systems. However, working from a holistic, ecosystem-based perspective, conservation and sustainable management of all nine societal services can ensure that the persistence of one service does not threaten or degrade benefits derived from others now or in the future.

The following sections aim to highlight the global importance of inland fishes by service. Each section includes a general description of the service, key stakeholders, threats, and a specific case study to exemplify the service.

Livelihoods and subsistence income

Inland fisheries utilize wild fishery resources in rivers, streams, floodplains, wetlands, lakes, inland seas, canals, reservoirs, and even rice fields. They represent a relevant livelihood providing poverty alleviation, income, and employment to more than 60 million people worldwide (Fig. 3; Béné et al., 2016; FAO, 2018). Inland fisheries can be a primary livelihood or can be used to support the acquisition of inputs and goods from other subsistence activities such as agriculture, beekeeping, and raising livestock. Individuals

linked to commercial fisheries are fishers, traders, processors, and informal and formal fish sellers in markets. As a low-cost opportunity for subsistence and livelihood support, inland fisheries can serve as social safety nets, offering alternative options when primary income sources fail. In addition to wider threats to the physical environment and fish populations, subsistence use of inland fisheries may be threatened by commercial encroachment, changes in governance arrangements, or the development of recreational fisheries over subsistence use.

Case study: Small waterbody fisheries in southern Lao People's Democratic Republic (PDR)

Small waterbody fisheries in southern Lao PDR provide an example of the different ways that inland fisheries can contribute to livelihoods and subsistence income. Small floodplain waterbodies are a common feature of the rural landscape in southern Lao PDR, playing an important, direct role in the livelihoods of almost all rural households and providing a safety net on occasions of crop failures. Within this landscape, perennial waterbodies are a particularly important source of aquatic resources in the dry season, when ephemeral water resources begin to disappear. Subsistence fishing in small waterbodies is an almost universal activity in Lao PDR and accounts for at least 70% of the fish acquired by rural households (Garaway et al., 2006). While most small waterbodies are available to villagers at all times for subsistence fishing, some may serve as a means to generate village income, with access to these locations being more restricted. The nature of restrictions varies among villages; examples include fishing days, where the waterbody is opened for fishing by particular fishing gears on purchase of a ticket, and organized collective harvesting and sale of fish by a small group selected by the village authorities. Leasing the use rights for a waterbody is also common and provides a means for villages to raise income while passing on the responsibility for organizing the harvesting to the leasing group. Where few alternative places to fish exist, regulations in these income-generating waterbodies may provide opportunities for individual subsistence fishing, albeit with a restricted set of gears.

Commercial income

Harvesting, processing, distribution, and sale of inland fish from wild-capture, stocked, and aquaculture systems generate revenue for people around the world (Fig. 4). For farm-raised fish, income is also derived from the rearing and propagation of commercially valuable fish, in addition to income provided by jobs related to the functioning of the aquaculture facility. The supply chain for

Fig. 4 Inland fisheries provide commercial income. (A) Aquaculture pens growing chambo (*Oreochromis lidole*) in Lake Malawi. (B) Fisher uses gillnets in the Parana River. (A) Courtesy Gretchen Stokes; (B) courtesy Trice Castillo.

inland fish often involves several intermediary actors (e.g., wholesalers, distributors) and serves both local and global markets. Major stakeholders are the commercial fishers, fish farmers, agri-businesses that run aquaculture facilities, other actors in the fisheries supply chain, and fish product consumers. Also, recreational fisheries provide valuable jobs and revenue derived from bait and gear sales, boat rentals, among other associated industries. Members of governance institutions are also key stakeholders and benefit from management and enforcement duties. Such institutions include those related to fisheries management as well as those focused on food quality, safety standards, and environmental quality. It is increasingly difficult for fishers to make a living solely from commercial fishing. Income from small-scale fisheries, in particular, is generally low, especially when the supply chain has multiple intermediaries. It is usually difficult for fishers to obtain a fair price and this generates inequitable value chains. While the dockside prices for many fish species have remained constant over the past few decades, commercial fishing costs have significantly risen. Additionally, commercial fishers often are competing for access to fishing grounds with recreational water users.

Case study: Commercial fisheries of the Laurentian Great Lakes

Commercial fisheries play an important economic and cultural role for coastal communities located along the shores of North America's Laurentian Great Lakes. Lake whitefish (*Coregonus clupeaformis*) and lake trout (*Salvelinus namaycush*) have long been an

important part of the cultural heritage of First Nations and Tribal communities in the region. The abundant fishery resources in the Great Lakes were also a key driver for later European settlement and development of this region. Together, lake whitefish, lake trout, and percids (e.g., walleye *Sander vitreus*) were the commercial fish species most targeted for harvest. Dockside value for Great Lakes commercial harvests landed in Canada peaked in 1988 at approximately CAD 57 million and peaked in the US in 1992 at approximately USD 24 million (Brenden et al., 2013). Since these peaks, dockside value has steadily declined. This decrease is, in part, due to the declining abundance of fish populations as a result of developments in fishing technologies that led to increased fishing efficiency, introduction of invasive species that compete with native fish for resources, and decreases in habitat and water quality, among other factors. Although the current state of commercial fisheries in the region is a specter of what it once was, the activity continues to be an important source of income and livelihoods to coastal fishing communities. These fisheries are often multi-generational enterprises and are deeply embedded in local communities. The fish harvested by these fishing families are generally sold to local restaurants and markets. Great Lakes fish are also sought after by many tourists to the region.

Food and nutrition

Inland fisheries are an important, yet often underestimated, contributor to global food security and nutrition (Fig. 5). Over 90% of global inland fish catch is used for direct human consumption (Welcomme et al., 2010). Capture fisheries provide the equivalent of the total dietary animal protein for 158 million people each year (Funge-Smith, 2018), and are particularly important for hunger and malnutrition alleviation among many of the world's poorest and most vulnerable populations. They also supply a critical source of micronutrients essential for human growth and development, especially in geographies reliant on starches as their primary food source. Proteins and lysine found in fish provide a source of amino acids necessary for growth; vitamins (A, D, B) that are important for cardiovascular health, energy production, vision and tissue growth; and minerals (calcium, zinc, iron, iodine, phosphorus, selenium) that support bone, blood and muscular health (Youn et al., 2014). Omega-3 fatty acids and calcium from consumption of fish meat and bones are especially important for pregnant and lactating women in low-income countries without access to dietary supplements. Storage methods (e.g., dried, preserved) for inland catch can provide year-round food access to nutrients that would otherwise be unavailable. Inland fisheries are also an important component of global food production systems, often serving as a buffer for crop failure or agricultural loss due to pests or certain extreme weather events. Indirectly, livelihoods provided by inland fisheries employment (e.g., fishing, processing, selling) supply income for trading or purchasing food staples and other necessities in the marketplace. Key stakeholders of food and nutritional services include subsistence and small-scale fishers, supply-chain workers (e.g., processors, market vendors, transporters, traders) and consumers of fish or fish products. Aquaculture or agricultural workers may purchase feed for fish or livestock made from fish unsuitable for human consumption. Threats to inland fisheries are numerous: flow modification for irrigation and power generation, introduction of non-native species, habitat degradation, fragmentation, eutrophication, water pollution, and overharvest have all contributed to declines in fish populations worldwide, and thus threaten food security in regions of high nutritional dependence. For example, a 90% loss of fish catch resulted from the construction of two dams built for agricultural irrigation on the Senegal River, and ultimately led to malnutrition without sufficient agricultural food compensation (Pirot et al., 2000). Similar consequences are expected if there is continued unmitigated damming of the mainstream Mekong River (Dugan et al., 2010). In light of a changing climate, recognition of the efficiency and sustainability of wild-caught inland fisheries (e.g., no irrigation, feeding, or land clearing required) is vital, in addition to consideration of the economic and ecological cost of replacing fish protein and micronutrients with alternative food sources.

Fig. 5 Inland fisheries provide essential and cherished food sources. (A) Smoked vendace (*Coregonus albula*) are highly valued in the Lake Peipsi region. (B) Fish for sale, Lake Malawi. (A) Courtesy Aimar Rakko; (B) courtesy Gretchen Stokes.

Case study: Small pelagic fisheries of the African Rift Valley Lakes

Small pelagic fishes, common to East Africa's tropical rift valley lakes, account for nearly three quarters of all fish catch across Africa (Kolding et al., 2019). For example, dagaa (*Rastrineobola argentea*) accounts for 60% of fish catch in Lake Victoria; kapenta (*Stolothrissa tanganicae*, *Limnothrissa miodon*) contributes 60–80% of catch in Lake Tanganyika, Lake Kariba and Cahora Bassa; and muziri (*Neobola bredoi*) and ragoogi (*Brycinus nurse*) comprise 80% of Lake Albert's fish catch (Kolding et al., 2019). The region's small pelagic fish value chain is distinguished by having high yield, high nutritional value, and being ecologically sustainable. Most small pelagic species tend to be short-lived, and highly productive (e.g., replacing harvested biomass up to five times per year). The highly perishable nature of small pelagic fish requires drying, salting, smoking, or frying to reduce post-harvest loss. Unlike larger fish that require more labor-intensive post-processing to remove guts, small pelagic fish can be easily dried on large racks in the sun in just a few days. One major nutritional advantage of this practice is that sun-dried pelagic fish can be consumed whole, thus preserving micronutrients in the head, bones, and intestines of the fish. Sun-dried fish can be stored without refrigeration for months, providing long-term food security for low-income families. Thousands of tons of dried pelagic fishes are traded annually both locally and to neighboring countries via wholesale markets for human consumption, feed production, pharmaceutical and food supplements, and other byproduct uses. Although previously viewed as food for the poor, sale and consumption of pelagic fishes has gained popularity across social classes due to the nutritional benefits and rapid processing time. Remaining challenges in the supply chain include the potential for disease from improper drying, contamination in transport, and limited quality control.

Recreational services

Recreational services supported by inland fishes, which include recreational fishing, snorkeling, boating, photography, and ornamental fish trade, are prominent across the globe (Fig. 6). Estimates of visits for recreational services (e.g., freshwater fishing, enjoyment, photography) to the world's freshwater lakes vary among waterbodies located in different regions, but are, for example, considered high in the Laurentian Great Lakes in North America, Lake Titicaca and the Pantanal in South America, and Lake Toba in Eurasia (Sterner et al., 2020). Riverine fishes and other aquatic biota are also highly valued for recreation, such as the Murray crayfish (*Euastacus armatus*) and Murray cod (*Maccullochella peelii*) in Australia. In addition, flagship species can play an important role in recreational tourism, such as Peacock bass (*Cichla* spp.) in Brazil. Inland fishes provide direct recreational services to a diversity of stakeholders, including fishers and hobbyists, and indirect services to the tourism industry, including boat and tackle shops, grocery stores, lodging, gas stations, and local governments in the form of fishing licenses or access revenue. In the United States alone, freshwater angling contributes USD 41.9 billion to the gross domestic product (ASA, 2018). Despite its importance, recreational fishing is often not evaluated as an ecosystem service or for its socio-economic impact in countries that do not closely manage their inland fishery resources. Given the importance of recreational services to stakeholders in many different regions, management and conservation of inland fishes and biodiversity resources is needed. Threats to recreational fisheries include overfishing, invasive species, pollution, and climate change, among others. Recreational fisheries can also negatively impact freshwater ecosystems, by polluting riparian areas, removing vegetation, or modifying shore areas (e.g., hardscaping for ease of access). Understanding the threats to and impacts from recreational services for inland fishes and biodiversity is key to maintaining and conserving these services.

Case study: Lake Peipsi recreational fishery

Lake Peipsi is a popular recreational area on the Estonian-Russian border. The lake's fish stocks are remarkably high, which makes the lake economically important for both commercial and recreational fishers. Ice fishing (e.g., catching fish with hooks on a frozen body of water) is an extremely popular leisure activity in the region. A typical winter weekend can host up to 3000 anglers fishing on the Estonian side of the transboundary lake, the most frequented area for winter fishing (Orru et al., 2014). The ice fishing period may last from a few days to up to 4 months, depending on how long sufficient ice cover lasts. Ice fishing is defined as a hobby; however, interviews with fishers show that financial gain from the sale of fish is an important incentive for retired or unemployed persons in the coastal villages of Lake Peipsi, where there are few employment alternatives. The landings of winter angling can be considerable in the case of long ice-cover periods, when anglers may fish out approximately 40% of the total annual harvest of Eurasian perch (*Perca fluviatilis*), the most popular target species, roach (*Rutilus rutilus*), and ruffe (*Gymnocephalus cernuus*) from the lake (Orru et al., 2014). The caught fish are used mainly for domestic consumption or are exchanged in a barter economy where they generate some economic benefits. Yet, enjoying nature, relaxing from everyday worries, the feeling of excitement from catching fish, and the company of other fishers were all estimated to be more important to anglers than other benefits (e.g., the financial or food gain from ice fishing; Orru et al., 2014).

Cultural services

Globally, numerous cultural services exist due to the significance of inland fish and fisheries within a community. Unlike provisioning services where there is direct monetary value associated with the activity, cultural services are considered invaluable.

Fig. 6 Recreational services supported by inland fishes are diverse. (A) Winter angling on Lake Peipsi. (B) Brightly-colored cichlids draw visitors to ecotourism in Lake Malawi National Park. (A) Courtesy Peeter Kangur; (B) courtesy Gretchen Stokes.

These include, but are not limited to, individuals experiencing a sense of community through cultural icons, spiritual and religious values, identity as fishers, and the enjoyment of the aesthetic beauty of fishes. The ornamental fish trade for the aquarium industry, for example, is based on the cultural service of the aesthetic beauty that fishes provide. Fish as cultural icons often play multiple roles as artforms, signifying the importance of fish in a society, and as religious allegory. For example, in the Mithila Region of Nepal and India, Madhubani art depicts a distinctive smiling fish which symbolizes fertility and abundance. Just north of this region, Tibetan Buddhism has the *Sernya*, a pair of large golden fish that represents happiness, spontaneity, and freedom of movement (Beer, 2003). In some cultures, fish have been the foundation for their very existence. Consider First Nation Tribes and their deep relationship with salmon, which have shaped their spiritual and ethnic identities (Willard et al., 2020). Cultural services also include aesthetic appreciation and inspirational pursuits (e.g., art, music, storytelling), so any individual with exposure to inland fish and fisheries could be considered a stakeholder. Worldwide, a diverse range of stakeholders have the potential to foster a deep environmental stewardship for the species and traditions they hold dear. In places where human and aquatic resources are intimately linked, cultural values are often overlooked or undervalued (e.g., Lowe et al., 2019). Festivities, traditions, and regionally-specific events that are related to inland fish or fisheries often have little preservation power in the face of larger economic development, such as damming of rivers, or industrial growth.

Case study: Spiritual beliefs and fishing on Lake Tanganyika

East Africa's Lake Tanganyika is a place where fish, economics, and culture are closely connected. The lake sustains a major inland fishery among its four surrounding countries. Here, fishers believe there is a direct connection between their spiritual beliefs and customs and their fishing success. They hold that certain sacrifices, prayers, rituals, and charms influence their fishing outcomes (Lowe et al., 2019). This link between the spiritual world and fishing is what guides fishers in their decision-making regarding the lake's resources, and influences fishery management decisions, regulations, and compliance. Understanding and respecting these connections is a critical component of effective management in these communities, where fishers believe that the health of their fish population is driven by the spiritual world.

Educational and scientific opportunities within fisheries

Because of the diversity of research areas encompassed within fisheries, there is a broad range of educational and scientific opportunities available within the field (Fig. 7). These opportunities range from formal education and outreach (e.g., capacity building among fisheries professionals, mentoring and engaging students in fisheries programs) to community engagement and public outreach among non-fisheries professionals (e.g., via social media outlets, citizen science projects). Key stakeholders for initiating and leading these efforts include local communities, policymakers (at multiple levels of government), and conservation organizations and nongovernmental organizations (NGOs). Some educational opportunities, such as World Fish Migration Day (https://www.worldfishmigrationday.com), were started locally by individuals who wanted to raise awareness of migratory fish species. Due to their efforts, and the importance of migratory fish in communities around the world, World Fish Migration Day has now grown into a global event that occurs every two years and offers a range of educational and outreach opportunities to communities worldwide. People tend to take their local sources of freshwater for granted, due to a lack of education and awareness of the links between the health of freshwater ecosystems and human wellbeing. While some programs are specifically designed for educational outreach, others are one component of a larger program. World Fish Migration Day, International Day for Biological Diversity (https://www.cbd.int/idb), World Water Week (https://www.worldwaterweek.org), and World Rivers Day (https://worldriversday.com), are all examples of focused efforts to raise awareness of a specific topic of concern.

Case study: Wonders of the Mekong Project

Larger education initiatives are often designed to target multiple stakeholders. The Wonders of the Mekong Project aims to maintain the ecological, cultural, and economic integrity of the Mekong River and delta system, a biologically rich system that supports the livelihoods of over 70 million people in East and Southeast Asia (Hortle, 2009). The Mekong faces a wide array of complex challenges from a growing human population and accelerating regional development. The Wonders of the Mekong Project recognizes that education is a key component and uses a multi-faceted approach including educational storytelling, multimedia communication, outreach for children, social media, recognition of community leaders, and community workshops. These efforts are designed to reach a range of ages and audiences on a variety of topics that will promote a sustainable future for the Mekong region. While many of these educational efforts take a passive approach to teaching, other Wonders of the Mekong programs are designed to directly involve individuals in conservation-oriented activities. Community science (also referred to as citizen science) initiatives are an educational method employed by conservation organizations, museums, and environmental agencies, among others, to directly include lay people in a research or conservation program. These efforts train laypeople to make scientific observations, maintain equipment, record data, or provide reports. Through this direct connection with the resource, individuals can gain a deeper understanding of the freshwater resource and serve as an ambassador for the Wonders of the Mekong Project within their own communities.

Biodiversity and ecosystem function

Healthy ecosystems, including natural physical conditions (i.e., floodplain connectivity) as well as functional and structural biodiversity, support sustainably-harvested inland fisheries. Inland fishes support ecosystem function, and the loss or decline of key species can result in disruption of nutrient and organic matter cycling and transportation (e.g., McIntyre et al., 2007). For example, sabalo (*Prochilodus lineatus*) in the Pilcomayo River of South America play a key role in sustaining several subsistence and commercial fisheries as they complete a seasonal migration from lowland swamps to upstream spawning grounds (Baigún and Salazar, 2019). Given that ecosystem roles of inland fishes are often poorly understood, biodiversity itself provides a societal service in the form of functional redundancy, providing "insurance" that ecosystem processes remain intact despite unanticipated species loss or ecological surprises. Key stakeholders include recreational and commercial fishers, consumers of inland fishes, community members who rely indirectly on processes supported by functioning freshwater ecosystems, as well as the resident organisms. Habitat degradation and fragmentation, overexploitation, invasive species, flow modification, inappropriate land use, hydropower, and pollution are primary threats to biodiversity and ecosystem function. Emerging threats range from impacts of climate change to the effects of evolving and growing technologies (e.g., nanomaterials and microplastics) on fishes and habitats.

Case study: The Amazon River-floodplain system

The Amazon River-floodplain is a fluvial macro-system where natural ecosystem function is critical to maintaining many societal benefits. The system is strongly tied to flood pulses and the ecological role of the floodplain. Specifically, floods trigger primary and secondary production in the floodplain by exchanging and allowing the flux of organic and inorganic matter, nutrients, fruits, leaves, fish larvae and seeds, derived from forests and flooded lands. In vegetated floodplain habitats, especially in nutrient- and sediment-rich rivers, lacustrine environments represent the main sources of primary energy production that support the aquatic food chain. Fishes migrate to and from floodplains, increasing productivity in the main channel. Longitudinal movement of fishes also plays an important role in ecosystem function: species migrations provide nutrient transport from mainstem channels to less-productive tributaries, while Amazon catfish migrations restructure foodwebs through the addition or subtraction of a top predator (Winemiller and Jepsen, 1998). The wellbeing of rural people who depend on Amazon River ecosystems is inherently tied to the exploitation of migratory fishes. The main disruptive factors that compromise ecosystem function and hydrological processes relate to 76 existing dams, mostly in the headwater areas (Andes Mountains), with 288 more dams planned for the basin (Latrubesse et al., 2017). In addition, land-use changes associated with gas, petroleum, and minerals extraction coupled with road construction have provoked massive deforestation, affecting water quality and runoff (Leitão et al., 2018). Such combined impacts have led to increased disruption of ecosystem function, loss of biodiversity, and could ultimately threaten the sustainability of fisheries. Further, additional degradation is likely to result in surprising and unpredictable changes to societal benefits as poorly-understood ecosystem processes are fundamentally altered by species loss.

Regulation and indicator of freshwater quality

An indirect service of sustainable inland fisheries is the protection, maintenance, or construction of fish habitat, including environmental conditions, connectivity, and water quality. Freshwater fishes can directly contribute to improving water quality through their role in facilitating ecological processes such as recycling nutrients as happens with migratory fishes in cold temperate rivers or tropical rivers and lakes such as Lake Tanganyika. In addition, an easily overlooked value of inland fishes is their role as ecological indicators. Fish respond rapidly to disturbance and changes in environmental conditions. Given that fish are relatively easily observed as compared to other freshwater indicators (e.g., excessive nutrients or pollutants), fish-derived metrics are often used to shape policy and management. For example, the Index of Biotic Integrity (IBI; Karr, 1991) is a commonly used assessment tool which examines local fish assemblages to identify aquatic habitat perturbations. Key stakeholders include recreational and commercial fishers, consumers of freshwater fish, community members who utilize freshwater resources for non-consumptive uses, and other diverse stakeholders, including regulatory agencies that require simple methods for assessing aquatic environments. Threats include land-use change (e.g., urban, agricultural) that degrades water quality, aquatic environment changes that impact fish communities and exacerbate the effects of nutrient and pollutant loading, and species invasions and introductions that disrupt natural ecosystems. Threats are exacerbated where a lack of support for aquatic environmental management occurs.

Case study: East Kolkata Wetlands

Kolkata, the capital of West Bengal with a population of approximately 15 million, is located in the Ganges Delta. Adjacent to the eastern edge of the city lie the East Kolkata Wetlands, which encompass over 12,000 ha of urban and peri-urban wetlands. These wetlands perform important ecosystem services based on natural ecological processes, including wastewater treatment and food supply, providing the city of Kolkata with around one-third of its daily fish supply. The East Kolkata Wetlands originated as a brackish swamp of the Bidyadhari River. Traditionally the area was used for rice cultivation and subsistence fishing. As the city expanded during the colonial period, challenges with managing human waste increased. The wetlands emerged as a more

eco-friendly sewage management alternative to direct waste disposal in the Hooghly River. Over time, the role of the wetland in regulating water quality has evolved, with up to one million cubic meters of wastewater passing through the wetlands daily (Bhattacharya et al., 2012). The changes in the wetland environment created opportunities to develop wastewater-based agriculture and fish production. Natural processes within the ponds decompose organic wastes and support plankton production and fisheries. Critically, urbanization and the need to regulate freshwater quality have continued to result in changes in the wetland environment and the nature of the fisheries. Diversion of anthropogenic wastewater into the wetland has changed the environment, and the management of water flow and quality has enabled a shift from a capture-based fishery system to one dominated by pond-based aquaculture production.

Regulation of freshwater quantity and natural flow regimes

In lotic environments (i.e., rivers, streams, and creeks), flow regimes shape the structure of the habitat, the composition of the biodiversity, and the ecological processes of these systems. For example, the success of fish spawning and recruitment can be tied to the natural rhythms of flowing waters. Spring floods and flow pulses in temperate rivers often act as an environmental cue to initiate spawning migrations, while sustained water levels in upper reaches of tributaries can help ensure larval fishes have a chance to enter the mainstem of the river or enter a lake or floodplain lagoons before those areas become stranded by reduced flow. Thus, the maintenance of intact and natural lotic environments, including their floodplains, supports healthy inland fisheries. Globally, many stakeholders are interested in large riverine habitats for human benefits such as food provisioning and livelihoods, hydroelectricity, freshwater, flood mitigation, irrigation, transportation of goods, as well as recreational boating and angling. As a result, it is estimated that >75% of the largest river systems in North America, Europe, and the former Soviet Union are moderately or strongly regulated (Dynesius and Nilsson, 1994) and that only 37% of the world's 246 longest rivers remain free flowing (Grill et al., 2019). Given the competition for freshwater resources, there are many threats to the regulation of freshwater quantity, flow timing, and variability, as physical manipulations directly alter the natural flow regime. Impoundments such as dams convert flowing environments to lake or reservoir habitats, disrupting ecological processes and aquatic communities including inland fishes and their prey. Determining how to prioritize interests of competing stakeholders becomes a management challenge.

Case study: Water allocations in the Murray-Darling Basin, Australia

The Murray and Darling Rivers of southeastern Australia are highly regulated to supply diverse stakeholders with critical water resources. For 40,000 years, the rivers of the 1,061,469 km^2 Murray-Darling Basin have been central to the cultures and livelihoods of 40 Aboriginal Nations (Rutherfurd et al., 2020). In the late 1800s, European settlers began developing irrigation structures, and plans for larger storage and distribution projects began after a decade of severe drought starting in 1892. Beginning with the River Murray Waters Agreement in 1914, river regulators have sought to balance the complex water needs among user groups and across legislative boundaries, which includes parts of four states and the capital territory. Today, the Murray-Darling Basin Authority (MDBA) coordinates water allocations among the diverse, and often competing, needs of an AUD 24 billion agricultural sector, an AUD 8 billion tourism industry, 2.6 million basin residents, as well as the environmental needs of fish, other animals, and plants native to the basin, and the cultural flows owned by Indigenous Traditional Owner groups (McLoughlin et al., 2020). In 2012, the MDBA began implementing a basin-wide plan that maintains baseline environmental flows necessary for fish and other aquatic life, establishes sustainable diversion limits, and allocates water rights among user groups. Because the basin has highly variable climate and rainfall patterns, the total allocation of water available to users changes each year, with highest priority given to drinking water supply in times of drought. Critical to the MDBA Basin Plan is the ability of regulators to adapt management to changing user and environmental conditions, as water supply to the basin has declined over the past 20 years.

Synthesis

Inland waters are highly varied and often dynamic. From seasonal watershed inputs to resident fish and human communities, these elements can, and frequently do, change. Most inland fishery services share the characteristic of being highly responsive, for better or worse, to basin management, particularly in transboundary watersheds. Progressively through time, and even seasonally, the services and benefits from inland fishes and biodiversity are different for inland systems. Regionally, these benefits are highly diverse and, in some cases, the benefits can be in direct conflict. Commercial fisheries (i.e., wealth-generating) can frequently be at odds with subsistence (i.e., welfare-motivated) or recreational (i.e., wellbeing-focused) fisheries; recreation and tourism can impact conservation; and introduced species can alter relationships among native fish species. Tensions can arise between the benefits from fish conservation (which can involve *restricting* access) and benefits from fisheries (which usually involves *enabling* access) because inland fishes are a limiting resource. However, most frequently, the threats to all services derived from inland fishes arise from external sectors and sources. Fish biodiversity and fisher livelihoods, for example, both depend on functioning aquatic ecosystems, which in turn are highly dependent on land and water use at the basin scale. Rather than pit the diverse array of services derived from inland fishes and freshwater biodiversity against each other, a unified front can lead to mutual benefits and "win-win" scenarios for all of the societal values (for more, see Phang et al., 2019).

Improving science, policy, and management for these vital societal services provided by inland fishes will require a number of key knowledge gaps to be addressed. The importance of inland fish to food security, nutrition, and economies is poorly known, and likely grossly underestimated. Beyond the fisheries, more information is needed on the impact of climate change and human developments on freshwater ecosystems and the effectiveness of regulations to maintain or improve water quality. The extent to which climate change together with land-use changes will alter the quantity, flow timing, variability, and connectivity of these environments and how resilient fish communities are to these changes is still largely unknown. These science information gaps are particularly severe for smaller-scale inland fishery systems.

Prioritizing these complex problems at a policy level often requires cohesive and comprehensive efforts to educate various constituents about inland fishes, freshwater biodiversity, ecosystem function, and the services they support. Though several valuation studies have been conducted, many policymakers still do not recognize the full economic, societal, and conservation contributions of the societal services provided by inland fishes. For example, the role that fish and fisheries plays in societies are often confined to a specific area or region. Once outside these inner circles, awareness can be limited on how fish are woven into the various components of a culture.

Translating these priorities to management may require a realignment of focus. Much of the current emphasis in fisheries management is directly on the fish and the fishers. The broader social and economic contributions that inland fisheries make, for example, through income generating opportunities and services remains an important gap. Likewise, understanding the cumulative effects of co-occurring stressors on inland fishes and freshwater biodiversity is an ongoing need for sustainable ecosystem management (as is described in the following case study).

Case study: The Pilcomayo River fisheries of Bolivia, Paraguay, and Argentina

Inland systems are often a complex integration of services and reflect the interaction between environmental features and anthropogenic impacts. The Pilcomayo River, a transboundary, free-flowing river crossing Bolivia, Argentina, and Paraguay, and ending in several diffuse swamps, is a notable example where human and ecosystem benefits directly overlap. Both the aquatic life and the humans that live there have adapted to the highly dynamic and seasonal nature of this river. Large amounts of sediment are transported during the summer flood pulses promoting remarkable changes in the river landscape by forming new channels and filling or isolating older ones, while contributing to the flooding of swamps and wetlands downstream. The Pilcomayo River is inhabited by several species of migratory fish, with the sabalo playing a key role in sustaining several subsistence and commercial fisheries along the basin (Baigún et al., 2019). The fisheries are highly seasonal and are strongly associated with the migratory movements during the autumn, when the water recedes into the lowland swamps obligating this species to migrate upstream to reach the spawning grounds in the middle and upper watershed (Baigún and Salazar, 2019). These fisheries play a fundamental role in the food security of poor river dwellers, including Indigenous and local people, and support a well-developed small-scale commercial fishery that has a strong impact on local economies during the catch season. However, the sustainability of the fishery could be severely threatened by reduced flood pulses due to adverse climatic conditions, loss of lowland swamps, mining pollution, channelizations for irrigation, small dams, and dikes (Smolders et al., 2002). Fisheries and livelihoods in unstable river systems such as the Pilcomayo will depend on avoiding alteration of the natural balance between sediment dynamics and hydrological regime to allow fish populations to complete their life cycle.

Conclusion

Inland fishes and freshwater biodiversity may be all around us, but their societal values are still often ignored in important decision-making arenas. Conservation of freshwater resources requires integrating not only different disciplinary perspectives but also improvements in water and land governance. However, freshwater governance is often dominated by other societally important sectors including agriculture, energy, and water for drinking, sanitation, and hygiene. Rivers are often perceived as generating economic activities (e.g., trade, tourism, and transportation) rather than as bodies of water that also generate other valuable ecosystem services, including fisheries. The lack of awareness of rivers as dynamic systems made up of channels and floodplains that need to be interconnected has led to many rivers losing their floodplains in favor of agricultural activities or urban development. Inland fishery services are impacted by these decisions at local, national, regional, and global levels. By joining this conversation, the inland fisheries sector can help increase recognition of the societal values of inland fishes and biodiversity and explore opportunities for improved outcomes for the aquatic ecosystems and the communities that depend on them around the globe (for more, see Cooke et al., 2016).

Societal Values, Water and Public Policy

Carolyn Johns[a] **and Samantha Stewart**[b], [a]Department of Politics and Public Administration, Ryerson University, Toronto, ON, Canada; [b]PhD candidate Policy Studies, Ryerson University, Toronto, ON, Canada

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Catherine Febria and Gail Krantzberg.

Glossary

Ecosystem A geographic area or scale where all living organisms exist together in a network of life.
Environmental rights The right of all living things to natural resources that enable life including air, water, food and shelter.
Environmental stewardship The responsible protection of the natural environment through conservation and sustainable practices to enhance ecosystem health and human well-being.
Human rights Universal rights of individual human beings that are inherent to us all regardless of geography, nationality, gender, ethnic origin, race, religion, language, or any other status.
Hydrosolidarity Multi-dimensional values and ethics for guiding and solving water governance challenges.
Personal values The attitudes and beliefs held by an individual.
Public opinion An aggregation of individual views, attitudes, and beliefs about a particular topic as expressed by a significant proportion of a community or population.
Societal values Collective attitudes and beliefs held by societies at different scales.
Water ethics The philosophical and moral aspects of human relations and interventions with water.
Water footprint The amount/value of water used by an individual, community, business or jurisdiction.
Water governance The social, economic and political arrangements used to value and manage water at various scales.
Water values Economic, social, ecological and cultural dimensions of water and its meanings.

Introduction

Societal values related to inland waters are part of our daily lives. Our daily routines, behaviors, and travels reflect our water values as citizens. Water sustains all life and human existence. People around the world consume and interact with water, want to be near water, seek travel destinations based on water, own property close to water, and have long-standing rituals and sacred relations with water. John Stanmeyer's photography and imagery clearly depicts how water is revered in human cultures and religion across the globe (2010). Photographer Edward Burtynsky's book *Water* (Burtynsky et al., 2013) and films *Watermark* and *Anthropocene* (Baichwal and Burtynsky, 2014; Baichwal et al., 2018) powerfully outline how human values continue to result in behaviors and actions that negatively impact water. Dams, irrigation, drilling for groundwater in aquifers, are all obvious reflections of societal values related to water over the past 100 years.

In the international realm water values and ethics take different forms in different culture and jurisdictions. Humans have complex relationships with water. A paradoxical example is the pilgrimage to the Ganges in India, a river that is spiritual and supports over 400 million people, yet is one of the most polluted in the world.

There are clear conflicts in our values related to water across the globe and at the heart of these conflicts lie water uses and policies. In Western societies, our values, rights and uses of water take the form of rules of use and behavior that ultimately are codified in law. In non-Western societies, they may take the form of beliefs and rights that develop into customs of behavior with the

social sanction of the community (Priscoli et al., 2004). Individual and collective actions are the foundation of different societal water values. Failures to fully value water in all in its different forms and uses is considered a root cause, or a symptom, of the political neglect of water and its mismanagement (WWAP, 2012).

Across the world, there is increasing recognition that societal values and human uses and behaviors related to water are at the heart of improving water governance and stewardship. This increased awareness of the centrality of water values to water governance is reflected in the United Nations 2021 World Water Development Report, Valuing Water (UN, 2021). The inclusion of this chapter and Thematic Section in the 2nd edition of the Encyclopedia or Inland Waters reflects the growing recognition that water values are at the heart of both water science and governance. This chapter reviews the scholarship and developments related to societal water values, water governance and public policy. It begins with an overview of water values and ethics at the global scale. It then reviews various approaches which embody different sets of water values. In this section examples and illustrative cases from inland waters in Canada and the North American Great Lakes region are used to outline the complexity of societal values and the various alternative approaches that underpin water uses and governance related to inland waters. The chapter outlines how many different approaches and values are simultaneously at play in various societies and jurisdictions around the world. Finally, the chapter underscores how human-centered societal values underpin most water governance and policy regimes and how many actors and organizations are urging jurisdictions and policy-makers around the world to take a more values-centered approach to water governance, particularly in the context of climate change, population growth, and unsustainable human uses and abuses.

Societal values, water and policy on the global scale

Water values are becoming centrally important in many societies around the world. Scientists stress how water values will only become more important over time. International organizations and global policy actors realize that the value of water to human beings is increasing. Conflict and crises related to water are evident in both water-abundant and water-scarce regions of the world - in both inland waters within nation state borders and in transboundary regions where water is shared. But what are water values and ethics?

The social value of water resources remains relatively poorly explored and understood because it is abstract (Wu et al., 2019, 74) and includes water as part of ecosystems and values related to supporting human life and uses. Using a social-ecological systems approach (Holling, 2001; Folke et al., 2010), the social value of water is complex and includes physical, social and psychological dimensions which affect social and individual well-being including economic, mental and spiritual meanings (Wu et al., 2019). Water values are also closely bound to culture and reflect beliefs about economic efficiency, social equity and environmental protection, the need to provide for future generations, esthetic and spiritual concerns, the role of government in society, and the human right to water (Gober, 2018, 91).

Water values are held by individuals, groups, cultures and societies. How societal water values are defined depends who is doing the defining, the context, and which change and differ across cultures, communities, space and time. Water values and their interconnections influence decisions made from individual to higher levels of social organization (Euzen and Morehouse, 2011, 239). For purposes of this chapter we use a simple definition, from the 2007 United Nations High Level Panel on Water, *Principles on Valuing Water* report - "valuing water means recognizing and considering all the diverse benefits and risks provided by water, and encompassing its economic, social, and ecological dimensions as well as its diverse cultural and religious meanings" (UN, 2007, 3).

Water ethics focuses on interventions and consequences of human impact on ecosystems of which humans are a part of. The "human factor" in water systems is at the core of ethical considerations (Grunwald, 2016, 12). Scholarship on water ethics has been motivated by environmental concerns and related to the field of environmental ethics (Grunwald, 2016; Stefanovic and Adeel, 2021). Although inherently anthropocentric (Grunwald, 2016), water ethics includes eco-centric principles often included in sets of ethical principles related to water in societies (Groenfeldt and Schmidt, 2013; Grunwald, 2016). Water ethics also focuses on criteria to assess human uses and behaviors and explores the options for more responsible water societies and governance (UNESCO, 2004).

Valuing water is a shared responsibility of us all (Gober, 2018, 91). Generally, there is not a distinction made between societal values related to inland vs. coastal waters, surface vs. groundwater, or values in systems of abundance vs. scarcity. Values are the basis of formulating water policies and clearly reflected in international agreements, domestic laws and policies, and in collective action (Johns, 2021). Societal water values thus include both values and ethics which are reflected in language, arts, discourse, human behaviors, collective actions, international agreements, and public policies.

Since the 1990s there has been 'an ethical turn' (Schmidt, 2011; Groenfeldt, 2019a, b) and there have been increasing calls for a "new water ethic" on the global stage. In the 1992 Dublin Statement on Water and Sustainable Development, the UN formally stated their view that all humans have the right to access clean water and sanitation at an affordable price, introducing a focus on water equity (Whiteley et al., 2008) and articulated several guiding principles for water (WMO, 2018). UNESCO's Ethics of Freshwater Survey in 2000, subsequent *Best Ethical Practices in Water Use* (UNESCO, 2004), and the International Law Association's Berlin Rules on Water Resources in 2004 further advanced the focus on water values and ethics (Dellapenna, 2004). Several UN resolutions also contain value statements and ethical principles for water based on human rights and environmental concerns (Rossi, 2015). Scholars have documented several international developments related to the rising concerns of ethical water issues and several key concepts, such as hydro-solidarity and Integrated Water Resource Management (IWRM) that include principles, values, and ethical dimensions (Matthews et al., 2007; Rossi, 2015; Schmidt, 2011). Hydro-solidarity as a concept features a

growing conviction that human and environmental welfare are inseparably linked (Gerlak et al., 2011, 252). It is a concept that is "all encompassing, multi-dimensional guiding ethic for solving water-related problems" (Falkenmark, 2005: 40) and includes calls for greater dialog around water values, beyond the dominant technical, economic, and political discourse.

Those at the forefront of calls for new water paradigms, values, and ethics generally are calling for more inclusion of social, cultural and environmental values of water – beyond the traditional economic and capitalist market foundations of water values and ethics.

Anthropologist David Groenfeldt, founder of the Water-Culture Institute in the United States and the global coordinator of the Water Ethics Network, has long been an advocate of the need to integrate values, ethics, and Indigenous and traditional cultural values into water governance and policies (Groenfeldt, 2003, 2019a,b; Groenfeldt and Schmidt, 2013). Groenfeldt and many other scholars who focus on water values and ethics, have advocated for a global water charter that "will be applicable at any scale where there is a governance body with decision-making authority" (Water Culture.org, 2014). This work culminated in the recommendation at the 2012 World Water Forum for a global Water Ethics Charter.

The proposed Charter is a moral statement intended to inform and guide public policy. It lays out general ethical principles which are intended as guidance for the development of operational policies and practices in specific contexts (Charter Draft 2.0: 2) (Table 1).

In the draft Charter, several central principles and concepts are articulated including: water ecosystems have inherent rights, and intrinsic value over and above their utilitarian value to people; water is intimately connected to society, forming a socio-ecological system that addresses social needs and provides opportunities; and social arrangements are instrumental for both socially just and economically effective water management. However, there has been no formal advancement of the draft Water Ethics Charter since version 2.0 was developed in 2015.

Around the same time as calls were being made for a global water charter, in 2015 the United Nations launched its 17 Sustainable Development Goals with 169 associated targets. Goal 6 reaffirms a global policy goal of ensuring availability and sustainable management of water and sanitation for all by 2030. In addition to these efforts, in 2015 the Organisation for Economic Co-operation and Development (OECD) Water Governance programme developed 12 water governance principles that were endorsed by OECD member countries. Three key components are at the core of these principles: effectiveness, efficiency, and engagement. Values and ethics are not explicitly part of the principles or the OECD's 36 Water Governance Indicators (OECD, 2018). The OECD's water governance indicators are grounded more in institutions and engagement of interests rather than being focused on societal values, however water vales are implicit in the OECD's reports.

The most recent United Nations latest World Water Development Report (2021) is entitled *Valuing Water* and focusing on the question: what is water worth? (UNESCO, 2021, 9). The report launched on World Water Day in 2021 in several languages, outlines current methodologies and approaches to the valuation of water using five interrelated perspectives (see Table 2).

Although the UN report is very comprehensive, it is not clear if the list in Table 2 reflects a hierarchy of water values. The report does outline that these interrelated perspectives are complex; must be complemented with varied experiences from different global regions; there are different approaches to understanding values related to water; and there are opportunities to reconcile multiple values of water through more integrated and holistic approaches to governance (UN, 2021). The report highlights and details some of the fundamental tensions related to different societal values and uses of water across many different contexts, including contexts of abundance, scarcity and very poor water quality.

Finally, the report itself does reflect dominant Western anglosphere values and perspectives on water.

Despite these important international policy developments and achievements, to date, there is no universal or widely accepted or applied set of values, principles, or ethics related to water policy and decision making for inland, coastal or ocean waters. Scholars

Table 1 Goals and aims of a global water ethics charter.

The aim of this Charter is
(1) to educate water policy makers, water users, and the public at large about their moral responsibilities in making choices which involve water directly or indirectly
(2) to foster an ethical attitude toward water bodies, and in so doing,
(3) to improve water management and governance

Source: Charter Draft 2.0: 1.

Table 2 United Nations *Valuing Water* 2021.

Five interrelated perspectives on water values:
i) valuing water sources (in situ water resources and ecosystems);
ii) valuing water infrastructure for water storage, use, reuse or supply augmentation;
iii) valuing water services, mainly drinking water, sanitation and related human health aspects;
iv) valuing water as an input to production and socio-economic activity, such as food and agriculture, energy and industry, business and employment; and
v) other sociocultural values of water, including recreational, cultural and spiritual attributes.

and practitioners continue to advocate for water values and ethics. The co-edited book entitled *Global Water Ethics: Towards a Global Ethics Charter* (Ziegler and Groenfeldt, 2017) and the recent edited book *Ethical Water Stewardship* (Stefanovic and Adeel, 2021) both contain contributions from international group of scholars calling for water values and ethics to be the foundation of water governance. Entrenched water paradigms and values in societies, economies and political systems across the globe, present significant challenges to embracing a values-centered approach to water governance.

In summary, there has been growing international and scholarly attention to water values, ethics and water valuation. Despite the growing number of scholarly publications and reports by international organizations espousing the virtues of a values-centered approach, sovereignty for water governance remains deeply embedded in the authority of nation states and dependent on human behavior. Across nations and jurisdictions, some laws and policies reflect water values and ethics based on valuing water in its natural, uninhibited, and free-flowing state, but other laws and policies clearly reflect the value that water is something to be controlled as a resource valued primarily for its human and economic uses. As noted in the UN *Valuing Water* report, there are many different approaches to understanding societal values related to water. For purposes of this chapter, the next section reviews some of these and provides illustrative examples and cases from Canada and the North American Great Lakes region.

Alternative approaches to societal values, water and public policy

There is growing awareness that a new set of values must be at the heart of water policy change if societies across the globe are to pursue more sustainable water policy paths and desired end states (Van Nijnatten and Johns, 2020) and a fundamental shift is required away from political liberalism and capitalist values that have dominated societal values related to water for the past 100 years (Schmidt, 2012, 108). There are many different approaches based on different sets of water values in the scholarly literature. It is beyond the scope of this chapter to offer a fulsome review of the various approaches however instead this section reviews some common approaches for understanding societal water values related to inland waters, human behavior and public policy.

Indigenous water values and stewardship

Indigenous peoples hold the view that water is more than a commodity or resource to be managed. Water is life. Indigenous cultures around the world recognize the spiritual nature and inherent value of water. Although water has different meanings across various Indigenous cultures and communities, Indigenous peoples share some fundamental values related to water. Many are associated with spirituality and creation stories. These stories vary from nation to nation, but as a fundamental component of the earth, water plays a central role in each of them. Indigenous organizations and activists have been formally advocating for incorporation of Indigenous values into water policy on the global stage since the Indigenous Peoples' Kyoto Water Declaration at the World Water Forum in 2003. Scholars have also been articulating that "insights from Indigenous communities' more holistic and long-term relationship with water could help define such an ethic" (Norman, 2018, 243).

Internationally, there is also some recognition that a gendered element exists in water values and ethics frameworks. Women in many communities have special responsibilities related to water, yet are rarely involved in strategic and policy decisions on water resource management (Priscoli et al., 2004: 18). Women have a special relationship with water, since, like Mother Earth and water, they have life-giving powers (McGregor, 2012). Honoring water means honoring the fact that water is life, the lifeblood of the land and of Indigenous peoples and cultures (Walkem, 2007: 310–311). For Indigenous peoples, water teaches us that everything is cyclical. It is deeply embedded in key Indigenous worldviews, such as the seventh-generation principle: the recognition that all living things are interconnected. Water bodies need to be valued for their own sake rather than merely for what they can give to humans (Walkem, 2007: 314). "Decisions relating to water must treat it with awe and reverence rather than merely one more resource to be managed, controlled, exploited and used" (Walkem, 2007: 316).

In Canada, over the past 15 years, water problems have been at the forefront of growing awareness of water inequities in society. Tragic water events such as long-standing boil water advisories, the evacuation of Kasheshewan in 2005 due to contaminated water, and the shocking reality that the majority of First Nations communities have problems accessing clean reliable drinking water, have led the UN and several environmental groups and Indigenous groups to demand action and policy change. The Assembly of First Nations and the Chiefs of Ontario have tried to formalize these proposals in formal water statements and declarations (Chiefs of Ontario, 2008; AFN, 2018). Indigenous water activists have made global impacts yet their plight has been very frustrating in term of generating political action in Canada. However, awareness of Indigenous water values is growing (Table 3).

These cases from Canada show a growing recognition that there are "important differences between the philosophies and worldviews that guide decision making in Indigenous and Canadian societies" (Walkem, 2007: 315). Indigenous laws and culture have much to teach us about emphasizing limits to human use, limits to science and technology, and moving beyond short-sighted water policies (McGregor, 2012). Traditional ecological knowledge needs to become more central in water policy (McGregor, 2012). Indigenous values related to water have both advanced thinking about water values and ethics, both by placing a common emphasis on the interconnectedness of water and other aspects of life (Matthews et al., 2007). Norman (2018) argues that a new water ethic based on Indigenous values could incorporate three precepts: (i) treat water as sacred; (ii) consider rights and responsibilities together; and (iii) practice hydrophilia - love and know your waterways (Norman, 2018).

Table 3 Indigenous Water Values in Canada.

Josephine Mandamin and the Great Lakes Water Walks
For thousands of years, Indigenous peoples have held Turtle Island and the Great Lakes as a sacred gift to be respected and valued. The Mother Earth Water Walkers are an example and testament to Indigenous water values. The first water walk by 77 year old Anishnaabe grandmother Josephine Mandamin to raise awareness about water pollution and abuses occurred in 2003 around Lake Superior and covered more than 1300 km. It inspired an annual water walk that seeks to remind people in the Great Lakes region and across Canada about their responsibilities related to water. At the time of her death Josephine Mandamin had walked over 25,000 km and these annual water walks continue to highlight Indigenous values related to water. Each walk works to raise awareness about water and to change the perception of water from that of a resource to that of a sacred entity.
Chiefs of Ontario Water Declaration
In 2008, the Indigenous organization, Chiefs of Ontario released their Water Declaration as First Nations on Turtle Island and occupants of the Great Lakes region from time immemorial. This declaration includes clear statements of Indigenous water values and rights. The text in the document clearly outlines the relations, values, conditions and rights that many of Canada's Indigenous peoples hold related to water. https://www.afn.ca/uploads/files/water/08-10-00.pdf
Indigenous Youth Water Activist Autumn Peltier
At the age of 12 Autumn Peltier Anishinaabe water youth activist and member of the Wiikwemkoong unceded territory on Manitoulin Island in Lake Huron in the Great Lakes, gained national attention when she confronted Canada's Prime Minister Justin Trudeau during the 2016 First Nation's annual meeting expressing her concerns about the long-standing boil water advisories and lack of safe drinking water in various Indigenous communities across Canada and Trudeau's support for controversial gas pipelines. In 2018, at the age of 13, she addressed world leaders at the UN General Assembly on the issue of water protection. Her words on the global and national stage embody Indigenous water values. In 2019 she was named the chief water commissioner in 2019 by the Anishinabek Nation, a position previously held by her great-aunt Josephine Mandamin. She is considered a "Water Warrior" using social media and her voice share Indigenous water values in the world and Canada to change water governance.

In the past several years there seems to be a slow progressive global movement to recognize that Indigenous peoples have much to offer in terms of teaching modern societies about water values. For Indigenous peoples, human rights are secondary to the roles and responsibilities humans should have as caretakers of ecosystems. This societal values approach has different implications for water governance and stewardship than those who advocate for a more anthropocentric approach based on fundamental human rights. This also relates to the UN Declaration on the Rights of Indigenous peoples, which Canada has been slow to adopt but is an important example of the close relationship between land, water and human rights.

Water values and human rights

Over the past two decades, considerable efforts have been made to advance water values and ethics on the international front related to water as a fundamental human right. In 2002, the United Nations Committee on Economic, Social and Cultural Rights adopted General Comment No. 15, stating that "the human right to water is indispensable for leading a life in human dignity. It is a prerequisite for the realization of other human rights" (UN, 2002). In 2010, the UN General Assembly explicitly recognized the human right to water and sanitation through a formal resolution: it acknowledged that clean drinking water and sanitation are essential to the realization of all human rights (UN, 2012) and this approach was also included in the Millennium Development Goals (MDGs).

There is now a substantial literature on water as a human right. As of 2015, some 52 countries had accepted the human right to water and sanitation in their laws and policies (Brunner et al., 2015) and South Africa has the right to water in the constitution. At the core of the human right to water is a normative principle of water access for all (Schiff, 2016), water as a public good, and the view that the state should ensure equal access and citizens have rights to clean water (Prieto, 2021, 11). This human-right-to-water view has an inherently anti-privatization and anti-commodification value set and a core component of the human rights framework is that water pricing and water allocation should be determined within the framework of social equity and the state must ensure equal access and distribution (Prieto, 2021). The scholarship on water as a human right is also closely aligned with the concept of water equity (Whiteley et al., 2008; Goff and Crow, 2014) and includes both individual and collective rights.

This approach consists of inherent human values related to water but is also aspirational in water governance as water rights and access are not equitable. Human rights are not equitable for all people. There is a significant body of literature highlighting how and why water security and access are not equitable in many societies. Those with lower socio-economic means, women, people of color, youth and other marginalized publics do not have equitable access to water (Donoso et al., 2021). The focus on drinking water (Goff and Crow, 2014) has also had negative consequences in terms of equity. In addition, private property is also viewed as a human right and there is an inherent tension between private water values and public water access (Prieto, 2021, 14). In addition, human rights are "ideals to which governments can and should aspire, but they remain just that—ideals—unless states internalize their implementation and take compliance" (Schiff, 2016, 277).

The Canadian case is again useful for illustration purposes. In an excellent case study by Schiff (2016), it is clearly documented that from 2002 to 2012 Canada opposed international moves to formalize water as a human right. Only after years of global pressure and consistent and dedicated lobbying by the Council of Canadians did Canada finally recognize the human right to water in June 2012 at the UN Conference on Sustainable Development (Karunananthan and Willows, 2012). Following this agreement, the challenge was for NGOs to continue applying pressure to the Canadian government in the hopes that it would internalize its international commitments within domestic water policy (Schiff, 2016).

Using the case of long-standing violations of basic human rights to clean water in many of Canada's Indigenous communities and the decades long boil water advisories, Schiff presents compelling evidence that outwardly Canada appears to be complying with its international water rights commitments but upon closer analysis has only superficially, rather than substantively, altered its behavior regarding water provision in Indigenous communities since its 2012 international acknowledgement of the human right to water (Schiff 2016). Despite enacting the Safe Drinking Water for First Nations Act (SDW Act) in 2013, her research provides convincing evidence that there has been a '*masquerade of compliance*' rather than true internalization of an emergent international human rights norm related to water (Schiff, 2016, 278). Almost 10 years later, this remains the case, despite a change in government in 2015, a formal commitment to national recognition and responsiveness to the Truth and Reconciliation Commission Calls to Action, and a formal commitment to eliminating all boil water advisories by 2021. At the time of writing, the landscape in Canada is an evolving one and the Trudeau government has stated that Indigenous engagement will be a key pillar in the establishment of the new Canada Water Agency and the long-overdue update of the Canada Water Act. However, sadly, Indigenous peoples are still being denied a fundamental human right to clean water in Canada.

Societal water values, infrastructure and the built environment

In addition to Indigenous and human rights approaches, there are a number of alternative approaches to water governance based on societal values that relate to core human uses of water, wastewater and stormwater services. Broadly these societal values are articulated related to water infrastructure and sanitation. For illustrative purposes, we highlight three such approaches in this section.

The first approach is what some scholars and practitioners refer to as the necessary value shift required in water governance systems from the 'hard path' to 'soft path'. The hard path refers to water societies and policy regimes that rely on centralized, engineered infrastructure and related decision-making values including: dams and reservoirs, pipelines and treatment plants, water departments and agencies where natural *sources* of water are typically shared, but the *end use* is not (Wolff and Gleick, 2002: 1, 7). Some even argue that this hard path in water policy leads us to an impoverished environment, undemocratic decision making, with growing social, political, and economic costs (Christein-Smith et al., 2013). Other scholars have made water values more central to the soft path arguing the soft path involves social choices and cultural values. In Canada, Oliver Brandes et al. argued over a decade ago that "a new script for water management is emerging" (2007) and that a new set of water values is shifting water policy in Canada from a hard path to a soft path (Brandes et al., 2007: 292). In this perspective, "[s]oft path analyses and strategies are explicitly normative establishing the values of sustainability and equity as social goals and promoting the changes in technology, institutional structures, and personal consumption patterns needed to achieve those goals" (Brandes et al., 2007: 293). While the soft path features some different ideas and values related to water policy and management (Brooks et al., 2009), it does not contain a set of ideas that fundamentally challenge the dominant anthropocentric policy frame that is centered on human use and economic development values. These values are also reflected in both the green infrastructure and "one-water" approaches.

The second approach is generally referred to as the shift from gray to green infrastructure related to uses of inland waters. Gray infrastructure forms the backbone of water systems in many communities and cities across Canada. It consists of engineered systems for managing water and connecting residents, industries, and a wide range of users to water and wastewater systems. Sewage, or used water, is channeled through gray infrastructure to treatment facilitates and then, in most cases, to receiving bodies such as rivers and lakes. These systems, which have been at the heart of water policies in Canada since before Confederation, underpin what Jamie Benedickson has called our "culture of flushing" (2007). In the past 20 years, the concept of green infrastructure has evolved in policy and scholarly discourse and research. Green infrastructure includes a wide range of natural vegetative systems and green technologies that provide many environmental, economic, and social benefits. At the core of this discourse related to water is the idea that a new set of values related to water is central to making the shift from gray to green infrastructure. Faith is placed in small systems, innovative technologies, and green infrastructure installations that reflect a fundamentally different set of water values. A growing literature explores the challenges of using and implementing a green infrastructure approach, particularly given the dominance of gray approaches ossified in policy regimes and evidence that there is not a shift in values occurring but more of a slow integration with gray approaches (Dhakal and Chevalier, 2016, 2017; Johns, 2019).

A third approach is what is referred to as the "one-water" approach (USWA, 2017). It builds on IWRM approaches on the global scale, but attempts to integrate new values related to water use in the future. Similar to green infrastructure approaches, the one-water approach challenges the conventional water paradigm and the dominant paradigm of centralized and siloed systems as well as short-term and fragmented views of water (Mukheibir and Gallet, 2014). The Water Research Foundation in the US has outlined that this approach requires a new blueprint for water users and the water industry by removing the value, technological, policy and management barriers traditionally separating water, wastewater, stormwater, and water reuse (WRF, 2017). The values that underpin 'one-water' approaches are fundamentally conservationist and anti-waste. The approach draws on global models of closed water systems, water recycling, and water-reuse technologies and policies. Recent scholarship on the circular economy is also reinforcing the values of not wasting water and valuing water for multiple and repeated uses, rather than single uses that return water to the natural environment. This approach is also based on faith in technologic futures. The main principle is that humans are stewards who hold some specific responsibilities related to water but that technology offers a new frontier for shifting and improving human uses of water through more integrated and responsible systems.

Economic valuation approaches

Some of the most common approaches to understanding and thinking about societal values related to inland waters stem from economic valuation approaches. Societal values that are more anthropocentric start from the human use values of water. Indeed, the United Nations states that "economics is the most widely applied framework for valuing water" (UNESCO, 2021, 21). There is a voluminous literature on economic and ecosystem services valuations of water. For purposes of this chapter, these two broad approaches to societal values are briefly reviewed in this section.

It is not surprising that the dominant societal water values are fundamentally economic values. In addition to the reality that the major water uses globally and in most nations are agriculture, industry and energy, the global water industry has an estimated value of over US$300 billion (Fidelity International, 2017). The S&P Global Water Index included more than 50 companies from around the world that are involved in water related investment businesses and research indicates that investment in the water industry is motivated by strong historical and anticipated future rates of return through various investment strategies and assets (De Duonni et al., 2019, 109). These powerful economic realities mean that societal values that underpin water economics in capitalist economies are fundamentally based on water use, extraction, technologies, commodification and public and private profits from water.

Societal water values based on economic valuation are inherently based on property rights, land rights, riparian rights, water rights and water entitlements. In the most market-based forms this take the form of tradable rights to access an exclusive share of a water resources, water entitlements and water access that are regarded as assets that have the potential to provide substantial returns to investors (De Duonni et al., 2019, 94). Economic valuations and the wide range of methods used to value water in the world reflect these values (UNESCO, 2021).

In Canada and the Great Lakes region, these historical water rights and values underpin both water quantity and quality policy regimes. They are institutionalized into water governance institutions and policies at all levels (Sproule-Jones et al., 2008). These water values are also embedded in citizen behavior related to water use and for many citizens their primary interactions with water are transactional and economic. There are some important variations in systems of abundance vs. systems of scarcity related to economic valuation approaches that are evident in Canada and other jurisdictions.

In the proposed Water Values Charter, economic water values are included as economic principles that should guide water use. As outlined in Table 4, they incorporate primary human-centric water values but when combined with the other sections of the Charter a more wholistic and ecological set of values is proposed.

There are also some tools that try to enlighten citizens around the values they have for water using the approach. For example, the water footprint is a tool used as an indicator of freshwater use that calculates both direct and indirect water use of a consumer or producer, and can be calculated for a particular product, for any well-defined group of consumers or producers, and for individuals (Hoekstra and Mekonnen, 2012). Tools such as these highlight the increasing awareness that some citizens and jurisdictions have related to their impact on water, and the multi-dimensional value that water has beyond strict economic value.

There is increasing recognition that societal values of inland waters must include both monetary and non-monetary values. This is reflected in the concepts of natural capital, blue-accounting, and ecosystem services. Ecosystems services are the benefits that people obtain from healthy ecosystems (Pardy, 2014). The concept provides both a value-orientation and a methodology for the economic and social valuation of such benefits. Common understanding of the value of ecosystems was greatly assisted by the 2005 Millennium Ecosystem Assessment which provided an essential typology of four categories of ecosystem services (Millennium Ecosystem Assessment, 2005) and the World Resources Institute (WRI) guidance on methodologies for review of ecosystem services.

Scholars and policy practitioners from jurisdictions around the world are using ecosystem service valuations to try to forefront ecological values in systems where economic values of water dominate. Ecosystem services valuation has been used by policy makers and water managers at the transboundary scale as well as at the local scale to force comprehensive reflection and thinking about societal water values related to inland waters. This approach inherently put ecosystems and the ecosystem approach at the heart of water valuation. It also highlights that many societal water values are at play and forces a dialog related to the inherent values that healthy ecosystems provide to humans that need to be recognized and valued properly. While ecosystem service valuation is primarily used by practitioners, when combined with tools such as the water footprint calculator, it can also be used to reveal and assess water values at the individual level.

Water values, public opinion and public policy

Most citizens express the value of water in their daily lives and recognize the value of water to their individual health, their livelihood, their communities, national identity and global well-being. Public opinion research reflects these social perceptions and

Table 4 Economic principles and water use.

Water Ethics Charter economic principles which should guide water use:
• User-pay and polluter-pay principles;
• Principle of cost-recovery for water services;
• principle of fair, transparent, and efficient financing arrangements for water-related investments;
• Principle of monitoring and sharing information about the status of water stocks (feeding into the principles of education and knowledge governance).

Table 5 Key findings from Canadian water attitudes survey.

Highlights from the 2017 National Survey

- Almost all Canadians (93%) "strongly agree" (59%) or "somewhat agree" (34%) that access to water is a human right
- 45% of Canadians continue to view freshwater as Canada's most important natural resource
- More than half of Canadians "strongly agree" that water is an important part of Canada's national identity
- 60% feel freshwater is very important to Canada's national economy; another 34% say it is somewhat important
- 79% are "very" or "somewhat" concerned about water conditions on First Nations reserves.
- Nearly half of Canadians "strongly agree" that commercial enterprises should pay the full cost of delivering and treating the water they use (49%) and obtain licenses for groundwater use (48%), and that there is a need for stricter rules and standards to manage water use by industries and municipalities (45%)
- Canadians feel they are individually making reasonable efforts (86%) to conserve freshwater
- 92% think that developing stricter rules and standards to manage water use by industry and municipalities is the best way Canada can better protect and manage freshwater

Table 6 Societal water values: the Great Lakes case.

- 90% of respondents indicated it is very important that the health and water quality of the Great Lakes basin be protected
- 35% felt governments should be responsible for protecting the lakes; with 29% indicating responsibility should be shared by all (governments and individuals)
- 84% indicated the very important role of individuals and households in protecting the health and water quality of the Great Lakes
- 59% felt there are too few rules, regulations and actions in place to protect the Great Lakes
- 51% indicated they would be willing to pay more to protect the lakes if it resulted in higher costs of consumer items;
- 25% indicated they would be willing to pay $20 more per month on their water bill to protect the Great Lakes; but 30% indicated they would not be willing to pay more
- 46% indicated they use the Great Lakes for leisure or recreational purposes each year; with 91% indicating it is very important that the lakes are of sufficient quality for leisure and recreational purposes
- 80% indicated actions should be taken now to ensure the health and water quality of the lakes for future generations

values around the world. Unfortunately, the World Values Survey does not include any questions related to water values (WVS, 2021). However, there are many public opinion surveys and polls that do try to gauge human values related to water. Two examples will be reviewed in this section: the Canadian Water Attitudes Survey and the Great Lakes Regional Poll.

For 10 years the Royal Bank of Canada, under its Blue Water program, conducted national surveys of Canadians about their values and perspectives on water. Consistently Canadians reported that they significantly valued water. As outlined in Table 5, the vast majority of Canadians feels water is a human right, that it is one of Canadas most valuable natural resources, that they are concerned about water inequality related to Indigenous peoples and water is central to the Canadian economy. Significant numbers of Canadians also feel governments play an important role in regulating water use and leading water protection. Although the RBC discontinued this poll in 2017, more recent polls of Canadians as residents in the Great Lakes region show these values related to water also hold in the shared context of the Great Lakes region.

A poll of 4550 residents of the Great Lakes region indicates citizens place a high value on the water quality of the lakes. As outlined in Table 6, high percentages of residents feel it is very important to protect the lakes, both governments and citizens are responsible for the lakes, and that they value the economic and recreational benefits provided by the lakes.

The poll also asked many questions about issues facing the lakes and provides some interesting insights into water values, ethics, and behavior. Residents reported most concerns with pollution (41%), invasive species (18%) and algae (8%). Although respondents clearly view individuals, governments, and industry as having responsibilities for water in the Great Lakes, there is not a lot of knowledge about how their own values and behaviors connect to the protection and state of the lakes. However, some populations seem to have particularly high levels of awareness grounded in a different set of values. The IJC's most recent poll included 500 Indigenous participants. Survey results show consistent and strong support for Great Lakes protection as well as high levels of awareness of the lakes and the issues affecting them. Some 49% of Indigenous respondents reported that the ways they engage with the lakes were threatened because of the poor health and water quality of the lakes (IJC, 2021).

Societal values, water and policy: Knowledge gaps

From this review of some of the alternative approaches to understanding societal values related to inland waters it is evident how societal water values are critically important in water science, governance and stewardship. As outlined in the sections above, many organizations and coalitions around the globe are in favor of developing new principles, guidelines, charters, and standards to support different water values and better water stewardship. There have been increasingly calls for making water values and ethics more central in water governance and policy at the global scale (Groenfeldt, 2019a, b; Stefanovic and Adeel, 2021) and in countries

Table 7 Six imperatives for a new water ethic.

1. meet basic human needs to enhance equity today and for the future
2. safeguard ecosystems by allocating sufficient water resources
3. encourage efficiency and conservation of water resources
4. establish open and participative decision-making processes
5. respect system complexity and emphasize precaution
6. 6. see multiple sustainability benefits from water centered initiatives

Source: Matthews, C, Gibson, and Mitchell B (2007) Rising waves, old charts, nervous passengers: Navigating toward a new water ethic. In: Bakker K. (ed.) Eau Canada: The Future of Canada's Water, 335–358. Vancouver: UBC Press (353).

such as Canada (Stefanovic and Adeel, 2021; Johns, 2021). The main knowledge gaps relate to deepening our understanding of the importance of water values and how they vary across societies, cultures, and watersheds. A secondary knowledge gap is learning more about how societal values interface with governance and public policy.

A values-based approach requires some faith that our beliefs may legitimately change over time, with new knowledge and evidence. Groenfeldt and Schmidt argue several policy approaches can be used to integrate a values-based perspective into water policy and enhance "explicit attention to underlying values" (2013:14). One fundamental step toward such change is to make values an explicit part of policy processes and discourse. Charters and statements are viewed as a way to align individual, organizational, and broader policy goals. If used as part of a broader values-based approach to policy development, implementation, and evaluation, they can be the source of what Groenfeldt and Schmidt call a more "explicit attention to underlying values" (2013).

In Canada, scholars such as Matthews et al. (2007) argue that there are some basic components of a new water ethic. Based on the scholarly literature, they argue six imperatives from the literature that must underpin a new water ethic (Table 7).

They argue that a new water ethic in Canada must be "incorporated into mainstream legislation and regulation, policies, programs, and project planning decisions so that, gradually, these underlying ideas become the assumed normal framework for water-related choices" (Matthews et al., 2007: 353). However, they also note that "a new water ethic is no magic wand" (2007: 355). There is very little evidence that Canada is explicitly placing water values at the heart of water governance and policy (Johns, 2021), although the recent federal government's announcement of its intention to create a Canada Water Agency and year-long public consultation has clearly generated some important discussion about water values in Canada, particularly related to Indigenous peoples and values.

One of the most common ways for policy practitioners to incorporate a values-based approach in everyday discourse and decision-making is through the use of a values lens. Lenses require policy practitioners to explicitly view policy from a certain perspective. They tease out underlying values that are embedded in policy processes, language, and documents. The water footprint and ecosystem services valuation approaches and tools discussed above are examples. Another example is the Water Culture Institute's Ethics-Based Decision Support Tool for guiding technology, policy, and investment decisions in the water sector (Water Culture.org, 2016). "It is intended for cities, watershed, and river basins, but could be applied at any level. Through a process of interviews and facilitated workshops, water stakeholders are guided through a process to document their priority values about local water and water ecosystems. The tool orders these values into a systematic framework, which can then be incorporated into existing local water governance arrangements" (Water culture.org, 2016). Another example is the Water Culture Institute's Handbook for Crafting a Local Water Ethics Charter (Water Culture.org, 2017).

The development and use of such tools are based on the assumption that policies are more likely to be developed, adopted, and implemented successfully when a values-based approach is used that engages a diverse set of policy actors with different sets of water values in dialog. The potential exists to develop similar tools to move toward more reflection, discussion and knowledge about current water values to improve water policy outcomes and governance in the future.

Conclusions

There are numerous, and often competing, ideas and values related to water globally and in different jurisdictions. A review of some alternative approaches in this chapter highlights that in any given society or jurisdiction, there are multiple values and approaches at play in the public debates, discourse, science and policy. The illustrative examples and cases from Turtle Island, specifically Canada and the Great Lakes region, highlight how these different, and often competing, values co-exist and underpin water policy. This review also highlights how there is a need for values to be reconciled, and the trade-offs between them resolved and incorporated into more equitable water governance and decision-making processes. No water governance systems and public policies are value neutral and a focus on societal water values related to governance and policies in various jurisdictions and watersheds reveals the complexity of water values.

A focus on water values and ethics explicitly recognizes that different governance constellations have the effect of legitimating certain normative positions while undermining others (Schmidt, 2012: 61). Some argue that the true driving forces behind water

governance and management are always economic and political powers, and that any attempt at change will not be successful (Rossi, 2015: 100). However, a societal values-based perspective places some faith in policy change and the central role of values in fostering that change, whether gradual or radical. Public policy scholars have demonstrated that by focusing on who participates in policy discourse, which existing ideational policy frameworks and values are dominant, and how alternative ideas are ignored or marginalized in the policy process, practitioners and scholars can become more aware of the ideas and values that are institutionalized in public policies and overcome barriers to policy change (Roe, 1994; Schmidt, 2008, 2011). Water ethics scholars affirm that moving toward a new water ethic requires "understanding the ethics we have" and making a concerted and intentional effort to incorporate more and stronger ethics into policies. It requires "defining the ethics we want," "making ethics explicit," and "comparing and debating competing ethical paradigms" as key parts of moving toward alternative water values and a new water ethic (Groenfeldt, 2019a).

The imperative of centering water values in governance and public policy will only become more important. Future water stress, crises and conflict, climate change and digital water futures are going to make societal water values increasingly significant. Reductions in time and space will also make water values more global. The way forward, therefore, will be to further develop common approaches to valuation where feasible, but also to prioritize improved approaches to compare, contrast and merge different values, and to incorporate fair and equitable conclusions into improved policy and planning (UN, 2021, 1). Effective water governance acknowledges competing values and adjudicates public disagreements about the meaning, purpose, and value of water (Gober, 2018, 91). By examining societal values related to inland waters on which humans and ecosystems depend, water governance systems will be better able to learn and adapt to looming water challenges.

The long-term success of governing inland waters will depend on how water values and equity are integrated into future water governance approaches.

Knowledge gaps/future research

This chapter attempts to make a contribution to broadening the study of inland waters at the interface between water values and public policy. There is also considerable scope for future interdisciplinary research that might focus on:

- intersectional approaches to valuation, policy and equity
- social and environmental justice related to water values
- Analysis of water laws and legislative values in specific jurisdictions
- comparison of water values across regions and watersheds
- water values related to coastal waters and oceans
- how water values may vary related to surface and groundwater
- analysis of water values in global public policy and international organizations
- the interface between societal water values and science
- Indigenous water values and knowledge

Glossary

Adaptation An incremental change that allows the system to retain its basic functions and characteristics.
Adaptive cycle The cycle of development and decay of a social-ecological system over time.
Anthropocene An unofficial geological epoch, referring to a new human-dominated period of the Earth's history.
Complex adaptive system A special type of system that is complex (i.e., it is made up of multiple interconnected elements) and adaptive (i.e., it has the ability to change and learn from the experiences).
Equity Fairness in access to and use of natural resources, and also in their decision-making.
Governance A set of actors and formal and informal mechanisms to coordinate a social practice towards a collective goal.
Human agency Ability and power of individuals to think and act independently and to make their own free choices.
Management Day-to-day actions and decisions to conduct or supervise a system.
Panarchy A nested set of adaptive cycles that influence each other.
Persistence Capacity of a system to resist change and maintain the same functions.
Power Ability to take part in and influence decision-making processes.
Resilience Capacity of a system to absorb disturbance while maintaining its essential structures, functions and identity.
Social-ecological system Integrated system in which human society, and its multiple cultural, political, social, economic, institutional and technological expressions, interact with ecosystems.
Transformation Radical change to shift a system into a new state.

Introduction

Water issues are largely issues of governance (Rogers and Hall, 2003; OECD, 2011). That is, the decisions we take to set directions for, and manage, water resources have enormous implications for water quality and availability. A system can be pristine, but if poor direction-setting and day-to-day management occur, over time that system will likely degrade. Similarly, a freshwater system with serious challenges may be improved with consistent decisions that have a positive impact. In this chapter we focus on freshwater governance and management from an integrated social-ecological systems perspective, and how it connects to the concept of resilience.

An integrated social-ecological systems perspective on water systems

Humans are undoubtedly having unprecedented impacts on ecosystems, and this includes freshwater systems (Steffen et al., 2007). Geologists are contemplating a decision to deem our current time the era of the Anthropocene, acknowledging that humanity has become a major force for global change (Lewis and Maslin, 2015). We see the impacts of humans on freshwater systems in many ways, including pollution, distribution and availability, the rise of invasive species and habitat degradation. Humans are closely interconnected with freshwater systems-we recreate in them, we draw on them for our needs, we build in them, next to them, we enjoy their beauty, we redirect water, add to it, take away from it. These interactions are just that—interactive. Recognizing that human and ecological systems are highly interconnected, we can refer to them as 'social-ecological systems' (Berkes and Folke, 1998; Colding and Barthel, 2019). Freshwater systems respond to our uses and impacts and change, which causes us to respond to those changes, and so on.

Complex adaptive systems

Social-ecological systems—that social and ecological systems are highly intertwined and are constantly interacting—represent a type of complex adaptive system. 'Complex' refers to the many parts of a system and the interactions both within the parts of the system, at a range of geographic extents and institutional levels and across time. These interactions can have unpredictable outcomes. 'Adaptive' means that the system is capable of changing in response to interactions, including purposive actions by humans to adjust to changing conditions, so that the system behavior as a whole is determined from the many interactions among the parts of the system, both human and ecological. This behavior is not always consistent over time—a major disturbance can have impacts that result in a re-organization of the interactions within the system—but interactions are path dependent. Path dependency means your current behavior is dictated to some extent by previous behavior. For example, we are more likely to sit in the same seat in a classroom over repeated visits than to change seats each time we enter the room. Understanding freshwater systems as complex adaptive systems is critical to how we define resilience and the suite of options we see as possible for freshwater system governance (Biggs et al., 2012; Bohensky et al., 2015).

Social-ecological systems example: Wetlands and agriculture

Let us consider an example (adapted from AgWeek, 2012) to help illustrate these concepts: A farmer drains a series of wetlands to convert them into agricultural land and to therefore increase crop production. The water that would have accumulated in those wetlands is now distributed across the surrounding area. In the following year, the farmer's land and surrounding fields experience more flooding which negatively impacts crop yield. The farmer, after a few years of consistently wet land, decides to install physical infrastructure to create better drainage for the land to support crop production. Now, the water flows very quickly off the affected land and floods an adjacent field. The farmers of adjacent land also put physical infrastructure in place to drain their land and as a result, periods of wet weather result in very substantive releases of water from these fields, which greatly increases flooding downstream. This new flooding prompts the region's government and residents to come together and discuss ways to mitigate flood impacts by managing water releases from their individual fields. As long as farmers work in a coordinated way (in deciding for example about the timing of water releases), flooding is minimized.

From the above example, it is clear that human / social systems and freshwater systems are closely connected and interact, with feedbacks influencing future conditions and decisions. This way of thinking about the relationship between humans (and the social system within which they operate) and ecosystems is called a 'social-ecological systems' perspective.

When we view freshwater systems as being interconnected with social systems, then the importance of our decisions and actions becomes clear. And, the ways in which we act, who we involve in decision-making, how the decision-making process is structured, and the flexibility to adapt or transform how we interact with freshwater systems are all critical to the quality of those social-ecological interconnections. The remainder of this chapter will describe current understandings of freshwater management, freshwater governance and finally, freshwater resilience as an overarching concept that requires appropriate management and governance in social-ecological systems and in light of our potential entry into an era defined by human impact on the planet.

Water management and governance

Decision making and actions related to freshwater are called 'management' and/or 'governance'. Freshwater management is defined as "the activities of analyzing and monitoring water resources, as well as developing and implementing measures to keep the state of a water resource within desirable bounds." (Pahl-Wostl, 2015, p. 27). Freshwater governance consists of the formal and informal institutions and processes by which multiple actors work together to set rules for water (and to set desirable outcomes) (Rogers and Hall, 2003; Lautze et al., 2011). Governance is a more encompassing concept than government. Governance includes government as well as informal and non-governmental mechanisms. Water governance is defined as "the social function that regulates development and management of water resources and provisions of water services at different levels of society and guiding the resource towards a desirable state and away from an undesirable state." (Pahl-Wostl, 2015, p. 26). In essence, it sets the directions or scope of work for water management. A boat analogy can be useful to understand the difference: management is like the rowing or propulsion mechanism, while governance is like the steering mechanism or direction setting towards a collective goal. The two work

hand-in-hand to maintain a desirable trajectory. Likewise, governance and management work together to impact (positively or negatively) freshwater systems and their trajectories. However, the boundary between management and governance is much less obvious than the distinction between rowing and steering. Actions and decisions blur the line and so we bring these terms together for the purpose of the chapter and refer to both together as 'water governance' from here forward, recognizing that this broadly refers to the actions and decisions that impact freshwater systems.

What is 'good governance'?

Governance is generally assumed to exist for the betterment of society. Early approaches to water governance emphasized the role of government and regulation for solving problems. These approaches are referred to as 'command-and-control' and tended to work well in situations where there was a defined issue (e.g., a pollutant entering a waterway) and a known source (e.g., an identified polluter with a specific location of pollution). However, many freshwater issues are complex (that is, they have multiple component parts that interact in sometimes unpredictable ways, and no one person or entity has full information/knowledge about them) and approaches that focus only on government decision-making and action are considered insufficient to address complex issues (Holling and Meffe, 1996).

There is no one definition of good water governance. However, there are generally accepted conditions that are exhibited in good governance approaches. These include: participation and inclusiveness, openness and transparency, accountability and integrity (corruption control), predictability provided by the rule of law, efficiency and effectiveness, and adaptability (Rogers and Hall, 2003; Lautze et al., 2011; Jiménez et al., 2020). Good water governance recognizes that no one authority or person has the potential to fully understand freshwater systems, and that meaningful participation by a wide range of actors (e.g., governments, civil society, private sector, Indigenous government) benefits governance outcomes. Further, addressing issues at the level in which they occur while coordinating with other decision-making bodies within and across levels of organization (e.g. from local to international)—called polycentric governance—is usually desirable.

How governance is connected to resilience

Resilience, as used here, has its roots in ecology. Buzz Holling, widely considered the originator of the concept within this field, used resilience originally as a way to explain and understand the capacity of ecosystems to persist within a specific state despite changes, or disturbances, to the system (Holling, 1973). From this initial thinking, resilience has expanded to the consideration of how humans, or social systems, interact with ecosystems (that is, a social-ecological system). 'Social-ecological resilience'—the application of the concept of resilience to social-ecological systems—is now its own topic of study and lens in which to view systems generally, and water systems (including freshwater systems) more specifically. Governance is a core consideration in resilience when we approach it from a social-ecological systems perspective because the processes of decision-making and the structures we as societies have created to do so (both formal like governments and laws and informal like networks of individuals with similar interests and unwritten rules of social behavior) have enormous implications for how freshwater systems function, and are affected by ecosystem dynamics. These feedbacks occur in ongoing cycles, leading to the building or degrading of resilience (Gunderson and Holling, 2002). Governance processes and structures that support social-ecological resilience include:

- Inclusive participation in decision-making, considering diversity and equity.
- Effective and strong leadership.
- Polycentric governance (described in more detail in Section "Resilience principles").
- Consideration of social memory (i.e., the accumulated experiences and knowledge within the system to cope with uncertainties and to build resilience).
- Capacity for self-organization (i.e., the ability of actors in localized interactions to form emergent 'order').
- Adaptable and flexible decision-making processes and institutions.
- Precautionary risk management.
- Inclusive considerations of system needs, benefits, and tradeoffs (Plummer et al., 2014; Plummer and Baird, 2020).

We will address the multi-faceted nature of resilience first, then how systems build and degrade resilience over time in the following section.

Resilience definitions and principles

Resilience, ultimately, is about how 'disturbances' (i.e., changes—whether known or surprising) affect the social-ecological system. Disturbances can be planned, for example, a policy decision made by a government that has impacts on freshwater systems such as expanding or contracting wetland protections. Disturbances can be surprising, for example, an extreme weather event that was not predicted that has major impacts on shoreline erosion. Disturbances can also be acute (quick to occur and short-lived) or more chronic in nature (slower to emerge, lasting a longer time). Further, disturbances can occur, and have impacts on, multiple levels,

from local to global. For example, a single occurrence of an invasive species introduced to one location in a freshwater system such as the Great Lakes may have much larger impacts on the system if the conditions are conducive to their propagation. Conversely, decisions made at a national level about programs or funding may have very specific impacts at the local level. Due to the complex nature of disturbances (their variety, predictability, and durability) and their impacts, it is difficult or impossible to predict all disturbances and plan for them. However, thinking about freshwater governance in terms of resilience offers a way to manage uncertainty and surprise, and to deploy coping mechanisms.

Definitions of resilience

Resilience has different interpretations depending on how you answer the question: 'Resilience of what?' (Walker and Salt, 2012; Rodina, 2019). If the focus is on, say, infrastructure within a system (e.g., a dam), then resilience is likely about withstanding or resisting disturbance. This is what is commonly referred to as 'engineering resilience'. If the focus is on communities (e.g., a specific group within a city) then resilience is likely about persisting despite, or adapting to, disturbance. This is referred to as 'community resilience'. There are many different ways to answer the question 'resilience of what?' and several definitions of resilience that address the diverse interests in it. In this chapter we focus on the resilience of social-ecological freshwater systems (a type of complex adaptive system) and so we adopt a definition of resilience that is consistent with that focus: the ability of social-ecological freshwater systems to persist, adapt or transform in the face of constant, and sometimes surprising change, in order to continue to support human wellbeing (Plummer and Baird, 2020; Folke, 2016).

Resilience terms

In the definition of resilience above, we use the terms 'persist,' 'adapt,' and 'transform.' Each of those terms are explained in turn here (Baird et al., 2020a):

Persistence: the capacity to resist change (that is, absorb or withstand stresses) as a result of a disturbance. The goal of persistence is to maintain the same functions of the system post-disturbance as existed pre-disturbance. For example, several Areas of Concern (rivers and watersheds where water quality has been substantially degraded over time) within the North American Great Lakes have been 'remediated' to a previous standard of water quality through government-initiated Remedial Action Plans (Hartig et al., 2020; Baird et al., 2020a).

Adaptation: the ability to adjust or change how a system responds to disturbances in order to maintain the same functions over time. These changes are usually incremental in nature and meant to maintain the current system, which distinguish them from transformations (below). For example, the Saint John/Wolastoq River Basin that extends across parts of Quebec, Canada and Maine, United States and much of New Brunswick, Canada is a stressed watershed that still provides well-being to people and contributes to ecosystem health. The system requires additional adaptive capacities to continue to provide well-being over time, and especially in light of increasing impacts of climate change (Baird et al., 2020a).

Transformation: major shifts in how resources, authority and power are structured and interact within a system, usually in response to a major disturbance that makes the current system structure no longer feasible to maintain. Transformations represent a holistic re-organization or the system, everything from people's values and beliefs to how decisions are made to how societies connect with ecosystems are changed. An example of this is the Cowichan Watershed in British Columbia, Canada, where system-level change is being actively pursued to manage the watershed differently, emphasizing Indigenous authority and preparedness for the surprises that climate change is likely to impart (Cowichan Watershed Board (CWB), 2018; Baird et al., 2020a).

Depending on the system's ability to function in a way that provides human wellbeing (including long-term ecosystem health), there may be one of these goals: persistence, adaptation, or transformation that becomes most important. Resilience can be built or shaped in ways that supports these goals.

Resilience principles

What is social-ecological resilience as it relates to freshwater systems and governance? There are seven principles that are important to resilience (Biggs et al., 2012). A few notes are worthwhile here: first, that these principles relate to the social-ecological system. The focus of this chapter is on freshwater system governance and so the explanations of the principles were developed with governance as the focus. Second, that these principles have somewhat fuzzy boundaries: there is some overlap and certainly relationships among them (e.g., such that increasing one principle also increases another) (Biggs et al., 2012). A graphic illustration of the principles is presented in Fig. 1.

1. *Maintain diversity and redundancy*: Diversity refers to the variety of elements and their relative abundance within the system, while redundancy refers to overlap in terms of the functions of those elements. These two concepts seem to oppose each other but actually work together. Diversity and redundancy working hand-in-hand provide options for how to respond to a disturbance. For example, if there are multiple non-governmental organizations (diversity) working to conserve a wetland area, and their work overlaps somewhat (redundancy), then if one or two lose their funding (disturbance) then conservation work continues and other non-governmental organizations may be able to address the gaps left by those organizations that lost funding.

   However, very high levels of diversity and redundancy can reduce the effectiveness and efficiency of governance, and even undermine resilience. High diversity increases the complexity (e.g. more groups involved in governance) and potential difficulty in responding to changing conditions, and high redundancy means a lot of overlap in governance roles and responsibilities which can be costly. Conversely, low diversity and redundancy mean that there are fewer response options and adaptation to change may be difficult. Accordingly, a balance must be struck.

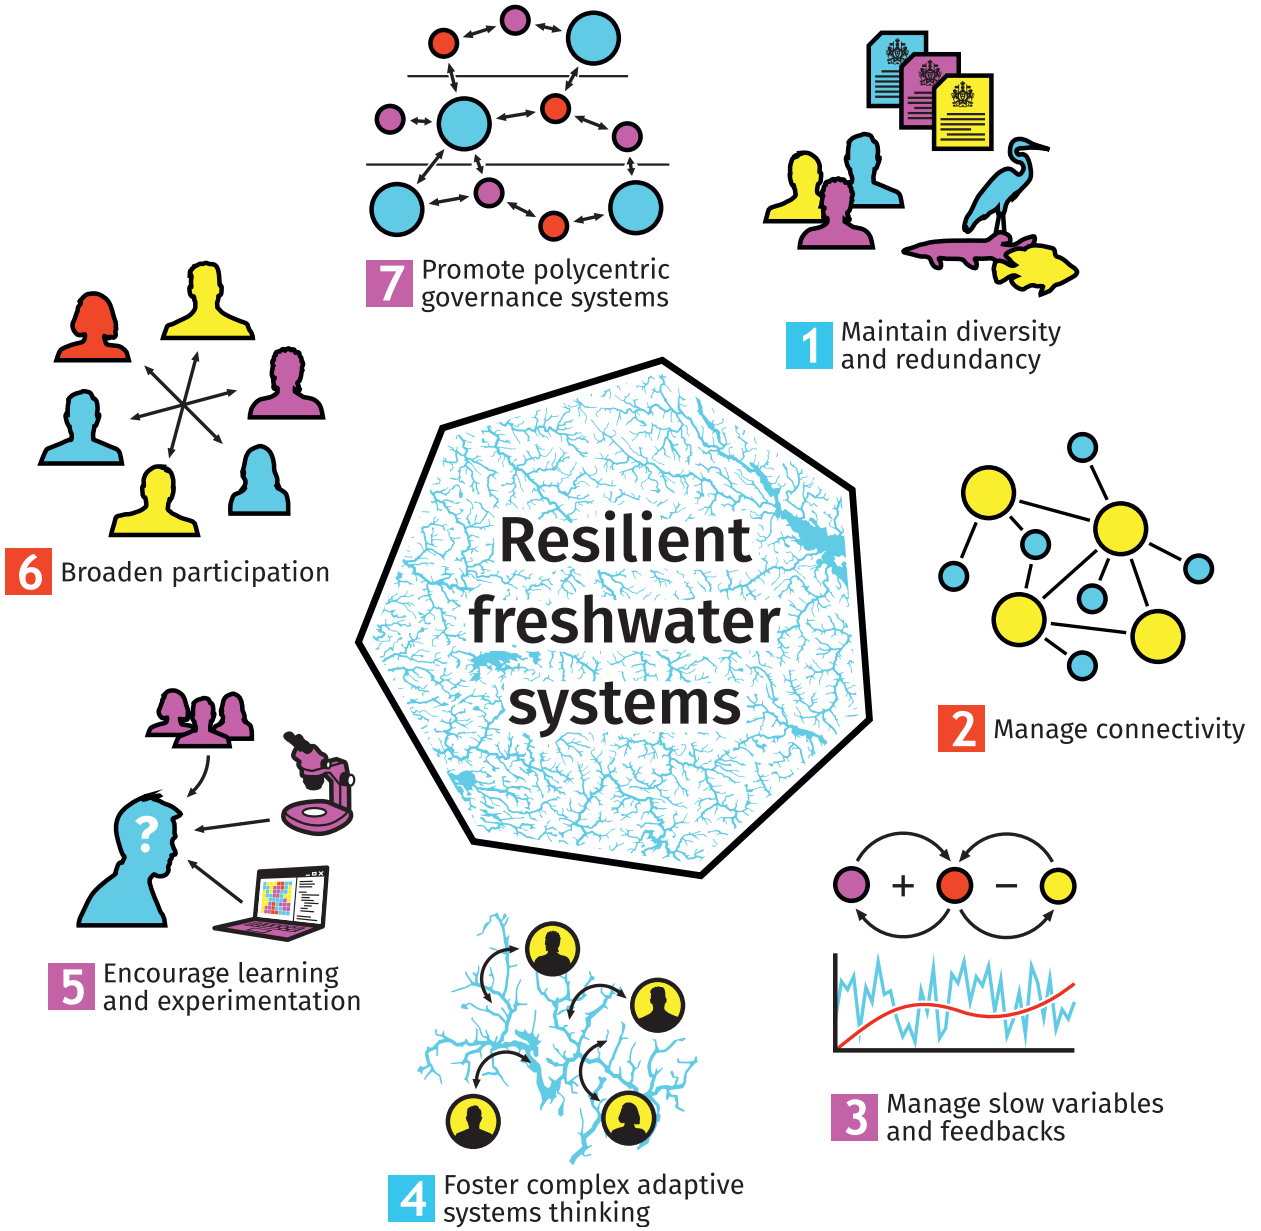

Fig. 1 Resilience principles as they relate to freshwater systems (created by Jesse Reib).

2. *Manage connectivity*: Connectivity is the structure and strength of interactions or relationships among parts of the system. We can think about this in terms of a network where connections can relay information (credible or not), support collaboration, and result in learning, among other functions. When considering freshwater systems as complex adaptive systems, it is important to build (and manage) connectivity among groups (decision makers and others with a stake or rights to the system) to enable better understanding of the system and decisions for its governance. No one perspective is sufficient to govern freshwater systems in isolation because they are complex. Further, connectivity across levels (from local to watershed and beyond) is important to ensure that local issues are represented at higher decision-making levels and that policies and programs developed at higher levels do not have adverse consequences at lower levels. Finally, more connectivity is not always better. Depending on the specific system and context, more or less connectivity may be needed. Too much can hinder the ability of new ideas to enter the network and create a rigid and self-reinforcing network of communication. Too little can result in a fragile network where communication and ideas do not flow between those who would benefit from being connected.
3. *Manage slow variables and feedbacks*: Slow variables are just that, variables that change slowly—so slowly, in fact, that the changes may not be noticeable. However, incremental changes can accumulate over time and suddenly have major impacts on a system. An example of this is incremental changes to the legal system, that on their own have little impact on freshwater conservation. Over time, however, these incremental changes may lead to an opportunity for a private company to exploit freshwater in a way

that was not possible before. Monitoring changes in slow variables is one form of feedback, as it ensures that knowledge of changes is kept current and provides the potential for assessing change over time. Feedbacks are the interactions between the slow variable and other system parts that lead to further changes in the slow variable. In the example above, a feedback might be an environmental watchdog group that reports on changes to the legal system, which might lead to heightened public concern and potentially reversal of decisions. Governance of slow variables and feedbacks requires connections to other resilience principles: broadening participation in governance to access relevant knowledges about the system when making decisions; connectivity to access information and maintain a suitable level of monitoring at the appropriate levels and scales (geographic, temporal, etc.), and adaptability to shift decisions/approaches if feedbacks indicate changes are needed.

4. *Fostering an understanding of social-ecological systems as complex adaptive systems*: This principle relates to, and brings together, the sections above that discuss freshwater systems as interacting and intertwined social and freshwater systems (social-ecological systems), how these systems have many, many interacting parts, are self-organizing (the behavior of the system as a whole is defined by the behavior and interactions of the parts), and are unpredictable (complex adaptive systems), and how worldviews and human agency interact to determine how we act and what governance approaches we support (e.g., human agency). The suite of approaches that we view as feasible in governing freshwater systems is dependent on how we understand the systems themselves. A complex adaptive systems perspective is consistent with social-ecological resilience and creates the capacity to govern in a way that supports resilience.
5. *Encourage learning and experimentation*: Learning about the system—especially learning that happens as a result of interactions with others who hold different knowledge and/or perspectives than our own—is important for responding to disturbances, no matter the goal (persistence, adaptation or transformation). Creating opportunities for learning is key to realizing this principle, and several other principles (managing connectivity, maintaining diversity, broadening participation) support this principle. Repeated interactions among those who are learning from each other builds relationships and trust and can enhance the ability of the system to respond to disturbances. Experimentation is the manipulation of parts of the system to understand how it changes outcomes. It is a key way that we learn about the system, and is particularly important when considering adaptation. In order to adapt, changes must be made, but because the system is complex and sometimes unpredictable, experimenting allows us to try different manipulations and compare outcomes to understand how best to respond to disturbances/changes. Both learning and experimentation serve to reduce the degree of uncertainty in the social-ecological system.
6. *Broaden participation*: Bringing more, and more diverse perspectives to governance is widely considered to improve decision-making in complex adaptive systems, like freshwater systems, through enhancing legitimacy, promote a more fulsome understanding of system dynamics, and increasing the capacity for monitoring. Who should be involved is a complicated question to answer—it depends on the specific system and who holds a stake or rights within it. How participation occurs is another complicated question: participation can range from being informed to partnerships among actors to full citizen control (Arnstein, 1969). Further, participation can happen at multiple different stages of governance, from setting goals to creating policies to evaluating outcomes. Despite the complex array of considerations of participation, broadening who is involved can result in increased cooperation among participants, increased transparency of governance processes, and increased ability to include relevant information in decision-making. There are clear linkages between this principle and maintaining diversity and encouraging learning and experimentation.
7. *Promote polycentric governance systems*: Polycentric governance refers to multiple centers of decision-making at different levels that are independent but work together towards common goals. Decision-making may happen by governments, non-governmental organizations, and others. Connections among centers of decision-making are most effective when they are horizontally connected (multiple centers that exist at the same level [e.g., municipal governments] interact with each other) and vertically connected (multiple centers that exist at different levels [e.g., municipal governments, watershed organizations, Indigenous governments] issues that jointly affect them. This principle is related to all others, as polycentric governance either exhibits the principles (e.g., maintaining diversity and redundancy) or enables them (e.g., encouraging learning and experimentation).

Additional considerations to the resilience principles

In many of the resilience principles, there is an underlying theme that is not explicitly stated, but deserves attention. A focus on equity, power dynamics and human agency is central to governance for resilience of freshwater social-ecological systems. Questioning the 'resilience for whom' is important. Whose wellbeing matters most? Which individuals' and groups' interests and preferences should be targeted? When is it deemed suitable or desirable to keep a social-ecological system in its current state? When is transformative change deemed relevant or necessary? Resilience is in fact a normative concept. This means that, for example, a resilient freshwater system may be good and desirable for a certain group of the society, but at the same time bad and undesirable for other groups. So, it is necessary to make normative choices, and it is important to understand who benefits and who loses, and how we can strike a balance among the interests. Governance is key to understand this social-political dimension of resilience. It helps us understand who is and should be involved in freshwater related decision-making processes; who has and/or should have the power, freedom, and agency to actively participate, to retain or enhance freshwater resilience, and ultimately shape the future of freshwater systems (Cinner and Barnes, 2019). By understanding inequities and power dynamics in governance of freshwater systems, we can better address them and enhance the ability to build good governance of freshwater that aligns with social-ecological resilience principles.

The role of individuals and human agency

The focus so far has been largely on governance structures and processes—the ways in which we organize ourselves in society and the rules by which we make decisions. However, individuals have important roles to play in social-ecological resilience of freshwater systems as well. The fourth principle of social-ecological resilience—fostering an understanding of social-ecological systems as complex adaptive systems—emphasizes that the ways in which we as individuals understand the world around us is important. Our 'worldview,' or the way in which we see and understand the world and how humans and ecosystems relate to each other, will determine in large part the ways in which we think decisions should be made (who should be involved and what they should consider) and the suite of options that are appropriate for governing freshwater systems (Bohensky et al., 2015; Baird et al., 2020b). Our worldview can either enable or create barriers to social-ecological resilience.

Human agency—the ability and power to act based on one's will—is of central importance in individual roles in social-ecological resilience. Agency can be exhibited through decisions in our daily lives through to political actions we take without decision-making authority (e.g., engaging in more environmentally friendly practices in our home, voting for a particular political party aligned with our values and beliefs, or engaging in environmental activism) and through the actions of those who do have decision-making authority (e.g., advocating for policies that support freshwater conservation measures, developing programs to support others' work in freshwater management/resilience). Human agency and worldviews intersect: the types of actions taken by individuals are generally reflective of their worldviews. The individual actions taken, whether by those in positions of authority or not, can have impacts on the larger system. For example, individual votes in an election in a democratic nation together decide who (and whose agenda) will govern that nation.

An important note on human agency is that it has constraints, and those constraints differ among individuals (as described above) (Baird et al., 2020b). We can use the ability to vote again as an example. The opportunity to vote based on an individual's values and beliefs is dependent on several factors: citizenship/residency status, whether they live in a democratic nation or not, age, ability to vote (access to transportation, financial means and time to allocate to voting, etc.). Certain groups within societies have less agency than others and thus their worldviews may be less represented in governance.

Resilience, governance, and panarchy

The ways in which social-ecological systems, as complex adaptive systems, function and system elements interact and change over time can be considered an 'adaptive cycle' (Gunderson and Holling, 2002). This cycle "describes the processes of development and decay in a system" (Garmestani and Benson, 2013, online) through four phases that can result in system reorganization in relatively the same configuration (persistence or adaptation) or in a new configuration (transformation). This cycle can happen at the local level (e.g., a single location along a creek), regional level (e.g., a watershed) and at broader levels (e.g., global) and adaptive cycles at these different levels operate on their own time scales, and also interact and can impact each other (called 'panarchy'). For example, a single point of pollution in a waterway can contribute to much larger water quality issues downstream over time once a threshold is exceeded, and global climate changes can have local effects on water temperature and aquatic habitat.

Resilience contributes to how a social-ecological system moves through the phases of the adaptive cycle. For example, a high degree of resilience can maintain a system in a state of conservation of resources for a long period of time, despite internal and/or external disturbances. While an ecosystem cannot expect surprises (disturbances) or anticipate their impact, social systems hold this potential (Angeler et al., 2014). Accordingly, resilience can be 'managed' through society's actions and decisions. The extent to which resilience is present in governance systems (see Sections "How governance is connected to resilience" and "Resilience principles" above) has impacts on how the social-ecological system is managed and moves through the adaptive cycle.

Conclusion

Governance and management—the decisions and actions taken to set direction and interact with freshwater systems—are central to freshwater problems. This is in part because of the entangled nature of human systems and ecosystems—together forming a 'social-ecological system' that is complex and adaptive. The disturbances that act upon the social-ecological system, and the interactions among components of it, can be difficult or impossible to predict. But, understanding the nature of the system, and its web of interactions, helps us to consider how we can address governance and management in a way that aligns with it.

The 'what,' 'who' (and 'for whom'), and 'how' of freshwater governance and management is critical for freshwater resilience. We outline seven principles of social-ecological resilience-based governance/management in this chapter: maintaining diversity and redundancy; managing connectivity; managing slow variables and feedbacks; fostering a complex adaptive systems mindset; encouraging learning and experimentation; broadening participation; and, promoting polycentric governance. We add to this an emphasis on power, equity and human agency, and highlight the role of individuals as potential change agents to build resilience at the system level.

Knowledge gaps/future research

- Applying the coupled and inseparable social (actors and institutions) and ecological (water resources) perspective in water resilience;

- Integrating all relevant actors in the water governance and enhancing the interactions among the different levels of governance (individual, local, regional, national, and international);
- Focusing on participatory, equitable, legitimate, and transparent characteristics of governance for water resilience;
- Addressing and dealing with power relationships and individual human agency in water governance and water resilience;
- Addressing trade-offs among actors in the water governance process for water resilience;
- Studying social learning (i.e., how knowledge is built, shared, and used in group settings) in water resilience research and practice;
- Bridging the water resilience science and policy gap to better align the goals, definitions, and approaches around water resilience;
- Overcoming challenges of multidisciplinary perspectives in order to operationalize social-ecological resilience in water sector.

The Gender Gap: Women as Authors and Leaders in International Publications in Fisheries Science

Brooke E Penaluna[a] **and Ivan Arismendi**[b], [a]U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station, Corvallis, OR, United States; [b]Department of Fisheries, Wildlife, and Conservation Sciences, Oregon State University, Corvallis, OR, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Catherine Febria and Gail Krantzberg.

Glossary

Gender gap Is the difference between or among genders owing to gender. In this case, the gender gap incorporates differences in citations and first authorship for women compared to men.
Gender Is a person's internal sense of being a woman, a man, some combination of man and woman, or neither man nor woman, including a range of identities and expressions. Gender is distinct from a person's assigned sex at birth and is often independent of physical or secondary sexual characteristics.
Impact gap Is the difference in the significant effect between or among groups. In this case, the impact gap is the difference between impact of women versus men across their citations in 18 fisheries journals, especially as it relates to a scientist's reach within and beyond their field by influencing management, policy, or society.
Impact Is used to describe researchers having a significant or major effect within and beyond their field by influencing management, policy, or society.
Minoritized individuals Are defined as being of the minority by a dominant group in society, most often white, cisgender, heterosexual men.
Productivity gap Is the difference in productivity levels between or among groups. In this case, the productivity gap is the difference between productivity of women and men in publications in 18 fisheries journals.
Productivity Is the effectiveness of productive efforts (output per unit of input) leading to results and benefits.
Sexism Is prejudice, stereotyping, or discrimination against a person on the basis of their perceived sex; or behavior, conditions, or attitudes that foster stereotypes of social roles based on sex.

Introduction

Productivity and impact continue to be important qualities to evaluate a successful science career, especially as they relate to a scientist's reach beyond their field by influencing management, policy, or society. Productivity and impact are traditionally measured by the number of articles published, especially in the prestigious position as lead author (Sekercioglu, 2008; West et al., 2013), and the number of times each article is cited by others (Franck, 1999; Biagioli, 2003; Bornmann and Daniel, 2008), respectively. However, gender imbalance between men and women in science has been a widely recognized issue for decades, with women having shorter careers and higher dropout rates (Blickenstaff, 2005) leading to an overall reduced productivity and impact (Huang et al., 2020).

Globally, for every article with a woman first author, there are nearly two (1.93) articles first-authored by men in science (Larivière et al., 2013). Differences in the sustainability of women's careers is proposed to explain these numbers (Huang et al., 2020). Reasons for such gender imbalance are deeply rooted in social, cultural, and legal norms, owing to differences in family responsibilities, work absences, resource allocation, isolation, sexism, racism, workplace culture, lack of women leaders, and gender stereotypes. Indeed, the gender gap is a paradox, as the inclusion of women and diverse people leads to more productive (Horta, 2013) and innovative teams (Østergaard et al., 2011) that produce high-impact research (Freeman and Huang, 2015), yet they are not consistently included. Consequently, understanding productivity and impact by gender and other identities is important for identifying continued barriers to inclusion and advancement of minoritized individuals, but also because these metrics provide the foundation of the current reward system.

The science of management and conservation of inland waters (i.e., fisheries, aquaculture, and aquatic science communities) has broadly affirmed the importance of diversifying its workforce, including gender diversity (Arismendi and Penaluna, 2016; Abernethy et al., 2020; Gopal et al., 2020). These efforts raised awareness of the need for competitive advantages and innovation, expressly as the field faces unprecedented challenges from complex human-environmental issues related to inland waters. Specifically, diversity is part of what makes people who they are (Batavia et al., 2020), and the science of inland waters depends on people. For example, women make up half of the fisheries workforce and play a prominent role in fisheries and aquaculture economies around the world, including in small-scale fisheries, yet women are unrecognized in official statistics, policies, and development programs (Gopal et al., 2020). As sciences of inland waters are called to diversify, demographic information related to productivity and impact will also increasingly be relied upon to inform decisions about equality, advancement, and the status of women.

If there is a shift in fisheries of inland waters to include more women and in leadership roles, especially women of color, we predict a paradigm shift toward the infusion of new ideas, which could only improve the management and conservation of inland waters. For example, women represent around 30% of the professional workforce in fisheries science across federal and academic positions in the United States, which is 20% less than expected if considering the pool of qualified talent (Arismendi and Penaluna, 2016). The number is even lower for women in in the professional workforce in leadership positions such as full professor, where representation is around 15%. In addition to career level, a gender gap has been noted in fisheries science, including in the representation of women authoring the most-cited articles in the field (up to 21% of most-cited articles had female representation: Branch and Linnell, 2016) and holding influential positions in academic collaboration networks (Arismendi et al., 2021). To understand why these discrepancies exist for women, we raise a critical question: what is the current state of productivity and impact of women in fisheries science? And what can be done to close the gender gap in the field?

To address this need, we conducted a bibliometric analysis of 15 years of publications in international English-language journals with a focus on freshwater fisheries science, which is a key part of managing and conserving inland waters. One of the main goals of this research was to extract basic information about lead author and number of citations from primary research, and to assign binary gender to author names to understand the effect this factor on productivity and impact in fisheries science. Doing so will help us to understand disparities between women and men involved in fisheries science publications beyond the most-cited fisheries references (Branch and Linnell, 2016). We were unable to quantify gender diversity beyond the male-female dichotomy, which does not represent the full range of gender identities, owing to the lack of available data on nonbinary and gender-nonconforming fisheries researchers. Drawing on the large body of diversity scholarship outside of fisheries, we discuss the challenges of including women in fisheries science, the risks of not including them, and long-standing problems of success related to productivity and impact.

Overview of recent fisheries science literature and gender assignment

Our focus on authorship information limited our analysis to the publishing careers of scientists, and consequently does not capture aspects of teaching, administration, mentoring, or government-related research activities. For example, women in academia have been shown to spend a disproportionate time on "invisible" work, which leaves less time for them to work on tenure and promotion (Social Sciences Feminist Network Research Interest Group, 2017). We extracted authorship information of published articles from the Web of Science database (WoS) focusing on 18 fish-related journals (Mather et al., 2008; Table 1) between 2006 and 2020 (WoS uploaded electronic information of complete first names, when available, starting in 2006). Although the Web of Science does not index the entire journal literature in fisheries sciences, it provides a reliable sample of citations comparable to broader citation indexing services such as Scopus (Archambault et al., 2009). As our study was comparative in nature, complete citation counts were not required. We included all regular publications (those identified as "*articles*" in WoS) and considered "*articles*" and "*reviews*" from specialized journals that focused on reviews, including *Fish and Fisheries*, *Reviews in Fish Biology and Fisheries*, and *Reviews in Fisheries Science and Aquaculture*.

From each article published between 2006 and 2020, we extracted the following fields: journal, WoS accession number (unique identifier), year of publication, names of authors (surname and first name), and the number of citations (up to 15 January 2021). Although gender includes a range of identities and expressions, we are only able to assign gender as female or male based on first names using the genderizeR package (Wais, 2016) in R statistical software (R Core Team, 2017) and GenderAPI (https://gender-api.com/). These tools assign the probability of a first name being female or male based on large database of names (>6 million). We validated this gender assignment procedure using the membership list of the American Fisheries Society, AFS (pers. comm. Eva Przygodzki, 2015). We used 6542 AFS members who voluntarily provided demographic information including surname, first name, and gender. We tested our gender assignment procedure using the AFS names and then contrasted the degree of agreement between the predicted gender from this procedure and the actual gender for AFS members. Our procedure identified the actual gender in 97.6% of the cases ($n = 6542$) for men ($n = 4925$) and 96.8% from women ($n = 1617$), although there is gender diversity that we were unable to capture, which we discuss in more detail in the discussion.

The year that each journal included in our analysis was founded ranged from 1872 (*Transactions of the American Fisheries Society*) to 2000 (*Fish and Fisheries*; Table 1) and the journal impact factor ranged between 1.04 (*Fishery Bulletin*) and 6.79 (*Fish and Fisheries*). Half of the 18 journals were founded by professional societies or other organizations. We tested the association between the age of the journal and the proportion of women lead authors using a simple Pearson's correlation analysis. We performed a similar

Table 1 Journal information, including year founded, impact factor, society/organization that the journal is associated with, number of articles used in analyses, and % of articles used in the analyses for 18 journals included in our analyses.

Journal Name	*Year Founded*	*Impact Factor (2019)*	*Society/Organization*	*Number of articles (2006–2020)*	*% of articles with lead author gender assigned*
Aquaculture	1972	3.23		8662	79%
Canadian Journal of Fisheries and Aquatic Sciences	1901	2.85	Natural Research Council, Canada	2693	92%
Ichthyology and Herpetology	1913	1.16	The American Society of Ichthyologists and Herpetologists	1197	95%
Ecology of Freshwater Fish	1992	1.95		936	65%
Environmental Biology of Fishes	1976	1.52		1964	90%
Fish and Fisheries	2000	6.79		645	96%
Fisheries	1976	2.70	American Fisheries Society	474	92%
Fisheries Management and Ecology	1994	1.73		789	18%
Fisheries Oceanography	1992	2.20	The International Journal of the Japanese Society of Fisheries Oceanography	635	81%
Fisheries Research	1981	2.15		3449	82%
Fisheries Science	1932	1.17	The Japanese Society of Fisheries Science	1929	93%
Fishery Bulletin	1881	1.04	U.S. Dept. of Commerce, NOAA	575	92%
Journal of Fish Biology	1969	1.50	The Fisheries Society of the British Isles	4447	16%
Journal of Fish Diseases	1978	2.32		1845	20%
North American Journal of Fisheries Management	1981	1.49	American Fisheries Society	1686	94%
Reviews in Fish Biology and Fisheries	1991	4.40		568	86%
Reviews in Fisheries Science and Aquaculture	1993	3.76		362	87%
Transactions of the American Fisheries Society	1872	1.44	American Fisheries Society	1841	91%

analysis between the journal impact and the proportion of women lead authors. Lastly, we used a simple Mann-Whitney rank sum test and a Yates continuity correction to compare the median of article citations (one time or more) by binary gender. Similarly, we used a Kolmogorov-Smirnov Test (K-S Test) to compare the overall distribution of citations by binary gender.

Representation of women in publications of fisheries science

We were able to extract 34,697 articles between 2006 and 2020 from WoS. Some articles were excluded from our gender analysis because first names were incomplete (3.8%) or not provided (24%). Some journals have not adopted the use of a full first name in the article and some people intentionally use initials, resulting in our inability to assign gender. Thus, our gender analysis is based on 24,857 articles. Collectively, these articles have been cited 411,116 times (as of 01/15/2021). These articles represent a total effort from 157,024 individuals.

During the past decade and a half, around 30% of the fisheries articles published in fisheries science journals were led by women, whereas men led approximately 70% (Fig. 1). However, lead authorship by gender varies by journal, with women leading more articles in the *Journal of Fish Disease* (46%) and leading the fewest in the *North American Journal of Fisheries Management* (19%; Fig. 2). Pearson's correlation analysis showed that the proportion of women lead authors was not associated with the age of the journal (P-value = .79) or its impact factor (P-value = .85). Journals from publishing companies had slightly higher participation of women as lead author (33%) compared to journals associated with professional societies or organizations (27%). Similarly, 30% of total citations of woman-led articles were from publishing companies, relative to 25% from professional societies or organizations.

The proportion of articles with single authorship was higher for men (5%) than for women (2%) across fisheries journals. However, women lead authors include the same relative number of coauthors on their articles (3–6 coauthors) as those led by men (Fig. 3). Citations for articles by gender vary by journal, with woman lead authors being cited most in *Reviews in Fish Biology and Fisheries* (34%) and the least in *Reviews in Fisheries Science and Aquaculture* (14%; Fig. 4). Overall, women are undercited relative to the proportion of articles that they lead, except for *Reviews in Fish Biology and Fisheries* and *Ichthyology and Herpetology*(Fig. 5).

Articles published across these 18 fisheries science journals had an average of 11.8 citations per article. There were statistically significant ($T = 72{,}113{,}635$; $N_1 = 6667$; $N_2 = 15{,}450$; P-value $< .001$) differences between the number of times that articles with a

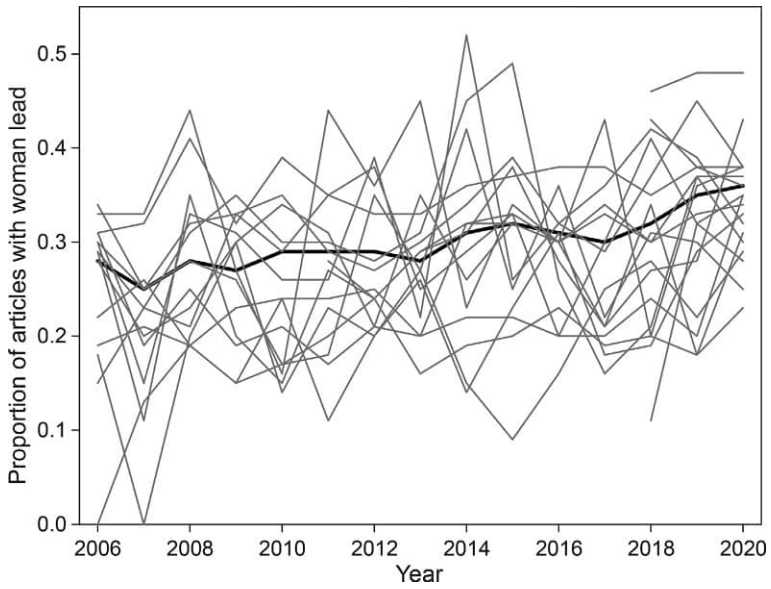

Fig. 1 Proportion of articles with woman lead over time from 2006 to 2020. Each gray line represents a single fisheries journal and the black line is the mean.

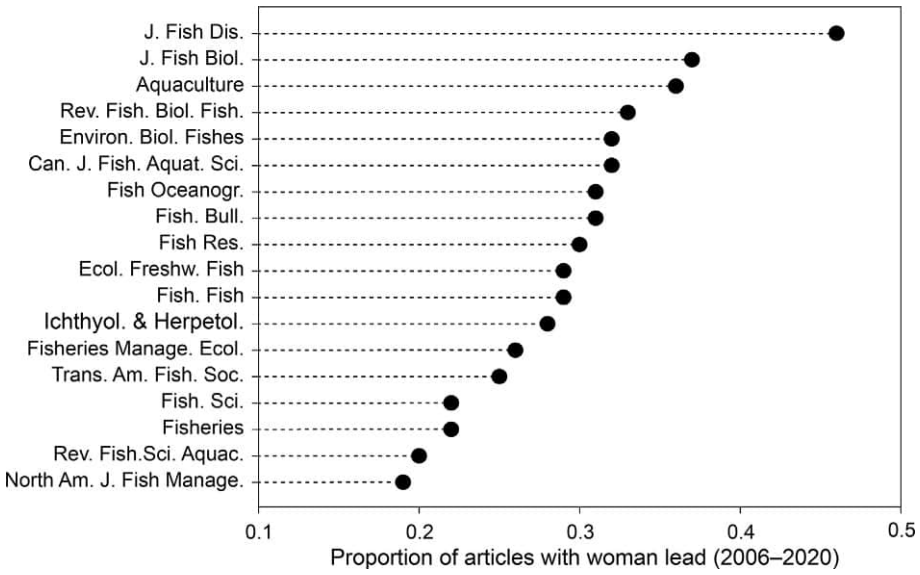

Fig. 2 Proportion of articles with woman lead by journal from 2006 to 2020.

woman lead author were cited versus a man lead author (Fig. 6). Similarly, only 10.6% of articles led by men authors had no citations compared to 12% of articles led by women authors. In general, the proportion of highly cited papers (30 or more citations) was dominated by men lead authors, as is shown by the different citation distributions by gender ($D = 0.027$; P-value $<.05$). More articles led by men authors (0.8%) had >100 citations compared to articles led by women authors (0.6%).

Identifying the gender gap for the management and conservation of inland waters

To advance women in science, the gender gap has been proposed as a 'productivity gap' (e.g., Abramo et al., 2009). We suggest that the productivity gender gap is not affecting women in fisheries science, at least superficially, because women publish in fisheries as lead author proportionate to their presence in the fisheries science community (~30%; Arismendi and Penaluna, 2016). The fact that women are keeping up in productivity is remarkable considering the barriers and biases that they face in their careers, including interactions with editors and peer reviewers (Bornmann et al., 2011). Similarly, research output of Spanish postdoctoral scientists shows no differences in publications by gender (Borrego et al., 2008). This is mirrored by results of professors in universities in the

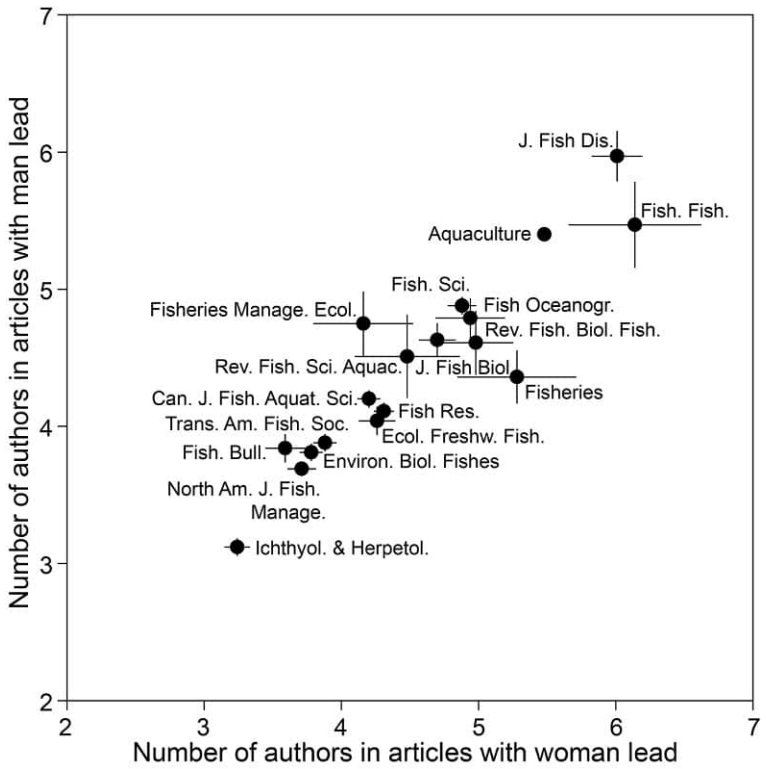

Fig. 3 Relationship between mean number of authors in articles with woman lead and mean number of authors in articles with man lead across 18 journals from 2006 to 2020. Each point represents the mean values for a journal with standard error.

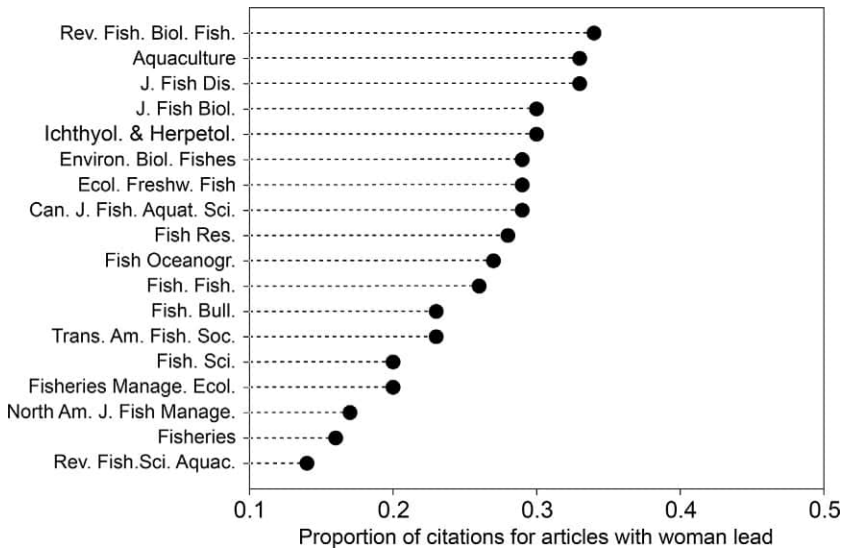

Fig. 4 Proportion of citations for articles with woman lead by journal from 2006 to 2020.

province of Quebec, Canada, where there are no differences in productivity between men and women until age 38, when women receive less funding, have fewer publications, and have less impact compared to men (Larivière et al., 2011). If women in fisheries are producing research at the same level as men, then the fisheries science community may consider improving the recruiting and retention of women in fisheries positions to achieve gender parity, in addition to addressing social, cultural, and legal aspects that contribute to the gender gap.

Women in fisheries have low numbers of citations relative to their productivity, suggesting that there is an 'impact gap' in fisheries, in addition to issues of recruitment and retention, rather than a 'productivity gap'. As impact incorporates the major effect

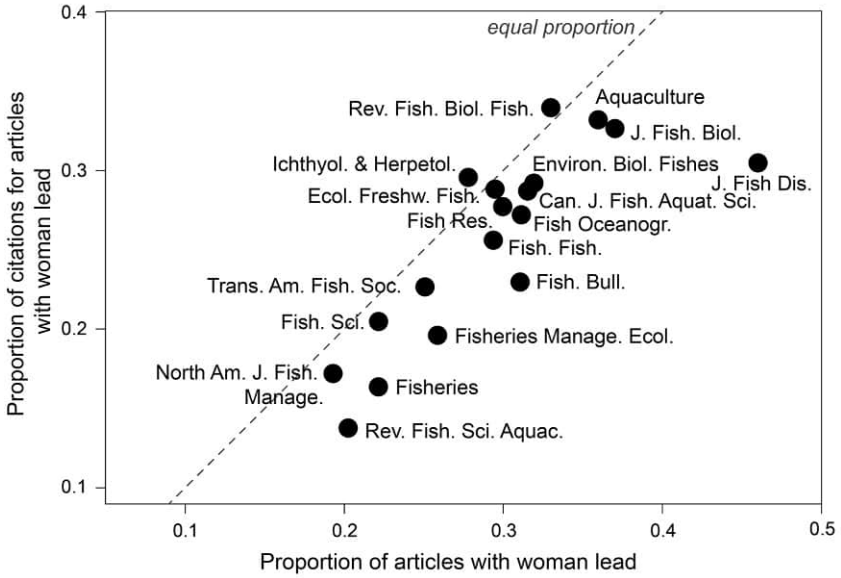

Fig. 5 Relationship between proportion of articles with woman lead and proportion of citations for articles with woman lead by journal from 2006 to 2020. Dotted line shows 1:1 relationship.

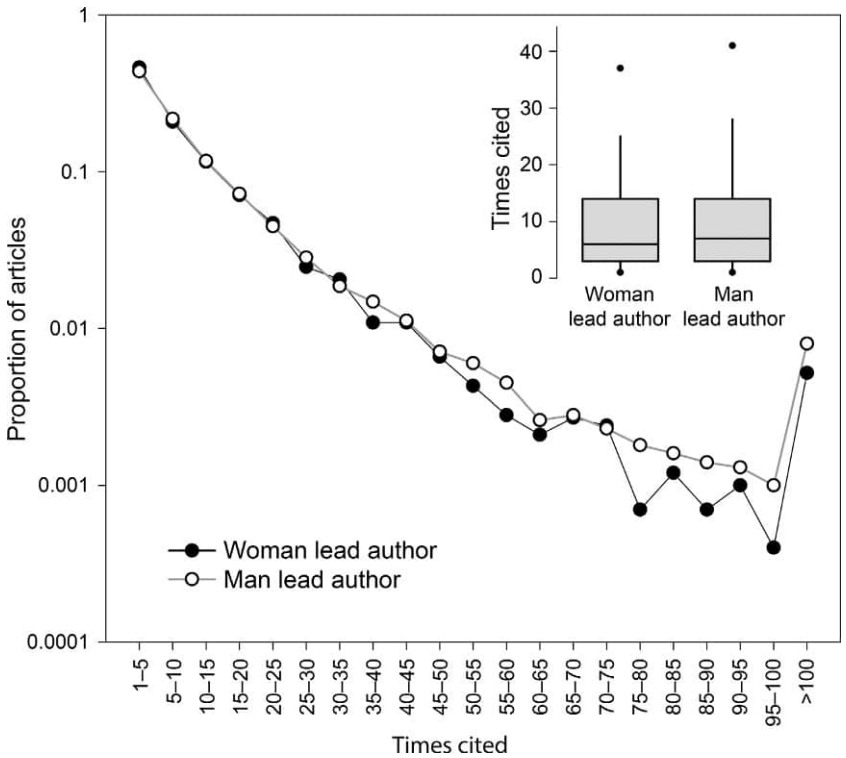

Fig. 6 Proportion of articles with woman lead author relative to man lead authors over time from 2006 to 2020. Inset shows number of times that articles are cited for articles led by women relative to those led by men.

of a person and their work both in their field and beyond by influencing management, policy, or society, our findings suggest that the reach of women is not as far as that of men. The challenges of impact for women fisheries scientists reflects the broader societal challenges that women face to both serve and be viewed as leaders. For example, the 'Matilda effect', a bias against acknowledging the achievements of women scientists whose work is attributed to their male colleagues, has been an ongoing problem for women for centuries (Rossiter, 1993). When considering co-authorship roles, women contribute to science by performing the experimental work disproportionately more often than men (Macaluso et al., 2016), and even when women are lead authors, they are less likely

to be the corresponding author, as demonstrated by Fox et al. (2016) for the journal *Functional Ecology*. When looking at impact, the most-cited fisheries articles come from men, with only 21% of most-cited articles including women coauthors (Branch and Linnell, 2016). We also show that articles that are highly cited are disproportionately led by men. Collaboration networks from top women researchers in the US fisheries science academic network show that top-ranked women have smaller networks than men, but their roles in the network are influential to the structure of the network (Arismendi et al., 2021). Collectively, we suggest that women are devalued relative to men, which makes it difficult to reach high-status or high-impact positions in their careers.

The value system in science could shift to broadly include metrics of justice, equity, diversity, and inclusion instead of continuing the perpetuation of citations and impact factors (Davies et al., 2021). This would help us to reimagine the fisheries science workforce as a collection of paths that change and adapt to the needs of the individual with a foundation of mentoring, which may also increase job satisfaction. For example, mentoring relates to more than a two-fold increase in job satisfaction for fish biologists in the USDA Forest Service (Penaluna et al., 2020). By broadening the value and rewards system in science, we would also add value to career pathways or duties that are not focused on publishing, including managers, private industry and policy makers, and it would make more visible work related to mentoring, relationships, and communication. If there were to be a shift in our scientific value systems, then inland fisheries science professionals would be additionally valued for contributions that influence aspects of mentorship, diversity, and well-being.

Single authorship was minimal for both women and men in fisheries, suggesting that fisheries science is inherently interdisciplinary, but the productivity and impact of women in fisheries varied by journal. In the journal *Fisheries*, there were some binary gender differences during the review process; articles led by women were published less often than expected by chance, suggesting bias (Handley et al., 2015). Overall, women publish less in journals associated with professional societies and organizations suggesting that women probably are less comfortable in those spaces and/or there is bias in the review process. We suggest that journal editorial teams should look for ways to increase the number of submissions and improve participation of women in their journals. They may strategically solicit and incentivize submissions by women, include women and people of color on their editorial boards, publish who is part of their editorial boards on their website, offer double-blind reviews, and require reviewers to check an agreement box that their reviewer comments will not be disrespectful or discriminatory.

The true gender diversity of fisheries science professionals includes people beyond the male-female dichotomy, such as nonbinary and gender-nonconforming individuals who identify as both male and female at one time, as different genders at different times, as no gender at all, or dispute the very idea of only two genders (Richards et al., 2016). For example, the prevalence of nonbinary genders was 1.8% in natal men and 4.1% of natal women in two separate data sets in one study (Van Caenegem et al., 2015) or as high as 35% in another study asking participants about their gender (Joel et al., 2013). The marginalization that transgender or nonbinary scientists face extends to the lack of information that we have about them related to their identities, professional roles, and successes in science. The victimization and stress from discrimination that these people face can be even higher than for women (Richards et al., 2016). Societal and institutional changes may be warranted to start quantifying the prevalence of nonbinary fisheries science researchers, including attention to safety and inclusion.

Although our study focuses on one dimension of social identity, there are additional barriers and specific challenges that people with multiple identities face, including able-bodiedness, race/ethnicity, age, class, country of origin, religion, or sexual orientation that could be explored. The interconnected nature of social identities leads to overlapping and interdependent systems of discrimination and disadvantage. Crenshaw (1989) posits that considering only one dimension of someone's being distorts the multidimensionality of their experience limiting our understanding of the issue, and rather by considering such intersectionalities the dynamics are more appropriately understood. If more information about social identities is known about people involved in inland waters, then a deeper understanding of who we are and how many lives are touched worldwide is possible.

Talented women have been and are leaders and role models in inland waters, including fisheries and aquaculture (Murphy et al., 2020; Zatkos et al., 2020). They continue to inspire new generations of women and girls to enter the field, or other fields of science. If we want women to be making high-level decisions about the management and conservation of inland fisheries, then we may invite them to the table where those decisions are being made and show that we value their experiences, ideas, and expertise.

Conclusions

The status of women in fisheries science publications brings attention to the broad problems that still exist globally, from low representation of women at all career levels, but especially in leadership roles, to discrimination and lack of access that affects career opportunities. To design science so that it represents everyone, we need to include women in conversations and in making decisions. Consequently, the fisheries science community may want to recruit women into fisheries positions, and particularly leadership, and put practices in place to retain them. Putting women in leadership roles is a first step in addressing gender inequalities in fisheries as it may also be important to rectify social, cultural, and legal issues more broadly. Women, like all people, are interested in being heard, and a key part of that is to accept and validate women's experiences, ideas, and expertise (Crandall et al., 2021). Consequently, it is increasingly important for researchers to devote time to issues that affect women in fisheries, to be better prepared to meet the ever-growing challenges facing society, and the management and conservation of inland waters. Binary genders do not represent the complete diversity of fisheries investigators. Accordingly, to understand more deeply about the complete diversity of genders in fisheries science, we need to create support systems and cultures of inclusion to recruit and retain people with diverse gender identities.

Knowledge gaps

- To address gender issues, or any diversity issue, information and data must be collected by asking individuals directly for information, and more than the English-speaking world may be considered. There is an information gap related to intersectional identities of people, including gender, race/ethnicity, sexual orientation, age, career/job, disability, and marital status (this may be particularly important for women who have small-scale fisheries).
- Additional information about people involved in inland waters would provide the opportunity for a deeper understanding of how many lives/sectors inland waters touches globally. For example, are there differences in representation of people if they are from countries in the Northern Hemisphere versus the Southern Hemisphere?
- To more deeply understand gender identities in fisheries and aquaculture, one would (a) have to recognize the legacy of oppression that affects nonbinary and gender nonconforming communities and (b) need more information than someone's name and presumed gender. Increasingly, as younger researchers enter the profession, names may not necessarily reflect a binary gender (e.g., Avery, Taylor, Skyler, McKenzie, Teal). Additionally, to capture racially, ethnically, and nationally diverse researchers whose names derive from many languages, a much larger database of first names is needed.
- Gender-diverse scientists need better protections against discrimination and harassment before we can expect them to publicly self-report. First steps can include offering a write-in option for gender and by offering non-gendered options for titles/honorifics such as Mx.
- With the information that is obtained from WoS, we are unable to determine whether women are not submitting articles to certain journals, or whether they remove their submission or are rejected during the review process. This type of information could be collected by journals and would offer insights to minimize bias during the publication process.
- We found that women publish less in journals associated with professional societies and organizations suggesting that women probably are less comfortable in those spaces, but that relationship should be evaluated more explicitly.

Glossary

SDGs The Sustainable Development Goals or Global Goals are a collection of 17 interlinked global goals designed to be a blueprint to achieve a better and more sustainable future for all. Set up in 2015 by the United Nations General Assembly they are intended to be achieved by the year 2030.

Value Worth, usefulness, or importance in standing or in comparison and a principle or quality that is intrinsically desirable by individuals or shared by many.

Water security The capacity of a population to safeguard sustainable access to adequate quantities of acceptable quality water for sustaining livelihoods, human well-being, and socio-economic development, for ensuring protection against water-borne pollution and water-related disasters, and for preserving ecosystems in a climate of peace and political stability (UN-Water, 2013).

Introduction

Water is essential for safe and balanced living, but freshwater is facing a global crisis due to exploitation, pollution, and climate change (Islam, 2017). While, clean water, fresh air, and a pristine environment are increasingly considered valuable natural assets, over the past five decades, population growth, intensifying industrialization, and agricultural advancement have profoundly altered natural ecosystems and stressed water quality and availability. In addition, the challenges from climate change impacts exacerbate the water risks, and increase the exposure of communities and populations, particularly in vulnerable settings (Evans et al., 2012). Global freshwater use has been growing at about 1% annually since 1980, especially in developing countries. In 2015, the annual global water withdrawal was noted as 4500 billion m^3 (WWAP, 2015). By 2030, the lack of water usage efficiency combined with increasing economic productivity is predicted to result in global water use close to 7000 billion m^3. Other projections show that by 2030 the global water demand could increase by 40% and 55% by 2050 (WWAP, 2014). Water is an indispensable component of a wide range of economic activities. Therefore, the increase in demand will likely come from the growth of industrial and domestic use, energy production, and agriculture. The water demand already exceeds available supply in many regions, particularly in developing nations with rapidly growing regions viz., Asia, North Africa, the Middle East, and Sub-Saharan Africa (FAO, 2017).

The water demand-supply dynamics is largely impacted by various globalization trends such as trade flows, change in production and consumption patterns, etc. either directly or indirectly. Septon et al. (2019) reflect on the multiple perspectives of water values such as economic, social, and cultural values in connection with understanding the water demand-supply dynamics stating that these interlinkages are critical for maintaining socioeconomic and political stability in communities and states. The increasing interconnection of water with various sectors also calls for the integration of diverse stakeholder perspectives while

shaping water management plans and policies. Defining 'water values' universally remains a challenging task due to context-based socioeconomic, sociocultural, and sociopolitical settings. Moreover, the western paradigms rooted in technological progress and the hegemony of the market economy have been playing a key role in influencing the notion of values (Euzen and Morehouse, 2011). Concurrently, in the globalizing economies worldwide, the valuing process is no static phenomenon, though the placement of water within the existing valuing systems is primarily focused on economic interests. The growing perspective of industrialization-based growth notions had made it tough for environmental, social, and cultural perspectives to be appropriately integrated into the 'value' proposal operational strategies.

Water is a vital source of life and thus embodies a diversity of interests and has various classifications or value propositions placed on itself by context or by definition. It is within this understanding that a wide variety of 'values' emerge. When looking at the importance of 'water' solely with an economic lens, the pressures posed by climate change and environmental stresses are not property reflected or adequately addressed. Management of water resources equitably and sustainably is becoming a demanding task due to discord and limited to non-existent collaboration between economists and other disciplines engaged in sustainable development agenda implementation. For example, no economists were involved in a special section on "Ecosystem Earth" published in science (April 2017) that encompassed discussions of population, consumption, agricultural production, land use, human behavior, collective action, and policy (Vignieri and Fahrenkamp-Uppenbrink, 2017).

Additionally, in the age of climate emergencies the environmental protection agenda can be best addressed through discussion of emerging and continuing flawed economic growth paradigms that undervalue nature's contribution to people as highlighted in recent global assessment report on ecosystems and biodiversity compiled by the United Nations (UN) agencies, global experts, regional and national researchers (IPBES, 2019). The challenge of the water crisis is that it is altered with various climate-related events and, in turn, can influence geopolitical balance and political stability in communities and states. For instance, persistent climate change-induced extreme flooding faced by Ecuador's indigenous people that live in resource-scarce settings of the Amazon region (Gabay, 2020), added stress and triggered conflict between communities, in some cases precipitating people to move and migrate. Haarstad's (2012) commentary on the episodes of environmental conflict in Brazil, Chile, Ecuador, Peru, Bolivia, Uruguay, Colombia points to the concept of environmental personhood as an emerging dimension in the value proposal narrative. Capturing and synthesizing these diverse elements in the 'value proposal' for freshwater, this synthesis highlights the need to deconstruct the complex interlinkages, the theoretical density as well as operational measures of this framework while planning water security and economic development agendas. Besides, it proposes an explanation based on arguments and case examples to exhibit the value narrative with an integrated perspective that suitably incorporates the environmental, spiritual, and cultural dimensions of water (Fig. 1).

Understanding multiple framings of 'valuing water'

Water is not only part of many economic and industrial processes; it is also essential for human life and wellbeing and is critical to food production. In April 2016, the UN and the World Bank Group (WBG) during the High-Level Panel on Water (HLPW) called for a comprehensive, inclusive, and collaborative form of leadership, which is necessary for developing, managing, and improving water and sanitization related services (Government of the Netherlands, 2020). The outcome of this HLPW was the '*Making Every Drop Count*' document released in March 2018. In this document the recommedations regarding the necessary collective betterment in understanding, valuing, and managing water. The overarching intent was to bring about systemic change that lay outside the margins and into the core of significant water challenges; and trigger the deconstructionism of how water is valued in practice, policy, finance, and behavior (Government of the Netherlands, 2020). The Bellagio principles and the Valuing Water Initiative (VWI) were launched in tandem to boost the implementation and adoption of outlined principles. VWI explains practical applications of valuing water principles to policy, business practices, and behavior across contexts, sectors, organizations, institutions, and agencies. And states that such a process needs collaborative initiative developed around four pillars centered on intervention and activities, as shown in Fig. 2. In this section, the focus is on Bellagio's Principles and UN Human Right to Water Resolution, underlined as examples of guiding frameworks that considers ecosystem and social objectives in tandem and allows integration of multiple 'water values' in the designing operational management measures in various sectors of the water domain.

The Bellagio's principles

Billions of people lack access to safe water and sanitation services. This crude fact calls for emphasizing the need for a collective and collaborative agenda to manage water resources and deliver necessary provisioning services to growing populations. Noting the importance of collective action, in May 2017 in Bellagio, the preamble of these principles was set on the recognition of eight key aspects: first, water is precious, fragile, and hazardous with the capacity to sustain or destroy life, societies, and economies, and these capacities act in interconnection with land, air, and energy resources. Water is not just a substance but an element with multiple values and meanings usually expressed in spiritual and cultural terms. The heritage of water language, norms, and artifacts provide deep perceptions, making it essential that stakeholders' relations and participation is duly acknowledged and represented in water management and governance measures. Furthermore, to ensure that water is available for multiple uses by various users, the supporting infrastructure, institutions, agencies, and policies systems remain important. And, transforming water from a natural resource to provision services, recycling, and reuse should be given appropriate consideration and thoughtful planning.

Second, making all the values of water explicit can provide recognition and platform to conventionally overlooked dimensions, and an alternative vision to the existing generalized cost-benefit approach to managing water demand and supply. In addition, focus on collective decisions and trade-offs while shaping sustainable solutions can help to overcome inequalities and bolster institutions and infrastructural innovations.

Third, creating initiatives through a collaborative process and building champions and ownership at all levels by presenting unique and mutually reinforcing concepts that consider water as necessary for equitable and inclusive human development.

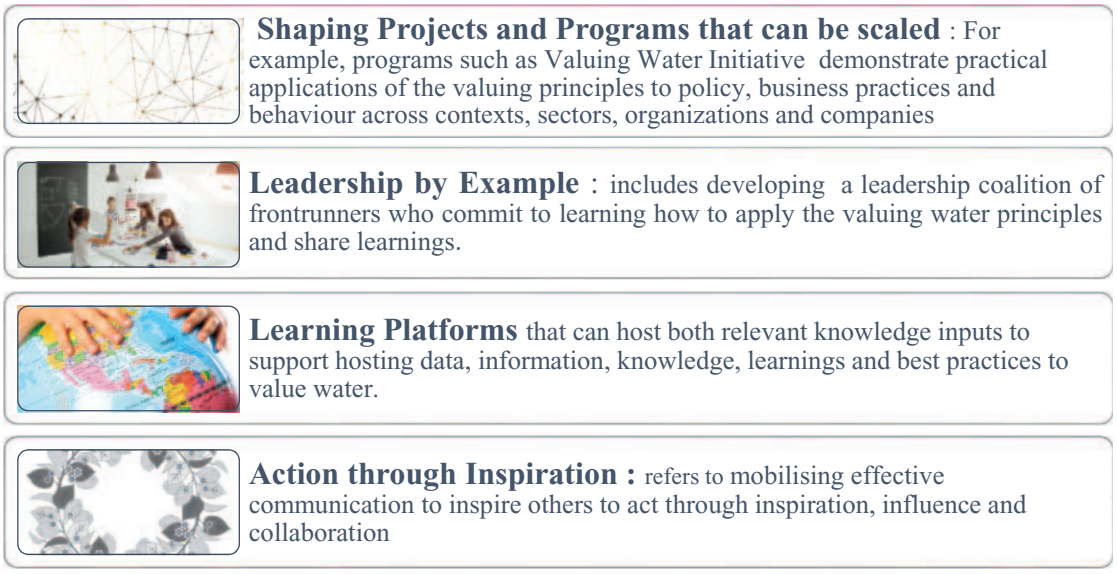

Fig. 2 Summary of aspects that are key in scaling and operationalizing valuing water concepts and frameworks. Created by authors adopting from Valuing Water Initiative.

Fourth, acknowledging that the world's freshwater systems face a mounting set of crises and threats from multiple direct and indirect drivers such as overuse, pollution, and impacts of extreme events, droughts, and floods and that these resources are finite while water demands are escalating.

Fifth, realizing and counting multiple values of water toward aggregation of various benefits provided by water in the economic, social, and ecological domains, local to national scales, and settings of social and cultural establishments is crucial.

Sixth, the valuing water perspective can stabilize the complex supply-demand dynamics through informed and balanced decisions on water allocations both for human and ecological wellbeing. Different ways apply to such a process, including but not limited to regulation and economic instruments, waste management, reuse, and recycle (green/gray infrastructure) systems, and restoration of water sources through efficient procedures and policies.

Seventh, efficient water management offers a ground for transforming risk to resilience, poverty to wellbeing, and degraded ecosystems to restorative landscapes through collaboration across sectors, communities, and states, and particularly for transboundary water systems.

Eight, the need for action, takes note of vast changes and innovation, and prospects to focus on human development-related challenges such as poverty, resilience building, management of shared resources, and underlying components of wellbeing. Furthermore, it takes into consideration the necessity to define practical roles or applications, for example, active and participatory stakeholders' consultations, agenda on common property resource (water) management, resource allocation strategies, resolving of resource-related conflicts, and supporting future investments in the water sector.

To understand the value perspective further, note that in the common understanding most of the value proposal surrounding the water systems point to the economic value. This understanding is often based on different variables and contexts such as quantity, time, location, and quality. This value notion is also affected by the climate crisis and the disaster events such as droughts that in turn can significantly impact the hydrological systems. For instance, water availability, referring in the terms of quantity is influenced by dry condition/droughts and change in rainfall patterns. The state of existing knowledge on valuing water is disaggregated. A standard guideline such as Bellagio's Principles that reckon spiritual, environmental, and cultural dimensions and outlines five principles, as shown in Fig. 3 offers a promising option toward holistic understanding of value proposal for freshwater systems. The critical element in this set of Principles include:

(a) recognizing water's multiple values by knowing the interconnectedness concerning human need, spirituality, economic well-being, and freshwater viability for and by different stakeholders carrying of that knowledge in the decision-making process and plans in the water sector.
(b) building trust through reconciliation of multiple values in an equitable, transparent and inclusive manner;
(c) protecting the source of water such as watersheds, rivers, and aquifers, associated ecosystems must be protected from pollutants and other stressors while managing the challenges related to water scarcity, adhering to the normative aspects of sustainable development agenda, in the current context of sustainability pathway for the water related SDGs);
(d) steering better-informed decision-makers regarding water-related issues by empowering communities and populations, strengthen their capacity through education initiatives, focus on public awareness surrounding water's essential role and intrinsic value;

Fig. 3 Key dimensions of Bellagio's Principles in the valuing water context. Figure by authors adapted from Bellagio's Principles documents.

(e) fitting investments and encouraging innovative mechanisms that draw on local, traditional, and indigenous knowledge and practices and apply to multiple facets of the complex water-food-energy nexus can serve helpful to realize full potential and value of water within by institutions, business, public sector unit in provision and infrastructure and the information and knowledge landscape on water.

Aligning to the discourse set by Bellagio's Principles is the United Nations resolution of universal access to clean, safe drinking water and sanitation declared as a fundamental human right. On 28 July 2010, through this Resolution [64/292], the United Nations General Assembly acknowledged the human rights dimension in the water sector and called upon states and international organizations to provide financial resources, support capacity-building and facilitate technology transfer to support countries and communities, in particular developing countries and people and populations living in vulnerable settings. The key dimensions of this resolution are outlined in Fig. 4.

Fig. 4 The important element of the *human right to water and sanitation* resolution of the United Nations (UN, 2010) toward access to safe water and basic sanitation is a legal entitlement, rather than a commodity or service provided on a charitable basis. The resolution emphasizes on accelerating the achievement of basic and improved levels of water access and to better manage inequalities and to focus on empowering communities to take part in decision-making processes.

Valuing Water and enabling change

Human existence and wellbeing depend on nature and its contributions in various forms. As a valuable natural resource, water directly contributes to human beings' daily life activities and life quality. It is essential to assess the variables and risks in a systematic manner in order to accomplish valuing water goals. The Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) introduced the concept of nature's contribution to people (NCP), emphasizing the importance of dynamic approaches to the assessment or valuation of NCP. The diverse value of NCP to the context of people's sense of identity, spirituality, and meaningful life is quite important as well, though the decision making often concentrates on instrumental assets of NCP like food, water purification, and flood prevention, among others (Pascual et al., 2017).

Furthermore, IPBES, with its recent publication, the Global Assessment Report (2019) recognized the immense benefits humans receive from wide-ranging access to natural assets like water, energy, food systems and other relevant materials to economic development process that are directly or indirectly harvested from nature. Over time, unregulated extraction and over exploitation of natural resources have adverse impacted and resulted in high declination of nature's capacity to allow contributions in different stages and formats and to regulate a good quality of life and implementation of the 2030 Agenda for Sustainable Development Goals (IPBES, 2019). It is vital to address these emerging challenges, which demand an enhanced knowledge of multiple values associated with nature and NCP. The emerging focus on 'values' also helps to move toward a more sustainable global community by communicating with a wide range of audiences for the policy and decision-making process (Pascual et al., 2017).

IPBES also commissioned a methodological assessment of diverse conceptualization of multiple values of nature and its benefits at the sixth session in Medellin, Colombia (IPBES, 2018). This initiative is targeting high-level discussion of stakeholders at the IPBES Plenary, its ninth session in 2022 (UNEP, 2020). The objective is to facilitate a strong foundation for knowledge and exchange for long term and efficient valuation of natural resources systems and to support decision-makers across various sectors in the development of policies and strategies that integrates coupled socioecological systems.

Another initiative in this direction is the World Business Council for Sustainable Development (WBCSD) publications on water valuation that help to clarify how businesses could establish their water valuation framework (Fig. 5) and supports them in undertaking a water valuation exercise while guiding scoping, planning, and embedding valuation into business processes across areas of operations, marketing, and reporting (Morgan and Orr, 2015).

'Valuing Water' is a nebulous domain, right from valuing rainwater and freshwater ecosystems to valuing water bonds or valuing water purification membranes, one can use different ways to express and ideate. To dissect the importance of the term, while adopting a business lens, it is evident that the financial impacts from water risks can be paramount. Take, for instance, the information provided by mining companies in 2018. The analysis covering >3000 mining sites worldwide points to the suite of the risks for countries, communities, basins, and companies and notes the spatial concentration of water risks as among various factors of interest and notes > USD20 billion of water-related financial risks, that have negatively impacted their operations (Morgan and Dobson, 2020). Such impacts can be drastic for a region or community with limited or no capacities to mitigate and adapt, for instance, 50% of the active and operating mines producing chromite globally are in South Africa's Limpopo basin and more than half of active and operating platinum mines are also in the same region. A significant scale of spatial crowding of commodity operations in specific regions is clearly a call of concern on many fronts and for the water sector.

Furthermore, the financial value of water risks is not of appropriate concern to all investors and companies, resulting in misinformed investment choices that unfavorably affects long-term business growth. The well-being of the communities and the environment is also influenced when water is judged solely based on economic value. The value proposal of the water beyond the financial and economic aspects is of utmost importance to ensure a water secure future for states and communities. To support this vision, '*Valuing Water Database*' a free resource containing over 100+ tools was launched in 2019 and integrated into WWF Water Risks Filter (Morgan, 2019). Amid the multiple water valuation methods and tools that have emerged in the past two decades, a rising need to comprehend how these methods vary and correspond toward enhancing the capacity of businesses, investors, government, and users is noted. The 2030 Water Resources Group (WRG) established multi-stakeholder partnerships to collectively manage the scarce water resources to benefit people, ecosystems, and economies. The report '*Valuing Water, Enabling Change*' tracked

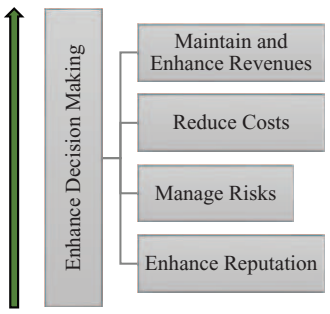

Fig. 5 Summary of WBCSD's Water Valuation Framework. Source: Modified based on Morgan A and Orr S (2015) *The Value of Water: A Framework for Understanding Water Valuation, Risk and Stewardship.*

the activities and impacts between July 1, 2019 and June 30, 2020 at the country level and provided a strategic approach for action (World Bank, 2020a,b). In the current context of the global pandemic situation, the 2030 World Water Resources Group hosted by the recent World Bank Annual Report endorses that the acceleration of adequate actions taking note of the valuation of water risks pointing it as a prevention strategy for COVID-19 (World Bank, 2020a,b) (Fig. 6).

Environmental personhood

The Anthropocene, an unofficial unit of geology, often describes the most recent period in Earth's history that is a period in which human activity has and continues to impact the global change and rampant degradation of ecological systems is seen. Amid this era of environmental change, the climate emergency with extreme events has prompted human societies, states, and populations to act for the restoration and protection of our natural heritage. The valuing water narrative also captures the framing of 'environmental personhood' as a viewpoint towards outlining operational measures. Presented as a legal concept that designates certain environmental entities' status as a regular person, this concept also extends to corporations (corporate personhood). In the contemporary environmental conservation scholarship, the concept is nearly 50 years old, when in 1974, Christopher D. Stone collected essays in a book titled 'Should Tree Have Standing? Toward Legal Rights for Natural Objects' (Bryant, 1975). The argument is, if an environmental entity is a 'legal personality,' it cannot be owned and has the right to appear in court, and it should be noted that by considering water a legal personality in the western lens, it is then legally valued. Some countries have already taken this concept to application—examples include the Whanganui River in Aotearoa, New Zealand; Lake Erie in Toledo, Ohio, and Vilcabamba River in Ecuador. In 2019, Toledo, Ohio, passed the Lake Erie Bill of Rights to protect its waters (Samuel, 2019).

This concept recognizes nature as a living, breathing force and allows creating space for all stakeholders, particularly indigenous peoples, to voice their concerns and perspectives, thus allowing a holistic approach to a complex problem related to water and the climate crisis. For the Anthropocene construct to be inclusive, the value systems of native people allow confrontation and acknowledgment of 'social nature' (Burke et al., 2016). In that framework the emerging set up of 'environmental personhood' calls for an ontological shift i.e. humans and nature are bound together, leaving us indistinguishable, into a complex but singular 'social nature.'

In indigenous settings around the world, the connection with nature (water, land, soil, and all dimension of the natural capital) is paramount. The social and cultural value of indigenous people and communities reflects on the healing power of nature and reflects on the circle of moral concern and encompassing partialities beyond the human species. Take for instance the case of New Zealand, the Whanganui River for >700 years is home for Whanganui tribes who managed, cared for, and depend on, calling it '*awa tupua*' meaning their river of sacred power. With European settlement in the mid-1800s, the traditional authority to manage the river was substituted by the nation-state decree. The inventions under that tenure included the use of dynamite to create an easy passage for tourism, gravel mining, and effluent dilution. Given such course of events in the modern era of river management, on March 20, 2017, New Zealand recognized in law what local and indigenous people such as Maori had widely supported i.e., the declaration of the river as a living being. This new legislation declared 'Te Awa Tupua,' the river and all its physical and metaphysical element as an indivisible, living whole, to henceforward holds all the rights, powers, duties, and liabilities of a legal person.

Water, energy, and food nexus—the value proposal

Few points are presented to expand on the value of water in the food sector. Modernization of irrigation systems have upgraded and improved the capacity of the production system to respond to the increasing food security needs, alongside the institutional, organizational, and technological changes and reforms governing the water-supply and demand dynamics through improvement in operation, maintenance, and management of canal irrigation and systems (Facon, 2005). These emerging management practices promoted or/and involved active participation both from government institutions and farmers, and inclusion of the stakeholders in decisions regarding the level of service and co-management. The private sector's emerging role in financing irrigation is another important and developing aspect toward improving the efficiency of water use as Eshete et al. (2020) highlights this point in the assessment for the Ethiopian region. In general, the evaluation of water resources for various uses and related allocation policies depends on the clarity of sectoral demand management.

In the 'value proposal' for freshwater systems, water pricing is a key attribute. For example, the agricultural sector in Ghana, Africa, noted decline in the past years (Dzanku and Aidam, 2013), thus impacting the national GDP and employment opportunities for the rural people, more so as the country specializes in the production of high-value crops such as cocoa, coffee, oil palm, cashew, and rubber. It is reported that seasonal variability in precipitation, particularly in the dry season, renders heavy reliance of the farming community on irrigation supply, and in recent years irrigation is noted as dominant source of water resource consumption in the country (FAO, 2016). Amid escalating water scarcity in the region and growing water demand of the agricultural sector, ensuring economic returns on freshwater use required fresh insights (Soto Rios et al., 2018). To mitigate the situation, as a short-term strategy, the urban farmers explored the use of wastewater to meet irrigation demand for vegetable production (Amponsah et al., 2015), however the health outcomes of such an intervention was not carefully evaluated. Therefore, the need for alternative options and careful measure of trade-offs while designing operational measures to address the value proposal to water is persisting. As valuation of water for food production at the cost of health outcomes could prove to be an unsustainable option.

In this above case, different systems and models to price water were debated as an option. The Multi-Analysis Tool for the Agricultural Sector (MATA) approach selects areas according to their resource characteristics (for example, land, labor, capital, and management), takes note of farmer management decisions while providing a framework for water pricing in the agriculture sector. The corresponding socioeconomic and agroclimatic environments are integrated into the tool along with the central assumption that income maximization is a priority for the farming community. The tool helps to understand trade-offs, specifically by adopting 2 cedi/m^3 (0.43 US dollar/m^3) annual volumetric rate as a measure that attracts farmers to a conscious use of freshwater resources and rationale for investment in water-saving technologies (Aidam, 2015). That said, public investment and policies need to recognize innovation and smart programs by providing proper incentives and an enabling environment for financing efficient water use systems and an integrated 'value' perspective.

In a similar context, the 'energy intensity analysis' by Hussey and Pittock (2012) points to water distribution systems that enable the identification of regions and districts where large amounts of energy are required to deliver water.

Narratives on water security and economic development

The water security and economic development interlinkages also involve objectives of safeguarding water needs for populations, household and livelihood requirements, and overall conservation and restoration of ecosystems. Therefore, securing water availability and allocations for sectoral needs such as food and energy production, industry, transport, and tourism are critical challenges in water management and governance. During past decades economics of water use, distribution and allocation received increased attention from academic, private, and policy communities. A crucial development report showcased trends of many regions worldwide focusing on water availability, noting that water security will remain a key catalyst for economic growth and sustainable development (World Economic Forum, 2017). Economic growth refers to an increase in the production of goods and services of economic value in a temporal domain. It is traditionally measured as the gross domestic product (GDP) linked to sustainable water management in multiple ways. Hence, the focus on water security is not only relevant to achieving sustainable development but necessary. However, there is no one concept or narrative to outline a clear agenda of water security. The working definition by UN-Water (2013) "*the capacity of a population to safeguard sustainable access to adequate quantities of acceptable quality water for sustaining livelihoods, human wellbeing, and socioeconomic development, for ensuring protection against waterborne pollution and water-related disasters, and for preserving ecosystems in a climate of peace and political stability*" provides a guiding framework framing while reflecting the vital need for efficient water use at economies of scale. Further, the emerging understanding of the various value and knowledge systems related to water management calls for water resources protection and priority attention to wastewater management, recycling, and reuse mechanisms (WWAP, 2019; Avellán et al., 2021). The general conceptual layout of water security (UN Water, 2013) clearly emphasizes the interconnectivity of multiple water needs-sectoral, environmental, and economic growth (Annexure).

The economic evaluation of water is generally shaped around the key dimensions of supply and demand dynamics, alongside the mechanisms for water quality management systems, storage infrastructure, and delivery or provisioning systems. These aspects are also crucial for the planning of water security for states and communities. Let's say, contamination of water resources is a water quality issue that renders a suite of risks to threat to human and ecosystem health. While the developed economies have been

experimenting since the mid-20th century to invest in improving the water resources systems, in some developing countries, the costs of treating urban and industrial waste far exceed their technical and financial capacity. Note a simple explanation- each cubic meter of on-site recycled water embodies one cubic meter that will not have to be withdrawn from a surface water source or groundwater. Reuse and recycling water and wastewater systems could also consider integrating industrial and municipal sewage/waste treatment agendas (WWAP, 2017). For example, reclaimed water can be used in industrial cooling and power generation, boiler feed, and extinguishing. Although the recycling and reuse approach is gaining popularity as an effective method of saving and valuing water both in industrial and municipal settings and is being integrated with the circular economy/circularity (Avellán et al., 2021) framework, the emerging theoretical and foundational knowledge is yet to demonstrate potential in societal well being and sustainable development vision. Besides, framings such as 'water auditing' has been developed that refers to the industrial sector or manufacturing facility, where water supplied to the plant is used for various activities and allows to measure how much water is used in each process and the water footprint of the entire chain/cycle production are being employed by various sectors of water use. The rainwater and evaporation rates impact the audit process, rendering information toward evaluating the water balance. It is acknowledged that an enhanced understanding of these framings could help to redefine the operational efficiency in water use.

Regional and national agendas for valuing water

People often understand the 'economics of water use' in a limited way; to enhance understanding in this direction the 'National Water Security Index' (NWSI) by Asian Development Bank includes five dimensions: household water security, economical water security, urban water security, environmental water security, and resilience to water-related disasters (ADB, 2013) and provides good insight into profiling the water security for various economic and non-economic sectors. Herein, the agriculture-focused subindex considers the different aspects of water security relating to food production, such as irrigated agriculture, import of water, and large storage structures like a dam. Also, mitigation and adaptation focus on disasters such as floods and drought risk for agricultural lands. The industrial-focused subindex is referred to as the financial value of industrial goods relative to industrial water use or consumption. The energy-focused subindex considers the use of overall hydropower and the ratio of hydropower to total energy supply. The direct connections between water and economic growth need in-depth investigation both for emerging and developing economies to evaluate their freshwater use, allocation, distribution plans, and policies. However, for several countries, especially in the developing world, crises related to access, availability, and quality of freshwater resources can unfavorably influence economic growth. Consequently, new technologies and business models need to be applied. International relations for knowledge sharing need to be established to ensure better capacity for sustainable use of water resources (Molden, 2007) and a water-secure future for people and societies.

The Inter Press Agency, during the Fourth Consultation of the HLPW (United Nations, 2017), noted that experts and policy-makers within the context of 'Valuing Water' alluded that regional cooperation is a must to resolve long-standing water problems in South Asian countries like Bangladesh, Bhutan, China, India, and Nepal, and to harness the full value of water (Islam, 2017). Focusing on several water-related diseases, including cholera and schistosomiasis, remains widespread across many developing countries. Only a tiny fraction (in some cases less than 5%) of domestic and urban wastewater is treated before its release into the environment. Although the rapidly growing cities in the developing countries are projected to become significant sources of nutrient emissions, South and East Asia, parts of Africa, and Central and Latin America are forecasted to become the hotspots for high nutrient emissions' increase in surface water systems (WWAP, 2019). Therefore, focusing on managing the ecological health of aquatic systems remains closely tied with tackling human health and the sustainable development agenda's goals, and the valuing water perspective.

The sense of urgency in tackling economic and development objectives and having an agenda alleviating the water crisis is increasingly noted in many countries' national agendas. At the national scale, the example includes the United States Bureau of Reclamation's water resource projects from 1930 to 1970 that reflected on the positive impacts on regional economic growth in the Southwest USA, particularly in regions experiencing water scarcity (Cicchetti et al., 1975). Another example is Spain, the largest semi-arid land in the European Union, which has outlined a complex multi-goal management approach to water security and develops water policies that address ecological, socioeconomic, and sociopolitical issues. Nevertheless, due to existing political instability in the past years, a comprehensive water policy is yet to materialize (Global Water Partnership, 2010). In a different part of the world, the Indus River, a transboundary water resource shared between India and Pakistan, provides an example to examine how in shared water systems, managing water for sectoral/economic needs poses complicated and multifaceted challenges. The Pakistan Council of Research in Water Resources reports that water shortage is dramatically increasing. The World Economic Forum (WEF) states that the country may deplete its water resources by 2025. Pakistan's economy is heavily reliant on agriculture, mainly irrigation-based production. Interventions like a dam could provide a solution for the pressing water needs. In rural Sindh and Baluchistan region, communities people walk several miles for daily water needs. However, transboundary water politics is complex, posing as a limiting factor as agreements of water sharing are not reflective of social, cultural, and humanitarian value systems (Adeel and Wirsing, 2016).

Case study: Water value perspectives in South Asia with focus on Nepal

Nepal is ranked among the top 40 water-stressed countries worldwide by the recent World Resources Institute report, having an average of 40–80% of the available water extracted every year to meet the annual demand. According to the institute's Aqueduct

Water Risk Atlas, the country faces 2–4 cm of groundwater depletion per year (Mandal, 2019). Thus, evidence shows that water demand increases significantly in Nepal, and access to safe and adequate drinking water is key to sustainable development agenda implementation. More than a quarter of the population has access to basic sanitation; those without access rely on local surface water sources like rivers for bathing, washing dishes, and clothes. Children under the age of 5 are the most affected by waterborne diseases, with an estimated 44,000 children dying every year. The public lacks awareness and education on safe drinking water rights and proper sanitation requirements; and domestic-industrial wastewater treatment plants need to be widespread (Ghimire, 2019). About 91% of Nepal's population drinks from an improved water source, however, recent studies also indicate *Escherichia coli* and total coliforms pollution is detected in water sources.

The study attributes the pollution of water resources from the human and animal densities, farm animal waste, manure application and livestock grazing, and the poor management of wastewater treatment plants and calls for better investment and focus on low-cost techniques to manage drinking water quality toward better health outcomes (Malla et al., 2018). Corrective actions in the water supply system and provisioning systems not connected to regulated piped networks (Slaymaker and Bain, 2017) also needs attention.

The Pokhara Metropolitan City (PMC) of Nepal's effort to respond to valuing water toward enhancing drinking water security is a pilot initiative research-based study '*drinkPani*' (Photos from the field shown in Fig. 8). The initiative intends to bridge the gap between water utilities and communities in information flow on water supply and quality, involving Youth as key actors and information and communication tools as the primary measures to navigate the path to reach policymakers for evidence-informed decision making. As part of ongoing research where 'water supply and quality monitoring are managed by using emerging technologies,' key-actors, the youth [Young Water Volunteers], are assigned official 'water clubs'- named *drinkPani are* provided

Concluding points

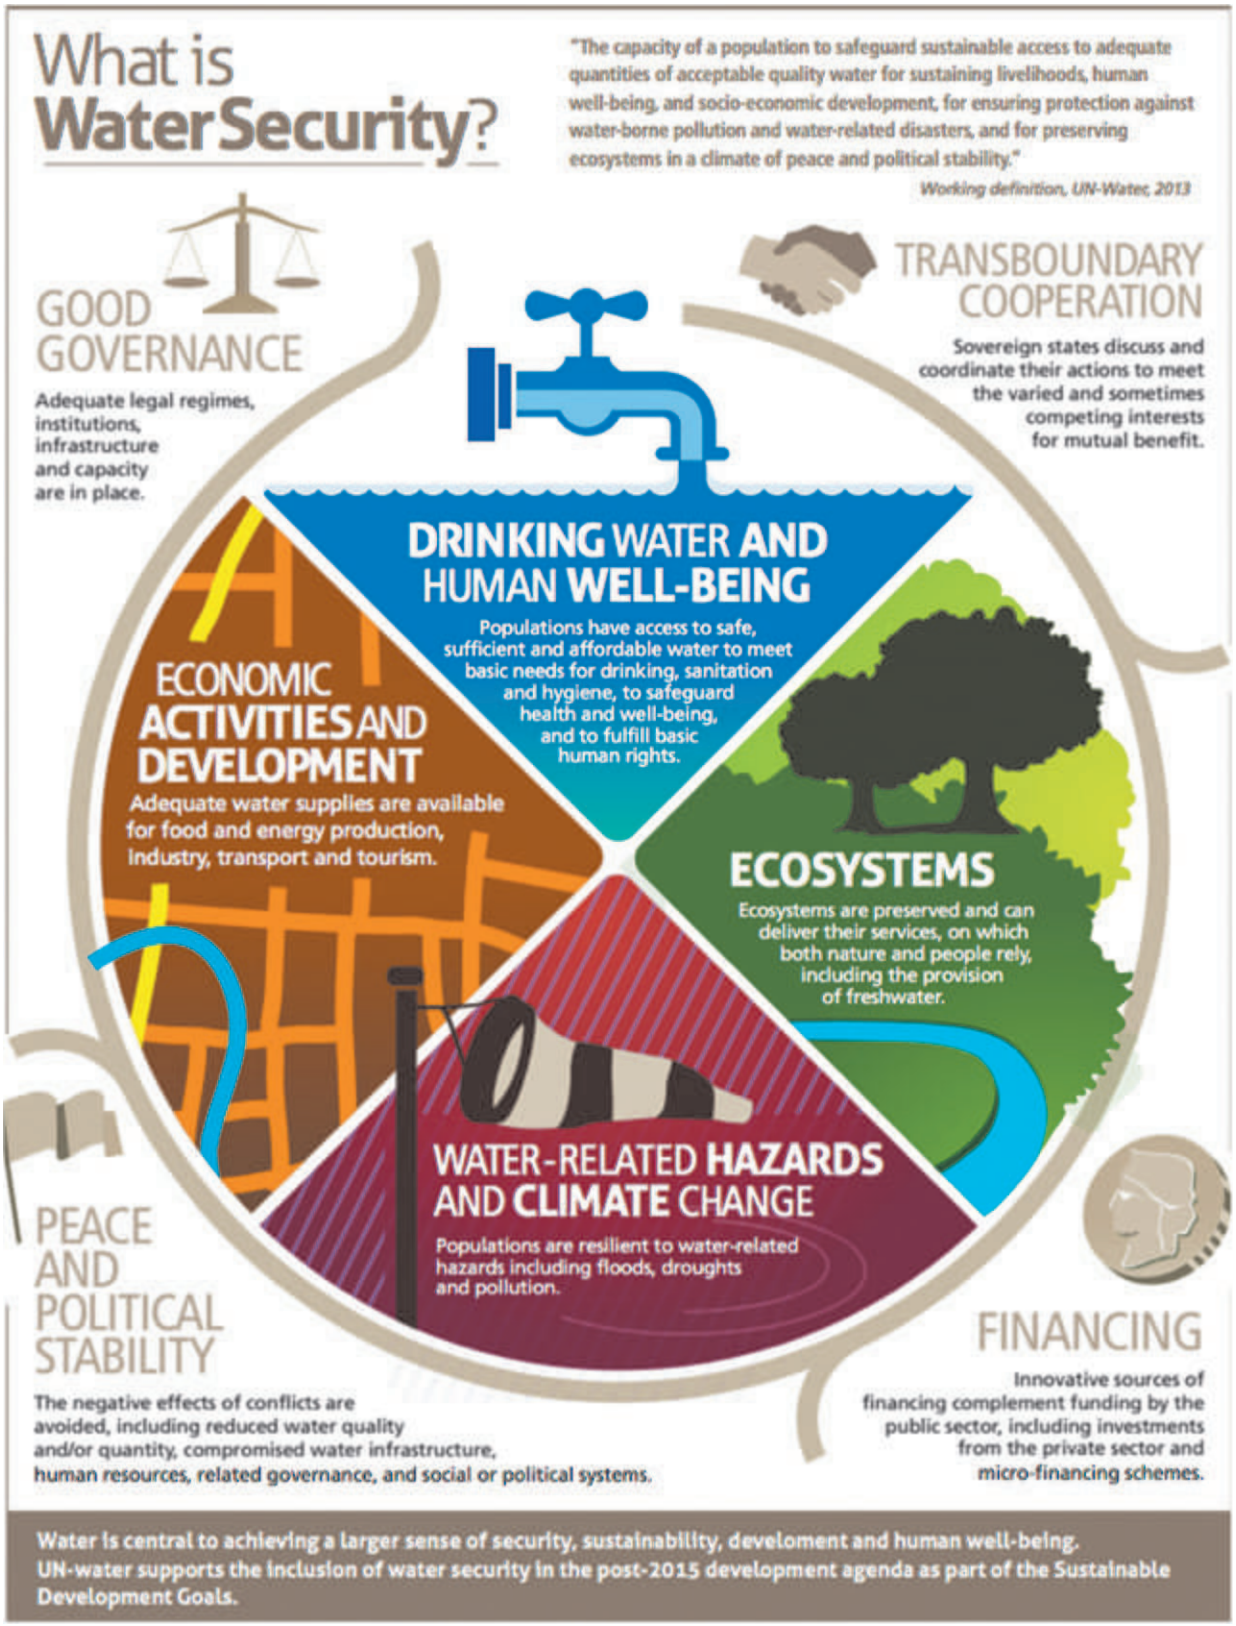
The framing of 'valuing water' is diverse, complex, and multifaceted; however, gradually, countries and communities are acknowledging and/or integrating multiple conceptualizations of values that apply to the water sector. Understanding these multiplicities from an economic and non-economic standpoint could help assess prior and current water use trends and likely future freshwater management trajectories. The existing knowledge surrounding valuing water is disaggregated. To this need, existing guidelines for managing water values' such as Bellagio's Principles and ongoing programs like the VWI, have potential. Additionally, the water security notion provides a useful perspective to design, plan, and address sectoral water needs with an integrated perspective. Thus, diverse values and aspects associated with water can be protected. Additionally, the concept of 'environmental personhood' provides a framing for *the* creation of valuing human rights to a valuing non-human entity rights holder and extending it to valuing nature, and by extension, water. Endowing water resources with this value proposition reflects the willingness to integrate multiple value systems, including but not limited to local and indigenous value and knowledge systems. The holistic approach to 'valuing water' can allow for a more equitable exchange of power and, in turn, access to political resources for effective management of freshwater resources via an optimal balance in economic growth and sustainability targets.

Knowledge gaps/future research

- In order to acknowledge and manage the 'value proposal' in the water domain, integrated approaches to managing food security, energy needs, and water security simultaneously remains a gap that should be addressed collectively and in participatory manner through a multi-stakeholder approach.
- Decision-makers should better put together interconnected challenges in the water, food, and energy nexus and design integrated freshwater-related policies and planning measures.
- Design mechanisms and tools that allow for assessing trade-offs while designing operational measures to address the value proposal to freshwater management systems.
- The interlinked sectors of water, food, and energy need can seek better ways of effective decision-making to optimize benefits, address financial barriers, and identify potential new partnerships.
- Promote research and development of smart and innovative strategies that allows integration of multiple values and knowledge systems in operational frameworks of water infrastructure, planning, and capacity development.

Annexure

UN Water (2013) water security conceptual framework emphasizes multiple dimensions that should be considered for inclusive planning and participatory management of water resources.



What is Water Security?
"The capacity of a population to safeguard sustainable access to adequate quantities of acceptable quality water for sustaining livelihoods, human well-being, and socio-economic development, for ensuring protection against water-borne pollution and water-related disasters, and for preserving ecosystems in a climate of peace and political stability."
Working definition, UN-Water, 2013
GOOD GOVERNANCE
Adequate legal regimes, institutions, infrastructure and capacity are in place.
TRANSBOUNDARY COOPERATION
Sovereign states discuss and coordinate their actions to meet the varied and sometimes competing interests for mutual benefit.
DRINKING WATER AND HUMAN WELL-BEING
Populations have access to safe, sufficient and affordable water to meet basic needs for drinking, sanitation and hygiene, to safeguard health and well-being, and to fulfill basic human rights.
ECONOMIC ACTIVITIES AND DEVELOPMENT
Adequate water supplies are available for food and energy production, industry, transport and tourism.
ECOSYSTEMS
Ecosystems are preserved and can deliver their services, on which both nature and people rely, including the provision of freshwater.
WATER-RELATED HAZARDS AND CLIMATE CHANGE
Populations are resilient to water-related hazards including floods, droughts and pollution.
PEACE AND POLITICAL STABILITY
The negative effects of conflicts are avoided, including reduced water quality and/or quantity, compromised water infrastructure, human resources, related governance, and social or political systems.
FINANCING
Innovative sources of financing complement funding by the public sector, including investments from the private sector and micro-financing schemes.
Water is central to achieving a larger sense of security, sustainability, development and human well-being.
UN-water supports the inclusion of water security in the post-2015 development agenda as part of the Sustainable Development Goals.

EMERGING METHODS AND TOPICS

Section Introduction: Exploring the Exciting New Landscape of Inland Waters Research

Kendra Spence Cheruvelil[a] **and Herbert Kasozi**[b], [a]Department of Fisheries and Wildlife, Lyman Briggs College, and Ecology, Evolution, and Behavior Program, Michigan State University, East Lansing, Michigan, United States; [b]Department of Fisheries and Wildlife, Michigan State University, East Lansing, Michigan, United States

Introduction

The study of inland waters has a robust and long history. However, what is most exciting to us (and many scientists), are the newest scientific questions that require us to develop different perspectives of freshwaters, engage with new areas of study, and develop or apply new approaches and methods. That's what this encyclopedia section *Emerging Methods and Topics*, is all about—the new frontiers that are advancing the understanding and management of inland waters.

Some of these new perspectives and questions are the result of emerging technologies opening new areas of research. Many of these questions come from our heightened understanding of the pressures facing our freshwater resources in the face of global changes, such as land use intensification, climate change, and the spread of exotic species. These global changes that are inextricably linked with humans, requiring us to interrogate the belief that science (and scientists) is objective and to embrace new ways of transforming knowledge and translating that new knowledge to those beyond academia. Therefore, many of these questions require limnologists to collaborate with experts in the social sciences, humanities, and communication sciences. The emerging approaches and methods required may be brand new, requiring algorithm or technology development and partnering with those in fields such as statistics, computer science, and engineering. Alternatively, these approaches and methods may already exist in those disciplines, but haven't yet been applied to understand inland waters.

This *Emerging Methods and Topics* section brings you chapters that highlight some of those exciting new questions being asked, perspectives being developed, and methods and approaches either being developed or applied to inland water research and management. These chapters are written by emerging leaders in limnology, mainly early-to-mid-career scientists who are pushing the boundaries of their specialties to answer important questions that are just now surfacing. The chapters are arranged to introduce you to a new perspective, research question, or area of research and then to share some of the new approaches and methods being used by those taking such perspectives, asking those questions, and developing these new areas of research.

First, we bring you a chapter that shifts our perspective of inland waters. We like to use a medical analogy when thinking about this perspective change. In the past, many limnologists were like medical doctors, studying and managing individual bodies of water, watersheds, or water-rich regions. More recently, some limnologists have become more like epidemiologists, seeking to understand and manage entire populations of inland waters. In *Macrosystems Limnology and Beyond: Re-Envisioning the Scale of Limnology*, the authors describe the importance of this perspective. We then follow that chapter with a series of five chapters that share approaches, tools, and methods that help advance this broad-scale perspective (i.e., high-frequency sensors; remote sensing; machine learning; research teams, networks, and networks of networks; and citizen science, crowdsourcing, and social media).

Next, we bring you a series of three chapters introducing you to some interesting new areas of inland waters research: dust and fog effects, understanding the soundscape (i.e., ecoacoustics), and fungi in the Anthropocene. Finally, we end the section with

three chapters that share exciting new approaches, tools, and methods to better understand and manage organisms in inland waters (i.e., environmental DNA or eDNA, electronic tagging and tracking, and fatty acid markers and foodweb tracers). Below, we provide a short summary of each chapter of the *Emerging Methods and Topics* section to pique your interest and prompt you to turn to each respective chapter to learn more about the future of inland waters research and management.

Macrosystems limnology and beyond: Re-envisioning the scale of limnology (McCullough et al., 2022)

This chapter discusses the emerging field of *macrosystems limnology*, which recognizes freshwater ecosystems as components of larger, integrated systems influenced by aquatic, terrestrial, and atmospheric components and processes at multiple scales of space and time. This field has its content roots in landscape limnology, biogeography, and systems science, and has been advanced with data from long-term monitoring networks, government monitoring programs, large compilation databases, coordinated snapshot surveys, remote sensing, and citizen science. The aim of macrosystems limnology is to uncover patterns that exist and the underlying processes operating at different levels of biological organization and across scales of space and time. A macrosystems perspective could be instrumental in predicting how freshwaters will respond to global changes and guide regional to continental (and even global) management efforts.

Creating and managing data from high-frequency environmental sensors (Rose et al., 2022)

This chapter discusses the relevance and applications of high frequency sensors for advancing limnological research. High frequency sensors facilitate fast and repeated sampling of ecological phenomena, even where it is impossible to make manual measurements (such as in sites that are not easily accessible), which has resulted in many insights into ecosystem dynamics. The chapter describes a range of sensors and outlines practical considerations for their use in data collection. In addition, the authors discuss key sampling concepts and their ecological implications and challenges, as well as some disadvantages of fast sampling rates such as increased dataset complexity, power consumption, and storage requirements. The chapter outlines practical considerations in sensor choice and management, including sensor type, system design, cost, and measurement variables. Rose et al. also explain the challenges associated with these methods, such as harsh environmental conditions, and explore considerations for ensuring data quality and adequate data management.

Remote sensing of inland waters (Tyler et al., 2022)

This chapter provides an overview of the principles and applications of earth observation (EO) technologies (e.g., satellite or airborne remote sensing) for monitoring water quality. The chapter describes ways to characterize water color and how light propagation, optical complexity, and water typology affect EO estimation of water color. Additionally, the chapter explores the evolution of remote sensing platforms and defines the criteria for selecting sensor and platform developments. Platforms discussed are spaceborne, airborne, drone, in situ above-water, and in situ subsurface sensors. The criteria discussed include size of distinguished objects, range, number and width of spectral bands, number of digital levels used to express collected data, and the interval between the different resolutions. The authors also discuss additional applications such as estimating chlorophyll *a*, phycocyanin, turbidity, and total suspended matter. Monitoring algal blooms, brownification, and primary production at both national and global scales using remote sensing can provide critical information for lake management.

Machine learning for understanding inland water quantity, quality, and ecology (Appling et al., 2022)

This chapter provides an overview of machine learning (ML) models and their applications to the science of inland waters. ML is the development and application of models that adapt and can analyze and draw inferences from patterns in large amounts of data. The authors describe many aspects of ML models, including their characteristics and how they compare with process-based and empirical models, ways to determine model trustworthiness, ways to choose among model classes, and ways to understand and interpret model results. They focus on four classes of ML approaches that are gaining in popularity when studying inland waters - neural networks, classification and regression trees, clustering and dimensionality reduction methods, and model interpretation techniques. The authors provide examples of ML model applications for predicting and understanding inland waters, including the prediction of water quality, quantity, and ecology across space or time.

Teams, networks, and networks of networks advancing our understanding and conservation of inland waters (Read et al., 2022)

This chapter discusses the important role of people working together to advance inland water science and management and provides case studies demonstrating the importance of teamwork for advancing knowledge. Teams, networks, and networks of networks lie at the forefront of inland water research, management, and conservation. This is largely due to the multi- and interdisciplinary and complex nature of inland water research and management. The chapter examines the role of teams, networks, and networks of networks in the

research and management of inland water resources, discusses aspects of team building and maintenance and their respective roles in propagating successful research and management, and methods for successful social connections within teams, networks, and networks of networks. The authors explain that teams, networks, and networks of networks may include individuals within the same or different organizations, but that they are bound together by a common goal, and that trust is the foundational tenet for success. Effective team and network dynamics are critical for effective flow of information, allocation of resources, coordination of logistics, knowledge generation and sharing, as well as building and engaging in collective action.

Citizen science, crowdsourcing, and social media advance our understanding and conservation of inland waters (Latimore and Lowry, 2022)

This chapter discusses how increasingly important it is for inland waters scientists and managers to engage with diverse audiences. The chapter focuses on three rapidly expanding methods for public engagement: citizen science, crowdsourcing, and the use of social media. These methods produce large amounts of reliable data; often represent cost-effective approaches to increase research scale, public relevance, participant knowledge of content and the scientific process; and empower participants to engage in stewardship and decision-making processes. The authors point to the recent growth of these approaches and provide case studies highlighting the use of these methods in both scholarship and application. Participation of non-scientists can result in more relevant research questions, can produce a richer set of data and knowledge, generate innovative solutions to complex conservation problems, and increase scientific literacy and public support for research and conservation work.

Dust and fog effects on inland waters (Brahney et al., 2022)

This chapter describes a new research area, that of the roles of fog and dust in the transportation of atmospheric nutrients to inland waters. Human activity (such as construction) is a major agent of dust generation and fog is critical in the deposition of dust into aquatic ecosystems. Nutrients carried by dust may alter the chemistry of the affected aquatic systems with negative effects on the ecology and behavior of microbial, phytoplankton, and zooplankton communities within. Fog is likely to have indirect impacts on inland waters through scattering and absorption of incoming light, and hydrologic and biogeochemical impacts on adjacent catchments. The authors discuss the process of dust and fog formation, controls on dust and fog composition, nutrient bioavailability, common measurement techniques of dust and fog, and provide case studies that exemplify the effects of dust and fog on water chemistry and the ecology of inland waters.

Freshwater ecoacoustics (Linke et al., 2022)

This chapter discusses ecoacoustics, an emerging interdisciplinary field that investigates the ecological relevance of environmental sounds. It examines fundamental differences between bioacoustics and ecoacoustics and highlights applications of the latter in aquatic systems research. The chapter discusses biotic, abiotic, and anthropogenic sources of environmental sounds. Biotic sounds discussed commonly emanate from insects, fish, and plants; abiotic sounds include flow turbulence, sediment transport, and river flow; and anthropogenic sounds include water transport, recreational water parks, and mining and construction activities. After highlighting problems with traditional sampling methods, the chapter makes a strong case for the need of ecoacoustics to improve understanding of aquatic soundscapes. The chapter concludes by highlighting knowledge gaps, technical challenges, and relevance of ecoacoustics to society.

Inland water fungi in the Anthropocene: Current and future perspectives (Grossart et al., 2022)

This chapter examines the biological, chemical, and physical effects of pollution on inland water fungi. Fungi species have different mechanisms of assimilating and breaking down the pollutants. For example, some fungi have extracellular enzymes that break down pollutants from human environments. The ability to process and detoxify anthropogenic pollutants qualifies fungi as an indicator of ecosystem health. The authors explore the diversity and ecology of aquatic fungi and fungi-like organisms, and highlight the emerging topic of fungi-virus interactions. The authors also highlight the effects of micro plastic pollution on aquatic fungi and the roles of fungi in decomposition of micro plastics. Micro plastics are commonly generated from urban environments and washed into inland waters. However, some fungi assimilate micro plastic pollutants in aquatic environments. Understanding the ecological roles of aquatic fungi is critical in examining the negative feedback loops of human pollution to human health.

Environmental DNA advancing our understanding and conservation of inland waters (Seymour, 2022)

This chapter explores the application of environmental DNA (eDNA) for sampling freshwater animals. The use of eDNA is an emerging modern technique facilitated by recent advances in molecular techniques that is rapidly gaining popularity within

freshwater ecological research. The method relies on extraction of free floating DNA samples in the environment without targeting a particular organism. The extracted samples are released by animals (e.g., as fecal material) into the environment and eDNA traces the source animal species. The chapter discusses concepts related to the accumulation of eDNA and its extraction from freshwater environments. The author discusses the use of eDNA for monitoring of organisms (including fish, macroinvertebrates, and diatoms), which would otherwise be laborious and invasive. He also highlights the importance of eDNA methods for detection of rare and invasive species and monitoring disease spread.

Electronic tagging and tracking of animals in inland waters (Cooke et al., 2022)

This chapter discusses the use of electronic tags to track inland water animals. This approach can be used to understand several aspects of aquatic animal ecology (such as habitat use and interspecific interactions), behavior (such as movement, migration, and dispersal patterns), and environmental conditions (many tags measure components such as depth and temperature). The authors describe biotelemetry and biologging as the major tools used to track inland water animals (e.g., radio and acoustic telemetry, Passive Integrated Transponders (PIT) tags), and provide example applications to study a diversity of animals ≥ 10 g body mass including invertebrates, amphibians, reptiles, waterbirds, fish, and some mammals. The authors discuss how information generated from animal tracking is used in the evaluation of conservation programs, including tracking animals reintroduced into the wild from captivity.

Fatty acid-markers as foodweb tracers in inland waters (Makhutova et al., 2022)

This chapter describes the use of fatty acid (FA) markers to trace the fluxes of matter and energy through foodwebs. The authors describe FAs and their use as foodweb markers in aquatic ecosystems, describe and compare the FA-marker analysis with other methods for studying aquatic animal diets, and describe the identifying characteristics of FAs in the main taxonomic groups of organisms inhabiting freshwater ecosystems (bacteria, algae and other photosynthetic eukaryotes, non-photosynthetic eukaryotes). The chapter also describes how FAs have been used to understand the feeding spectra of many aquatic consumers and have contributed to scientists successfully differentiating between external and internal sources of organic matter in inland waters (i.e., allochthonous versus autochthonous inputs). FA-marker analysis has facilitated discoveries such as selective feeding of filter-feeders, diet variability of detritovores, and adaptations of feeding behavior to changing environments.

Acknowledgments

Thank you to Thomas Mehner for inviting me to edit this encyclopedia section and Paula Davies for keeping us all on track. The lake health analogy with epidemiology was co-created with KSC's co-director, Patricia Soranno. I appreciate Allie Shoffner for her editorial support. Hats off to all of the authors who have contributed their time, energy, and brilliance to this section during a global pandemic and a time of social and environmental crises.

Macrosystems Limnology and Beyond: Re-Envisioning the Scale of Limnology

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Kendra Cheruvelil.

Glossary

Big data Massive volumes of data, often of many varieties, that are not readily handled by the usual data tools and practices and present unprecedented opportunities for advancing science and informing resource management through data-intensive approaches (Hampton et al., 2013).

Component Biological (e.g., species, populations, communities), geophysical (e.g., climate, physiography, hydrology, geochemistry), and social (e.g., political systems, economies, cultures) variables and phenomena that span timescales ranging from days to millennia. When interacting with one another and with phenomena at other spatial or temporal scales, these components constitute a macrosystem (Heffernan et al., 2014).

Cross-scale emergence A macrosystems interaction where local-scale components interact and accumulate across broad geographic space to produce macroscale phenomena (Heffernan et al., 2014). Example: The additive effects of dam construction on individual stream reaches that result in highly fragmented river networks and impair migratory fish habitat. A single dam on a stream segment may not have a large effect on fish populations, but the cumulative effect of multiple dams on a stream network can significantly reduce habitat connectivity and adversely affect fish populations.

Cross-scale interactions A macrosystems interaction where processes at one spatial or temporal scale interact with processes at a different scale and result in unexpected ecosystem responses (Heffernan et al., 2014; Soranno et al., 2014). Example: The relative role of local wetlands as nutrient sinks and sources depends on regional setting. In regions with high levels of agriculture, local wetlands may act as a nutrient sink preventing excess nutrients from entering receiving lakes and streams, whereas in regions with minimal agriculture, local wetlands may act as a nutrient source to receiving waterbodies (Fergus et al., 2011).

Landscape limnology The spatially explicit study of lakes, streams, and wetlands as they interact with freshwater, terrestrial, and human landscapes to determine the effects of pattern on ecosystem processes across temporal and spatial scales (Soranno et al., 2010).

Macroscale feedbacks Macrosystems interactions where one macroscale component can amplify (positive feedback) or diminish (negative feedback) the effects of another macroscale component. These feedbacks can promote thresholds or alternative stable states in freshwater ecosystems (Heffernan et al., 2014). Example: The positive macroscale feedback loop between rising air temperatures and methane emissions (a potent greenhouse gas) from freshwater ecosystems. Rising temperatures caused by high greenhouse gas concentrations can promote methane emissions from warming, stratified lakes and melting permafrost. This reinforcing macroscale feedback leads to greater greenhouse gas levels, which then promote warmer air temperatures and conditions that result in freshwater ecosystems releasing more greenhouse gases.

Macroscale Regional to continental extents with distances spanning hundreds to thousands of kilometers (i.e., larger than landscapes; Heffernan et al., 2014).

Macrosystem A set of interacting biological (e.g., species, populations, communities), geophysical (e.g., climate, physiography, hydrology, geochemistry), and social (e.g., political systems, economies, cultures) components that range in spatial extent from very fine to very broad and that can interact over very large distances and can span timescales ranging from days to millennia (Heffernan et al., 2014).

Macrosystems ecology Study of diverse ecological phenomena at the scale of regions to continents and their interactions with phenomena at other scales (Heffernan et al., 2014).

The views expressed are his/her own and do not necessarily represent those of the United States or the U.S. EPA. It has not been subject to the Agency's review and therefore does not necessarily reflect the views of the Agency, and no official endorsement should be inferred.

Macrosystems limnology Study of freshwater ecosystems (rivers, streams, lakes, reservoirs, wetlands, and groundwater) that explicitly recognizes the important role of integrated terrestrial, aquatic, and atmospheric components and processes operating at multiple spatial and temporal scales from the local watershed to regional, continental, and even global extents (this article).
Open science The concept of transparency at all stages of the research process, coupled with free and open access to data, code, and papers (Hampton et al., 2015).
Scale The spatial or temporal domain of study, reflecting data resolution (i.e., grain size or measurement frequency) and extent (i.e., study area or length of study) (Turner et al., 1989). Scale often refers to spatial or temporal hierarchies in ecological studies (e.g., local or continental for spatial scale and decadal or centennial for temporal scale).
Teleconnections Macrosystems interactions that connect geographically distant and otherwise disconnected regions via the movement of materials, organisms, energy, or information. Example: Anthropogenic acidification of freshwater ecosystems. In the 1970s in North America and Europe, lakes in remote, pristine settings had abnormally low pH to the point that biota could not be supported. The cause of acidification was coal combustion emissions that were transported via atmospheric processes from distant energy plants to remote, poorly buffered freshwater ecosystems.

Introduction

The historical roots of limnology are grounded in local-scale, single-ecosystem studies that intensely study and/or manipulate a few waterbodies and their watersheds over time. While these studies have created foundational knowledge for limnology, there are limitations in how findings from individual systems may apply to other freshwater ecosystems, especially those located in different landscape and regional settings. Additionally, these localized studies are insufficient to address the pressing, long-term scientific and management challenges facing fresh waters at regional to global scales such as climate change, land use conversion, and invasive species. Alternative approaches are needed for limnology to meet these challenges at broad spatial and temporal scales.

We suggest that understanding freshwater responses to global change stressors (e.g., climate change, land use/cover change, invasive species) will be enhanced by taking an integrative, multidisciplinary, and multiscale perspective such as offered by the emerging subdiscipline of macrosystems limnology. We define macrosystems limnology as the study of freshwater ecosystems (rivers, streams, lakes, reservoirs, wetlands, and groundwater) that explicitly recognizes the important role of integrated terrestrial, aquatic, and atmospheric components and processes operating at multiple spatial and temporal scales from the local watershed to regional, continental, and even global extents (Glossary). With advances in ecological knowledge and theory, the emergence of global change stressors, and the "big data" era of ecology embracing open science practices, limnology is expanding to regional, continental, and even global scales. In this article, we describe macrosystems limnology by describing the what, why, how, who, where, and when of this new era of limnology.

The what

Macrosystems limnology is a framework for studying and managing freshwater ecosystems (rivers, streams, lakes, reservoirs, wetlands, and groundwater) that explicitly recognizes that freshwater ecosystems are shaped by terrestrial, aquatic, and atmospheric components and processes operating at multiple spatial and temporal scales (Fig. 1). From this perspective, macrosystems limnology studies multiple freshwater ecosystems that generally span regional to continental extents to identify distributions (frequency, patterns) and multi-scale determinants and drivers (causes, risk factors) of ecological condition and processes. By identifying broadly occurring patterns and processes, the aim is to uncover general mechanisms operating at different levels of organization (Smith et al., 2008; Dodds et al., 2015, 2019) and overcome the limitations of local-scale studies that may have spatial and temporal contingencies specific to the local ecosystem and time of study (McGill, 2019).

It can be argued that a macrosystems limnology framework is necessary not only to understand freshwater ecosystem dynamics and properties that emerge from a set of multi-scale interactions, but also to predict how fresh waters will respond to global change. In fact, macroscale (i.e., regional- to continental-scale; Glossary) studies have increased in freshwater sciences over the past 20 years (Fig. 2). This trend mirrors a previously recognized shift in limnology toward more global-scale studies, accompanied by a growing recognition of the role of broad-scale phenomena such as climate change in aquatic biogeochemical cycling and aquatic ecosystem management, as well as greater availability of broad-scale datasets (Lapierre et al., 2020). This trend is expected to continue with advances in macrosystems theoretical frameworks, data and technology resources, open science culture, and the need to address pressing, broad-scale environmental problems.

Macrosystems limnology integrates and extends concepts, theories, and approaches from the fields of landscape limnology and macrosystems ecology. These ecological subdisciplines provide robust frameworks to guide and motivate the study of limnology across multiple spatial and temporal scales. From a landscape limnology perspective, freshwater ecosystems are viewed as discrete patches embedded within landscape mosaics composed of natural terrestrial, aquatic, and anthropogenic features that are

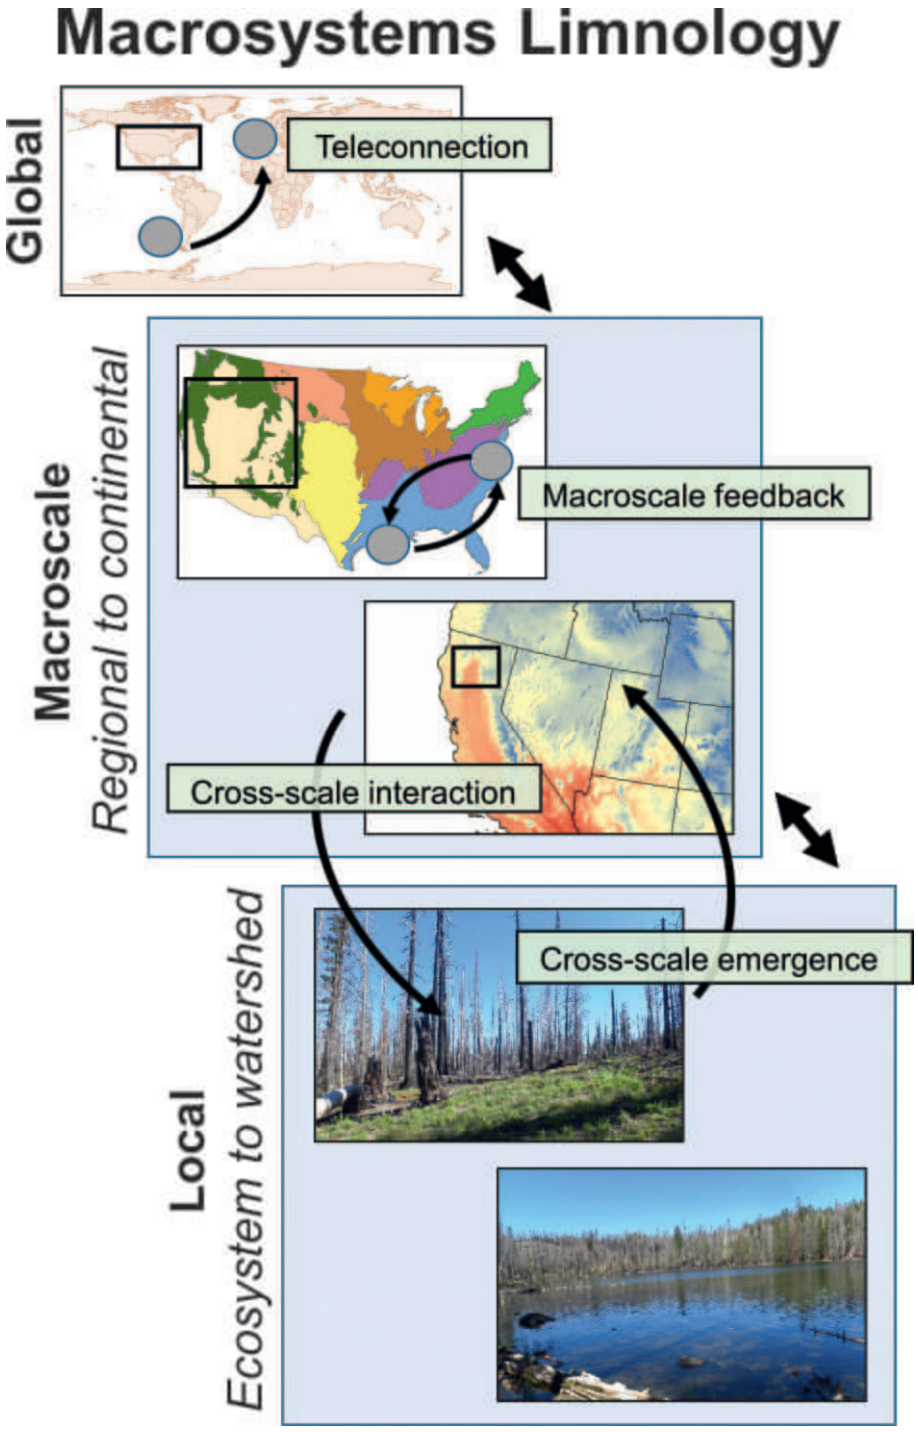

Fig. 1 Conceptual diagram of macrosystems limnology. Macrosystems integrate processes operating at spatial scales from local to global and at temporal scales from days to millennia. Macrosystems consist of various interactions within and across spatial scales, including teleconnections, macroscale feedbacks, cross-scale interactions, and cross-scale emergence (see Glossary for definitions and further examples). Shown at the macroscale are ecoregions (Herlihy et al., 2008) and regional climate (Daly et al., 2008). Ash from a volcanic eruption in Southeast Asia influences air temperatures in Western Europe (teleconnection). Precipitation influences forest growth and distribution, whereas forests also influence precipitation via transpiration (macroscale feedback). Fires are influenced by regional climate and local vegetation (cross-scale interactions), but individual fires across a given region also combine to influence regional air quality (cross-scale emergence). At the local scale (ecosystem to watershed), there is burned watershed vegetation and a nearby lake in California, USA. Photos: Ian McCullough.

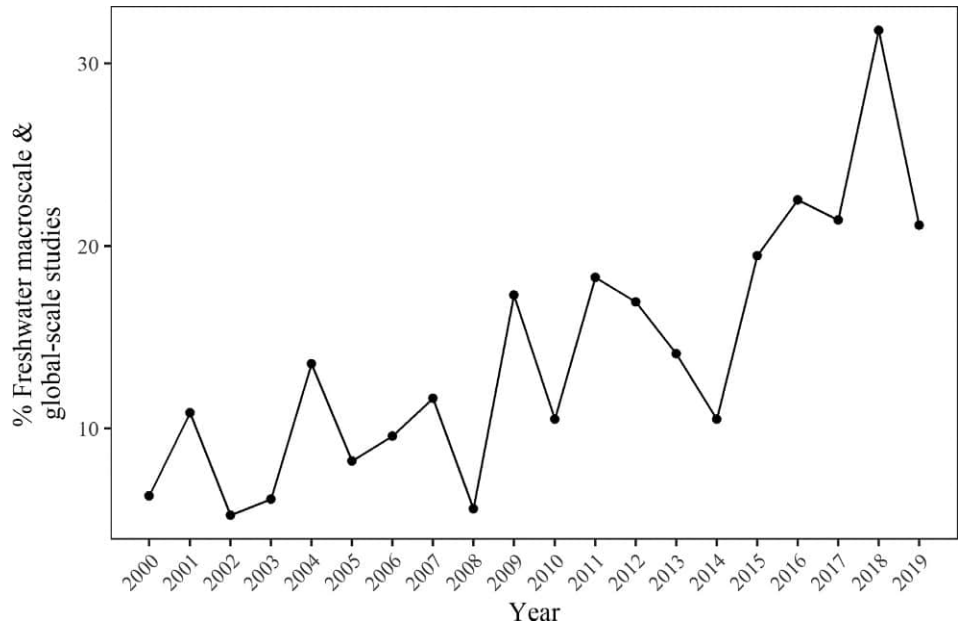

Fig. 2 Recent trend in macroscale (i.e., regional- to continental-scale) studies published annually in *Limnology and Oceanography* from 2000 to 2019, expressed as the percent of freshwater studies published in a given year conducted at macro- and global scales. We performed a spring 2020 Web of Science search using the following terms (and related forms of each using the * wildcard) "macroscale", "macrosystem", "region", "continent", "ecoregion", "subcontinent", "nation", and "global" to select studies conducted at large spatial extents. Marine and estuarine studies were excluded.

hierarchically structured and interact to influence freshwater ecological patterns and processes that emerge at different spatial and temporal scales (Soranno et al., 2009, 2010; Glossary). Freshwater ecosystems are generally the topographically low areas on the landscape that integrate terrestrial, aquatic, anthropogenic, and atmospheric processes structured at multiple scales. In addition, surface and subsurface hydrologic connections link freshwater ecosystems to geographically-distant landscape components and can enhance cross-ecosystem transport of materials, organisms, and energy. These properties make freshwater ecosystems particularly sensitive to global change stressors.

The macrosystems ecology perspective expands this landscape limnology view to consider explicitly the influence of macroscale phenomena operating at regional to continental extents (i.e., spanning hundreds to thousands of kilometers; Heffernan et al., 2014) on freshwater ecosystem properties and dynamics. Macrosystems consist of multiple biological, geophysical, and anthropogenic components that can interact across different spatial and temporal scales and result in emergent or potentially unexpected ecosystem properties in fresh waters that would be difficult to predict from local-scale observations alone (Heffernan et al., 2014; Soranno et al., 2014). These complex ecological relationships are important components of macrosystems and can be grouped into different classes: macroscale feedbacks, cross-scale emergence, cross-scale interactions, and teleconnections (Heffernan et al., 2014; Glossary). Macrosystems interactions can be defining characteristics of freshwater ecosystems and are a driving motivation for a macrosystems approach to limnology.

Integrating perspectives from landscape limnology and macrosystems ecology provides the framework for macrosystems limnology (Fig. 1). There are three key items that need careful consideration to address research and management objectives applying a macrosystems limnology framework. First, identifying the spatial and temporal resolution (i.e., grain size and measurement frequency) and extent (i.e., study area and length of study) is particularly important in macrosystems studies when scales extend beyond conventional watershed and season limits. Although scale is ultimately defined by the spatial and temporal characteristics of the phenomena of interest, it has frequently been constrained by observational data limitations that tend to be conducted at fine spatial scales and for short durations and thus may not accurately represent the full range of variability. Second, macrosystems are multi-scale, heterogeneous systems and to distill this complexity requires identifying ways to quantify biological, geophysical, climatic, and anthropogenic components that promote the patterns and trends of interest. Third, it is important to identify the disciplinary expertise (e.g., limnology, hydrology, climatology) needed for macrosystems studies because multiple drivers are hypothesized to affect freshwater ecosystems and thus macrosystems limnology often requires collaboration across multiple disciplines. With these three items defined, macrosystems limnology can be applied to understand and explain variation in freshwater ecosystems, responses to change, and prediction using scaling relationships at broad spatial and temporal extents. This macrosystems approach to limnology opens the door to address complex and challenging ecological questions facing fresh waters and provides a framework to support research and management objectives.

The why

Macrosystems limnology can lead to advances in understanding pressing environmental challenges facing fresh waters and guide management efforts. Current environmental challenges include both major causes of change in ecosystems (e.g., climate change, land use change, and invasive species) and major ecological responses to change (e.g., biodiversity loss, shifts in biogeochemical and hydrologic cycles, infectious disease transmission). Freshwater ecosystems are particularly sensitive to such phenomena because fresh waters integrate terrestrial, aquatic, and atmospheric processes over large geographic areas. We need a macrosystems framework to disentangle the effects of current global change stressors on fresh waters, which are complex and occur at, and interact across, multiple spatial and temporal scales (Fig. 1). Although many ecological questions can be answered at the local scale, understanding and predicting the consequences of global change for fresh waters require studies that contain numerous observations across wide ecological gradients, often over large geographic extents and long time periods.

The time scale at which global change stressors operate is often longer than that of a typical single study. For example, climate change studies should ideally last several decades to differentiate signal (i.e., response to climate change) from noise (i.e., response to interannual variation). Consequently, scientists should recognize that certain types of questions particularly benefit from long-term data and that in these cases there are potential limitations of relying predominantly on spatial data, as macrosystems studies often do. Therefore, long-term data should be incorporated into macrosystems studies when possible, particularly when investigating phenomena that operate over long temporal scales. Furthermore, long-term studies contribute disproportionately to both ecological knowledge and policymaking in a broad sense, demonstrating their value for both theoretical and practical applications (Hughes et al., 2017).

Studying freshwater ecosystems from a macrosystems perspective can also guide management efforts. First, and potentially most importantly, managers and natural resource agencies are often responsible for many ecosystems spanning large geographic areas. Therefore, developing management plans for ecologically diverse freshwater ecosystems in heterogeneous landscapes may necessitate identifying generalities to predict responses to multi-scale global change stressors. Results from single-ecosystem studies may be confounded by local factors (e.g., lake morphometry, watershed characteristics), making it unclear how such results apply across a more diverse group of ecosystems. Macrosystem studies, however, can reveal general patterns across wide ecological gradients and help disentangle the effects of multi-scale drivers. Further, given that managers often lack the resources to sample all ecosystems being managed, they may benefit considerably from the more generalizable findings of macrosystems studies. For example, researchers and managers are concerned about the spread and ecological impacts of aquatic invasive species in inland waters. Regional-scale models or frameworks that estimate the potential spread or impacts of aquatic invasive species represent a useful approach to scale up local-scale knowledge (e.g., local abundance, habitat suitability) and increase the efficiency and effectiveness of management interventions at the state or provincial level by identifying types of lakes that are most susceptible to invasions (Papeş et al., 2011; Vander Zanden et al., 2017). In a broad sense, an improved understanding of ecological responses to global change stressors across wide gradients can help managers anticipate responses of their ecosystems of interest to ongoing global change, which is also useful for communicating their plans and strategies to public audiences and policymakers.

The how and who

The move toward practicing macrosystems limnology was motivated by a combination of long-term monitoring networks, government monitoring programs, large synthetic databases, coordinated snapshot surveys, remote sensing, and citizen science. Numerous agencies, organizations, and people contribute to these programs and data products, including academic researchers across a wide range of disciplines, governments at different levels (e.g., city to national), and volunteers. Although these various actors often have different individual goals, all have collectively made important contributions to the growth of macrosystems limnology through data collection, open science, and knowledge development (Fig. 3).

Long-term monitoring networks generally entail intensive data collection at select ecosystems to document long-term ecosystem change. For example, the Global Lake Ecological Observatory Network (GLEON) operates standardized, automated sensors that collect high-frequency lake data (e.g., dissolved oxygen, water temperature) across over 50 lakes and reservoirs worldwide. GLEON began in the mid-2000s as an initiative among a relatively small group of scientists to share and combine lake datasets from across the globe. GLEON has since evolved into a diverse, grassroots organization of lakes, data, and people, involving researchers from many disciplines, practitioners, information technologists, students, and others. Today, membership is nearing 1000 people representing 61 countries and participating observatory sites exist on all continents except Antarctica (Hanson et al., 2016). Like GLEON, StreamPulse is a coordinated, global network (although mostly located in North America) aimed at measuring stream metabolism using automated, high-frequency data. Since the mid-2000s, StreamPulse has grown to over 200 member sites that openly share data through a centralized data portal (https://data.streampulse.org/). Other long-term monitoring networks such as the US Long-term Ecological Research Network (LTER) and the US big-science initiative National Ecological Observatory Network (NEON) collect long-term limnological data from a wide range of freshwater ecosystems across the entire US. Despite relatively few freshwater sites compared to global networks such as GLEON and StreamPulse, networks like NEON can make valuable contributions to macrosystems limnology through the use of standardized methods across a wide range of regional settings, as well as strategic co-location of observational and high-frequency instrument measurements. In addition to serving as one of the best sources for long-term limnological data, freshwater LTER sites such as the North Temperate Lakes (Wisconsin) and Arctic (Alaska) have also contributed rich foundational knowledge for limnology as a field through decades of research, data sharing, and training of scientists (Huang et al., 2020).

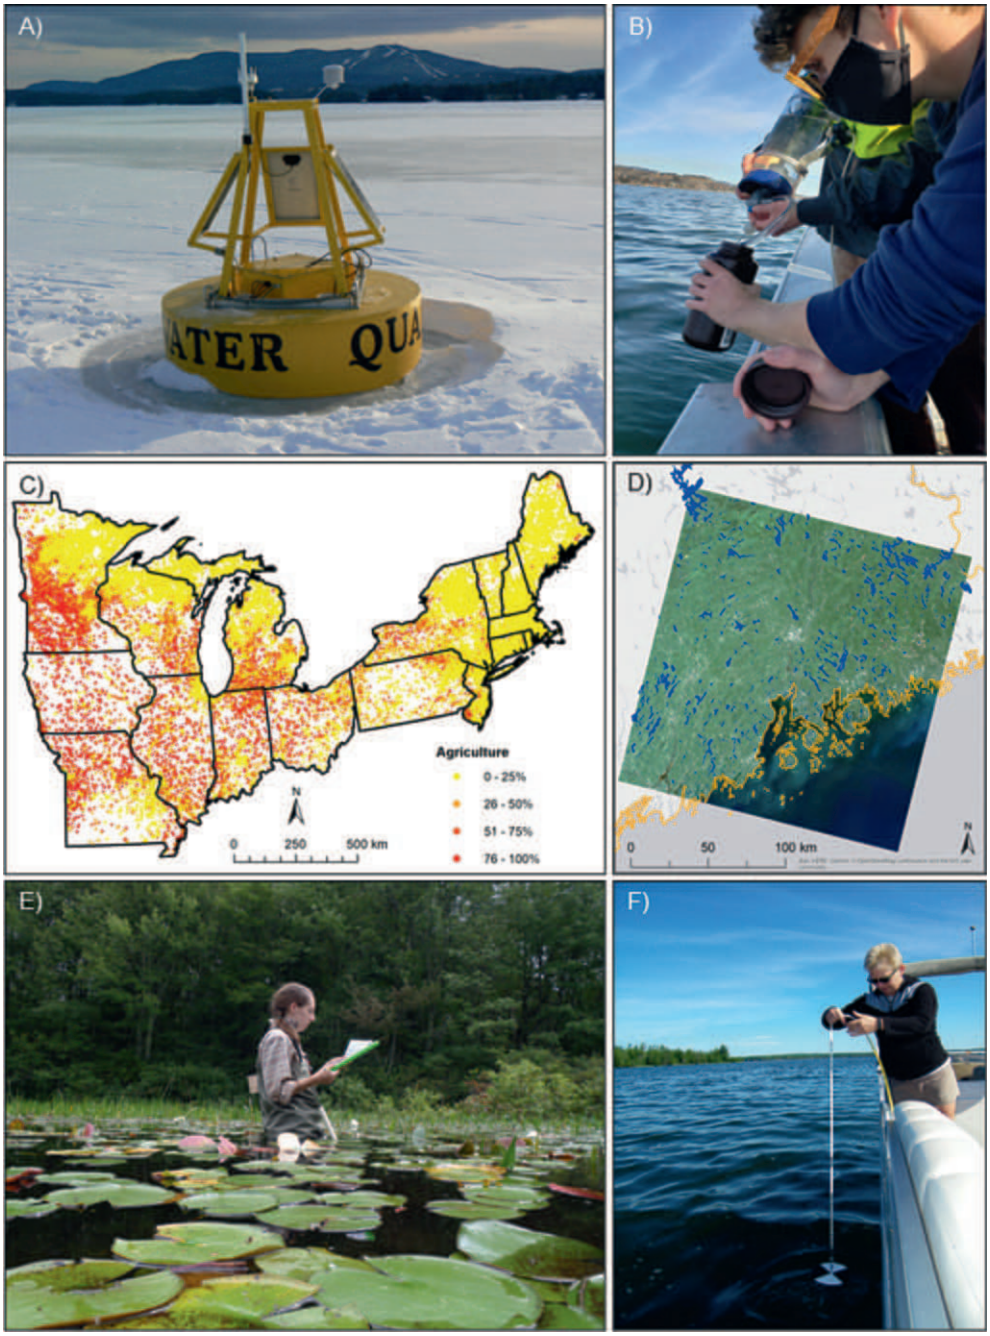

Fig. 3 The how and who of macrosystems limnology. (A) Long-term monitoring networks: this automated sensor on Lake Sunapee, New Hampshire, United States is part of the Global Lake Ecological Observatory Network and is operated by the Lake Sunapee Protective Association (photo: M. Eliassen). (B) Government monitoring programs: Lake County Water Resource Department scientists collect water samples from Clear Lake, California, United States (photo: A. DePalma-Dow). (C) Large synthetic databases: LAGOS-NE contains watershed ecological context data for approximately 50,000 lakes in the northeastern and mid-western US and lake water quality data from approximately 10,000 lakes compiled from various government, university, nonprofit, and citizen science monitoring programs (Soranno et al., 2017). Shown is lake watershed (represented as lake centroids) percent agriculture (row crops and pasture) in 2011 (Soranno and Cheruvelil, 2017b). (D) Remote sensing: shown is a true color composite Landsat 8 Path 11, Row 29 image from September 2018 of Maine, United States that can be used to estimate lake water quality variables. Lakes $\geq$4 ha are overlaid from Soranno and Cheruvelil (2017a). (E) Coordinated snapshot surveys: a scientist collects wetland data in Rhode Island, United States for the US Environmental Protection Agency's National Aquatic Resource Survey (NARS) (Photo: Tetra Tech, Inc.). (F) Citizen science programs: a volunteer measures lake water clarity using a Secchi disk in Lake Margrethe, Michigan, United States (Photo: Michigan Clean Water Corps).

Government agencies also operate some of the longest running limnology monitoring programs. These programs generally strive to maintain freshwater ecosystem services, often to ensure compliance with national, state/provincial, or local policies and standards. These efforts may entail maintaining water quality and quantity, limiting the spread of nonnative/invasive species, or managing commercial or recreational fisheries. Due to resource limitations and the desire to provide baseline data for as many individual ecosystems of interest as possible, government agencies often intentionally sample individual ecosystems relatively infrequently (i.e., annually at best). As a result, such programs often collect relatively little long-term data and are commonly biased toward particular types of ecosystems. For example, several state monitoring programs in the northeastern and mid-western US collected considerably less long-term ($\geq$15 years) lake water quality data than citizen science programs and were biased toward large lakes (although so were citizen science programs) (Poisson et al., 2020). Key challenges associated with using these data include public data access (i.e., not all programs publish data online with complete documentation) and different assessment, sampling, or laboratory procedures used by agencies or through time as instrumentation changes. For example, participating nations in the European Water Framework Directive have collectively assessed tens of thousands of rivers, streams, lakes, and groundwaters since 2000, but use different nutrient criteria for waterbody assessment, which can complicate international comparisons and efforts to pool data (Poikane et al., 2019). Nonetheless, government monitoring programs operating at national, state/provincial, or regional extents are currently among the largest data sources for macrosystems limnology.

There have been recent efforts to compile and standardize data collected by disparate government monitoring programs, as well as other sources, into large synthetic databases. Currently, two prominent examples are from North America. In the northeastern and mid-western US, LAGOS-NE is a database of lakes, water quality, watersheds, and landscape characteristics for 50,000 lakes (Soranno et al., 2017). LAGOS-NE contains lake water quality data from 87 separate federal, state, nonprofit, university, tribal, and citizen science programs. Constructing such large databases, however, requires enormous effort, such as contacting and communicating with data collectors, uncovering and reconciling different field/laboratory techniques, producing large amounts of metadata and documentation, and conducting quality assurance/quality control (QA/QC) (Soranno et al., 2015). Therefore, database engineers, computer scientists, and statisticians are valuable collaborators for database construction. Similarly, in Canada, the Canadian Lake Pulse Network is preparing the Lake Data Archive, a large database consisting of disparate historical datasets from across Canada (Huot et al., 2019). Likely owing to the steep challenges associated with compiling and harmonizing disparate datasets into large synthetic databases, such databases are currently rare. They may become more common in the future, however, as more data are published online in open repositories or are made available for sharing. Open science practices such as data sharing and data publication make possible the synthesis of disparate, local- to regional-scale datasets into larger, more complete databases that contain numerous observations distributed across wider ecological gradients and through longer periods of time than individual programs (Cheruvelil and Soranno, 2018). Given the necessary effort for producing large databases, such databases benefit from a culture of open science and in turn, represent some of the most powerful data resources for macrosystems limnology.

Coordinated snapshot surveys that seek to provide single observations across a large number of ecosystems at a particular point or window in time (Mantzouki et al., 2018; Pollard et al., 2018) are also becoming increasingly common. These programs are often motivated, coordinated, and supported by national governments. An example is the US Environmental Protection Agency's National Aquatic Resource Survey (NARS), intended to assess physical, chemical, and biological indicators in thousands of aquatic ecosystems across the lower 48 US states. NARS for inland waters encompasses the National Lakes Assessment (2007, 2012, 2017), the National Wetland Condition Assessment (2011 and 2016) and the National Rivers and Streams Assessment (2008–09, 2013–14, and 2018–19). A unique feature of the NARS program is the probabilistic sampling design developed by statisticians, which helps ensure that sampled sites are representative of a larger target population. This design facilitates population-scale assessment of ecosystem condition to meet policy and management objectives at national or regional scales. Similarly, the Canadian Lake Pulse Network sampled 680 lakes across Canada from 2017 to 2019 using standardized methods as part of an academic-government partnership (Huot et al., 2019). An example of an international collaboration is the 2015 European Multi-Lake Survey, which sampled 369 lakes across 26 countries to cover wider ecological gradients than exist in individual, often relatively small countries (Mantzouki and Ibelings, 2018). Disadvantages of snapshot surveys are the required high levels of planning, organization, and cooperation among numerous partners to cover broad spatial extents, which can be expensive and limit the frequency of surveys, resulting in little temporal data. Advantages of snapshot surveys, however, are standardized data with temporal coherence and broad spatial coverage across ecological gradients of interest, and that avoid the major challenges associated with compiling disparate data sources. Particularly when made publicly available, as the example programs described above have done or plan to do, snapshot surveys represent uniquely powerful resources for macrosystems limnology, especially when repeated to document changes over time.

Another promising approach for producing macroscale snapshots is through satellite-based remote sensing. Some of the earlier freshwater remote sensing programs were developed to help government agencies monitor waterbodies that they otherwise would be unable to sample frequently (Pulliainen et al., 2001; Olmanson et al., 2008). More recent research advances, particularly in image processing, have facilitated subcontinental-scale remote sensing of lake water quality (e.g., United States: Ross et al., 2019, China: Song et al., 2020). Compared to field-based snapshot surveys, however, remote sensing is currently only able to monitor a relatively small number of variables, mostly water clarity and to a lesser extent pelagic algal biomass, turbidity, dissolved organic carbon, and surface temperature. This limitation is related both to satellite resolution (spatial and spectral) and the need for large amounts of in situ calibration data, which are typically most available for a limited number of widely collected variables. Developing models that can be successfully applied across broad ecological gradients requires large amounts of in situ calibration data collected from ecologically diverse waterbodies. As such, remote sensing scientists must often rely on existing water quality

monitoring programs for calibration data collected at approximately the same time as satellite image capture. Public, well-documented observations such as those found in large synthetic databases represent a major calibration data source due to their spatial and temporal coverage, enabling use of historical satellite imagery to estimate long-term trends in water quality variables. As such, remote sensing, like other data resources for macrosystems limnology, also greatly benefits from a culture of open science.

Finally, citizen science is a main contributor to macrosystems limnology. Unlike state/provincial, national, or international monitoring programs, citizen science organizations are often motivated by individuals' desire for involvement in environmental stewardship and to protect the natural resources that they personally value (Bonney et al., 2009). Many citizen science groups are organized at local, regional, or state/provincial/national levels and train volunteers to use standard sampling techniques without professional supervision. Additionally, citizen science organizations are often jointly operated or supported by government agencies or academic research programs to increase data collection capabilities beyond what can be amassed without volunteer contributions. Given that limnological citizen science data have generally been found to be reliable (Hoyer et al., 2012; Scott and Frost, 2017), citizen science programs represent a major boost to macrosystems limnology, particularly when their data are made publicly available and are pooled across larger geographic areas in large synthetic databases (e.g., Poisson et al., 2020).

The where

Much of the research focus and data resources for macrosystems limnology have been concentrated in Europe and North America, largely reflecting the geographic roots of limnology as a discipline. These research traditions have fostered the growth and prevalence of long-term monitoring networks, snapshot surveys, and government and citizen science monitoring programs. Although providing a country-by-country assessment of where macrosystems limnology has been conducted is beyond the scope of this article, it is clear that such research and associated infrastructure is increasing in prevalence globally, including outside of North America and Europe. Examples include studies of invasive species spread in Kenyan lakes (Mergeay et al., 2005), land use effects on Brazilian Amazonian stream fish communities (Leitão et al., 2018), and patterns and drivers of ecosystem properties of Argentinian Patagonian lakes (Baigún and Marinone, 1995). There are also examples of national-scale efforts to synthesize disparate datasets (New Zealand rivers and streams; McDowell et al., 2009) and to establish standard field and laboratory methods and make data publicly available (Korean rivers and streams; Jiang et al., 2016) for macrosystems research. Studies such as these will build on our rich existing knowledge of high-latitude and temperate ecosystems and further our understanding of tropical and subtropical ecosystems, their contributions to global cycles, and how they are responding to global change stressors.

The growing subdiscipline of global limnology (Downing, 2009) also contributes to macrosystems limnology. Currently, global studies are often dominated by European and North American in situ data, biased toward larger ecosystems, and/or rely on remote sensing to attain global coverage (which also may bias studies toward larger ecosystems due to satellite image resolution). For example, global surface temperature trends in large lakes have been quantified using a combination of in situ and remotely sensed data (Sharma et al., 2015), whereas studies estimating global lake counts and area have relied entirely on remote sensing (Verpoorter et al., 2014; Labou et al., 2019). Global-scale remote sensing, however, provides numerous future opportunities to extend macrosystems limnology and high-frequency monitoring to regions and countries where regular field monitoring is difficult or impractical. Given the increasing availability of satellite imagery and growing interest in large synthetic databases, coordinated snapshot programs, and open science, it is likely that global-scale studies will become increasingly viable in the upcoming decades.

The growth of macrosystems limnology and global limnology reveals the high future potential for increased international collaboration, including sharing of data, methods, and expertise as part of an ascending culture of open science. Although the abilities to establish and maintain monitoring programs or to combine data from disparate studies and programs are major boosts to macrosystems limnology, international collaboration can potentially help redistribute necessary resources and support growth in underrepresented locations. As such, international collaboration may be particularly beneficial for smaller countries, including those with limited resources or where national-scale studies do not span particularly wide ecological gradients (as was the case with the European Multi-Lake Survey, which encompassed 26 countries; Mantzouki and Ibelings, 2018). Like coordinated snapshot surveys, collaboration that prioritizes methods compatibility across research sites helps ensure that all observations are equally valuable. International collaboration also can be particularly useful for remote sensing efforts by encouraging co-production of algorithms and sharing and reuse of in situ data across large geographic areas (e.g., LIMNADES program; Palmer et al., 2015) and for helping researchers link relatively coarse-resolution, remotely sensed global-scale datasets with finer-resolution continental- and regional-scale datasets within a macrosystems limnology framework. Collaboration and open science, which are key elements of the "how" of macrosystems limnology, are crucial for expanding this type of research across the globe.

The when

There has been a recent coalescence of many factors motivating macrosystems limnology, including the development and convergence of key scientific theories and concepts, major technological advances, and important shifts in scientific practices. The steady increase in macroscale and global-scale limnological studies over the past 20 years (Fig. 2) reflects the broad scientific recognition that macrosystems studies are increasingly necessary to address the current environmental challenges facing freshwater

ecosystems. By combining foundational theories and concepts from macrosystems ecology and landscape limnology, limnologists are currently better positioned than ever before to address major global change stressors facing fresh waters such as climate change, land use/cover change, and invasive species. Such stressors often operate at regional or larger scales, and so must be studied at these scales, but with the key recognition that various ecological processes combine to influence freshwater ecosystems at multiple spatial and temporal scales. A macrosystems limnology framework is necessary to tackle these challenges and emphasizes that traditional, local-scale approaches are insufficient to capture inherent variation in freshwater ecosystems and multi-scale drivers (and stressors) that shape ecosystem composition and function. Until recently, the scientific focus on single-system or single-region studies and restricted data and technological resources kept a macrosystems approach to studying limnology out of reach. As these barriers have come down, however, scientists are leveraging broad-scale and long-term datasets to understand and protect fresh waters better under changing environmental conditions. This recognition within the research community has been echoed within research funding agencies, resulting in increased allocations to macrosystems studies over time.

As limnologists have acknowledged the growing complexity of studying fresh waters under global change, recent advances in tools and technology also facilitate ongoing growth in macrosystems limnology. Macrosystems studies are inherently data-intensive and therefore require more data storage and computing resources than small-scale, individual researcher studies. Notably, increasing deployments of automated sensors and satellites provide an ever-increasing source of data, sometimes available in real-time, across broad geographic extents. Today, advances in cyberinfrastructure and data science expertise enable collection of coordinated, broad-scale snapshots and syntheses of disparate, existing data sources, and macrosystems limnology studies that were until recently, largely impractical.

Finally, as scientists, volunteers, automated in situ sensors, and satellites collect more and more data, we have also seen the shifting of scientific cultures to embrace collaboration within and across disciplines, open science, and data science in limnology. Many macrosystems studies now rely, sometimes exclusively, on data collected by other researchers to achieve desired spatial and temporal coverage. Additionally, the increasing availability of large datasets describing the ecological settings of fresh waters (e.g., downscaled climate, land use/cover) facilitates studies that consider numerous variables operating across multiple spatial and temporal scales. Although not all such datasets are currently public, investment in developing and maintaining public spatiotemporal datasets as part of a growing open science culture is highly promising for the future of macrosystems limnology. Coupled with the rise of open science and limnological big data, the multi-scale, integrative perspective of macrosystems limnology represents an essential framework for meeting the scientific and management needs for fresh waters under intensifying global change, both now and in the future.

Therefore, the time for macrosystems limnology is now. Across landscapes, regions, and continents, limnologists are in prime position to make major advances in both understanding and predicting responses of freshwater ecosystems to different aspects of global change. We must capitalize on the present and increasing scientific understanding, emerging technology and data resources, and growing culture of open science.

Creating and Managing Data From High-Frequency Environmental Sensors

Kevin C Rose[a], Christopher G McBride[b], and Vincent W Moriarty[c], [a]Department of Biological Sciences, Rensselaer Polytechnic Institute, Troy, NY, United States; [b]Limnotrack, Cambridge, New Zealand; [c]IBM Research, Yorktown Heights, NY, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Kendra Cheruvelil.

Glossary

Aliasing The inability to detect a phenomenon due to infrequent observations below the Nyquist rate.
Biofouling The colonization and growth of microrganisms on in situ sensors, which can often interfere with sensor operation.
Data versioning The creation of progressive iterations of a data set as it moves through a quality control process.
Integration time The amount of time a sensor is turned on and measuring the environment.
Integration volume The volume of water being observed by a sensor.
Nyquist rate (or Nyquist interval) The minimum sampling frequency necessary to detect a phenomenon. The rate is twice the frequency (i.e., observations are made twice as often) as the dominant scale of variation of the process being examined.
Sensor drift The process of increasing bias and/or decreasing accuracy in sensor measurements over time due to physical changes in the sensor.

Introduction to high-frequency sensors and data

Novel scientific insights are often built on technological advancements. Galileo Galilei had the telescope, Rosalind Franklin had X-ray crystallography, and contemporary aquatic ecologists and resource managers have a range of sophisticated tools at their disposal, including high-frequency sensors. Many environmental processes are poorly characterized by infrequent, manual measurements. Continuous and automated sensor measurements can generate observations on important aspects of aquatic ecosystems, supporting a deeper understanding of patterns and processes and the development of novel hypotheses. Near real-time environmental measurements can also support adaptive management and public engagement to improve scientific literacy. Complementing traditional manual methods of ecological research and management, as well as advancements in cyberinfrastructure and data processing, high frequency sensors are reshaping fundamental aspects of how aquatic ecology research and management are conducted.

In ecological sampling, "high-frequency" typically refers to measurement at sub-daily intervals, although in practice sampling may be as frequent as multiple times a second. High-frequency measurements are regularly contrasted with manual measurements, which require the presence of a person to collect, process, and or store samples, and which must often be processed in a lab at a later time. In practice, how frequent should sampling occur? In addition to practical considerations (e.g., regarding memory and battery life), there are important tradeoffs to consider when using high-frequency sensors. Signal processing theory posits that sampling

should be conducted at least twice the frequency (i.e., twice as often) as the dominant scale of variation of the process being examined. This concept is known as the Nyquist–Shannon sampling theorem, with the corresponding minimum sampling rate termed the **Nyquist rate (or Nyquist interval)** (Nyquist, 1928). Sampling at lower rates (i.e., coarser temporal intervals) can lead to what is referred to as **aliasing**. Aliasing occurs when samples are collected too infrequently, which results in the inability to detect an actual estimate of the frequency or magnitude of a response variable of interest. This phenomenon can be observed in videos when the camera frame rate (i.e., sampling frequency) is too slow, and things like the rotation of helicopter rotor blades occur at a similar frequency. In this example, the effect of aliasing of rotor blades is that they appear to be moving much slower, standing still, or even moving in the reverse direction than what they are actually doing.

Aliasing has important ecological implications for the minimum sampling rate for high-frequency sensors. For example, imagine a research program designed to study zooplankton diel vertical migration. This phenomenon is generally characterized by a downward migration of some zooplankton species during the day and an upward migration at night to avoid fish predation and exposure to damaging ultraviolet light (Lampert, 1989; Williamson et al., 2011). Consistent with light cycles, a full diel vertical migration cycle (downward movement, then back up to the original starting position) typically occurs once every 24 h. Before conducting their field research, researchers estimate the frequency at which they need to collect measurements of the vertical position of zooplankton in the water column. They want to minimize their sampling frequency to reduce the workload (zooplankton sampling requires quite a bit of manual labor), but sample frequently enough to adequately characterize the magnitude of diel vertical migration. If the researchers were to only sample once every 24 h, observations of zooplankton vertical position would show that the zooplankton were in nearly the exact same location in the water column at every time point, and therefore the diel vertical migration would not be discernible from other drivers of variation of zooplankton vertical position. The Nyquist-Shannon sampling theorem posits that to characterize a phenomenon like zooplankton diel vertical migration that occurs at frequency of 24 h, the researchers should sample at a frequency of at least every 12 h.

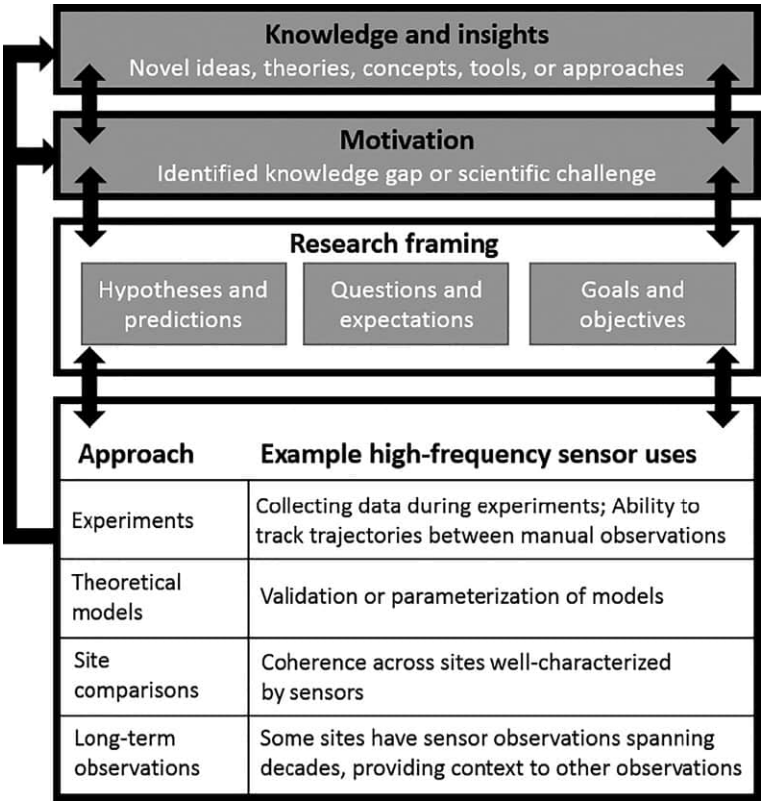
One challenge of using the Nyquist-Shannon sampling theorem to choose a sampling interval is that the maximum or dominant frequencies of many ecological phenomena are not known. Like zooplankton diel vertical migration, many ecological phenomena vary over a 24-h cycle. Thus, sampling every ~12 h can serve as a general guideline for the minimum sampling frequency recommended for most ecological observatories, unless there are other important tradeoff considerations (e.g., data storage or power; see Section "Sensors, platforms, & configurations"). Furthermore, given the possibility of even higher-frequency cycles (e.g., seconds to hours) in many phenomena, there can be substantial benefits to sampling much more frequently than every 12 h. Ecosystems are dynamic across many orders of magnitude in temporal scale. At a sub-daily time-scale, for example, variations in weather and organism behavior can introduce substantial heterogeneity in many measurements. Thus, many researchers often set high-frequency sensors to sampling intervals at the scale of several minutes (e.g., an interval of one to fifteen is common). Increasing the sampling rate (relative to, e.g., every 12 h) enables researchers to study diverse ecological phenomena without much prior knowledge of the dominant scales of variation, and thus avoid aliasing potentially important dynamics. Additionally, more frequent sampling has other potential benefits, such as a greater ability to calculate statistical attributes with greater accuracy and identify potential interferences (e.g., shadows on light sensors, when sensors are pulled from the water).

Despite the advantages of fast sampling rates (e.g., at the scale of 1 min to 1 h), there can be important tradeoffs that reduce the benefits of even-faster sampling rates. First, very high sampling rates can introduce data set complexity and management challenges. For example, increasing a sampling rate from once every 12 h to once a minute increases the number of data points generated every day by 720-fold. Although it is possible to downsample a dataset post-hoc, researchers must be prepared for a data-deluge if sampling rapidly, and especially if sampling at sub-minute time-scales (Porter et al., 2012; Rode et al., 2016). High sampling rates (e.g., sampling intervals at the scale of seconds to minutes) may not be useful unless researchers also have the corresponding technical capacity to ingest, manipulate, process, analyze, and visualize massive data sets. Additionally, faster sampling rates increase power consumption and data storage requirements at the point of data collection. In a power- or storage-limited environment, fast sampling rates may not be achievable. However, the additional power and memory required for some sensors is minimal, and often the most limiting factor to sub-minute sampling rates is technical capability in data handling.

There are other practical considerations that reduce the benefits of further reductions in sampling interval. For example, many sensors require time to equilibrate in situ (i.e., in its aquatic sampling location). If a sensor is moving through the water column (e.g., on a profiler—see Section "Sensors, platforms, & configurations"), a minimum equilibration time may be needed, for example, for the diffusion of gasses through gas permeable sensor membranes. Often, this can take several minutes if there is a steep concentration gradient and the user wants to have near 100% measurement accuracy. Additionally, sampling at the scale of seconds often means that sensors are running nearly continuously. This means that there is limited or no down-time for removal of accumulating substances on sensor surfaces (e.g., with mechanical wipers) and the potential for organisms that respond to the sensor lights to increase (see QA/QC section for further details). Accordingly, many observatories do not collect or log data at sub-minute time scales. Nevertheless, these challenges must be evaluated against any potential future utility of additional time-resolution in the measurements being undertaken.

Observations and hypotheses using high-frequency sensors

High-frequency sensing holds substantial potential to complement and extend traditional methods and has already demonstrated its utility in numerous research applications. However, a criticism of high-frequency monitoring is that it can represent a surveillance-based approach to conducting science that is not necessarily guided by specific questions or robust experimental



Approach	Example high-frequency sensor uses
Experiments	Collecting data during experiments; Ability to track trajectories between manual observations
Theoretical models	Validation or parameterization of models
Site comparisons	Coherence across sites well-characterized by sensors
Long-term observations	Some sites have sensor observations spanning decades, providing context to other observations

Fig. 1 Conceptual diagram of the scientific process as an iterative process, including the role of high-frequency sensors in research. Table at bottom describes example roles of high-frequency sensors during the data collection phase. Adapted from Elliott KC, Cheruvelil KS, Montgomery GM, and Soranno PA (2016) Conceptions of good science in our data-rich world. *Bioscience* 66(10): 880–889. https://doi.org/10.1093/biosci/biw115.

design (Lindenmayer et al., 2018). Indeed, the production of large volumes of observational data can enable research based on data exploration and discovery, which contrasts with a traditional hypothesis-driven approach to scientific discovery and the creation of knowledge. However, despite the bias against data mining, high-frequency sensing can serve an important role in understanding ecosystem dynamics, especially when science is viewed as an iterative process (Fig. 1; Elliot et al., 2016). For example, a first step in understanding an ecosystem is often to collect data, and it is important that measurements are objective and verifiable. Traditional lower frequency ecological monitoring can be insufficient to generate enough observations for events that occur infrequently or change rapidly. Rapid and frequent monitoring of ecosystem dynamics such as changes in turbidity or dissolved organic matter in response to storm events can be impractical to near-impossible without high-frequency sensors. Without sensor data, hypotheses that explain dynamics at short time-intervals may not otherwise be created.

In addition to providing initial data to support the creation of hypotheses, high-frequency sensors can serve an important function in testing hypotheses. There are multiple ways ecologists test hypotheses, including using experiments, theoretical models, site comparisons, and long-term observations (Carpenter, 1998). High-frequency sensing can be used in all of these approaches, depending on the nature of the research question and mode of conducting the research (Fig. 1). For example, high-frequency sensors can also play an important role in providing contextual information to understand research conditions (e.g., during experiments, site comparisons, or long-term observations) and, when applicable sensors exist, in testing hypotheses directly.

Research and monitoring applications

High-frequency sensors provide the capacity to autonomously and frequently characterize ecological conditions. Thus, a primary advantage and use of high-frequency sensing is in situations where it would be difficult or near impossible to make manual measurements. This can include applications where high-frequency observations are desired or required (e.g., every minute for months-long deployments), but it also applies to inaccessible sites. Accessibility can be limited due to, for example, distance (e.g., remote field sites such as mountain lakes), as well as for difficult or hostile conditions such as under-ice deployments. In fact, there is historically a dearth of research on under-ice ecology due in large-part to the difficulty in conducting manual sampling-based research in such environments (Hampton et al., 2017).

Many ecological processes and characteristics exhibit substantial variability at short-time scales. For example, while lake near-surface water temperature is often assumed to be a slowly changing characteristic, measurements from high-frequency sensors demonstrate that it can vary many degrees over the course of a day (Woolway et al., 2016). More generally, high-frequency

monitoring enables the characterization of phenomena that exhibit high temporal variance. There can be tremendous value to characterizing variance at short intervals, as there can be abrupt changes in ecological state that have long-term implications (Pace et al., 2015). For example, disturbance events, by definition, are short-term punctuated events such as severe storms that can alter the structure and functioning of aquatic ecosystems, sometimes for years to decades afterwards (e.g., Blaen et al., 2016; Jennings et al., 2012; Klug et al., 2012; Lin et al., 2022; Perga et al., 2018). Tracking dynamics during disturbance events and immediately thereafter often requires the use of high-frequency sensors. Additionally, high-frequency measurements can be used as indicators of impending large and persistent changes in ecosystems (i.e., regime shifts), irrespective of disturbance event impacts. For example, in an experimental manipulation of nutrients designed to stimulate the formation of harmful algal blooms, researchers found that features of high-frequency time-series data, such as variance and auto-correlation, were predictive of impending cyanobacterial blooms (Pace et al., 2017).

In addition to the value of high-frequency monitoring to understand short-term events, these sensors also provide important contextual information to understand long-term trends. This can be as simple as tracking conditions (e.g., in temperature, conductivity, or other variables) during a months-long experiment or understanding the degree to which a one-time manual sampling value was representative of conditions during a longer period. In this fashion, high-frequency monitoring improves the ability to understand ecosystem dynamics between lower-frequency samples. When correlations can be drawn between high-frequency observations and other difficult to measure attributes, high-frequency data can be used to infer other features. For example, high frequency sensors have been used to estimate methyl mercury concentrations (Bergamaschi et al., 2011) and estimate ecosystem metabolism characteristics, including gross primary production, ecosystem respiration, and the balance between these, net ecosystem production (Staehr et al., 2012).

High-frequency sensing is also useful to ground truth measurements or predictions from satellite based imagery or ecosystem models. For example, hydrodynamic models are often dependent on a time-series of meteorological observations to drive the model, and outputs are validated against in situ observations of water temperature. Ecological and biogeochemical models are likewise often validated against high-frequency observations of characteristics such as dissolved oxygen, conductivity, chlorophyll, and dissolved organic matter fluorescence. An advantage of high-frequency sensors over traditional manual observations is that temporal (and/or spatial) variability can be quantified in both sensor measurements and model output. Comparisons of variability across orders of magnitude in time scales provides the capacity to improve model forecasting accuracy and reduce uncertainty (Kara et al., 2012).

In addition to research applications, high-frequency monitoring is increasingly a component of water quality management programs and a mechanism for stakeholder engagement, especially when data can be provided online and in near real-time. Many high-frequency sensors exist that complement traditional managed-for characteristics, including turbidity, dissolved oxygen, water clarity, chlorophyll, and phycocyanin (see Table 1). For example, many jurisdictions have water quality mandates such as maximum turbidity levels. High-frequency sensors make it easy to rapidly assess water quality conditions and immediately respond to out-of-compliance occurrences. High-frequency monitoring can also increase the likelihood of observing out-of-compliance readings even if water quality conditions are, on average, favorable. This is because the more frequent sampling provides better characterization of the full distribution of conditions, including rare events (e.g., high turbidity levels). In this case, a running (e.g., daily) mean may be more appropriate than relying on individual time point observations. High-frequency sensors can also be used for adaptive management when telemetry enables near real-time access to the data. For example, reservoir managers may select water withdrawal depths based on water quality conditions, or turbidity monitoring could be used to avoid out-of-compliance conditions during dredging. Finally, high-frequency sensors can be a means to engage the public. Just as weather forecasts provide real-time data on outdoor conditions, so too can many in situ sensors. For example, sailors may want on-lake wind speed and direction measurements, and fishermen may want information on dissolved oxygen and temperature to identify the likely depths of cold-water species.

Sensors, platforms, & configurations

Sensors

It can be argued that high-frequency sensing is not only a contemporary approach to ecological research and monitoring. For example, various methods to characterize river flow volume in an automated fashion have existed for over 100 years. However, the recent expansion of high-frequency ecological sensing emerged from contemporary advancements in sensor, battery, and storage technologies. Today, there are many types of high-frequency sensors used to study aquatic ecosystems. Sensors are generally categorized by whether they are in situ (i.e., underwater) or ex situ (e.g., above surface) measurements, by the type of characteristic(s) they sample (physical, chemical, and/or biological) or by the underlying technology they employ. A detailed list and description of high-frequency aquatic sensors is available in (McBride and Rose, 2018; see Table 13.1). Here, Table 1 provides a broad summary of many types of high-frequency environmental sensors used in research and monitoring of inland waters.

Sensor selection can be a challenging part of study design, with a sometimes overwhelming amount of options of manufactures, models and measurement principles (i.e., the underlying technology) available for many variables. For example, while most commercial dissolved oxygen sensors for underwater applications use optical technology, there are other types of technological options available (McBride and Rose, 2018). Optical sensors have come to dominate the market owing to their long-term stability; however even among optical sensors there are multiple measurement principles (e.g., fluorescent intensity versus lifetime

Table 1 Summary of many types of high-frequency environmental sensors used in research and monitoring of inland waters.

Variable	*Typical units*	*Typical underlying technology*	*Popularity*	*Price*
Chlorophyll	RFU	Fluorescence using LED excitation and emission detectors tuned to chlorophyll pigment	Common	$$$
Conductivity	$\mu S\ cm^{-1}$	Current between electrodes is conductivity dependent	Common	$
Dissolved carbon dioxide	$g\ m^{-3}$	Non-dispersive infrared detector (NDIR)	Uncommon	$$$$
Dissolved methane	$g\ m^{-3}$	Non-dispersive infrared detector (NDIR)	Rare	$$$$
Dissolved organic matter	RFU	Fluorescence using LED excitation tuned to peak C	Common	$$$
Dissolved oxygen	% saturation or $mg\ L^{-1}$	Optical: quenching of fluorescence signal dependent on oxygen concentration; several other technologies exist	Common	$$$
Methane	$g\ m^{-3}$	Non-dispersive infrared detector (NDIR)	Rare	$$$$
Nitrate	$g\ m^{-3}$	Spectral absorbance signature in deep UV	Rare	$$$$
Oxidative/reduction potential	mV	Voltage between electrodes	Common	$
pH	unitless	Electric potential between electrodes is pH dependent	Common	$
Phosphate	$\mu g\ L^{-1}$	Wet chemistry	Rare	$$$$
Phycocyanin	RFU	Fluorescence using LED excitation and emission detectors tuned to phycocyanin pigment	Common	$$$
Phycoerythrin	RFU	Fluorescence using LED excitation and emission detectors tuned to phycoerythrin pigment	Rare	$$$
Solar radiation	$\mu E\ m^{-2}\ s^{-1}$	Silicon photodetector	Common	$$
Tryptophan	RFU	Fluorescence using LED excitation and emission detectors tuned to peak T	Uncommon	$$$
Turbidity	NTU, FNU	Light source with detector at an offset angle, often 90°	Common	$$
Water level or depth	m or Pa	Hydrostatic pressure measurement in sensing diaphragm	Common	$$
Water temperature	°C	Thermistor or integrated circuit	Common	$

RFU, relative fluorescence units; NTU = nephlometric turbidity units; FNU = Formazin Nephelometric Units. Price range $ to $$$$ roughly equates to <$1000 to > $10,000 US.

luminescence methods), materials quality, and measurement response times (a few seconds to several minutes) that affect price, longevity, and data quality. There are some objective resources available that provide sensor evaluations for their stated characteristics and sensitivities. For example, the Alliance for Coastal Technologies (https://www.act-us.info/) provides evaluations of many types of in situ aquatic sensors. Additionally, scientists in NETLAKE (Networking Lake Observatories in Europe) assembled a series of factsheets that summarize many important aspects of sensor selection and deployment (Laas et al., 2016). Finally, it should be noted that caution is warranted in reviewing older resources, as technologies and best practices can advance quickly.

There is no single agreed-upon suite of sensors or configurations, as differences in priority research questions and monitored variables, budget, conditions of the site (e.g., depth, productivity, remoteness), sensor accuracy requirements, and spatial coverage needs all impact the suite of sensors selected and the manner in which they are deployed and maintained. Despite the range of variables that need consideration, many sites share a similar suite of common measurements. The most common variables measured at high-frequency are dissolved oxygen and temperature (Meinson et al., 2015). Temperature is typically measured at multiple depths, with greater vertical resolution near the surface where conditions are more dynamic. Often, other chemical and biological sensors are bundled together on a sonde (also known as a multi-probe; see platforms and configurations section below for more information), but the specific sensors selected depend on the priorities for the site. Commonly measured variables include pH, oxidation reduction potential (ORP), conductivity, turbidity, fluorescent dissolved organic matter (FDOM), and pigment fluorescence (e.g., chlorophyll *a*nd/or phycocyanin). FDOM sensors are also referred to as peak C fluorometers, based on the excitation and emission wavelengths used to quantify the signal (Carstea et al., 2020; Coble et al., 2014). Regardless of the specific sensor, it should be noted that many in situ sensors do not conform to the same measurement principle used for laboratory analyzes of the same variable (see Section "Processing and interpreting high-frequency sensor data", data corrections).

Other sensors include fluorometers to measure phycoerythrin, tryptophan, refined fuels, rhodamine, and optical brighteners/fluorescent whitening agents. Many of these sensors are not particularly common in freshwater ecology research and monitoring but can be easily added to many sondes and serve particular functions. Phycoerythrin is predominantly used in marine applications, but this accessory pigment is also found in some freshwater cyanobacteria (e.g., Harrison et al., 2018). Tryptophan fluorometers (also known as peak T fluorometers) are common in wastewater research and monitoring, but less common in aquatic ecology research (Baker et al., 2015; Carstea et al., 2016, 2020). Rhodamine sensors are commonly used in dye tracer studies that seek to understand water movement and storage dynamics (Runkel, 2015). Refined fuels and optical brightener sensors are often used to study specific types of anthropogenic impacts on aquatic ecosystems.

Another common sensor measurement both above surface and below is solar radiation. When deployed underwater, light measurements are often made at two or more depths using photosynthetically active radiation (PAR) sensors (measuring wavelengths from 400 to 700 nm), enabling calculation of a light attenuation coefficient (Kirk, 1994). Light attenuation regulates numerous aspects of aquatic ecosystems, including the depth range of photosynthesis and the distribution of heat in the water column (Rose et al., 2016). In most deployment configurations, light sensors are mounted on underwater arms away from the

surface buoy or float to avoid shading effects. Temperature measurements may also enable estimation of light attenuation during calm day-time conditions when heat gain differences between sensors at multiple depths can be solely attributed to light attenuation (Read et al., 2015). This enables greater use of temperature sensors, which are one of the most deployed sensor types.

In addition to light, some of the most common above-surface measurements include meteorological conditions (e.g., air temperature, barometric pressure, wind speed, wind direction, relative humidity, and multiple forms of precipitation). Meteorological sensors are often used to provide contextual information on conditions regulating water quality or to provide data to implement models of hydrodynamics and/or water quality. One of the most common applications of high-frequency sensors is to understand lake metabolism (Meinson et al., 2015; Solomon et al., 2013), where gas flux models are typically parameterized using wind speed measurements (Cole and Caraco, 1998; Dugan et al., 2016; Klaus and Vachon, 2020). Sensor height is an important consideration in many situations because of the importance of wind speed (and direction), and the potential for platform listing in waves, which can affect wind speed measurements. Often, most meteorological variables are measured together in an integrated weather station that is located on a pole above a lake buoy at a height of ~1.5–2 m above the water surface. Sensor height is then often normalized to 10 m for various calculations and comparison across sites (e.g., Cole and Caraco, 1998; Liu and Schwab, 1987). Rotation of the platform (common in single mooring-line deployments) can make wind direction measurements meaningless if an on-board compass is not part of the system. These integrated systems can be fairly robust and often contain no moving parts but can be sensitive to damage or fouling by birds. Bird-spike kits can reduce this problem, but some species are quite persistent.

In addition to these relatively common sensors, there are a number of less common to rarely deployed sensors. These include, for example, wet-chemistry sensors to measure phosphate. In situ spectrophotometers or spectrofluorometers can also be deployed to characterize a number of water quality attributes that may be inferred from light absorbance data made across ranges of the electromagnetic spectrum, such as nitrate, dissolved organic matter concentration and quality, and turbidity (e.g., Puiu et al., 2015). Additionally, there are some sensors that characterize multiple phytoplankton groups based on different fluorescence signatures or images (e.g., Fossum et al., 2019; Kring et al., 2014), and still others that characterize dissolved gasses (e.g., CO_2, CH_4). Acoustic doppler current profilers (ADCPs) can sample at very high frequency and be used to characterize water movement, gas flux, and particle size and movement including organisms. The use of sensors that passively sample aquatic acoustics is not widespread but shows promise for various applications such as fish species identifications (e.g., Browning et al., 2017; Noda et al., 2016). There are even sensors capable of conducting complex genomic analyzes in situ (Scholin et al., 2017). Most of these sensors are uncommon in sensor deployments, often due to the high cost associated with complex instrument designs. In some cases, the equipment can also have high detection limits, be sensitive to interference, or be difficult to maintain, thus requiring a high degree of expertise and specialization.

Data from high-frequency sensors are usually recorded by a data logger or computer before use. Sensors use many different communications standards. These can be broadly divided into analog (voltage, e.g., 0–5 V or current, e.g., 4–20 mA), and digital communications protocols (e.g., SDI-12, RS232, RS485 MODBUS, ethernet, I2C, 1-Wire). The data logger should have compatibility with the signal standards employed by the desired sensor suite, although a vast range of aftermarket signal converters are available. Different signal standards have unique pros and cons related to ease-of-use, robustness, cable length/capacitance, and susceptibility to noise. Serial standards that allow connection of multiple devices to single data lines (e.g., SDI-12) are user-friendly and can greatly reduce wiring complexity, but may increase the vulnerability of all connected sensors to faults in one sensor connected to the same bus. Oversight or otherwise involvement of qualified and experienced personnel are important for successful design of robust measurement systems, adequate circuit protection and grounding. Issues related to signal-to-noise (i.e., the strength of a process being measured relative to background variations in the measurement) or incorrect sensor/logger configuration can take months or years to detect and correct, by which time a great deal of expensive, ultimately unusable data may have been collected.

Platforms and configurations

The simplest design for collecting high-frequency sensor observations requires a sensor, a power source, and a device to store (i.e., data logger) and/or transmit the data. Platforms can take multiple forms, including stationary buoys, vertically profiling buoys, portable autonomous multi-probes and sondes, and vehicles (Figs. 2–4). High-frequency sensor platform designs correspond to the manner in which sensors are powered, data are logged, and the mobility of the system (Table 2). In many cases, multiple platforms are used at the same site. For example, a stationary or profiling buoy may be deployed during the stratified open-water season, and autonomous internally-logging sondes may be deployed under ice. Together, this approach enables year-round characterization of a waterbody.

While high-frequency sensing enables detailed characterization of environmental variables, the approach does not necessarily permit broad spatial coverage. The actual volume of water (and its constituents) being observed by many common sensors each time they turn on is often quite small (e.g., perhaps one cubic cm). However, depending on the degree of homogeneity of the environment and movement of water past the sensor (and/or the sensor through the water in the case of profiling systems), the actual volume of water being measured can be much larger. This sensed volume is referred to as an **integration volume** and is dynamic. Faster water movements correspond to greater movements of water and its constituents past a sensor, and therefore also increase the integration volume. The integration volume is also sensitive to the **integration time**, which is a measure of the amount of time a sensor is turned on and measuring the environment.

Integration time can be contrasted with sample frequency. A sensor can be programmed to turn on to measure the environment for a relatively long period (i.e., have a long integration time), such as measuring for 15 min, and reporting a measurement every

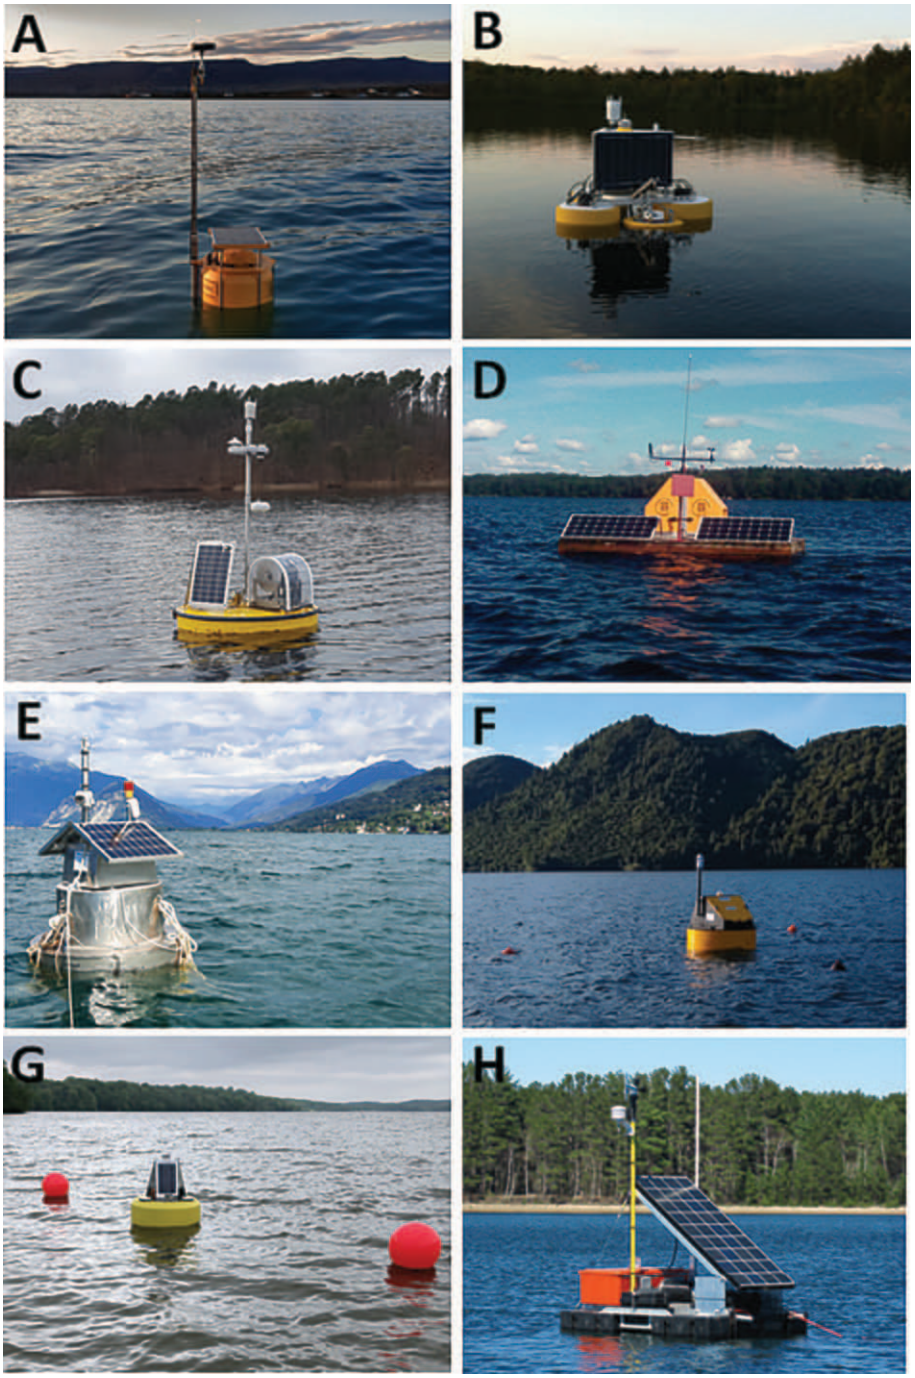


Fig. 2 Example buoys in lakes around the world, demonstrating a range in designs. (A) Argentino Lake buoy, Argentina; (B) Lake Lacawac, Pennsylvania, United States; (C) Lake Stechlin, Germany, (D) Lake Erken, Sweden; (E) Lake Maggiore, Italy; (F): Lake Okareka, New Zealand; (G) Acton Lake, Ohio, United States; and (H) Crystal Lake, Wisconsin, United States. Buoys A, E, and G are stationary buoys; all others are vertical profilers. 15 min (i.e., a 15-minute sample frequency). This is functionally similar to sampling continuously, but only reporting a measurement every 15 min. This contrasts with very fast sampling rates and logging, such as measuring and logging every second. An advantage of long integration times and less frequent logging is that the approach can reduce the variance in observations by taking more measurements before reporting. Additionally, a lower logging frequency reduces the size of the dataset and simplifies the burden on data storage, transmission, and management. A downside is that higher frequency measurements, and the variance they display, can provide additional information about the system or sensors. For example, sampling and logging dissolved oxygen every second can provide information to understand how long a sensor takes to reach equilibrium (e.g., if it is on a vertical profiler

Fig. 3 (Left) High-frequency sensors (dissolved oxygen, FDOM, and chlorophyll fluorescence) removed from a eutrophic lake after 11 months of autonomous sampling reveal substantial biofouling. Despite this growth, sensor faces were still clean due to wiping at a 6-h interval. (Right) The face of an underwater PAR sensor was still clean after 11 months of in situ sampling and the same frequency of wiping in an oligotrophic lake. Note the difference in overall fouling on sensor bodies pulled from eutrophic versus oligotrophic waters. Credit: Jenna Robinson.

Table 2 Common deployment designs depend on the desired mobility of the sensors and the way sensors are powered and data is logged.

	Internal power & logging	*External power & logging*
Stationary sensors	Autonomous sondes and probes	Surface buoy with static sensors
Mobile sensors	Autonomous vehicles	Vertically profiling buoy

moving through the water column). It can be important to understand whether a sensor that is reporting a value every 15 min is reporting the mean of 15 min of continuous measurement or a single (instantaneous) measurement once every 15 min.

A typical deployment on many lakes is a stationary surface buoy with sensors that hang underwater, just below the buoy, typically 1–2 m below the water surface (e.g., Fig. 2). In addition, it is common for a string of temperature sensors to be deployed, which enables frequency characterization of water temperature from many depths throughout the water column. Often, stationary buoys are moored with a two or three-point design, are solar powered, and contain an on board data logger and communications equipment, to provide the option for near real-time data. While inexpensive compared with mobile sensor deployments, stationary buoy deployments are often more expensive than sondes and autonomous probes, but provide the capability for longer deployments (e.g., due to on board power production) and near real-time data telemetry.

Contrasting with surface buoys and sensors are vertical profilers (e.g., Fig. 2). This configuration usually consists of a surface buoy that contains a sonde, which is hung from an onboard winch and moored with two or more lines. Often, the winch cable also provides power and communications with underwater sensors and enables a single line to connect underwater sensors to the buoy's power supply (e.g., batteries and solar power) and logger. Vertical profiles can look similar to stationary buoys but are often

substantially more expensive than traditional buoy deployments with stationary sensors, but enable full-water column characterization (e.g., Brentrup et al., 2016). However, an equivalent sensor deployment (i.e., with many stationary sensors hung throughout the water column) would be even more expensive and therefore this design is a cost-effective solution when full-water column monitoring is a priority. Weaknesses of this design are the high cost and need for substantially more power and oversight due to moving parts. The system must also have a way to identify the depth of the sensors (e.g., include a depth or pressure sensor). Additionally, short sample intervals (e.g., every min to 15 min) are often not possible due to the fact that the sensors must move through the water column and equilibrate at each depth. For example, if a vertical profiler is sampling every meter through a 20 m deep water column and the equilibration dwell-time at each depth is 2 min, then a max sample rate at any given depth is 40 min. Vertical profilers also usually require substantially more power than stationary equivalents. Conversely, because profiler buoys use the same individual sensor(s) to cover the entire water column, maintenance demands related to the calibration and cross-validation of multiple sensors for the same measurement variable are eliminated, and the relative accuracy and thus comparability of measurements at all depths is ensured.

Internally logging autonomous probes and sondes are another approach to sample single depths or sites (Fig. 3). There are a number of integrated autonomous sensing systems, often referred to as sondes, that provide power and logging capability in either single or multi-sensor platforms. These systems also often store sensor calibration data to correct sensor measurements. The ability to provide power and data logging in a relatively small and inexpensive package enables underwater sondes to be used in a range of conditions, such as extended under-ice deployments. Deployment designs are flexible and can include bottom mounted systems or single mooring line systems. Sensors can also be deployed relative to the bottom, which can be important in some situations (e.g., to make sure sensors stay below seasonal ice cover). However, these systems usually lack the capability to transmit data back in near real-time, and power is typically limited to the capacity provided by onboard batteries. The inability to transmit data means that sensor failures may not be detected for weeks, if not months. Furthermore, if sensors are lost before retrieval (e.g., due to a mooring line failure or vandalism), data are also lost. Additionally, the inability to recharge batteries means that batteries must be changed frequently when power-hungry sensors are used. However, it is also possible to have extended deployments with other sensors that do not consume much power. For example, a dissolved oxygen logger may log measurements for over a year at a 15-min interval on two AA lithium-ion batteries. Due to the relatively low price of autonomous probes and sondes, they represent a smaller up-front cost than many other platforms, and complex sensor networks can thus be built out over time. Indeed, many sondes can be configured to accept external power inputs and transmit data to an external logger. However, if many autonomous sensors are used, internal clock drift (i.e., inaccurate time keeping) over time can present a problem to synchronizing data streams after long deployment intervals.

Vehicles are a general class of sensor platforms that can drift, drive, or glide horizontally across a waterbody surface, or in the case of underwater vehicles, move both horizontally and vertically (Fig. 4). There are many related categories of vehicles, including autonomous surface vehicles (ASVs) and autonomous underwater vehicles (AUVs), which are sometimes called underwater drones or unmanned underwater vehicles (UUVs). Depending on the design, AUVs are also sometimes referred to as gliders. Power sources are often from internal batteries, but can be from other sources, including tethers. AUVs facilitate a three-dimensional characterization of many aspects of aquatic ecosystems (e.g., Robbins et al., 2006). Relatedly, manual (e.g., on or towed behind human-piloted craft) use of high-frequency sensors for spatial studies is more common (e.g., Crawford et al., 2015). However, autonomous vehicles are relatively underutilized for high-frequency data collection in inland waters due to high costs, often large size and weight, and potential regulatory hurdles in many jurisdictions. However, despite their high cost, vehicles can be cost-effective if the alternative is a high-density network of stationary autonomous in situ sensors.

Platform design considerations

Site selection is an important aspect of platform design and configuration. Ideally, the site(s) should be broadly representative of the inland water habitat of interest, while also maximizing accessibility and minimizing the potential of vandalism or unintentional damage. Local regulations may require that sensor platforms be clearly marked and visible both night and day, particularly where powered craft operate. Relevant authorities should be consulted to gain consent for the installation, approve the desired location, coloration and lighting, radar or other navigation aids. On public water bodies, signage and clear markings can reduce the chance of vandalism and encourage engagement with the public about what is being measured, and how/where data are available (e.g., displayed online) and being used. Wind and wave conditions at the site need to be well understood and the platform and moorings designed or chosen carefully to suit. At exposed locations, moorings designed by qualified engineers are advisable or may be required. The platform should be stable enough to withstand even the largest of likely storms, and to accommodate sufficient power generation and storage for the required measurement regime and associated hardware. Sites that are exposed to harsh field conditions (e.g., strong winds and waves) should be checked regularly for equipment wear and tear.

Sensors and associated hardware (e.g., navigation lights, data loggers) require power. In certain deployment configurations, AC line voltage can be provided to the site. However, more often, sensors and buoys require batteries and on-site power generation, usually from solar panels, but also occasionally from wind turbines. Calculating a power budget to start and operate sensors and all associated hardware is an important consideration when designing a system. The aim of a power budget should be to ensure that batteries are never completely drained and a sufficient amount of backup/emergency power storage is available at all times. Collation of manufacturer specifications for current consumption of all hardware is a starting point. Often, a warm up time may be required for the sensor to work properly and should be accounted for in power budgeting. Where solar generation is to be used,

the light climate and its seasonality at the site needs to be well understood, as well as temperature effects on storage capacity. Additionally, solar panels are not always at the ideal orientation in direction or angle to maximize energy production and fouling or wear and tear can reduce generation.

Data telemetry and analytics

Many deployment configurations enable the near real-time transmission of sensor data. One exception is when a configuration is completely subsurface (e.g., under ice). Telemetry can be achieved using radio (including recent IoT approaches, e.g., LoRa), cellular network, or satellite. Radio is generally the cheapest option, but can require a clear line-of-site between an internet connected base station and the data logger. A cellular network connection typically requires an onboard modem and a monthly fee. It works well where cellular signals are sufficient to send text messages. Satellite telemetry is a good option for very remote deployments where real-time data acquisition is a priority, but is substantially more expensive than radio or cellular telemetry. High-gain cellular antennas, which can increase weak signals, are worth considering before committing to satellite communications.

The frequency of data transmission varies among sites, but transmission usually occurs at least once daily. Data transmission can be one of the largest power consumers on a buoy, and therefore endpoint intelligence that prioritizes data collection over transmission during power limited circumstances can be valuable (see next paragraph for more details). The provisioning of data in near real-time can be used to conduct automated altering for various purposes, such as the collection of manual measurements during disturbance events.

Analytics can be built into some data loggers. Alternatively, small single-board computers (e.g., Arduino or Raspberry Pi) can be deployed on a sensing platform, which enables logging as well as analytics at the site of data collection. Example applications include stopping logging (and transmitting) solar radiation measurements at night when there is no light. More complex decision making can enable automation to improve data quality or quantity given pre-determined events or dataset characteristics. For example, systems can be set to increase the sampling frequency of lake water quality measurements when stream inflow rates or precipitation measurements exceed predetermined thresholds. Additionally, some sensors such as dissolved oxygen sensors can take up to several minutes to equilibrate, with the specific amount of time depending on factors such as the depth and dissolved oxygen concentration gradient. When dataloggers have the capacity to analyze sensor data in real-time, they can adjust sensing to maximize the value of the data being generated. For example, analytics can enable the dwell-time (i.e., the amount of time a sensor is equilibrating) to be dynamic, as the system can recognize when measurements stabilize following movement into waters with a different dissolved oxygen concentration. This type of adaptive sampling allows the sensor and datalogger flexibility in how it captures and stores data. Advanced decision-making methods, including machine learning or more complex rule-based decisions, can not only greatly increase deployment durations, but can provide greater characterization of dynamic and rapidly changing phenomena.

Processing and interpreting high-frequency sensor data

Sensor versus laboratory-based measurements

While many high-frequency sensors share a measurement variable name (and units) with a related laboratory measurement, they often depend on a fundamentally different technical process to make a measurement. For example, in situ sensors such as turbidity, FDOM, chlorophyll, and phycocyanin all share laboratory analogs with similar names, but use fundamentally different ways to quantify the variables (see Table 3). Other high-frequency sensors such as temperature, dissolved oxygen, pH, and conductivity are directly comparable with laboratory-based measurements. When methodological differences exist between field and laboratory samples they can result in different sensitivities and biases. Therefore, when laboratory and in situ high-frequency measurements have the same name, they may not be directly compared or assumed to represent the same quantity.

Some in situ sensors represent a hybrid between more traditional in situ high-frequency sensor designs and laboratory-grade measurements. Sensors can be equipped with complex fluid handling and processing systems, effectively enabling laboratory methods, and the established standards they rely on, to be performed in the field. For example, some laboratory methods have been automated, miniaturized and packaged into environmentally hardened housings, enabling reagent-based measurement of phosphorus or applying qPCR to understand genetic diversity within ecosystems. For these sensors, direct comparisons with laboratory measurements may be possible.

A general preconception is that laboratory-quality instruments provide higher levels of precession and accuracy compared with in situ analog sensors and are thus considered the "gold standard" of measurement of many characteristics. Thus, in the next section we focus on known biases, sensitivities, interferences, and other data quality issues that challenge the reliability of high-frequency sensors and comparability to laboratory-based measurements. However, in situ sensors contain some advantages and laboratory measurements are not uniformly superior to high-frequency sensor-based measurements. For example, the process of collection, processing, storage, transport, and preservation from the field to a laboratory can introduce biases, errors, and uncertainties that reduce sample integrity.

Table 3 Interferences or other problems that affect the degree to which high-frequency aquatic sensors are comparable with traditional laboratory measurements.

Sensed variable	*Lab analog*	*Interference or problem*	*References*
Fluorescent dissolved organic matter (FDOM)	Dissolved absorbance (e.g., a_{254}, a_{440}), spectral slope (e.g., $S_{275–295}$) and/or dissolved organic carbon concentration	Temperature bias; inner filter effects; turbidity interference; relationship between fluorescence and lab analogs not necessarily uniform through time or across sites	Watras et al. (2011), Downing et al. (2012), Carstea et al. (2014), Lee et al. (2015), Saraceno et al. (2017), de Oliveira et al. (2018), and McKay et al. (2018)
Chlorophyll fluorescence	Chlorophyll *a* concentration or total chlorophyll concentration	Temperature bias; Inner filter effects; Non-photochemical quenching; Zooplankton interference; variable response due to cell size, biovolume, and cell agglomeration	Serra et al. (2009), Watras et al. (2017), Xing et al. (2018), Lucius et al. (2019), Moiseeva et al. (2019), Kuha et al. (2020), Moriarty et al. (2021), and Liu and Georgakakos (2021)
Phycocyanin fluorescence	Phycocyanin concentration or cyanobacterial cell counts	Temperature bias; inner filter effects; turbidity interference; detritus containing degradation products can also fluoresce; possible interference by other pigments; variable response due to cell size, biovolume, and cell agglomeration; potential of light-induced quenching is debated	Zamyadi et al. (2016) and references therein, Watras et al. (2017), Cremella et al. (2018), Hodges et al. (2018), and Rousso et al. (2021)
Tryptophan fluorescence	Tryptophan concentration	Temperature bias, inner filter effects; turbidity effects	Khamis et al. (2015), Wasswa and Mladenov (2018), and Goffin et al. (2020)
Turbidity	Turbidity or total suspended solids	Inner filter effects; particle size, geometry, and chemistry influences relationship	Downing and Lehr (2005), Daphne et al. (2011), Hannouche et al. (2011), Spackman Jones et al. (2011), Snyder et al. (2018)
Nitrate (UV optical)	Nitrate	Inner filter effects, particle scattering	Pellerin et al. (2013) and Snyder et al. (2018)

Data quality

There are multiple challenges associated with the process of collecting high-frequency sensor data that can impact data product quality. High-frequency sensors are susceptible to a range of issues associated with exposure to potentially harsh and variable environmental conditions. Some of the most common issues encountered during sensor deployments include biofouling, physical shock or damage, sensor drift, interference with non-target substances, variable temperatures or light, and excess electrical noise. **Biofouling** is the colonization and growth of microorganisms on sensors that can degrade their performance (Fig. 3; see also Section "Biofouling"). **Sensor drift** is the process of increasing bias and/or decreasing accuracy in sensor measurements over time due to physical changes in the sensor. Some individual sensor technologies also have known biases specific to a sensor type that require additional correction to make them relatively comparable with established analogous laboratory measurements (e.g., Table 3). While many of these challenges are not unique to high-frequency sensor data, the large volume of generated data poses an additional hurdle to ensuring data reliability and integrity. While manual identification of erroneous or otherwise biased data points is feasible with certain low frequency datasets, complete manual review and correction of large high-frequency datasets becomes nearly impossible. As high-frequency sensor datasets continue to grow in size and complexity, automated methods for identifying potentially problematic data points are becoming increasingly important.

Quality assurance and quality control

Quality assurance (QA) and quality control (QC) are two terms often used interchangeably in data science, but have different meanings. QA is process oriented and refers to any process, protocols or procedures implemented to reduce or prevent erroneous or biased data points from entering the data record. QA steps are thus typically implemented before planned sensor deployments. In contrast, the emphasis of QC is on the data product and refers to post-collection methods to detect erroneous data within a dataset, and either flag, adjust, or remove observations to remove biases or errors.

Data quality flags are used to convey information concerning the quality of individual high-frequency sensor data points, which increases the integrity and reliability of data for downstream users (Campbell et al., 2013). The most common use of data flags is to draw the user's attention to suspect data that have failed some aspect of QC (Fig. 5). Flags can also be used to denote missing data, version level, method of data processing, or important events (e.g., calibrations or site visits). Simple data flags can be assigned using an initial automated filtering process (see Table 4), easing the burden for secondary manual reviews. Data flags can be human-readable descriptive character-based strings, or machine-readable numeric codes. There is no community-wide standard for data flagging definitions or use, and most data owners choose a flagging system that best fits the needs of an individual project. Whatever the flagging system used, definitions of each flag and the methods used to create them should be clearly documented in easily accessible metadata (see metadata section).

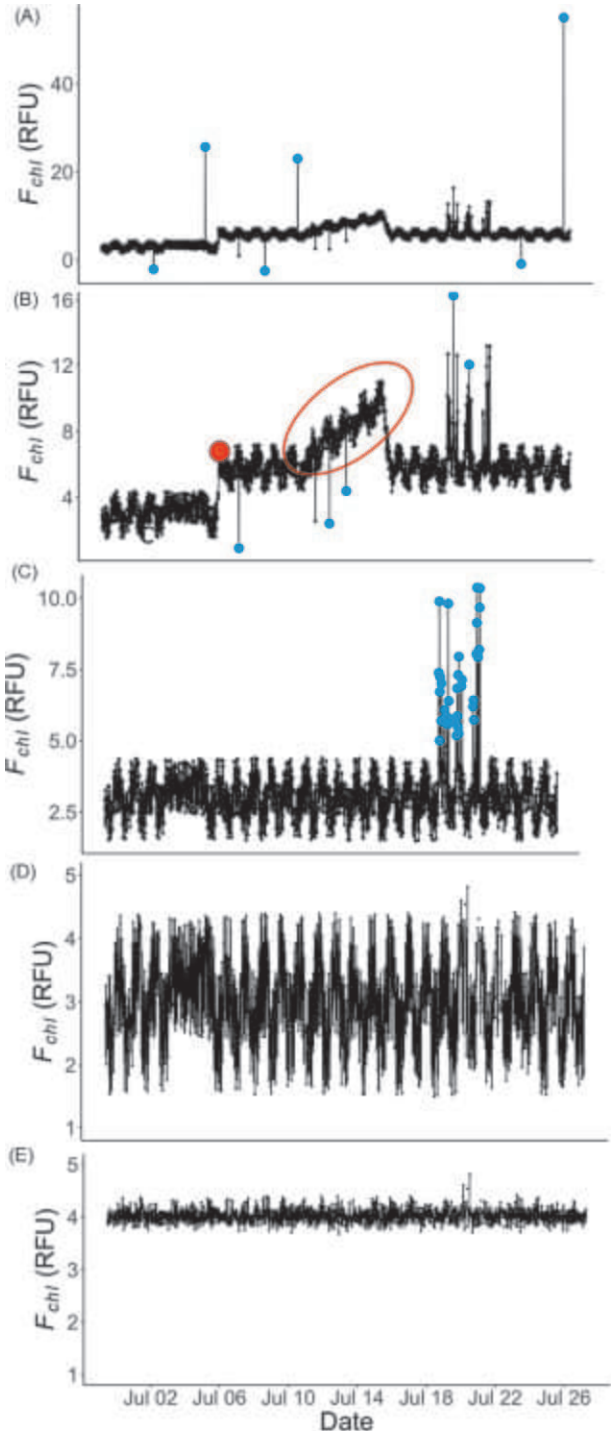

Fig. 5 Example of combined automated and manual data processing steps of chlorophyll fluorescence measurements from 1 month of measurements taken at a frequency of every 3 h. First (A), data are mechanically flagged using predetermined minimum and maximum value thresholds (blue dots). In (B), these initially flagged outliers are removed, enabling a rescaled y-axis; note the flagged step function increase (red dot; flagged by an automated "change-in-slope" filter), as well as a suspect upward trend in data starting Jan 13th (red oval; flagged as suspicious by manual review). Blue dots, representing data points that were mechanically flagged and removed. In (C), data blue dots in (B) have been removed for clarity and the step change previously flagged was identified as a calibration point. The data were adjusted between the two calibration periods (a Category 1 Correction). An unusual decrease in temperature was associated with the trend seen in B (red circle), and a temperature correction applied to the entire data set (Watras et al. 2017; Category 2 correction) removed the temperature bias. An automated analysis flagged additional data points (C, blue circles) that were later identified as fluorescence interference by zooplankton (Moriarty et al., 2021) and removed. (D) shows the dataset after these flagged points have been removed, when revealing a clear diurnal signal associated with non-photochemical quenching. A machine learning approach was applied (Lucius et al., 2020), resulting in a more accurate representation of chlorophyll at this site (E). Overall, 49 data points (2.4% of the month) were flagged and removed.

Table 4 Example data versions for high-frequency sensor data.

Level	*Data processing level*	*Description*
0	Raw	Unprocessed data and data products that have not undergone any alterations or annotations
1	Flagged	Actual data remain unaltered, but separate fields have been added to the original Level 0 data file, adding flagged data columns for each applicable raw data variable
2	Corrected	Dataset retains data flags from Level 1, but now may contain corrections, offsets, or complete removal. Additional flags are added to note these data alterations
3	Published	Data have undergone all levels of review and correction and are in a format suitable for publication and/or release to external parties

Regardless of the specific process, all steps should be clearly documented to enable repeat creation of data products.

Data flagging is an additive and annotative process where no data is changed; it is only described. It is good QC practice to maintain an unadulterated copy of the raw data file, before any initial flagging or filtering is begun. After an initial flagged dataset has been established, subsequent data products may include alterations or corrections of the raw data. Common data adjustments can include temperature or other bias corrections, corrections for sensor drift, various static offsets, or down sampling of data through various averaging methods (see data corrections section below). It is critical that such data manipulations be thoroughly documented, describing both the methods used and the reasoning behind the data alterations.

The creation of progressive iterations of a data set as it moves through a QC process is termed **data versioning**. Not only does versioning establish a well-defined provenance for all future data products, it offers protection from inadvertent or ill-advised changes to the original data values (Michener and Brunt, 2009). As an example of data versioning, Table 4 describes levels commonly applicable to high-frequency sensor data downloaded and initially stored in a simple text format (either .csv or .txt files). However, the specific steps taken in each data version depend on the needs of individual data users, the sensors used, and conditions experienced during sensor deployments.

The creation of metadata can be as important as actual data for understanding and using high-frequency sensor data. Metadata includes a description of the who, what, where, when, and why of a data set. This includes aspects of the study site and sampling location (e.g., depth, surface area, long-term mean water quality conditions); information on how samples were collected (e.g., whether samples are collected relative to surface or bottom); sensor information (e.g., manufacturer, model, and serial number); information on sampling design (e.g., sampling frequency, integration time, and wiping frequency); time stamp information (e.g., including possible GMT offset or daylight savings accounting), and QA/QC procedures. A robust QC workflow should include the ability to augment or add important metadata (calibration points, site visits, etc.) created at different points within the QC and versioning process. This would include metadata created through both automated processes or gleaned from manual reviews of either visual or tabular data. A published data set should be sufficiently described (i.e., documentation) such that it could be easily understood by external users with no knowledge of the original data collection, QA, or QC processes. Consistency in the collection, storage, and formatting of metadata is key in maintaining its usefulness. Maintaining a constant format allows for machine readable metadata, and easy ingestion of metadata into QC tools.

Before and during deployment

Assuring high quality of final data products begins before sensors are deployed. Pre-deployment, sensors should be calibrated according to manufacturer's recommendations within a range commensurate with the expected exposure conditions. Best practices for sensor calibration should also include a post-calibration check to confirm proper sensor functioning and quantify drift (see below for more information). Typically, a two-point calibration (e.g., where sensors are calibrated with a blank and a non-zero standard) is recommended. It should be noted that while some sensors, such as pH, dissolved oxygen, and temperature can be calibrated against known laboratory standards, other sensors, such as chlorophyll or phycocyanin fluorescence cannot be easily calibrated against standards due to the type of standard they rely on. For these sensors, calibration (e.g., using a known concentration of a fluorescing standard such as quinine sulfate or rhodamine) is used primarily to document and correct sensor drift over time (Earp et al., 2011).

Once a sensor has been properly calibrated and deployed, during the data collection process both internal (i.e., sensor drift, biases, electrical noise) and external factors (i.e., bio fouling, interferences, and physical impacts) can reduce data quality and reliability. If remote telemetry is available, near real-time sensor data should be regularly reviewed with a combination of mechanical inspection (see data cleaning and corrections sections below) and visual inspection by experienced personnel. Any suspected issues found as part of a real-time monitoring system should be recorded as part of the sensor metadata and investigated by field personnel promptly.

Site visits should be scheduled on a regular basis (and/or opportunistically, for example after disturbance events) to visually inspect sensors for damage and fouling. The recommended frequency of visits depends on many factors, but in general visits should be more frequent in high fouling environments (e.g., in more eutrophic or turbid environments), where there is a greater risk of damage from vandalism or natural variation in the environment (e.g., flooding), and when sensors are known to have a fast drift

rate. When regular site visits are not practical, deploying co-located replicate sensors can be a useful (but expensive) QA strategy. Not only will having replicate sensors minimize the chance of data loss due to sensor failure, data from duplicate sensors measuring the same environment can be used for detecting and correcting measurement errors.

The process of increasing bias and/or decreasing accuracy in sensor measurements over time due to physical changes in the sensor is referred to as **sensor drift**. This occurs due to factors such as internal sensor functioning changes or corrosion. The drift rate can be highly variable among various sensors. For example, sensors that utilize ion-selective electrode technology (e.g., pH sensors) drift rapidly and may require calibration at least every several weeks. In contrast, optical sensors measuring variables such as dissolved oxygen, FDOM, turbidity, chlorophyll fluorescence, or phycocyanin fluorescence drift relatively slowly and may only require a once-annual calibration. At a minimum, sensors should be calibrated immediately before and after deployment. However, it should be noted that more frequent recalibration is not necessarily better for assuring more accurate data, as calibrations can introduce greater uncertainty in measurements relative to the amount from sensor drift, especially for more stable (e.g., optical) sensors.

Biofouling

In highly productive warm waters (e.g., eutrophic lakes during summer months, Fig. 3), biofouling can be rapid, with visible growth in under a week (Delauney et al., 2010). Fouling in high turbidity environments due to sediment settling is also possible under some conditions. Like sensor drift, fouling can impact sensor measurements and therefore should be controlled as much as possible. There are multiple approaches to reduce fouling (whether biological in origin or not), including mechanical wiping, anti-fouling materials and chemicals, UV-C light, air blasts, and ultrasonic disruption (Delauney et al., 2010; Patil et al., 2007). Often, a combination of approaches is employed, with the most common approach being mechanical wiping and incorporation of antifouling materials (such as copper) into the sensor housing. After-market mechanical wipers are available that fit many third party high-frequency sensors.

When using a motorized wiper, choosing a wiping frequency should be given careful consideration. In general, warm and productive freshwater bodies will require frequent wiping, but minimum wiping intervals for an individual deployment area will need to be derived through experience. Fouling rates are seldom linear, and will often increase exponentially as biofilms are first established. Often, wiping can be much less frequent than sensing, at a frequency of hours to days. Additionally, there are potential downsides to wiping too frequently. Powering a wiper motor can be an energetically expensive task compared to the current draw of a typical sensor. Wiping a sensor face too often can also cause separate quality concerns. Sensor brushes have finite lifetimes, and over-wiping can cause premature breakdown of brush material. Sand, grit, and other detritus can foul sensor brushes, and over-wiping can also cause damage to delicate optical glass or sensor membranes (e.g., on dissolved oxygen sensors). The act of wiping a sensor also requires momentary pauses in data collection. Frequent sensor wiping can result in a cumulative loss in data fidelity, especially when sampling at higher frequencies. Finally, if wipers are powered by the same source as sensors, activating wipers can introduce unintended data distortions due to poor isolation of electrical components. This type of sensor bias can persist long beyond the wipe activation period (Fig. 6).

Data cleaning

Data cleaning, also known as data "wrangling" or "munging," refers to any method whereby a data set is fed into various QC processes capable of identifying, correcting, and potentially removing erroneous data points. Once raw sensor data have been collected and stored, data cleaning QC protocols should be implemented to ensure the final data product(s) are of the highest possible quality. In most QC workflows, there is a distinction between automated or mechanical QC procedures and those performed by a human researcher (i.e., manual). Automated QC methods are becoming increasingly necessary and common as the volume of data being collected by high frequency sensors grows rapidly (Campbell et al., 2013; Durre et al., 2010).

Most common automated QC methods rely on simple threshold or statistical attribute checks. For example, in the US, the National Ecological Observatory Network (NEON) has a well-documented initial QC checklist for sensor data consisting of six "plausibility tests" (Taylor and Loescher, 2013). These tests include checks for data outliers, variance, step changes, and missing

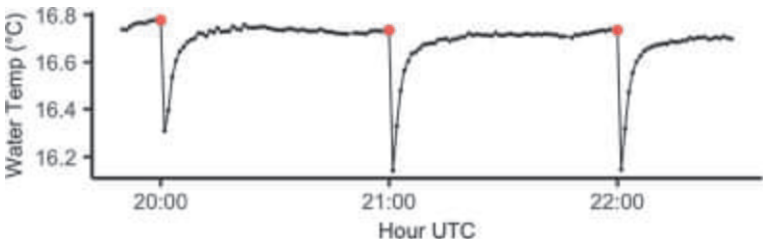

Fig. 6 Water temperature data from a wiped high-frequency sensor with a manufacturer reported accuracy of ±0.01 °C. Here, both the sensor and wiper were powered by a sonde. Water temperature data were collected at a 1-min interval, and the sensor faces were wiped every hour (red dots indicate when a wipe occurred). Temperature data can be seen to drop as much as 0.6C immediately following a wipe and took ~20 min to fully return to expected readings.

data, which are all common issues with high-frequency sensor datasets. The list below describes six quality control tests that are recommended for automated QC protocols of high-frequency sensor data (Campbell et al., 2013).

1. *Date and time*: Each data point must be associated with a timestamp. Time series sensor data should always be collected in chronological order, and this first step is a simple check that timestamps are sequential.
2. *Range*: Ensure measurements fall within an established upper and lower bound. Bounded limits are usually determined using previous knowledge of the system, or by absolute bounds (i.e., many sensors such as rainfall, PAR, wind speed, conductivity, or dissolved oxygen should never measure values below zero).
3. *Persistence*: When the same value is repeated with no change, it can be indicative of a sensor or system failure.
4. *Change in slope*: When evaluating a time-series, sudden changes in slope can indicate that a sensor was disturbed or malfunctioned.
5. *Internal consistency*: Many sensors that are commonly paired together have known relationships. This check makes use of these relationships and checks for consistency between co-located sensors. For example, a sensor recording snow accumulation when a co-located air temperature sensor reports temperatures of 20^0C should be flagged for QC concerns.
6. *Spatial consistency*: If available, comparisons of neighboring sensors can be helpful to evaluate data.

In addition to traditional statistical checks, more advanced methods from machine-learning and other computer science communities are increasingly being adopted for use with ecological sensor data. Methods specifically designed to work with time-series data such as Fourier transformations and wavelet analyzes (Cazelles et al., 2008), time series decomposition (Duan et al., 2018), symbolic representation (SAX; Ruan et al., 2017), or piecewise polynomial models (Gal and Anderson, 2010)can be used to help identify erroneous data points and trends associated with malfunctioning or failing sensors. However, despite the advantages of automated QC protocols, these approaches may miss unique situations. Thus, a combined automated and manual approach is often adopted, and automated processing checks and flags (see below) are typically reviewed by a person. Whether using an automated tool or developing manual check protocols tailored to a specific sensor and location, QC protocols should contain certain key functionality including data visualization, flagging, and metadata curation. An example data cleaning procedure is documented in Fig. 5.

Data corrections

There are many reasons raw high-frequency sensor data may need correcting, with many example reasons detailed here. Decisions to alter data should have a well-defined and defensible reasoning, and be well documented in accompanying metadata (see above). Raw data should always be maintained. Here, we define three categories of data corrections: (1) corrections associated with known and documented observations or incidents, (2) corrections associated with specific sensor technologies, and (3) corrections associated with unknown or undocumented observations in the data set itself. Sections below describe recommended protocols to correct data associated with category 1 and 2 issues. In contrast, category 3 issues emerge from unknown or undocumented phenomena. These issues often manifest themselves as curious patterns in the data or changes in statistical attributes over time. Accurately identifying these issues relies on local knowledge about a particular system, or well-defined relationships concerning the variable being measured for correction. While these issues may be flagged by automated QC protocols, researchers should be conservative when attempting to make data corrections in these circumstances and supply detailed metadata on the reasoning behind and methods used for corrective actions.

Corrections associated with known and documented observations or incidents: These correction types are the easiest to justify, as the underlying issue has been identified and should be documented in associated metadata. A common example of this type of correction would be those associated with calibrations. Issues discovered during pre or post deployment calibration checks (e.g., sensor drift or calibration errors) are easily documented, and provide solid justification to adjust data values. Changes in sensor data associated with field events or observations, such as physical movement of sensors during a site visit, are common during typical sensor deployments and can be easily corrected, assuming metadata are well-documented.

Corrections associated with specific sensor technologies: This type of correction is often derived from biases of certain sensor technologies that cause them to generate poor estimates of a variable in certain conditions. Corrective actions are often implemented to increase the comparability of the sensor output with an analogous laboratory measured variable. These corrections can be rooted in simple adjustments, such as correcting for barometric pressure when using a non-vented pressure transducer to measure water height. However, in many cases the corrections require more sophisticated post-processing techniques and site-specific adjustments. Many optical sensors are often subject to these Category 2 issues (Table 3).

The origin of multiple category 2 issues with optical sensors is associated with matrix effects. A matrix effect occurs when water and its constituents influence light in such a way as to bias a sensor's estimation of a variable. A common matrix effect is known as the inner filter effect, which occurs when light is absorbed after it is emitted from the sensor or following the stimulation of fluorescence. This leads to fluorescence being measured lower than it is at the source, and the effect typically increases with increasing DOC concentrations. However, the effect can also result from high concentrations of other light absorbing substances, including algal cells. Some sensors come equipped with FDOM sensors to correct for inner filter effect. Another matrix effect occurs in high turbidity waters, which scatter light and usually results in less light measured by the sensor's photodetector (e.g., Saraceno et al., 2017). The overall magnitude of matrix effects depends on both the properties of the water and constituents as well as

specifications of the sensors (e.g., path length, intensity and wavebands used for excitation and emission). Universal correction factors are therefore usually not possible and site-specific (and perhaps even season or event-specific) corrections may be necessary.

In addition to matrix effects, there are other factors that create category 2 issues and influence the degree to which many sensors can be used to accurately estimate laboratory analog variables. These issues include temperature-dependence effects (e.g., Watras et al., 2011, 2017) and fluorescence interference by zooplankton (Moriarty et al., 2021). Temperature effects are typically manifested as lower observed fluorescence measurements at higher temperatures. However, temperature also affects sensors other than fluorometers, too. For example, conductivity sensors exhibit temperature dependence similar to that of fluorometers. While this temperature dependence can be an important factor driving overall variation in sensor measurements, the temperature-specific coefficient can vary across sensors and manufacturers. Therefore, an instrument-specific calibration is recommended.

Fluorescence inference by zooplankton can occur because many zooplankton species are attracted to visible light (i.e., positively phototactic; (Storz and Paul, 1998) and thus are attracted to the excitation light source on some sensors at night (e.g., chlorophyll fluorometers; Fig. 7). High fluorescence interference by zooplankton increases both the mean and variance of nighttime chlorophyll estimates. The effect occurs when sensor light sources are on long enough such that zooplankton congregate at the sensor light source. This occurs when sensors are sampling frequently (e.g., every second) or integration times are long (e.g., 20 or more seconds; Moriarty et al., 2021). While this phenomenon has not been tested for in other types of sensors, it is likely to occur in phycocyanin sensors given excitation light sources are in the visible wavelength range. It is unclear if this phenomenon affects FDOM or turbidity sensors, as excitation light sources can be outside the visible range (depending on the sensor design). For example, FDOM sensor excitation light sources are often in the ultraviolet range where many zooplankton exhibit negatively phototactic behavior. Overall, the magnitude of the effect of zooplankton interference will vary depending on length of time sensor lights illuminate, the concentration of zooplankton, and the dominant zooplankton species, as phototaxis behavior is not universal (Moriarty et al., 2021; Overholt et al., 2015).

In addition to the above issues facing many sensors, FDOM and chlorophyll fluorescence sensors also face unique issues challenging the degree to which they can be used to estimate laboratory analog variables. First, FDOM sensors are frequently used to estimate characteristics of the dissolved organic matter (DOM) pool, including dissolved organic carbon (DOC) concentration, dissolved absorbance (e.g., a254, a440), and spectral slope (e.g., S275–295). DOM source and chemistry influences the relationship between FDOM and these other inferred characteristics, and the relationship cannot be assumed to be constant (Jaffé et al., 2012). Thus, often site-specific correlations may be necessary to accurately predict attributes of the DOM pool from fDOM sensors. In sites with substantial variations in DOM composition, corrections may even need to be season or event specific.

Chlorophyll fluorometers are sensitive to interference by non-photochemical quenching (NPQ; e.g., Serra et al., 2009). NPQ is a photoprotective mechanism common to most plants and algae by which potentially harmful excess light energy is dissipated as heat. NPQ is frequently observed during periods of high light intensity, and results in a decrease in the normal chlorophyll fluorescence signal as recorded by an in situ fluorometer. NPQ bias is frequently observed as a diurnal fluctuation in chlorophyll fluorescence values, with substantial reductions (upward of 90+%) in sensor-estimated chlorophyll in well-lit surface waters (e.g., Fig. 5). A common method to avoid the effects of NPQ when using high-frequency chlorophyll fluorescence as an indicator of chlorophyll or algal biomass is to only use nighttime data, as data collected at night is often assumed to be free of NPQ bias (Carberry et al., 2019; Rusak et al., 2018). While usually a sound approach, this method results in significant data loss and

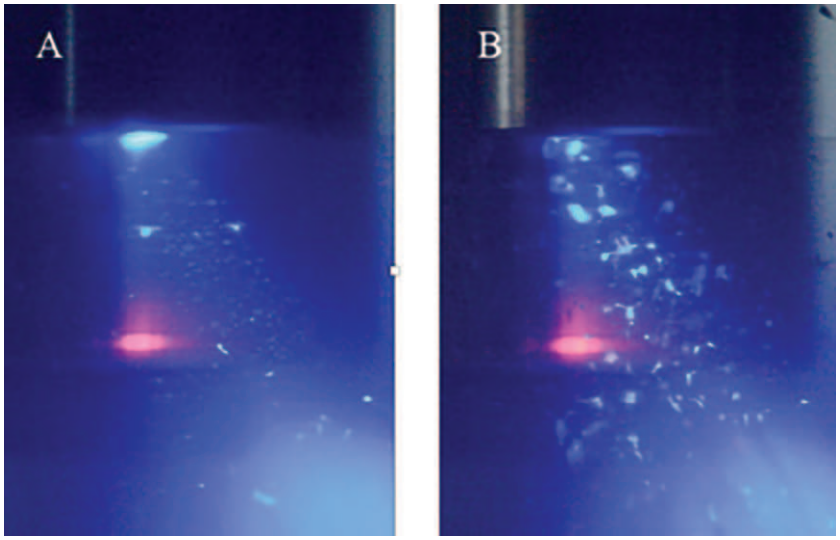

Fig. 7 Laboratory-based photographs of zooplankton responses to a YSI EXO2 chlorophyll fluorometer taken 5 s (A) and 50 s (B) after the sensor's blue (410–485 nm) LED was turned on, sampling (i.e., LED flashing) at a 4 Hz frequency. A large swarm of zooplankton can be seen congregating directly under the sensor face in B. See also Moriarty et al., 2021. The pink light visible in the images is a reflection from another optical fluorometer. Included video associated with this figure that shows fluorescence interference by zooplankton: https://drive.google.com/file/d/1kzQlLlJEGHwAHJAR1s8G03L3wCeXoCWj/view?usp=sharing.

eliminates the possibility of studying important daytime phytoplankton dynamics. Additionally, nighttime measurements can suffer from fluorescence interference by zooplankton under some sampling scenarios (see above). Multiple methods to correct daytime chlorophyll fluorometer data for the effects of NPQ have been developed (e.g., Liu and Georgakakos, 2021; Lucius et al., 2020; Rousso et al., 2021; Serra et al., 2009; Carberry et al., 2019; Xing et al., 2018), but often require the use of advanced methods or equipment, and may not be viable for all high-frequency sensor datasets. NPQ can be challenging to correct because many factors affect the amount of NPQ, including the species assemblage, cellular geometry, nutrient status, light exposure history and potential acclimation, temperature, mixing depth and rate, and incident light field. Thus, NPQ corrections should be carefully constructed on a site-by-site basis. Evidence that other sensors, such as phycocyanin sensors, are also sensitive to NPQ effects is mixed (e.g., Rousso et al., 2021; Zamyadi et al., 2016). Overall, NPQ is a substantial issue that must usually be addressed to accurately infer chlorophyll measurements from in situ fluorometers.

Beyond sensors and data: The power of ecological networks

The growth of high-frequency sensors in research and monitoring has spurred the development of ecological observatory networks (EONs) of people, data, and infrastructure. EONs, and the high-frequency sensor data that underpin them, are often associated with a high degree of collaboration and data-sharing. There are likely many reasons for this. First, the technical nature of the sensors requires expertise in diverse areas such as engineering, design, fabrication, cyber-infrastructure, data science, and ecology. Second, the volumes of data that are generated from high-frequency sensors provide the opportunity to ask many different types of research questions that are often beyond the scope of any single research organization. Third, once established, autonomous sensors and platforms continue to generate data at a low ongoing cost. When individual data points are inexpensive, there is a smaller barrier to sharing. Finally, the proliferation of high-frequency sensors has coincided with increased emphasis on understanding macrosystem-scale patterns in ecosystems, thus promoting the formation of EONs (Rose et al., 2017; Rüegg et al., 2014).

One such grassroots example is GLEON, the Global Lake Ecological Observatory Network, which is an inclusive community of people, lakes, data, and infrastructure dedicated to conducting and supporting lake research and management using high-frequency sensors (Weathers et al., 2013; Hamilton et al., 2015; Rose et al. 2016). A key strength of GLEON is the fact that the grass-roots nature of the organization and the prioritization of team science best practices means that the diverse community of individuals are empowered to lead research and other activities. Most network activities are underpinned by an evolving working group structure that enables teams to form and focus on topics where interests align. Members of GLEON have generated important insights into aquatic ecosystem dynamics using both high-frequency data (e.g., Solomon et al., 2013) and lower-frequency measurements using sensors (e.g., Jane et al., 2021). GLEON data have also been used in numerous ways to engage with stakeholders outside of academia to improve the understanding and management of lakes (Smyth et al., 2016). The grass-roots nature of GLEON means that individual sites often differ in many aspects, such as the types of sensors deployed, the frequency, depth, and duration of sampling, what other ancillary data that are collected, and the nature of who owns the data. The diversity in what and how data are collected and managed can often present a challenge to cross-site synthesis. The data management practices recommended herein can help reduce the barrier to effective use of network data. The overall rapid growth in community engagement and GLEON products highlights the power of network science.

Due to the complexity of high frequency sensor network data and the volume of data they generate, there have been considerable investments made in data processing tools, many of which are freely available (Read et al., 2016). These tools often help to (1) facilitate the QA/QC process or (2) assist in calculating derived characteristics, such as thermal stability indices from temperature measurements. Freely available tools to assist with automated QC include MATLAB based software (GCE Data ToolBox) capable of automating the collection and processing of high-frequency sensor data (Sheldon, 2008) and various R packages such as DriftR (Shaughnessy et al., 2019) and anomalize (Dancho and Vaughan, 2020). Additionally, the python based "ODM Tools" software packages have several QC-specific tools and were developed specifically for working with hydrologic and water quality data (Horsburgh et al., 2015). Freely available scientific workflow management software, such as Kepler, can be tremendously valuable in overall project management. Commercial time-series management platforms, including Kisters' 'WISKI' and Aquatic Informatics 'Aquarius', provide a range of native and customizable tools for detection of outliers or suspicious measurements.

Some software tools have been created to calculate derived indices from high-frequency sensor data. Some of the most popular examples are R packages such as Lake Analyzer (Read et al., 2011), Lake MetabolizeR (Winslow et al., 2016) and Lake Heat Flux Analyzer (Woolway et al., 2015). Lake Analyzer provides calculations of indices of mixing and stratification from depth-resolved measurements of temperature and other data including bathymetry and salinity. Lake Metabolizer provides estimates of lake metabolism from different types of metabolic models using time series measurements of dissolved oxygen, water temperature, and other variables. Lake Heat Flux Analyzer provides the capability to estimate surface energy fluxes such as sensible and latent heat fluxes, incoming and outgoing long-wave radiation, and surface momentum fluxes from time series measurements of water temperature and meteorological conditions. In sum, these tools enable the calculation of derived characteristics primarily associated with temperature and oxygen, the two most commonly measured high-frequency variables (Meinson et al., 2015). As other sensors become more common, associated processing tools that standardize output and estimate important derived characteristics will be increasingly valuable.

Conclusions

High-frequency sensing can provide numerous benefits in research, management, and outreach. There are many aspects to consider when planning a high frequency sensor deployment. There is rarely a single solution to a given technical problem, and there are important tradeoffs to consider in many aspects of sensor and platform selection and use. Additionally, deploying equipment and obtaining data is only a part of the challenge of effectively using high-frequency sensors to conduct research and management. Data management, including the creation and preservation of critical metadata, represents an important challenge and can be as important as the data itself in determining the long-term usefulness of data. Overall, high-frequency sensors greatly increase the capability of research and management. The ability to characterize ecological variability across massive temporal scales provides the capability to advance understanding of ecological processes and forecast future conditions. Growing cross-site syntheses, enabled by a growing culture of open and shared data, further facilitate insights into ecological dynamics across both time and space.

Acknowledgments

KCR acknowledges the support of NSF grants 1754265, 1761805, and 2048031, as well as Craig Williamson, Tim Kratz, Kathie Weathers, and Paul Hanson, whose support fostered his use of high-frequency sensors and involvement in GLEON. KCR and VM also acknowledge NSF grant 1655168 and New York State Higher Education Capital grant 7290. Data used in Figs. 6 and 7 were collected using equipment funded through the Jefferson Project at Lake George, which is a collaboration of Rensselaer Polytechnic Institute, IBM, and the Lake George Association. The authors also acknowledge the support and assistance of Dr. Kendra Spence Cheruvelil in bringing this chapter to fruition, assistance with gathering buoy photos by Eleanor Jennings and Alo Laas, and constructive input from Carl Watras.

Glossary

Absorption The disruption of the light beam that passes through.
Adjacency effects The scattering of light into neighboring pixels.
Apparent optical properties (AOPs) The reflectance characteristics of a medium that depend on both on the medium (the IOPs) and on the geometric (directional) structure of the ambient light field.
Atmospheric correction Removes the scattering and absorption effects of atmosphere on the reflectance measurements made by airborne or spaceborne sensors.
Atmospheric optical thickness (AOT) The optical depth or thickness of the atmosphere and is the vertical thickness from the earth surface to the top of the atmosphere.
Calibration The process of converting a signal from a sensor into a recognizable unit of measurement.
Downwelling irradiance The radiation from the sun that hits the earth's surface.
Earth observation Gathering information on the Earth's physical, chemical and biological systems through remote sensing platforms, which can be in situ, airborne or spaceborne.
Ensemble approach The selection of the most appropriate calibration for a given set of circumstances.
Inherent optical properties (IOPs) The various measures of the absorption and scattering properties of a water body.
Match-ups The number of coincident observations from airborne or spaceborne platforms with in situ measurements.
NADIR The point on the earth surface that is directly beneath the sensor.
Optical water types (OWT) A typology of water color that provides statistically distinct clusters of reflectance spectra, each characterized by discrete ranges of IOPs.
Overpasses Occurs when the field of view of a sensor passes a point of interest.
Radiative transfer models The modelling of the propagation of light through a medium.
Radiometric resolution The degrees of intensity that a sensor is able to resolve.
Remote sensing Acquiring information about an object from a distance.
Scattering The redirection of light by a substance.

 https://doi.org/10.1016/B978-0-12-819166-8.00213-9

Sky radiance The diffuse solar radiation that hits the earth's surface after being scattered by molecules or particulates in the atmosphere.
Spatial resolution The on the ground dimension that represents a pixel in an image.
Spectral bands The wavelength range over which reflected light is integrated for a sensor.
Spectral resolution The ability of a sensor to resolve fine wavelength intervals.
Temporal resolution The time taken to revisit or acquire data from the same point on the earth surface.
Transmittance The ratio between the incident light and the light that passes through the substance.
Validation The process of verifying the accuracy of a measurement.
Water-leaving radiance The upwelling radiance from water to the air following interaction with water constituents.

Introduction

Surface waters are a fundamental resource, providing key ecosystem services that support the way we function as a society as well as supporting life itself. Yet water is also the primary medium through which we are feeling the effects of climate change (UN Water, COP21), where increased episodes of extreme events and climate shocks (flooding and drought) often coupled with complex interactions with changes in the catchment, lead to the deterioration in water quality. At the global scale, this results in an increasing imbalance in the availability of clean, safe and sustainable water, exacerbating issues of poverty and hunger as well as biodiversity declines and carbon losses. Effective water management is critical to mitigate these effects but also enables us to sustainably manage water as a resource to blue and green economic growth opportunities. However, the inherently dynamic and heterogeneous distribution of water bodies across our landscape poses very real challenges for effective monitoring through conventional sampling and in situ techniques (Tyler et al., 2016). These issues are compounded further by inconsistencies in sampling and measurement strategies within and between organizations and nation states, constraining our systematic understanding of how surface waters are changing at local, regional and global scales (Carvalho et al., 2011; Palmer et al., 2015; Tyler et al., 2016).

There are estimated to be about 117 million lakes globally that cover around 3.7% of the planet's non- glaciated land surface (Verpoorter et al., 2014). Lakes have been described as 'sentinels, integrators and regulators' as a result of their sensitivity to climate change either directly or through changes occurring in their catchments (Williamson et al., 2009). Their importance in global biogeochemical cycling is increasingly being acknowledged (Bastviken et al., 2011; Cole et al., 2007), yet understanding of their role in transforming carbon is limited. Earth observation (EO) of lake color has an important role to play towards fully understanding the state and functioning of lakes within a global climate context and supporting sustainable management practices into the future.

The last 10 years or so has seen a rapid growth in the exploitation of satellite EO technologies for monitoring water quality (Tyler et al., 2016), shifting from the focus on individual lakes to the global scale. Three key developments that have enabled these advancements include: (i) the investment in ocean color remote sensing platforms that provide the sensitivities to detect and resolve constituents in water constituents that affect water quality; (ii) the computational solutions that allow us to resolve the optical complexity of inland and coastal waters for the reliable retrieval of water quality parameters (Spyrakos et al., 2018; Neil et al., 2019) and (iii) recent improvements in atmospheric correction to resolve the influence of the atmosphere in scattering the light reflected from water bodies, which tend to be dark targets compared to the adjacent land; examples include ACOLITE (Vanhellemont, 2019), POLYMER (Steinmetz and Ramon, 2018), C2X (Brockmann et al., 2016) and iCOR (De Keukelaere et al., 2018), which are among a series recently tested by Pahlevan et al. (2021). This change in capability has resulted in a step change in our ability to move the remote sensing science from observing individual lakes to enable the global population of lakes to be sampled and monitored from space with the accuracy that allows us to understand how these critical ecosystems are changing in response to climate change and changes occurring in their catchments. Here we will provide an overview of the principles and state of the art of the application of EO for water quality monitoring.

Using EO to detect water color

Water color is science of extracting information about the constituents within the water that affect its color. Water color can range from blue, through green to brown and yellow. The color of water is determined largely by the proportion of three main constituents, which we often refer to as optically active constituents (OAC) as they affect water color: (i) living phytoplankton measured by the chlorophyll *a* (ch*la*) pigment concentration; (ii) dissolved organic matter measured by the amount of color dissolved organic matter; and (iii) the amount of inorganic matter or Non Algal Particles (NAP) such as sediment measured as total suspended matter. Measuring these parameters allows us to understand the ecological status of inland waters and how they are changing with environmental pressures and the impact that might have on their ecosystems and the ecosystem services that these water bodies can provide.

Here we provide an overview of how light interacts with water and how we can use this to estimate the concentrations of these optically active in water constituents by classifying water into Optical Water Types through which computational methods for estimate optically active water quality parameters can be more reliably applied.

Light propagation

The estimation of water color by EO relies on the spectral shape of the radiometric signal, which can be detected by remote sensors deployed or onboard of drones, airplanes, or satellites. The radiometric signal detected is the sum of the interaction of several components such as: the atmosphere, the air-water interface, the dissolved and particulate material of the water column and, if visible, the waterbody's bottom. These components influence the remote sensing signal by transmitting, scattering and absorbing the light. Within the water column, light can be transmitted, scattered, or absorbed (Mobley, 2001).

These light interactions are defined as optical properties of water and are usually described in terms of their Inherent Optical Properties (IOPs) and Apparent Optical Properties (AOPs). AOPs are dependent on both the environment (the constituents in the medium) and the geometric (directional) structure of the radiance distribution (Mobley, 1994). In contrast, IOPs rely only on the biogeochemical properties of the environment, such as the absorption and backscattering of the major OACs such as phytoplankton pigments, CDOM and NAP.

AOPs are commonly used for the development of remote sensing algorithms to estimate water quality (Uudeberg et al., 2019). One of the most common AOPs is the remote sensing reflectance (R_{rs}) which is influenced by the response to the IOPs of phytoplankton pigments, CDOM and NAP within the water column (Kirk, 2011). Fig. 1 shows the variability of R_{rs} spectra from different coastal and inland aquatic systems. Because of the optical complexity of inland waters, remote sensing algorithms usually do not have the same performance for different water bodies. For example, algorithms developed over turbid shallow lakes will probably have a poorer performance in deeper clearer lakes.

Optical complexity and water typology

Earth observation methods in inland waters are often challenged by high optical diversity and dynamic variability. Inputs of external material (particulate and/or dissolved) into inland waters can decouple bulk optical properties from phytoplankton. This means that methods developed for waters where the phytoplankton community are the main sources of variability in water optical properties are not directly applicable to inland waters. A common strategy to work with the complexity of inland waters is to classify the derived remote sensing reflectance signal into Optical Water Types (OWT) which is an approach that has been used in several studies (Moore et al., 2009, 2014; Vantrepotte et al., 2012; Spyrakos et al., 2018; Botha et al., 2020). The traditional OWT classification defines water as Case 1 and Case 2 (Gordon and Morel, 1983) with the former being referred to as open ocean waters (dominated by phytoplankton) and the latter as coastal and inland waters (driven by a mix of different OACs which do not co-vary with each other).

However, this simplistic classification was not sufficient for inland waters, which can be very different from each other. Therefore, recent classifications of inland waters took the traditional classification to a new level based on statistical clustering of the apparent optical properties (AOPs), such as Rrs spectra, providing distinct Optical Water Types (OWTs) (Lubac and Loisel, 2007; Shi et al., 2014; Melin and Vantrepotte, 2015; Spyrakos et al., 2018). Another possibility was the cluster analysis to group IOP data derived from the inversion of the Rrs (Botha et al., 2020). The motivation to propose OWT classifications is to define which remote sensing algorithms may be better used for each OWT (Neil et al., 2019), which will improve the estimation of water quality parameters.

Evolution of remote sensing platforms

Since the beginning of remote sensing for inland water applications, the landscape has evolved significantly. Four major criteria define the requirements for sensor and platform developments to achieve a certain outcome: (i) minimum size of distinguishable

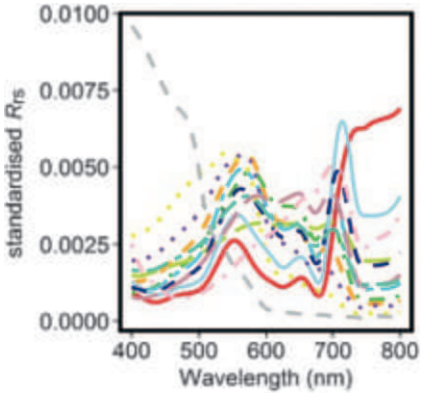

Fig. 1 Mean remote sensing reflectance spectra (Rrs) for each statistically distinct cluster of standardized remote sensing reflectances obtained for inland waters (Spyrakos et al., 2018).

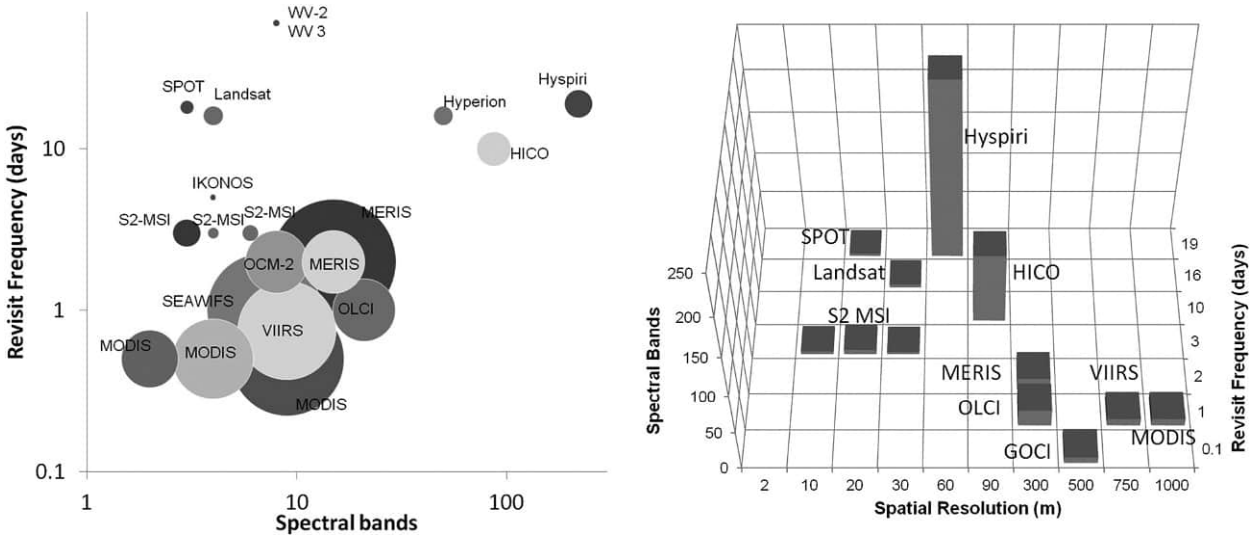

Fig. 2 Trade-off between spatial, spectral and temporal resolution of different satellite missions. Acronyms are provided for different satellite platforms, including: Envisat MEdium Resolution Imaging Spectrometer (MERIS); Hyperspectral Imager for the Coastal Ocean (HICO); and Hyperspectral Infrared Imager or HysplRI; Moderate Resolution Imaging Spectroradiometer (MODIS); Satellite pour l'Observation de la Terre (SPOT); Sentinel 2 Multi Spectral Imager (S2 MSI); Sentinel 3 Ocean and Land Colour Instrument (OLCI); and Visible Infrared Imaging Radiometer Suite (VIIRS). Source: Hestir E, Brando V, Bresciani M, Giardino C, Matta E, Villa P and Dekker A (2015) Measuring freshwater aquatic ecosystems: The need for a hyperspectral global mapping satellite mission. *Remote Sensing of Environment* 167: 181–195.

objects (spatial resolution), (ii) range, number and width of spectral bands (spectral resolution), (iii) number of digital levels used to express collected data (radiometric resolution) and (iv) the interval between image acquisitions (temporal resolution or revisit frequency) (Tatem et al., 2008). There is a trade-off between the different resolutions (e.g., the higher the satellite, the larger the area which can be covered at once, yielding a higher temporal resolution but at a reduced spatial resolution). Fig. 2 shows the trade-off between spatial, spectral and temporal resolution of various satellite missions. Here we provide an overview of the different remote sensing platforms that can facilitate Earth observation science of water quality monitoring.

Spaceborne

Satellite imagery has been used for decades to monitor inland and coastal waters. Initially, mainly ocean color sensors were considered, like SeaWiFs (launched in 1997), MODIS Terra and Aqua (launched in 1999 and 2002 respectively), MERIS (launched in 2002) and Sentinel-3 (launched in 2016). These sensors have spectral bands dedicated for water observations and have frequent revisit times (1–3 days). But their medium spatial resolution (100–300 m) hampers their use for observing smaller inland waters, like streams and narrow rivers or small lakes (Topp et al., 2020). As a consequence, land satellite missions became investigated for water applications. Although not designed for water (e.g., sensors are mounted pointing directly downwards (nadir), causing increased risk of sun glint contamination (Harmel et al., 2018)), the increased spatial resolution (10–60 m) has been shown to be an asset. Two successful examples are Landsat-8 (launched in 2013) and Sentinel-2 (launched in 2015) (e.g., Wang et al., 2019; Toming et al., 2016; Vanhellemont and Ruddick, 2015). But the temporal resolution (5–16 days for Sentinel-2 and Landsat-8 respectively) can be a shortcoming, increasing the vulnerability to cloud cover, reducing the observation frequency still further. Hyperspectral satellite missions provide hundreds of bands across the visible and near infrared parts of the spectrum allowing spectral shape to be observed and allowing new insights into water color remote sensing. Examples are the PRISMA (launched in 2019), EnMAP (expected launch 2022) and others.

The latest upcoming technology are CubeSats—small nanosatellites with standardized dimensions. CubeSats are made up of multiple cubic modules of 10 cm each side, weigh no more than 1.33 kg, and often use commercial off-the-shelf components for their electronics and structures. An example are the PlanetScope Doves (launched in 2013) by Planet (Planet Ltd, 2019). As they fly in a constellation, PlanetScope Doves can reach meter-scale resolution products at a daily revisit time. The spectral bands are suitable to derive water turbidity (Vanhellemont, 2019). Another example is the HYPer-Spectral smallsat for Ocean observation (HYSPO-1 and HYSPO-2) (both expected to be launched 2023), which will observe oceanographic phenomena through a small satellite with hyperspectral camera and intelligent on-board processing.

Airborne

Airborne remote sensing campaigns provide the excellent trade-off between spatial resolution (<10 m) and data coverage. This is in contrast to ground observations that are difficult to be used for regional scale monitoring and satellite data that have a relatively lower spatial resolution. With airborne remote sensing, data can be collected when the weather conditions and sun orientation are optimal. The platform is also ideally suited for testing new sensors and algorithm development. A lot of hyperspectral measurements occur from airborne platforms. With hyperspectral sensors it is possible to capture specific absorption features and backscatter peaks within a waterbody's spectral signature which provides new levels of precision to measure optically active constituents (Gholizadeh et al., 2016; Govender et al., 2007). Hyperspectral sensors consist of hundreds of narrow (1–10 nm) contiguous bands spanning visible to shortwave infrared spectral range. Since the 1980s, airborne imaging spectrometers such as APEX (Schaepman et al., 2015), CASI (Babey and Anger, 1989), AVIRIS (Vane et al., 1993) and others have been shown to provide accurate and quantitative information for inland and coastal water monitoring. The technology is ever evolving and new state-of-the art sensors are being generated. Two examples are the AVIRIS-NG (Chapman et al., 2019) which already conducted flights over Europe during the summer of 2021, and the upcoming Compact Wide-Field-of-View Imaging Spectrometer II (CWIS-II).

Drone

Drones are a relatively new and upcoming technology in the context of inland and coastal water monitoring. They have the advantage of being highly flexible in terms of use, can collect data over hard-to-reach areas and have a high spatial resolution. Fixed wings, copter-style airborne platforms and Vertical Take-Off and Landing (VTOL) are different aircraft designs. The copter-style systems have the advantage that they can hover over a certain spot, capturing dynamics at small scale, (e.g., Inflow of sediment plume in a harbor caused by tidal effects). Fixed wing drones have a longer endurance and can cover larger areas. While initially the focus for drone applications was to collect true-color images for visual observations, attention gradually shifted towards quantitative information such as turbidity, chla concentrations, macrophytes and more (e.g., Flynn and Chapra, 2014; Su and Chou, 2015; Larson et al., 2018; De Keukelaere et al., 2019). Technological innovations facilitating this shift include: a variety of conventional cameras and narrow-band imaging sensors (e.g., MicaSense Dual camera, with 10 spectral bands in visible and near infrared), irradiance sensors which are needed to measure changing light conditions. Real-Time Kinematic (RTK Global Positioning System (GPS) in combination with Inertial Measurement Unit (IMU; measures the roll, pitch and yaw of the platform) improve the projection of the images onto georeferenced maps.

In situ above-water measurements

The acquisition of high-quality in situ radiometric measurements is a primary concern for the calibration and validation of airborne and spaceborne remote sensing observations. The two main forms of radiometric data that are regularly measured synchronously with satellite overpasses include shipboard radiometric measurements to enable the computation of remote sensing reflectance and sun photometer measurements from aquatic and/or terrestrial stations for the derivation of properties such as Atmospheric Optical Thickness (AOT). These measurements can be obtained from small or large research vessels, ships-of-opportunity or from fixed platforms (e.g., jetties and buoys).

The in situ measurement of remote sensing reflectance can be achieved using a wide variety of instrumentation, methodologies and protocols. These include the manual use of single handheld radiometers used to consecutively measure the three constituent fluxes that enable the computation of remote sensing reflectance: (i) downwelling irradiance (usually via a reflective panel); (ii) sky radiance; and (iii) water-leaving radiance. However, this approach is rather onerous and can be subject to high uncertainties particularly under variable illumination conditions. Hence it has become common practice to employ a trio of radiometers making near-synchronous measurements of the three radiometric fluxes; in this case the downwelling irradiance measurement can be obtained by an upward looking radiometer fitted with a cosine diffuser. Regardless of the sensor(s) used for above-water radiometry, it is critical that measurements are made in the correct sun-sensor geometry to minimize the unwanted effects of phenomena such as sunlight on the quality of remote sensing reflectance (see Fig. 3). Further details on recommended instrumentation, sensor calibration, measurement protocols and data processing routines can be found in Zibordi et al. (2019).

In recent years, there has been a move towards more automated solar-tracking radiometry systems for the measurement of remote sensing reflectance that can collect data continuously during research cruises or while mounted on fixed platforms (e.g., jetties, lighthouse, buoys). The automated systems are designed to maintain an appropriate sun-sensor geometry by constantly adjusting the position of the sensors to optimize the solar azimuth angle. The use of automated radiometer systems is particularly advantageous during research cruises because it enables data to be collected continuously while the research vessel is underway and not only while it maintains a fixed station. In contrast, systems on fixed platforms enable high-frequency data to be collected at a single, well characterized station. Dedicated data processing routines have also been developed for quality control measurements made by automated systems. These automated approaches greatly increase the number of 'match-ups' between satellite overpasses and synchronous in situ measurements available for calibration and validation studies.

Measurements of properties such as AOT are important for the parameterization of atmospheric correction models for the processing of satellite data. These measurements are commonly obtained using sun photometers and, ideally, measurements should be made in parallel to radiometric measurements for computation of remote sensing reflectance. Sun photometers can be small, mobile, manually operated devices or autonomous (including robotic) systems often mounted on large research vessels or fixed

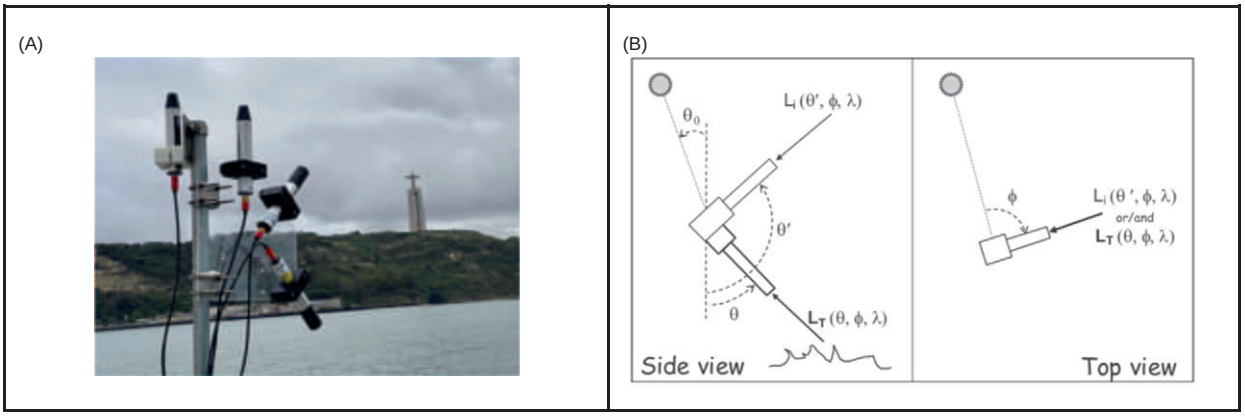

Fig. 3 (A) Three radiometers used for radiometric measurements to compute remote sensing reflectance (the fourth is a redundant downwelling irradiance sensor). (B) The recommended measurement geometry for above-water radiometry using a trio of radiometers has a sensor viewing angle (θ) of 40 degrees and a relative azimuth (φ) of 90 degrees (the third sensor measuring downwelling irradiance is not shown). From Zibordi G, Voss KJ, Johnson BC and Mueller JL (2019) *IOCCG Ocean Optics and Biogeochemistry Protocols for Satellite Ocean Colour Sensor Validatio 3: Protocols for Satellite Ocean Color Data Validation: In situ Optical Radiometry.* Dartmouth, NS: IOCCG.

platforms. The autonomous and/or robotic systems provide high frequency data, which increases the likelihood of match-ups with satellite overpasses while largely removing the need for manual operation. The NASA-led Aeronet network (https://aeronet.gsfc.nasa.gov/) is a global federation of robotic sun photometers for the measurement of atmospheric properties and imposes strict standardization of instruments, calibration, data processing and distribution to ensure high quality data are available for satellite validation studies.

In situ subsurface measurements

Subsurface measurements of both inherent (IOPs) and apparent optical properties (AOPs) are also widely utilized to aid the development, calibration and validation of remote sensing observations. Measurements of AOPs (i.e., subsurface remote sensing reflectance) are typically obtained using a set of profiling radiometers with two in-water sensors simultaneously measuring the downwelling and the upwelling radiance, while a single above-water radiometer measures the downwelling solar irradiance at the water surface to allow for changes in the illumination conditions to be corrected. These systems can be deployed manually from ships or autonomously from a profiling buoy. Further details on instrumentation, sensor calibration, measurement protocols and data processing routines can be found in Zibordi et al. (2019). One advantage of measuring subsurface radiometric fluxes is that it removes the need to measure and correct for reflected skylight, but the fluxes need to be numerically propagated through the air-water interface to enable comparison with satellite radiometry and this can also introduce significant uncertainties.

Subsurface measurements of the inherent optical properties (IOPs) are also used for the calibration and validation of remote sensing observations where algorithms directly retrieve such properties from the physical inversion of remote sensing reflectance. They are also essential to the quantitative understanding of underwater radiative transfer processes and the interpretation of above-water radiometric measurements whether measured by in situ, airborne or spaceborne sensors. The IOPs measured by in situ instrumentation include the spectral absorption (a) coefficients of dissolved and particulate matter and the (back) scattering (b or b_b) by suspended particulate matter (including both phytoplankton and non-algal particles) (example Optics Cage Fig. 4).

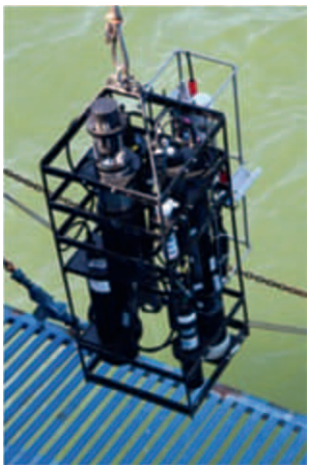

Fig. 4 Optics Cage housing instrumentation to characterize the IOPs of optically complex waters.

Spectral absorption and scattering can be measured using beam transmissometers (otherwise known as absorption and attenuation meters or simply 'ac' meters) or by point-source integrating cavity absorption meters (PSICAMs). Backscattering measurements are measured using dedicated meters, although commonly only at a limited number of wavelengths—although hyperspectral backscattering sensors have recently become commercially available; the so-called volume scattering function (VSF) can also be obtained by measuring scattering at multiple angles using specialized instrumentation. Further information on instrumentation for IOP measurements can be found in the protocols published by NASA (2002) and IOCCG (2019).

If the IOPs of all OACs are known, remote sensing reflectances can be computed through forward modelling of appropriate radiative transfer equations that provide an analytical route to interpret reflectance measurements. Moreover, mass-specific representations of the IOPs can be used to simulate the expected remote sensing reflectances for different optical water types and constituent concentration ranges, enabling large synthetic datasets of remote sensing reflectances to be established to support the development and parameterization of remote sensing algorithms. Sophisticated radiative transfer models such as Hydrolight can be used in this manner (Pyo et al., 2021), although the optical complexity of inland waters, and the large uncertainties associated with IOP measurements in turbid waters, can militate against this approach and various studies have reported difficulties achieving optical closure (quantitative agreement between modelled and measured spectra).

Water quality products from EO

The science of Earth observation of water quality now enables measures of the optical characteristics (reflectance) and water quality, e.g., turbidity, Total Suspended Matter (TSM), chla and CDOM to be accurately derived from remote sensing platforms. Here we provide an overview of examples of such products.

Aquatic reflectance

The removal of the atmospheric effects on the reflectance values is essential for water-color applications of remote sensing in inland waters, particularly for the estimation of biogeochemical parameters. Accurate atmospheric correction in inland waters is still considered challenging, as water has a low reflectance and the contribution of the atmosphere on the signal received by the satellite sensor represents 80% or more of the total at-sensor radiance. In contrast to typical open ocean atmospheric correction algorithms, for inland water, additional consideration is necessary, incl. (i) altitude of the inland water body, (ii) non-negligible reflectance in the near infrared region if the water contains high sediment concentrations, (iii) non-water spectra in the case of floating vegetation and (iv) adjacency effects originating from neighboring land pixels and affecting the spectral signal from water (Fig. 5). But several methods have been developed and now widely tested (Warren et al., 2019; Pahlevan et al., 2021) over a range of Optical Water Types found in inland waters. A number of water-targeting and land-surface AC processors (e.g., iCOR, POLYMER, ACOLITE, C2X) have been developed and used over inland waters. Selection of the AC processor used in different studies and applications is typically based on remote sensor, regionalities, its maturity and the derived products of interest.

Chlorophyll-*a* algorithms

Chlorophyll-*a* (chl*a*) is arguably the most commonly retrieved parameter in aquatic remote sensing studies, partly because it is such a well-established and widely used indicator of trophic state but also because it can be readily estimated using a range of multispectral ocean color satellites and some other high-resolution satellite sensors originally developed primarily for terrestrial applications. However, the retrieval of chl*a* concentrations over inland waters is generally far more challenging than over the open ocean and, as a consequence, the methods used are not only by necessity more numerous but also, in some cases, more sophisticated.

In ocean color remote sensing, most algorithms for the retrieval of chl*a*, whether based on simple empirical approaches or more complex analytical inversion methods, utilize ratios or other combinations of reflectance in the blue and green parts of the spectrum (so-called blue-green ratios). These methods are used to retrieve estimates of chl*a* in waters where phytoplankton are the only optically active constituents exerting a marked influence on remote sensing reflectance. This is the situation encountered in most 'Case I' OWTs that include open ocean waters, but algorithms that employ green-blue ratios have also been applied to inland waters, particularly in lakes with low to moderate chl*a* concentrations and low and invariant NAP and CDOM.

In the more turbid and complex OWTs (i.e., those that would be classically identified as 'Case II' waters), algorithms based in blue-green ratios generally do not perform well because the chl*a* absorption features that lie within the blue part of the spectrum are readily masked by the presence of high and non-covarying concentrations of CDOM and NAP. In these waters, it is more common to employ algorithms based on ratios or other combinations of reflectance in the red and near infrared parts of the spectrum. This avoids the confounding influence of other OACs in the blue spectrum while utilizing the measurable signal at red and NIR wavelengths that is encountered in more turbid waters.

The ability to exploit red-NIR wavelengths for chl*a* retrieval in inland waters is not sufficient to enable universal application of these methods. The high optical complexity encountered in inland waters, from CDOM-rich dystrophic lakes, through sediment-

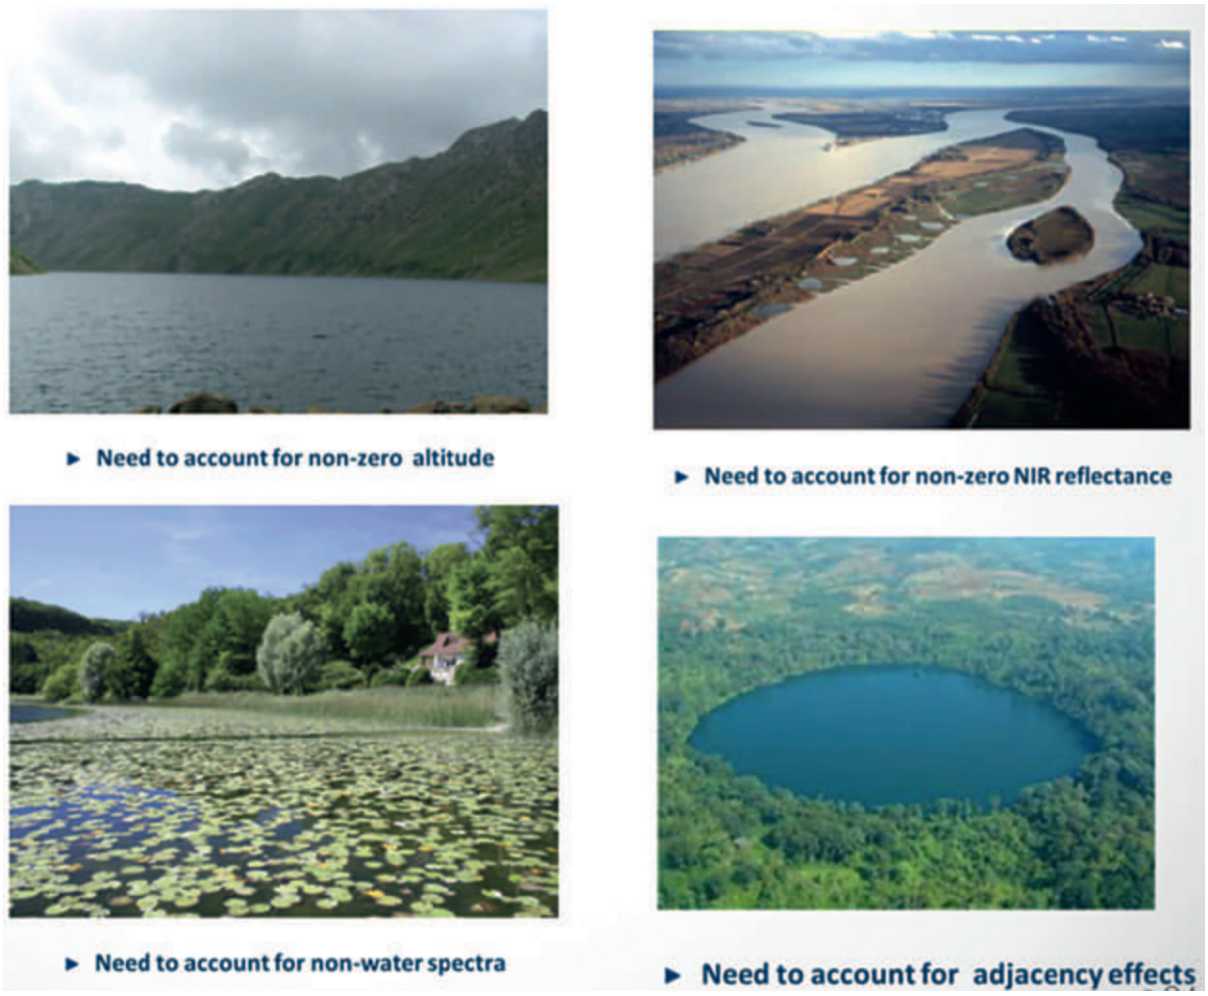

Fig. 5 Inland water bodies are complex and require atmospheric correction approaches which can handle different altitudes, non-negligible reflectance in NIR spectral region, presence of non-water spectra and adjacency effects caused by surrounding land pixels.

laden Alpine lakes, to algal-dominated eutrophic lakes, means that estimates of lake chl*a* concentrations often have far higher uncertainties than seen for ocean waters. It is also notable that no single chl*a* retrieval algorithm has universal application across a wide range of OWTs.

In an effort to improve the performance of chl*a* retrieval algorithms for inland waters, a variety of different methodologies have been employed. Simple empirical algorithms can be tuned using statistical approaches to reduce retrieval uncertainties for individual or small populations of optically similar waterbodies (e.g., Gilerson et al., 2010; Gurlin et al., 2011). In more challenging cases, more sophisticated analytical inversion (e.g., Hoogenboom et al., 1998) or machine learning approaches (Smith et al., 2021; Werther et al., 2021) have been applied and shown to outperform simpler methods. The use of ensemble approaches has also gained traction in recent years whereby the most appropriate algorithm (or algorithms) from a suite of models is dynamically selected based on the optical characteristics of the waterbody. This approach generally involves the pre-classification of the observed remote sensing reflectance to identify the dominant OWTs. This informs the selection and application of algorithms. Fuzzy classification approaches can also be used, with the resulting OWT membership function used to weight the retrieved chl*a* concentration. An example of this approach is described in Neil et al. (2019) and is used by operational services such as the UK Lakes Observatory (https://www.eo4ukwater.stir.ac.uk/) (see Fig. 6) and the Copernicus Global Land Service (https://land.copernicus.eu/global/products/lwq).

Phycocyanin algorithms

The development of algorithms for the retrieval of phycocyanin (PC) concentrations, and to a lesser extent phycoerythrin (PE) concentrations, as a marker for the presence and/or abundance of cyanobacteria has been a highly active area of research for over two decades. Numerous studies have demonstrated the diagnostic absorption and fluorescence characteristics associated with PC can be resolved in remote sensing reflectance signals (e.g., Gons, 1999; Wynne et al., 2008; Matthews and Odermatt, 2015) and used

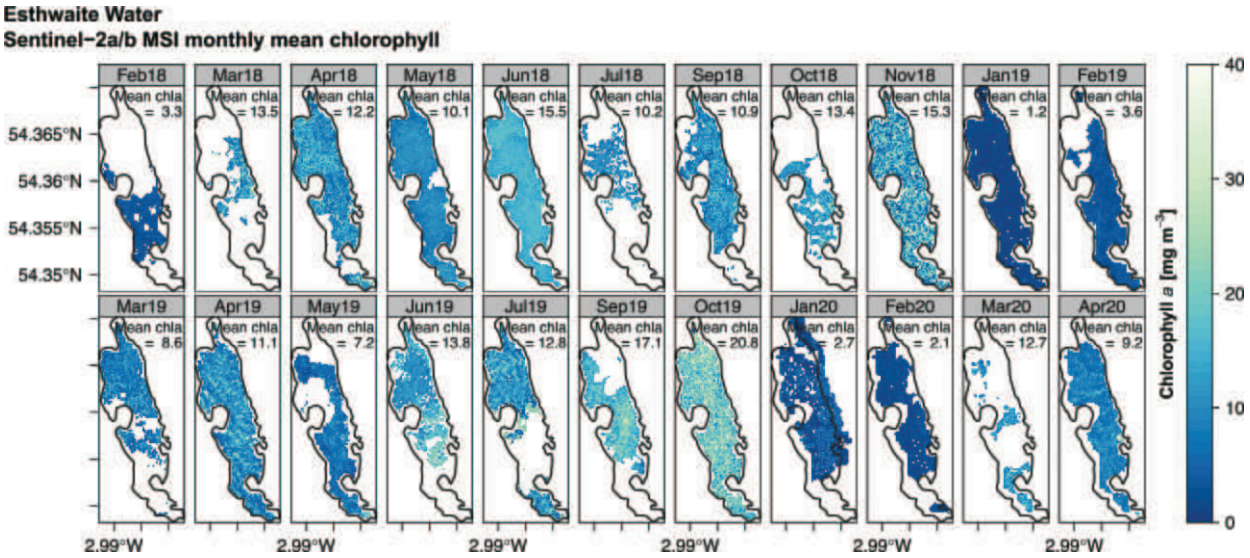

Fig. 6 Monthly aggregated chlorophyll-*a* concentrations in Esthwaite Water (2018–2020) from Sentinel-2a/b data retrieved using a processing chain based on the dynamic selection of algorithms from an ensemble following OWT classification. Data obtained and replotted from the UK Lakes Observatory (https://www.eo4ukwater.stir.ac.uk/).

to diagnose blooms dominated by cyanobacteria. Moreover, the magnitude of these features in remote sensing reflectance spectra can be quantitatively related to the concentration of PC in near-surface waters using empirical- and quasi-analytical algorithms (Simis et al., 2005; Hunter et al., 2009; Mishra et al., 2009; Li et al., 2015). The resolution of the diagnostic features associated with PC requires sensors to have a band centered at approximately 620 or 650 nm to capture the pigment absorption and fluorescence maxima (e.g., as per Sentinel-3a/b OLCI).

In recent years, significant improvements in the algorithms have been made (e.g., Qi et al., 2014; Matthews and Odermatt, 2015; Liu et al., 2018) and their performance has been rigorously evaluated in a number of studies (e.g., Ogashawara et al., 2013; Beck et al., 2017; Yan et al., 2018; Riddick et al., 2019) providing increased confidence in the data products generated. However, the uncertainties associated with the retrieval of PC are higher than those associated with the retrieval of chl*a*. This is due to the confounding influence of absorption by other phytoplankton pigments (e.g., chlorophyll *a* and chlorophyll *b*), the comparatively higher contribution of absorption by colored dissolved organic matter (CDOM) at the PC absorption maximum, and because the determination of phycocyanin in the laboratory and its relationship with cyanobacterial biovolume carries greater uncertainty.

Total suspended matter

Since Total Suspended Matter (TSM), chl*a* and CDOM constituents affect the color of the water, it is possible to detect their presence in water using remote sensing and to quantify their respective concentrations. Therefore, relatively simple global algorithms developed for open oceans are not applicable to these waters. TSM algorithms developed for inland and coastal waters range from purely site-specific empirical relationships between measured remote sensing reflectance and TSM to complex analytical methods.

The empirical approach is based on a statistical calibration and utilizes the relationship between spectral data and TSM measured (e.g., in situ TSM measurements). A large variety of empirical based TSM retrieval algorithms have been published. These empirical relationships have been set-up based on in situ reflectance data (e.g., Forget and Ouillon, 1998; Doxaran et al., 2002), satellite-derived reflectance (e.g., Miller and McKee, 2004), or atmospherically uncorrected at-sensor radiances (Onderka and Pekarova, 2008). Empirical relationships are established through linear (Forget and Ouillon, 1998; Binding et al., 2005), logarithmic (Siswanto et al., 2011), and exponential (Doxaran et al., 2003) regression analysis on the data. Both single band (Forget and Ouillon, 1998; Miller and McKee, 2004) and multi-band based empirical algorithms (Doxaran et al., 2002; Siswanto et al., 2011) have been developed.

Analytical approaches use sophisticated radiative transfer models to characterize the reflectance as a function of inherent optical properties (IOP) like absorption (a) and the backscattering (b or b_b) coefficients. A well-known bio-optical model is the one developed by Gordon et al. (1988).

To overcome the limitations of both the simple empirical approaches and the complex analytical methods, semi-analytical approaches are gaining more and more attention (Chen et al., 2013; Doxaran et al., 2012; Nechad et al., 2010). Semi-analytical methods have a strong theoretical basis. For instance, they consider the relationship between the absorption or scattering properties and TSM concentration, which they combine with statistical methods.

Turbidity

The turbidity of a water sample is an optical measure of the extent to which the intensity of light passing through water is reduced by the particles in the water. Turbidity is therefore strongly related to TSM. Turbidity can be expressed in various units, such as Formazin Turbidity Unit or FTU, Nephelometric Turbidity Unit or NTU. Turbidity is listed by the European Union as one of the prime water quality parameters to be measured regularly. Due to the fact that turbidity is an optical property, it is more related to reflectance through the backscattering than TSM. Measures of turbidity provide an indication of the potential health of the aquatic ecosystem and the potential impact on the quality of water, including the possible presence of other harmful constituents such as contaminants and pathogens.

In situ measurements of TSM are costly and are time-consuming as they require dedicated field campaigns in order to take water samples and these water samples need to be filtered, weighted and dried in an oven. Turbidity can be measured automatically using in situ turbidity meters which are often part of autonomous buoys like the Centre for Environment, Fisheries and Aquaculture (CEFAS) SmartBuoys. Turbidity meters can also be used on site, which allow a direct measurement of the turbidity of the water sample without much effort and specialized equipment. However, care has to be taken when combining turbidity data from different instruments or sensors as they might read light scatter from suspended particles differently, outputting different measurements for the same water sample etc. Some sensors are more accurate at low turbidity levels, while others offer the ability to measure a wide turbidity range.

Whereas there are many remote sensing publications on TSM, there are only a few focusing on turbidity (e.g., Warren et al., 2021). While the existing TSM algorithms are site-specific, algorithms proposed in the literature for turbidity retrieval are more globally applicable (e.g., Ouillon et al., 2008; Nechad et al., 2009; Vanhellemont et al., 2013; Dogliotti et al., 2015).

Color dissolved organic matter (CDOM)

CDOM is arguably the most challenging water quality parameter to retrieve from remote sensing reflectance, particularly from spaceborne sensors, yet it provides a valuable measure of dissolved organic matter content in water. CDOM has a near negligible contribution to light scattering in water bodies, but it strongly absorbs light at UV and blue wavelengths (a process that declines exponentially with wavelength towards the NIR spectrum). Hence waterbodies with high CDOM (but low phytoplankton and mineral particles) generally have uniformly low reflectance and thus changes to CDOM concentrations may exert little influence on remote sensing reflectance.

Moreover, algorithms for CDOM retrieval target blue wavelengths where the absorption maximum occurs (at least within the spectral sampling range of most remote sensing instruments). However, this part of the spectrum is also where the performance of atmospheric correction models is generally weakest resulting in significantly higher errors and uncertainties on remote sensing reflectance products.

In spite of these challenges, several studies have demonstrated it is possible to retrieve estimates of CDOM absorption from satellite radiometry. Much like the algorithms used for other OACs, approaches vary greatly, but several studies have developed empirical algorithms employing a combination of blue, green and (occasionally) red wavelengths. For example, Kutser et al. (2005) successfully mapped CDOM absorption coefficients across 34 Scandinavian lakes using multispectral satellite imagery and an empirical algorithm employing green and red bands.

Example applications of earth observation in inland waters

Algal blooms

One of the oldest applications using satellite imagery for monitoring algal blooms is the "Harmful Algal Blooms Monitoring Products" (https://coastalscience.noaa.gov/research/stressor-impacts-mitigation/hab-monitoring-system/) by the United States National Oceanic and Atmospheric Administration (NOAA). These products were used for quantifying algal blooms in coastal and lake regions of the United States and they were based on an integrated approach combining satellite remote sensing data with circulation and empirical models (Wynne et al., 2010, 2011, 2013). The ocean color sensors used in this application was the Medium Resolution Imaging Spectrometer (MERIS) for images acquired between 2002 and 2011, the Moderate Resolution Imaging Spectroradiometer (MODIS) for images from 2011 to 2016 and now the Ocean and Land Color Instrument (OLCI) from 2016 and continuing through future years (Stumpf et al., 2016). For a global application of satellite data to monitor algal blooms, there is the CyanoAlert (www.cyanoalert.com) which is a commercial service that automatically processes water quality information. This service provides satellite-derived measures of cyanobacterial occurrence and concentration, eutrophication, and additional water quality measures.

Brownification

Dissolved organic carbon (DOC) concentrations are increasing in many inland waters in the northern hemisphere (Roulet and Moore, 2006; Meyer-Jacob et al., 2019) and this is resulting in the browning of these aquatic systems. The brownification process has profound physical, chemical and biological repercussions affecting water quality, biological community structures and aquatic

productivity. Because of this issue, remote sensing has been used to monitor CDOM—the colored part of the DOC—which can be used as an estimator of DOC (Tranvik, 1990). Thus, satellite derived CDOM information can be used to assess DOC spatial and temporal distribution (Vantrepotte et al., 2015). An application using these principles is the LakeBrowser (https://lakes.rs.umn.edu/), which provides data for over 10,000 Minnesota lakes since 2002. The current version of this application is based on the automated imagery processing of Landsat 8 OLI and Sentinel 2 MSI sensors (Olmanson et al., 2020) and provides daily (when clear imagery is available) and monthly (May–October) median CDOM values.

Primary production

Remote sensing of primary production (PP) in inland waters has mainly been based on methodologies developed for oceanic and coastal waters (e.g., Behrenfeld et al., 2005; Westberry et al., 2008; Barnes et al., 2014). These range from simple empirical approaches that approximate PP as a function of the Chla to more complex models that estimate PP using knowledge of the underwater light field. The majority of remote sensing methods for PP in lakes require knowledge of Chl*a* but more recently, phytoplankton absorption or phytoplankton carbon have been employed to improve accuracy. Other inputs to the PP models such as downwelling, irradiance, diffuse attenuation coefficient and lake surface temperature can be taken from remote sensors. RS applications of PP have been primarily focused on larger (Deng et al., 2017) and optically deep lakes. Recent developments in field techniques for PP estimation and a revolution in EO capabilities have now started to empower RS applications of PP in smaller lakes and incorporate benthic gross primary production (GPP) to the models (Kuhn et al., 2020).

National and Global scale assessment

Successful implementation of EO approaches can now be achieved at the global and local scales. Examples of implementation can now be found that are operationalized, providing real opportunity for driving change in lake management at the local and global scales. Validation is critical to build confidence such that stakeholders will adopt these new approaches, although legislative changes are likely to be required to facilitate the incorporation of EO data into monitoring frameworks. Nevertheless, examples of operationalization exist around the world, where global processing is available through the Copernicus Land Service (Home | Copernicus Global Land Service), developed from the UK Natural Environment Research Council funded project GloboLakes (Fig. 7) and exploits Sentinel 3 OLCI and Envisat MERIS data.

Fig. 8 demonstrates an example of the UK Lakes observatory (UKLO). The service currently uses data from the European Space Agency's Copernicus Sentinel-2A/B satellites to produce weekly aggregated estimates of the phytoplankton chl*a* concentration at a 20 m pixel resolution (UK Lakes Observatory | eo4ukwater (stir.ac.uk). The processing chains used to support both the UKLO and the Copernicus Land Service use state-of-the-art approaches for the atmospheric correction of the satellite data and combines this with an ensemble of algorithms for the estimation of chl*a* which are implemented dynamically depending on the optical characteristics of the lake under observation. This approach has been shown to significantly improve the accuracy of chl*a* estimation over a large and diverse population of lakes.

Conclusions and perspectives

Significant progress has been made in the development of EO science in both the remote sensing platforms technology and more intelligent automated computation approaches to processing the remote sensing data. This has facilitated a step change in capability, transforming previous applications limited to individual water bodies to the reliable observation of many hundreds to thousands of water bodies globally. This now facilitates new ways of understanding how our inland water bodies are changing in response to pressures from climate change or from more direct human induced pressures occurring in their catchments. Such global assessments provide key insights into global biogeochemical cycles and are core to our water, food and energy security. This new capability is now also being recognized by water managers and the implementation of operational EO technology is being explored for routine monitoring purposes. At the international level, the opportunity now exists to provide water quality information for data poor regions of the world.

Despite these successes, development work is still required. The tendency of science and policy to focus research on more problematic inland water bodies that exhibit, for example, eutrophic characteristics has resulted in lakes of good ecological status to be under-sampled. As a result, more work is required to develop the EO capability for waters with low chl*a* concentrations, so that change can be detected early to support more effective lake management strategies and interventions. Greater coverage of in situ instrumentation for satellite calibration and validation is needed. The development of low costs instrumentation and citizen science approaches all play a role in supporting the interpretation of satellite data and filling data gaps where EO data has been unable to collect data due to weather conditions or the size of water body.

EO science is now sufficiently mature for the data to be used not only to reconstruct past events and changes in water quality statues as well as the current state of the environment, but critically provide the data to drive and update models for forecasting over the near term, in the same way that we can forecast the weather. This will be fundamental tool for water utilities to manage water and ensure secure water supply under increasing pressures from climate change and extreme events.

Glossary

Black box A model whose inner workings are not known to the user, whether because they are hidden or because they are too complex to readily grasp.
Design The use of human intelligence and knowledge to shape the structure, inputs, or algorithms of a model.
Discovery The use of algorithms to find values of model parameters, states, and/or equations that can suitably describe or reproduce observations.
Distillation Reducing large volumes of information to smaller ones.
Features The variables used as inputs to a model; also sometimes called predictors, dependent variables, or drivers.
Inference Discovering the model values - including parameters, equations, or internal states - that best fit the observations, with an interest in what the discovered values say about the real-world system and processes being modeled.
Knowledge-guided Rooted in machine learning while also formally incorporating knowledge of real-world patterns or processes; also sometimes called process-guided, physics-guided, theory-guided, or process/physics/theory/knowledge-informed.
Loss function A function quantifying the success of a set of model predictions, usually by comparison to observations; also sometimes called objective function or cost function. The *loss* is the output of a loss function for a given set of training examples.
Machine learning The use of algorithms that learn about the world based on feedback rather than relying on a human-defined set of facts or equations; abbreviated ML.

Prediction Estimating values of a dependent variable as a function of some inputs and a model; predictions may describe the past, present, or future at sampled or unsampled locations.
Process-based Primarily containing equations and parameters that are human-interpretable representations of physical, chemical, or biological processes.
Supervised Algorithms trained or calibrated to make predictions that closely match known outputs; contrast with unsupervised algorithms, which are trained to discover patterns in the data based on similarities among inputs.
Training The process by which machine learning models are iteratively modified until their performance minimizes the output of a loss function; roughly equivalent to model fitting or calibration for statistical or process-based models, respectively.

Introduction

Design and discovery

Limnology began with laborious field campaigns, from which observations were then used to develop empirical models to describe and explain patterns in aquatic ecosystems (e.g., Lindeman, 1942; Dillon and Rigler, 1974; Vollenweider, 1975). The advent of powerful new in situ and ex situ sensing techniques has given modern-day limnologists a much greater volume and variety of aquatic observations for testing theories and developing new models. At the same time, increases in computing power have opened the door to machine learning (ML) approaches that take advantage of this new wealth of data. A growing number of limnological studies now benefit from the strengths of ML models, which can include accurate predictions, short runtimes, and flexible equation structures that can capture non-linear relationships precisely (e.g., Hsu et al., 1995; Maier and Dandy, 1996; Fienen et al., 2013; Pacheco et al., 2017; Nolan et al., 2018; Kratzert et al., 2019c; Read et al., 2019).

ML models and their alternatives - process-based, empirical, and statistical models - take a great variety of forms and can be distinguished by the degree to which they contain two elements: *design* is the extent to which humans have manually specified the structure or parameters of the model to reflect current understanding, and *discovery* is the extent to which algorithms ingest observations to learn useful values of the model parameters, equations, and states (Fig. 1). For inland waters, design is guided by scientific knowledge of physical, chemical, biological, and ecological processes and patterns in aquatic systems; discovery is guided by data from in situ sensors, field samples and observations, remotely sensed images, etc. The strength of design is that it formalizes and enables tests of scientific theories, whereas discovery makes fuller use of the data and thus often yields the best predictions and may suggest new connections among variables. Both design and discovery can contribute substantially to our understanding of the natural world, especially when they are used in combination.

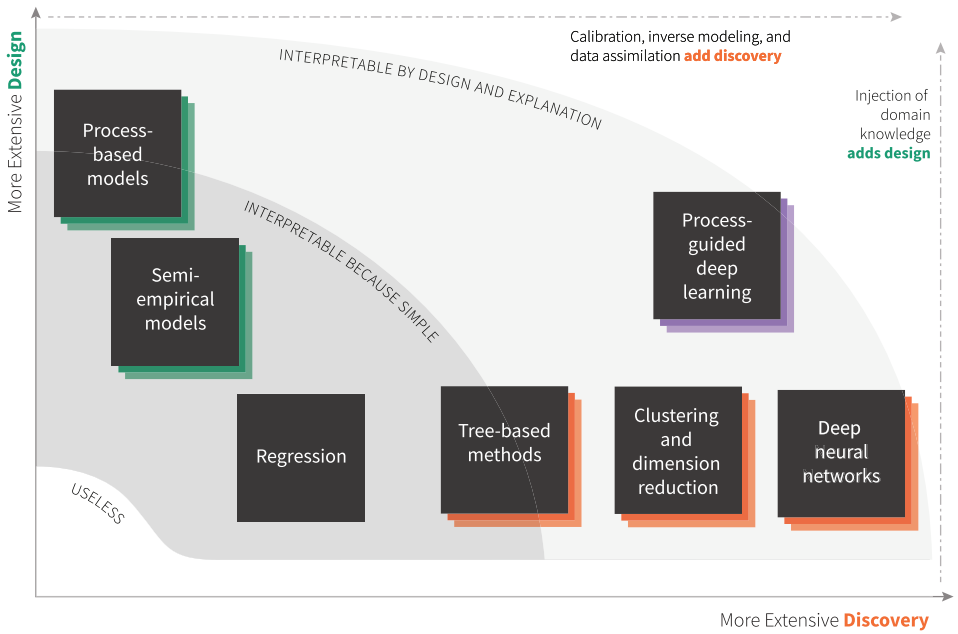

Fig. 1 Model types positioned by their use of design and discovery. Machine learning models may be purely discovery-based (orange) or can include design (purple), and they are distinguished from other model types by their capability for substantial data-driven discovery of model parameters, equations, and/or states. As discussed in Section "Interpretation techniques," the methods of interpretation by design and/or ML explanation have expanded rapidly in recent years such that it is now possible to derive some interpretive insights from nearly any model, and more for those discovery-based models that include some design.

ML models are distinguished from process-based and empirical models by their substantial use of discovery, which enables these models to benefit from large datasets. While substantial design is the distinguishing feature of process-based models, all models - from the simplest regressions to the most black-box-like ML models - contain some design in the form of expert-selected input variables and model structures that reflect expected relationships (Robson, 2014). ML models can be infused with additional limnological design elements in the numerous ways we will investigate throughout this chapter. Conversely, process-based and empirical models can be infused with discovery; this can be done by calibration, inverse modeling, or data assimilation, all topics that we leave to other texts.

Compared to non-ML models, ML models can offer greater prediction accuracy, faster training and execution times, and the flexibility to capture nonlinear relationships for which we lack good theory or direct observations (Solomatine et al., 2008; Shen, 2018; Reichstein et al., 2019; Sun and Scanlon, 2019). Despite these many benefits, ML models have seen only moderate adoption in inland water sciences, perhaps because newcomers to ML often worry that ML is severely lacking in two areas: trustworthiness and contribution to scientific understanding. We argue that both of these areas deserve rigorous attention when applying ML and yet are poor reasons to shy away from ML, because (1) trust and understanding can be earned by ML models, sometimes in ways that outshine non-ML alternatives; (2) trust and understanding are also challenges for non-ML models; and (3) the drawbacks of ML models are often outweighed by their benefits. We expand on these themes below and throughout the chapter.

Model trustworthiness

Models merit our trust when the outputs are accurate for all intended uses, often including application to new water bodies, time periods, aquatic communities, environmental conditions, or situations where data are sparse. Because we rarely have the right data to test a model for all intended uses, we often lean on a heuristic of process design: We tend to trust models whose equations and coefficients express processes as described in textbooks and the literature. However, this design heuristic is neither necessary nor sufficient. It is unnecessary because, as ML models have repeatedly demonstrated, transferable accuracy is achievable with black-box solutions and sufficient training data (DeWeber and Wagner, 2014; Kratzert et al., 2019b). It is insufficient because models are always imperfect: In addition to the omnipresent lack of perfect input data about ecosystem properties and drivers, even our most "process-based" models are always semi-empirical simplifications of the true processes occurring at ecosystem scales (Simon, 1962). In fact, it can be argued that given enough data, ML models containing more parameters than a process-based model are capable of representing limnological processes more completely.

Instead of relying on a heuristic of textbook-like equations, the growth of ML pushes us to judge trustworthiness based on (1) consistent accuracy across a challenging range of test conditions and (2) model inspection to determine whether the model respects known physical and biological constraints and cause-effect relationships. Similarly, we *create* trustworthy models not by keeping them tied to hypothesized processes but by training on larger datasets, following known best practices for ML model development and testing, and - perhaps most importantly for limnology - by injecting design into ML models to encode well-understood processes, physical laws, and reliable patterns, while leaving less-understood phenomena to be discovered by the algorithms.

Limnological knowledge can be designed into ML models at many points in the model structure and in the model development process (Fig. 2). All models permit - and in fact require - injection of knowledge-based design at the point of selecting and preparing input variables. Many ML models are capable of residual or hybrid modeling, i.e., ingesting residuals or outputs from other

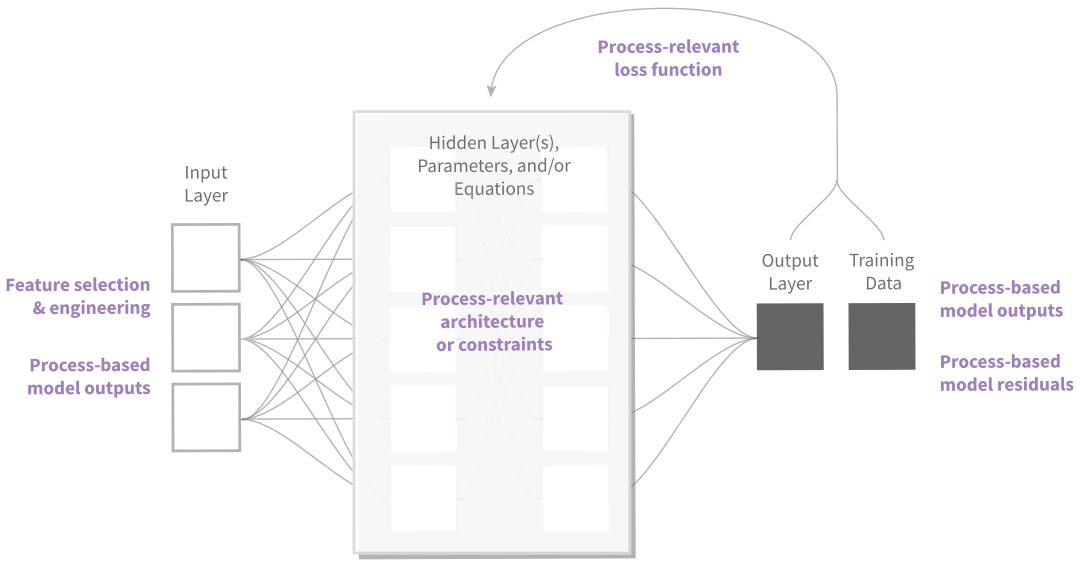

Fig. 2 Injection of limnological design into machine learning models can occur at the points (purple text) of the model inputs, architecture, training data, and/or loss function.

design-rich models and generating more accurate predictions of the same target variable. Some more advanced forms of design injection are limited to the more flexible model structures - for example, neural networks can be designed to assume temporal and/or spatial patterns in the inputs and outputs, and they can be trained or constrained to avoid violation of specific physical or biological rules. Specific modifications are discussed in detail in the Tools section of this chapter.

Discovery-driven models have proven so powerful at prediction that Anderson (2008) questioned the value of continuing to develop new research theories at all. However, theory-based design is a powerful complement to discovery-based models, enhancing model trustworthiness and utility when the two are used together. Further, outside a modeling context, theory remains an important means to discuss, teach, and engage meaningfully with our world. So, it is fortuitous that even as theory-based design improves the realism and out-of-bounds accuracy of ML models, ML models of all kinds can be used to build understanding, including new and revised theories (Mazzocchi, 2015; Nearing et al., 2020), as discussed in the next subsection. Theory and data will always be imperfect and incomplete, and the largest advances in limnological modeling will occur when flaws in either are identified and overcome by leveraging the other.

Pathways to understanding

Limnologists use models to improve understanding of inland waters - specifically, we seek the ability to concisely describe general aquatic patterns or processes via equations, natural language, or digestible images - i.e., we seek "intelligibility" (de Regt, 2017). Understanding of this form enables action: researchers can test hypotheses, develop new ones, and make predictions; environmental managers can choose and justify courses of action; and water users can appreciate and decide how to use water resources. Modeling typically supports understanding via pursuit of three major modeling pathways: *prediction*, *inference*, and *distillation* (Fig. 3).

Prediction asks, "What does the current model say about the world?" The goal of prediction is to estimate values of a dependent variable as a function of a model and some inputs, where the dependent variable is usually a property of the world such as water quality, a nutrient transformation rate, or the size of a fish population. Although predictions are sometimes too detailed for immediate understanding, they provide the raw material from which patterns can be discovered, theories proposed or tested, and understandable summaries derived (Douglas, 2009). Predictions also support water resources decision-making directly, by precisely estimating aquatic ecosystem states and process rates for decision-relevant locations and time periods.

Inference asks, "What do the observations tell us about the underlying process being modeled?" Here we use "inference" in the statistical sense to mean discovering the model values (parameters, equations, and/or internal states) that best fit the observations, i.e., "answer[ing] questions about the model in the light of the data" (Cox, 2006). Fitted parameters, equations, and states often yield understanding directly or can be distilled to something even more understandable. Inference using discovery-driven tools is sometimes called "statistical learning" and distinguished from "machine learning" by the user's objective (inference via statistics, prediction via ML; Bzdok et al., 2018), but because the tools are almost always the same, we consider data-driven inference using ML to be within this chapter's scope. We also expand the statistical definition slightly to include the use of one model to make inferences about another, where the second model may be data-driven, process-based, or even conceptual.

Distillation asks, "How can we say this more simply?" Distillation uses models to reduce large volumes of information to smaller ones. Distilled information may be directly useful to researchers or managers because it is more intelligible than the raw inputs, thus

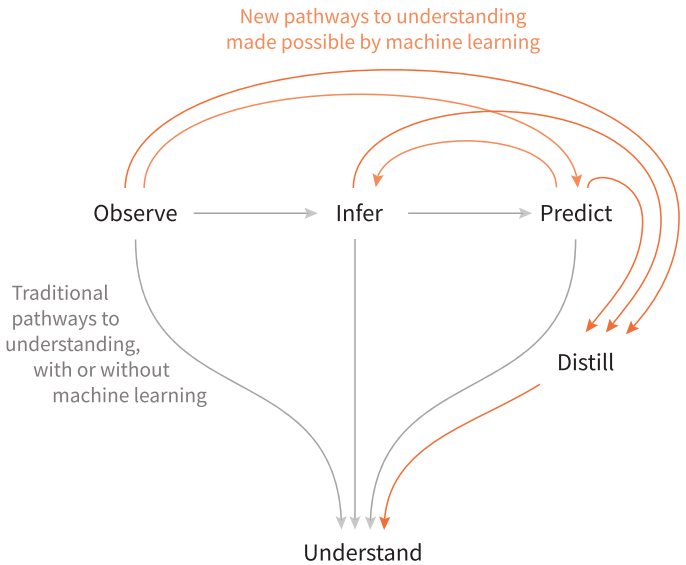

Fig. 3 Pathways from data to understanding. Some data can be directly understood. Process-based, semi-empirical, and traditional statistical models enable inference, which can directly provide understanding or can lead to understanding via predictions (gray arrows). Machine learning (ML) models can yield understanding by the same pathways as non-ML models but also introduce additional pathways, including predictions that bypass inference, inferences that emerge from predictive models, and ML-enabled distillation of observations, inferences, and predictions (orange arrows).

Table 1 Suitability of five major modeling approaches (columns) for three major modeling pathways (rows).

Objective	*Process-based models*	*Statistical models*	*Neural networks*	*Tree-based models*	*Clustering and dimension reduction models*
Prediction	**	*	***	***	*
	Simulation, out-of-bounds predictions	Regression, additive models, time series models	Prediction, recurrence, convolution	Random forests, boosting	Classification of new observations
Inference	***	**	**	*	*
	Calibration, inversion	Regression, hierarchical models	Attention, prediction of parameters	Decision trees	Cluster and dimension characteristics
Distillation		**	**	**	***
		Regularization, model selection	Autoencoders, regularization	Pruning	Simplification of inputs

Number of stars indicates level or frequency of suitability. Cells contain names of more specific methods for applying the approach to the pathway. Inference may also be addressed for all modeling approaches using model-agnostic interpretation techniques (see Section "Interpretation techniques").

enhancing understanding of pattern or process. In addition, distilled information may be used as input to subsequent models, thereby reducing computation costs for those later models (because the distilled inputs are smaller and simpler) or improving their accuracy (because the distilled inputs contain less noise). While inference and prediction are commonly recognized as the core pathways trod by modelers (Sanders, 2019), distillation is an important third pathway because it bridges the gap between raw data or model outputs and truly useful information.

Although ML models are sometimes criticized for failing to contribute to understanding, we argue that such criticism fails to recognize the several pathways by which modeling can inform understanding. We agree with the critics that little understanding would be gained by making inferences about ML equations and parameters that have little interpretable meaning (e.g., parameters in artificial neural networks or random forests). But ML models can support inference about meaningful limnological processes and states if we use ML differently - if we set the focal variables as the inputs or outputs of the model, or if we infuse certain parameters with meaning through strong doses of limnological design. And ML models are often *better* than non-ML models at prediction and distillation (Fig. 3, Table 1). As we describe specific tools and applications throughout this chapter, we will elaborate on the diverse uses of ML to build understanding.

Chapter overview

In this chapter we present four classes of ML approaches - neural networks, classification and regression trees, clustering and dimensionality reduction methods, and model interpretation techniques. We chose these four classes because we see much application of them in the recent literature and great opportunity for fusion of discovery and limnological design, especially for neural networks. There are many other ML approaches and variants on these approaches (e.g., Support Vector Machines) that are not covered in detail here. To learn more about these other options, please refer to a primer on machine learning methods written for ecologists (Olden et al., 2008) and a review of deep learning in the hydrologic sciences (Shen, 2018), and keep a watchful eye on new publications in this fast-growing field.

The main body of this chapter is divided into descriptions of these focal modeling approaches (Tools), guidelines for rigorous use of ML models (Implementation), and examples of how these approaches have been applied to meet goals for prediction, inference, or distillation for inland waters research and management needs (Applications). Recurrent themes throughout the chapter include gaining understanding of process or pattern, assessing model trustworthiness and prediction uncertainty, and injecting process design into model structures and the model-development process. We show that ML models, particularly when applied according to best practices and with heavy doses of both design and discovery, are powerful tools to support limnological investigation, understanding, and management.

Tools

Neural networks

Neural networks (NNs) are highly flexible black-box models that can mimic virtually any relationship between inputs and outputs, as long as the model and the training dataset are both sufficiently large (Goodfellow et al., 2016). The flexibility of NNs makes them suitable for any of the three modeling pathways (prediction, inference, or distillation), although their prediction accuracy is most frequently touted. As computing power and datasets have grown to enable ever more complex NNs, the resulting growth in predictive accuracy has driven the explosive popularity of NNs, with a turning point at a series of high-profile modeling competitions on tasks such as speech recognition, image classification, and time series modeling (LeCun et al., 2015). Deep learning, which employs NNs with multiple layers, has also risen in popularity within limnology (see Sections "Applications" and "Conclusion").

NNs are collections of connected variables, or *nodes*, where each node contains the weighted sum of its designated input nodes as transformed by an activation function such as a logistic curve (Fig. 4). Nodes are typically organized into *layers* to represent discrete

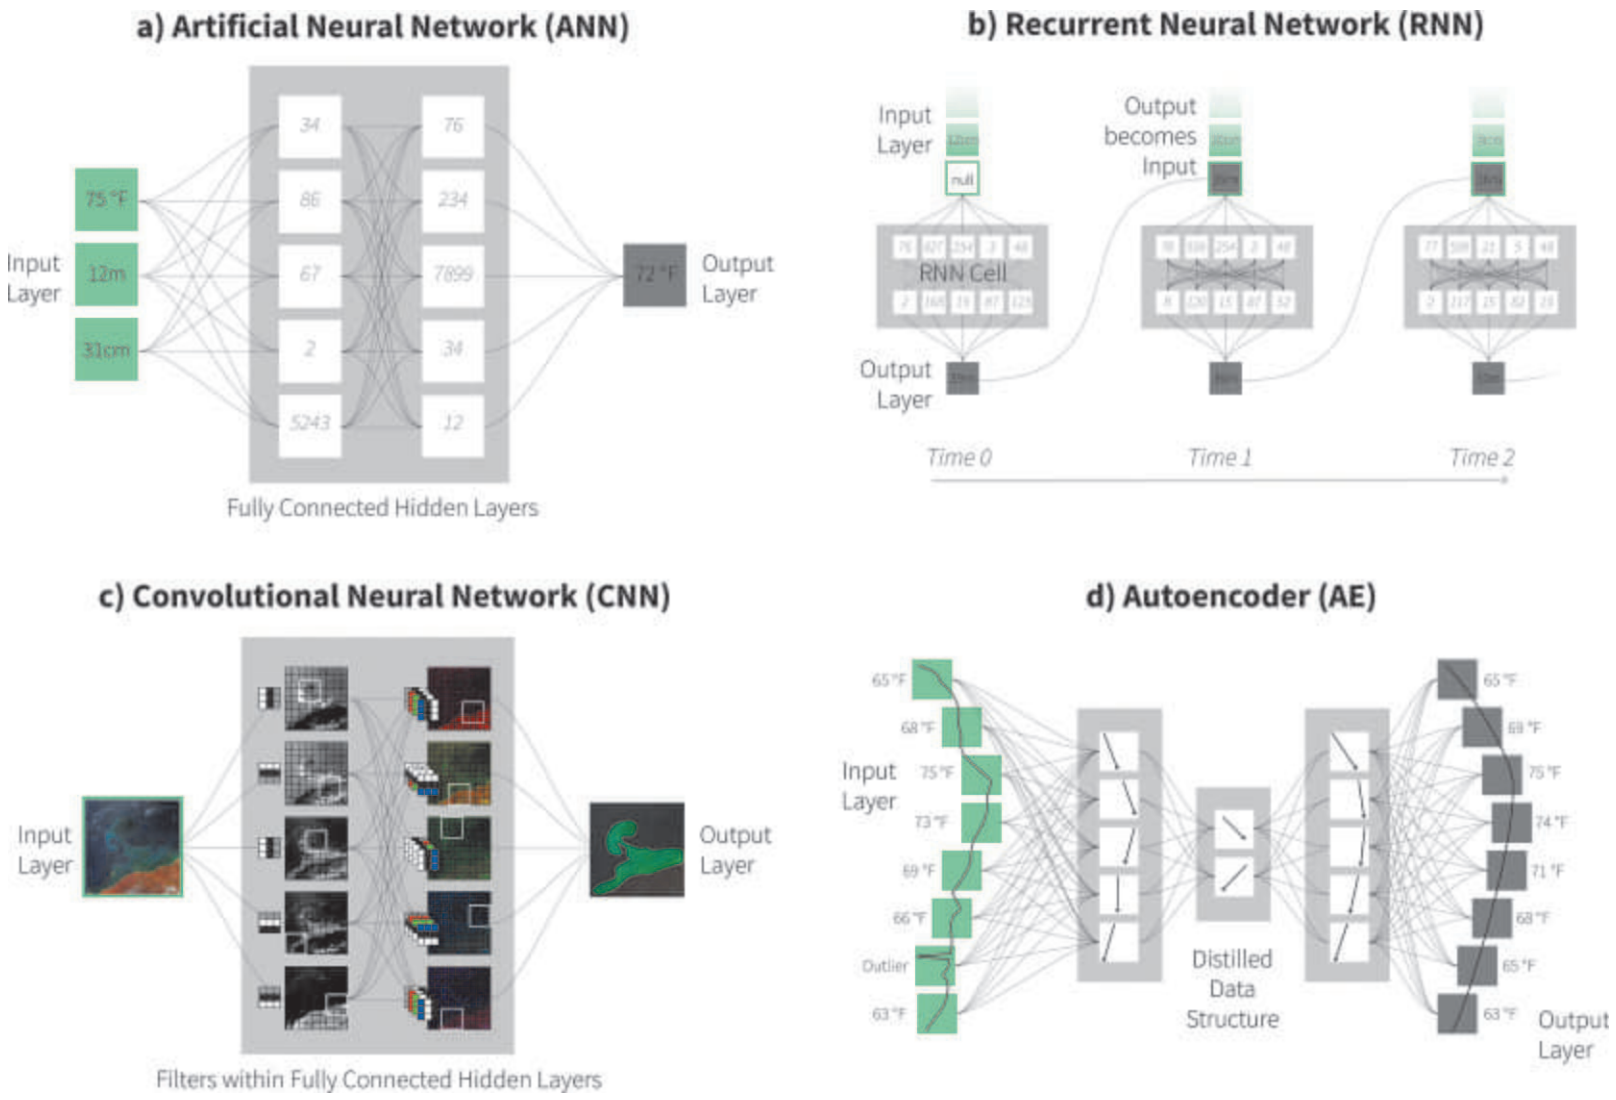

Fig. 4 Structure of (A) a basic NN, with expansions useful for (B) temporally correlated data, (C) spatially structured data, and (D) compression or de-noising of complex inputs. Within each panel, information flows along the curved arrows. Where arrows meet, values are combined by a weighted sum, the addition of a constant (bias), and transformation by an activation function such as sigmoid or tanh. Light gray rectangles indicate the conceptual gathering of nodes into layers. Green, white, and dark gray boxes represent input, intermediate, and output nodes, respectively.

stages of information flow through the network, where successive layers build from preceding layers to extract increasingly complex features, compute interactions among features, and ultimately generate predictions. NN parameters are initialized to random values and then iteratively trained until the model performance minimizes the output of a *loss function*, a function that returns a designer-specified accuracy metric such as the root mean squared error of predictions relative to observations. Model training follows an iterative process in which a set of trial predictions is generated, then blame for the *loss* (the output of the loss function) is apportioned among the parameters, then the parameters are each slightly adjusted in proportion to their blame, and then the next iteration is begun. The efficiency of this training procedure is what makes it practical for NNs to be substantially more complex, and therefore more flexible, than other ML modeling structures.

NNs can be a simple stack of fully connected layers (artificial neural networks, ANNs, Fig. 4A), or they can have more complex structures that are suited to specific prediction problems. Recurrent neural networks (RNNs, Fig. 4B) are useful for modeling time series of water chemistry (Li et al., 2019), temperature (Rahmani et al., 2020), quantity (Nagesh Kumar et al., 2004), community composition (Chon et al., 2001), etc. because they model whole sequences of inputs and outputs, using the same set of parameters for each transition between timesteps. RNN variants such as Long Short-Term Memory (LSTM) and Gated Recurrent Units (GRU) transfer more detailed information among timesteps, enabling a memory of recent and more distant past events and cumulative ecosystem status (e.g., snowpack depth; Kratzert et al., 2018). Raster-based convolutional neural networks (CNNs, Fig. 4C) apply to spatially structured datasets such as remotely sensed images and 2D representations of water bodies (Syariz et al., 2020). CNNs pass specialized parameter sets (kernels) over an input raster one spatially contiguous window at a time, extracting higher-level features from each window and representing those features in a new 2D layer that can itself be treated as a raster. Graph convolutional neural networks (GCNNs) allow spatial connections via a graph rather than a grid, which may be preferable for modeling systems such as river networks or food webs (Jia et al., 2021). Autoencoders (Fig. 4D) are a means of information compression or smoothing; the network is trained to re-predict the original inputs after passing data through one or more constrained hidden layers, which typically have fewer nodes than the input layer. After training, these constrained layers concisely represent the essential information and may therefore support inference about properties of the aquatic system (Li et al., 2020); alternatively, the modeler may be most interested in the final predictions for their smoothness or reduced noise relative to the original inputs. Other NN structures exist and continue to be invented, but ANNs, RNNs, CNNs, and autoencoders are readily and widely applicable for limnological modeling objectives.

Estimating Uncertainty: Many methods are available to quantify uncertainty in NN predictions (Kabir et al., 2018). For example, some NNs are trained to directly predict two or more moments of the probability distribution of each prediction (e.g., the mean and variance; Nix and Weigend, 1994). Alternatively, Bayesian NNs represent each node as a distribution and thus can represent uncertainty throughout the network (e.g., Graves, 2011; Blundell et al., 2015; Louizos and Welling, 2016; Pearce et al., 2018). Ensemble methods are another option, where the ensemble prediction is the distribution of predictions from many different instances of the NN (Tibshirani, 1996). Variation among the ensemble members can be obtained by training each member separately, e.g., with different initial parameter values or resampled training data (Dietterich, 2000), or by dropout from a single trained model, where a random subset of the weight parameters are set to 0 at the time of prediction (Gal, 2016).

Integrating Design: NNs are highly amenable to the injection of limnological process knowledge, especially when the NN structure already represents temporal or spatial dimensions of an aquatic ecosystem. Beyond that structural decision, Willard et al. (2020) describe the following approaches to adding design: (1) Custom loss functions can encourage physically, chemically, or biologically realistic values of internal model states and final predictions (e.g., Beucler et al., 2020; Jia, 2020). (2) The model architecture, i.e., the choice of layers and activation functions, can be designed to strictly enforce physical, chemical, or biological rules (e.g., Daw et al., 2020). (3) Model weights can be initialized, or "pretrained," to emulate a process-based model by treating process-based model outputs as observations (Read et al., 2019). (4) Models can be trained to predict the residuals between process-based model predictions and observations, rather than predicting the observations themselves. (5) NNs can be hybridized with process-based models, e.g., by passing the outputs from the process-based model as inputs to the NN (e.g., Karpatne et al., 2017), or chaining outputs from the NN into the process-based model, or embedding one model as an intermediate component of the other model. Applications of such methods for Earth system sciences have been recently reviewed (Reichstein et al., 2019).

Tree-based methods

Classification and regression trees (CART) algorithms (De'ath and Fabricius, 2000; Breiman et al., 2017) can represent very complex, non-linear, multivariate relationships and are most useful for building understanding via prediction (e.g., predicting groundwater pH from landscape features; Stackelberg et al., 2021) or *supervised* distillation (e.g., identifying syndromes of lake properties and warming rates, O'Reilly et al., 2015; or assigning phytoplankton species to functional groups, Kruk et al., 2017). CART algorithms lack some flexibility relative to other methods described here, especially in their ability to simulate spatial and temporal relationships among states, provide unsupervised distillation, or accommodate designed structural components to integrate limnological knowledge. However, CART algorithms excel at ingesting and predicting categorical variables, are often competitive with basic NNs for prediction accuracy, and are highly interpretable at the level of individual decision trees, which can be drawn and visually inspected.

CART algorithms are like NNs in that they obtain their flexibility from many connected nodes that each perform a simple calculation. Whereas each NN node is a weighted, transformed sum of preceding nodes, CART nodes are decision points within a tree of if-else statements, each of which is a split on the axis of one input variable. Terminal nodes ("leaves") of classification trees

predict class membership, while leaves of regression trees predict a continuous value as a simple average of the dependent variable from the training data for that node. Extensions of the regression tree include more complex functions at the leaves and sometimes the nodes, including using the last or all upstream predictors in a linear model to predict the continuous value (Quinlan, 1992).

Many popular CART algorithms use ensembles of trees, created largely by bootstrapping (bagging) or boosting methods. Bagging methods train many different trees and then report the average of the trees' predictions; for example, the random forest algorithm grows many trees by withholding random subsets of the inputs and randomly permuting a subset of features (Breiman, 2001). Boosting methods such as AdaBoost (Freund and Schapire, 1997) and Extreme Gradient Boosting (XGBoost; Chen and Guestrin, 2016) build an ensemble of trees whose predictions are added together, where each new tree is trained to predict the residuals of the sum of the previous trees' predictions. Ensemble CART methods perform well even for collinear predictors, high dimensionality data, and non-linear relationships between predictors and responses.

Estimating Uncertainty: Uncertainty in individual CART algorithm predictions can be estimated using method-specific algorithms, e.g., several methods for random forests (Meinshausen, 2006; Coulston et al., 2016; Mentch and Hooker, 2016; Zhang et al., 2020), ensembling for AdaBoost (Zhou et al., 2017), and quantile regression for XGBoost (März, 2019). Many of these approaches leverage concepts from Bayesian statistics, from which they gain uncertainty estimates and also benefits to model robustness and accuracy (e.g., Quadrianto and Ghahramani, 2015). Bayesian Additive Regression Trees (BART) combine boosting and a Bayesian approach that generates predictions from a probability distribution rather than a point estimate (Chipman et al., 2012). New methods continue to be developed for uncertainty estimation, such as the probabilistic models implemented as NGBoost (Duan et al., 2019).

Integrating Design: CART algorithms have a fairly rigid structure that limits the amount of knowledge-based design that can be injected. However, as with any model, modelers still use limnological knowledge when choosing which variables to input; knowledge-rich input variables may include derived variables that reflect important hydrologic or limnological properties. In addition, some algorithms and implementations offer opportunities to customize the training loss function (Chen and Guestrin, 2016) or constrain the output to be monotonic with respect to one or more input variables (Incer et al., 2018), permitting limited but intriguing opportunities to design knowledge into these aspects of the model.

Clustering and dimensionality reduction methods

Clustering and dimensionality reduction techniques provide understanding via distillation, i.e., they condense large, complex datasets into more manageable, interpretable, or otherwise useful forms (Borcard et al., 2018). Unlike most other ML models, the techniques described here use unsupervised learning: Rather than seeking to make predictions that match observable answers, they aim to reduce complexity while preserving the meaningful features of a dataset. Clustering methods classify similar observations into groups, which can yield insight about complex or high-dimensional data (e.g., quantifying changes in microbial community structure over time; Rubbens et al., 2021), reveal previously unknown structure in the data (e.g., identifying distinct seasonal patterns in stream photosynthesis rates; Savoy et al., 2019), or identify anomalies (e.g., detecting erroneous spikes and level shifts in water quality sensor data; Leigh et al., 2019). Dimensionality reduction methods compress high-dimensional data to fewer dimensions, which can be useful to reduce noise in data (e.g., remove distortion from underwater images; Fabbri et al., 2018), increase data-driven model performance by providing fewer and more meaningful predictor variables (e.g., simplify hyperspectral imagery to a set of independent variables; Dierssen et al., 2021), and aid in interpretation of results (e.g., describe effects of floodplain restoration on species richness of macroinvertebrates, macrophytes, and fish; Pander et al., 2018).

Methods for clustering include k-means clustering, Gaussian mixture models (GMMs), and hierarchical clustering (Scrucca et al., 2016; Bramer, 2020). In k-means clustering, data are grouped into k clusters by randomly selecting k data points to serve as the initial group centers, then iteratively adding nearby points to each group and computing the centers of the updated groups. K-means clustering performs best on groups that are spherical; GMMs overcome that limitation by describing each cluster with a different mean and standard deviation in each dimension, and allowing clusters to overlap, which allows clusters to take on complex shapes. Hierarchical clustering methods build trees by sequentially splitting or gathering data points into groups (divisive and agglomerative clustering, respectively). An important modeling decision for any clustering algorithm is the number of clusters to use (set directly for k-means clustering and GMMs or via tree depth for hierarchical clustering). This decision may be based on expert knowledge or by finding the value that minimizes within-group variance and/or maximizes between-group variance.

Dimensionality reduction techniques include time-honored linear transformation methods such as principal components analysis, linear discriminant analysis, and factor analysis; and non-linear methods such as isometric feature mapping, non-metric multidimensional scaling, locally linear embedding, t-distributed stochastic neighbor embedding, and uniform manifold approximation and projection. These methods have been joined by neural-network-based approaches such as autoencoder NNs (described above) and self-organizing maps (SOMs). SOMs are specially structured NNs that map multi-dimensional data points onto a 2-dimensional grid or honeycomb of nodes, simultaneously organizing similar data points spatially (a sort of "soft clustering") and reducing data dimensionality. Unlike most NNs, whose weights are adjusted based on their contribution to a loss function, the weights associated with each SOM node are iteratively updated until the map spans the full data space while preserving similarity among neighboring SOM nodes.

Estimating Uncertainty: Uncertainty in clustering and dimensionality reduction usually cannot be defined with respect to differences between predictions and observations because there is no "true" group membership or dimension definition to observe (autoencoders are a rare and partial exception). Instead, confidence in model output is assessed through goodness of fit, as

described by measures of group distinctiveness or preserved distances among samples (see 8.3 Model evaluation). Among clustering methods, GMMs shine with respect to uncertainty estimation because they naturally predict the probability that each data point belongs to its assigned cluster.

Integrating Design: Despite the data-driven, unsupervised nature of clustering and dimension reduction algorithms, design can be injected into these methods at the time of application. The researcher first chooses the variables to reduce, e.g., a set of potentially related biogeochemical measurements or gene abundances or a time series of model predictions across a set of sites that exhibit environmentally meaningful variation. For clustering algorithms, the researcher also selects meaningful measures of similarity, which may vary depending on the probability distribution, sparsity, or temporal or spatial structure of the data. Lastly, the researcher may apply expert judgment to the selection of model hyperparameters such as the number of clusters or dimensions to use, where the "right" number is often a compromise that explains substantial variance and yet is still simple enough to yield scientific insight.

Interpretation techniques

Model interpretation is useful for assessing trustworthiness and extracting insight from ML models. It has sometimes been assumed that ML models sacrifice interpretability for the sake of accuracy, but the inevitability of that tradeoff is belied by recent progress in ML model design (Rudin, 2019) and ML explanation techniques (Samek et al., 2019; Molnar, 2020) (Fig. 1). Process-based components of ML models are intrinsically interpretable, another point in favor of integrating design into ML. Additionally, ML models may be structured so that they explain themselves, e.g., by making predictions based on similarity of the current inputs to prototypes encountered during training (Chen et al., 2019). These structural approaches to interpretability are largely new to limnology, but the field of model explanation for artificial intelligence (called "Explainable AI" or "XAI") offers a slightly better-trodden and complementary approach to model interpretation. Having already addressed process-guided designs in Sections "Neural networks," "Tree-based methods," and "Clustering and dimensionality reduction methods," here we provide a taste of the current options in XAI.

When inspecting predictions one at a time, intuition suggests that there should be some quantifiable contribution of each input feature such that the prediction is some fixed intercept plus the sum of all features' contributions. Shapley values are these quantifiable contributions (Shapley, 1951). For a simple linear regression with normalized features, Shapley values are equal to the fitted coefficients, but for more complicated models, the calculation of Shapley values must consider many possible combinations of feature values to isolate the effect of the feature of interest. SHapley Additive exPlanations (SHAP; Lundberg and Lee, 2017) further generalize the Shapley value idea from the effects of individual input features to the effects of feature combinations, e.g., all the pixels in a specific fish in an underwater image.

SHAP values can be inspected at multiple levels of detail (Lundberg and Lee, 2017). For a single prediction, the direction and magnitude of the contribution of each input feature can be visualized in a stacked bar plot. From there, stacked bar plots can be positioned side-by-side for many individual predictions, with predictions optionally grouped by the similarity of the input feature contributions to reveal clusters of conditions for which different sets of input features drive the predictions (note the use of a clustering algorithm to distill the SHAP results, already putting into action the tools described above). Effects of each feature can be summarized as a single value giving the mean absolute effect of that feature (one way to measure feature importance); as a density plot showing the distribution of effects of that feature over all training examples; or as a scatter plot with one point per training example showing the feature's effect (SHAP value) versus the feature's value.

Fast estimation algorithms have made SHAP a leading interpretation method in recent years; however, SHAP values are still computationally expensive to derive, are less informative when features are correlated with one another, and can't answer the question, "If I increase this feature by 5%, how will the prediction change?" An approach that does better with the first and third of these issues is Local Interpretable Model-agnostic Explanations (LIME; Ribeiro et al., 2016), in which a locally linear model is fit around a single input example to intelligibly describe the sensitivity of that prediction to small changes in the inputs (even for models that are globally nonlinear). There are also alternatives to SHAP for estimating feature importance (Breiman, 2001; Fisher et al., 2018) and partial dependence (Friedman, 2001) or variants that deal more elegantly with interactive effects (ICE; Goldstein et al., 2015; ALE; Apley and Zhu, 2019).

While the above methods are model-agnostic or can be implemented for a variety of ML models, there are also interpretation methods specific to neural networks that offer additional forms of insight (Samek et al., 2019; Toms et al., 2019). We will highlight two such methods here. Integrated Gradients (IG; Sundararajan et al., 2017) quantify the rate of change in the output with respect to change in an input feature, using a discrete computation approach that reduces unwanted sensitivity of the interpretation to tiny variations in input values. Layerwise Relevance Propagation (LRP; Bach et al., 2015) produces relevance scores that indicate the contribution of each model node to the nodes in the next NN layer, where the sum of the relevance scores in any one layer of an NN is equal to the predicted value. LRP can describe complex NN architectures including those with recurrence (RNNs; Arras et al., 2019) and convolution (CNNs; Montavon et al., 2019). As with model-agnostic approaches to ML interpretation, the subfield of NN-specific ML interpretation is evolving rapidly, and new techniques continue to emerge.

Implementation

Choosing a model

Various modeling challenges are best met with different models. To select a core model for a specific science challenge, first consider the degrees to which data availability enables reliable discovery and well-understood theory enables sound design. Next, bear in mind that many limnological questions may be best addressed with a combination of models that fill different roles; for example, ML models may make inferences about process-based model parameters or may make predictions that serve as inputs to a model of any other type. Thus, the best set of models to address an inland waters science question will depend on the extent of current understanding, the availability of data, and the pathway by which each subtask will be pursued (Fig. 5).

- For *prediction*, discovery-rich models (e.g., tree ensembles and neural networks) of sufficient complexity can be very accurate in familiar conditions and are a clear best choice when theory is limited and data are abundant. Process-based, design-rich models may be less accurate in well-observed conditions but are often assumed to predict more reliably in new climates, geologies, etc. However, design and discovery need not be mutually exclusive: Process-guided neural networks have shown impressive accuracy in both familiar and new conditions, and both tree-based models and neural networks can be trained to emulate process-based models but with faster runtimes that make it feasible to explore predictions for many scenarios.
- For *inference*, very simple models or those whose design includes physically or biologically meaningful parameter values are the most rewarding, regardless of how much discovery is included. Simple decision trees and process-guided NNs are the ML models that best meet these criteria, while a wider variety of ML models can be used to make inferences about simpler statistical or process-based models. Lastly, model interpretation methods can be applied to any ML model to quantify the importance and effects of each input variable, describing relations between inputs and outputs that may yield insights into the limnological processes being modeled.
- For *distillation*, clustering and dimension-reduction models are good choices. Additionally, autoencoder neural networks, neural network regularization methods, and tree ensembles all provide built-in filtering or weighting of candidate predictors and constraints on model complexity, such that these methods can implicitly or explicitly distill input data down to the most important information. In general, ML models are substantially more useful than process-based models for distillation, because ML models can discover rather than assert the structure of complex data.

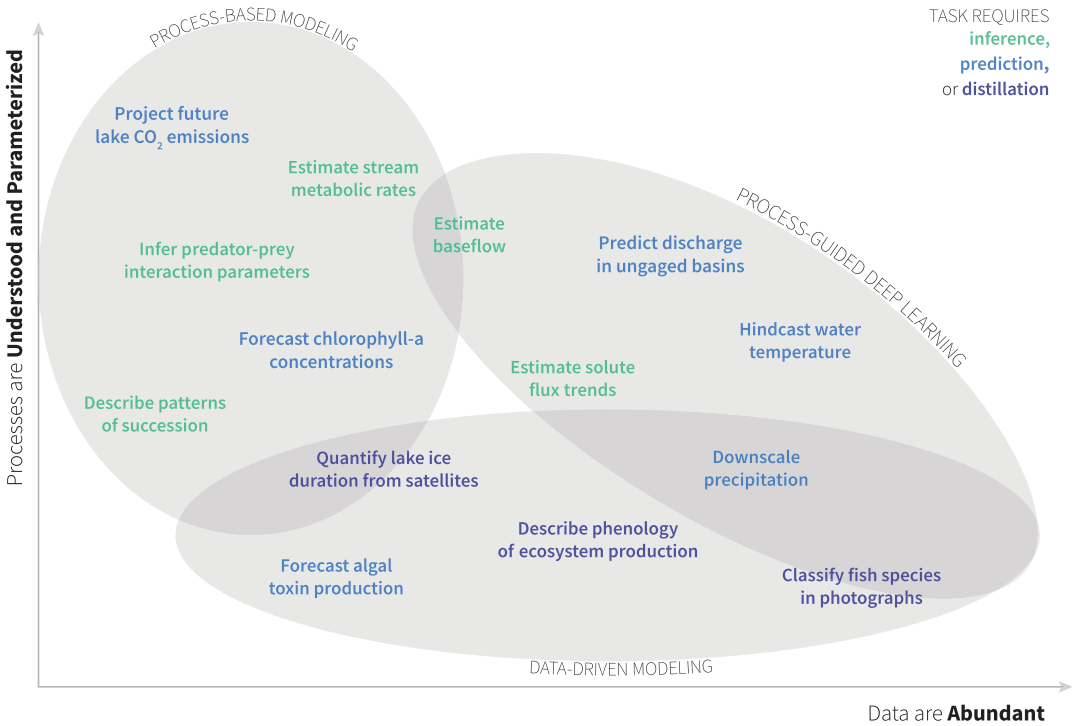

Fig. 5 Limnological research tasks (words in colors) begin with differing amounts of data (x axis) and knowledge of the underlying processes and parameters (y axis). Where the modeler's task falls on this plot can help in selecting a modeling approach (labeled gray regions, roughly corresponding to position in Fig. 1). The different tasks are colored according to whether the main goal of the task is to infer, predict, or distill, illustrating that each class of modeling approaches can serve several goals. Although the precise position of each research task can be debated, this figure illustrates the broad diversity of research tasks for inland waters with respect to theory, data, and beneficial approaches.

Ensuring reproducibility

Reproducibility ("re-performing the same analysis with the same code using a different analyst"; Patil et al., 2016) is essential to modern science, and applications of ML bring unique reproducibility challenges. One of the fundamental hurdles to clear is achieving reproducibility in the code scripts used to define and/or apply the ML models in a study. General guidelines for open and reproducible scientific computing are available elsewhere (Wilson et al., 2014; Gil et al., 2016), but a few guidelines are especially relevant to applying and experimenting with ML. First, if you are experimenting with variants in model structure, follow the Don't Repeat Yourself (DRY) rule: Write your code so that every variant can be run from the same code base, using concise arguments to specify which model variant is to be applied. When publishing for reproducibility, publish an archive of every model training and prediction run. Include well-explained source code, information about the software and hardware environment, hyperparameter values, inputs, raw outputs (if not too large), and summary and evaluation metrics. Lastly, report how you selected the hyperparameters (see "Model refinement" below); this is an often undocumented but important step in the modeling process.

Arguably even more scientifically important than computational reproducibility is replicability ("re-performing the experiment and collecting new data"; Patil et al., 2016). The odds of replicability are higher if you avoid over-tuning your model to match the dataset in hand. Specifically, at the very beginning of your project, divide the available data into three partitions: a training set, a development ("dev" or "validation") set, and a test set. Use the training data to train your model, select hyperparameters based on model performance on the dev data, and withhold the test data until the very end of your project, after you have fully developed your model, to provide an honest assessment of model performance. If data are limited, use a variation on the basic train-dev-test partitioning to make fuller use of the available data while still ensuring that test data have no effect on the selection or refinement of the model - e.g., use cross-validation to do training and testing on several overlapping partitionings. Ideally, the dev and test sets will each provide some surprises relative to the training set, representative of the surprises that would occur when applying the fitted model to an entirely new dataset - to make surprises more likely, split time series data into temporally contiguous chunks so that whole sequences of events remain unseen during training, and split geospatial data in spatial chunks so that dev and testing data are less spatially autocorrelated with training data (Ploton et al., 2020). To improve potential for both replicability and reproducibility, use the published model archive to identify which data were used for training, development, or testing, and document the rationale behind the selected data partitioning strategy.

Model evaluation

Rigorously evaluating model performance is the first step to building trust in an ML application. Model evaluation can be used to compare or choose among several candidate models, determine where each model fails, inform model refinements, and provide essential context for users of the model predictions. Post-hoc evaluation complements any uncertainty estimation method that may have been built into a model, allowing assessments of more diverse aspects of the model fit and providing a check on the uncertainty reported by the model.

For those models that predict observable states, prediction performance can be quantified with metrics such as root mean squared error, mean squared error, classification error, bias, or Nash-Sutcliffe efficiency. The accuracy of a model's uncertainty estimates can also be quantified, e.g., with the bracketing frequency metric. Alternatively, accuracy might be most usefully assessed with respect to values that are computed from the model predictions before being used by the target audience - for example, fisheries managers may be most interested in values computed from daily predictions, such as growing degree days, annual nutrient loads, or the probability of an algal toxin exceedance in a given week. Accuracy in predicting threshold exceedances may be assessed with Receiver Operating Characteristic (ROC) curves and/or Heidke Skill Scores (HSS), with the ROC curves providing a more nuanced view of event prediction by evaluating model sensitivity (false positive rate) against model specificity (false negative rate) for a range of thresholds (Shin et al., 2020). Continuous Ranked Probability Scores (CRPS) can also be used to evaluate probabilistic predictions and are analogous to mean absolute error (Gneiting et al., 2005; Thomas et al., 2020).

At the community level, accuracy of predictions (or of values computed from those predictions) on common datasets is a valuable means of comparing multiple models to one another. The inland waters community has made recent gains in data sharing through the publication of large, model-ready datasets such as GAGES-II (Falcone, 2011), LAGOS (Soranno et al., 2015; Cheruvelil et al., 2021), CAMELS (Addor et al., 2017), AquaSat (Ross et al., 2019), and DeepFish (Saleh et al., 2020). Development of more such datasets, and widespread use of them for model testing and reporting, would substantially improve our ability to identify top-performing models for limnological prediction.

For unsupervised ML models (e.g., those that provide clustering or dimension reduction), truth is often unmeasurable, and thus prediction accuracy cannot be directly assessed. Instead, clustering models are typically assessed by measures of distinctiveness such as the amount of variance within each group relative to the total variance of the data. Dimension reduction methods can be evaluated by their success in preserving the relative distances among the data points. Bootstrapping methods can also be used to compute the frequency with which a cluster appears over many resamplings of the data or to assess the robustness of conclusions drawn from dimensionality reduction.

Model refinement

Most ML models are defined by (1) a structure and training algorithm and (2) hyperparameters that specify variations within that general framework (James et al., 2021). Examples of hyperparameters (also called "tuning parameters" or "parameters") include the learning rate in neural networks, the number of candidate features per tree in a random forest, the possible shapes of the relationships among features in a Gaussian mixture model, and the map size of a self-organizing map. Although a sense of effective hyperparameter values can sometimes be pulled from published model applications or software defaults, optimal hyperparameter values are usually discovered by trial and error for each specific application. Data partitioning into training and development sets enables this trial-and-error exploration: Models are trained with a variety of hyperparameter values and then assessed on the development set to identify the most successful combination of hyperparameter values, where success is evaluated by a metric of the modeler's choice (e.g., root mean squared error). Because the number of possible hyperparameter value combinations is usually infinite, modelers explore a finite number of combinations and then accept the best of those options. This exploration can be done manually, with brute-force search algorithms such as random sampling or grid-based sampling of possible hyperparameter combinations, or using an additional layer of modeling ("surrogate modeling") to iteratively predict and explore promising regions of hyperparameter space (Feurer and Hutter, 2019).

Perhaps the most important consideration when tuning hyperparameters is the balance between underfitting (unnecessarily limiting the complexity of a model) and overfitting (excessively tailoring a model to the sample in hand). The flexibility of ML models makes them especially vulnerable to overfitting; fortunately, principled train-dev-test data partitioning and hyperparameter tuning are precisely the tools needed to find the right balance. Hyperparameters that affect underfitting and overfitting typically relate to model complexity and include the number of nodes and training iterations in neural networks, the depth and pruning methods for tree-based models, and the number of clusters or dimensions in distillation-focused methods. The values that best balance overfitting with underfitting are those for which accuracy is high for training predictions and yet only modestly worse for development predictions. Underfitting manifests as inaccurate training predictions, which can be addressed by adding model complexity or (if possible) providing additional input features. Overfitting manifests as substantially worse development predictions, which can be addressed by reducing or constraining model complexity, or (if possible) collecting more training data.

Model complexity is most obviously a function of the number of parameters in the model (neural network nodes, k-means clusters, etc.), but model complexity can also be reduced by constraining the range of values that each parameter can take on. Process-agnostic versions of this approach are known as regularization; a common example is to include a penalty term for the sum of all parameter values in the loss function used for model training, such that the model learns to achieve reasonable prediction accuracy with smaller and/or fewer parameters. Physical or limnological knowledge can also be used to guide parameter values toward a subset of the mathematically possible options; for example, a gradient boosting regression might be constrained to predict photosynthesis rates that increase monotonically relative to light intensity, and a neural network might be encouraged, via a loss function term, to predict changes in nutrient flux that conserve mass balance. Although neither of these process guidance examples constrains or penalizes parameter complexity directly, both indirectly limit the range of parameter values that the trained model is likely to include.

Reducing overfitting by collecting more observational training data is only sometimes an option in limnological modeling, despite major data-compilation initiatives (e.g., Soranno et al., 2017) and the continual expansion of public monitoring and remote-sensing datasets (e.g., Read et al., 2017; Topp et al., 2020). Fortunately, limnological expertise can be used to sensibly augment the training dataset, making up with quantity what is lacking in quality in the augmenting information. For example, when remote-sensing-based estimates of a variable can be used to complement in situ measurements, these two data sources can be assigned different weights, reflecting their known information quality, in the loss function that guides model training. Another effective approach is to embed information from the lower-quality, higher-volume data into a pretrained model, which can then be finetuned (i.e., trained further) with the high-quality data. For example, Kaya et al. (2019) finetuned a generic neural network image classification model, which had been pretrained on images of all kinds, to classify plant species. Synthetic data are also sometimes an option for pretraining or training a useful model; for example, synthetic images with realistic features and background can be used, or a model of depth to groundwater might be trained on synthetic observations of depth = 0 at the margins of streams and lakes. Similarly, Read et al. (2019) first pretrained a neural network on process-based model predictions of lake temperatures, then finetuned the model on in situ temperature observations. A distinct advantage of pretraining on process-based model outputs is that the ML model can learn from predictions for input conditions that have never yet been observed, allowing the ML model to learn from the process-based model about how to extrapolate to those new conditions in limnologically realistic ways.

Applications

Quality control

Raw data inevitably contain measurement error, whether due to human mistakes, sensor malfunctions, or environmental interference. Previously, human inspection was used to flag errant data, but today's larger and always-growing datasets can only feasibly be processed with automation. A major challenge in quality control (QC) is in distinguishing between errant measurements (e.g., biofouling of a sensor; sun flecks interfering with a remote sensing measurement) and surprising realities (e.g., an extreme algal bloom or sediment transport event), a task that ML models can perform either with no human intervention (for easier problems) or by directing human attention to the ambiguous cases (for harder ones). The line between "easy" and "hard" continues to shift as ML techniques improve, training datasets grow, and theory develops to guide QC targets.

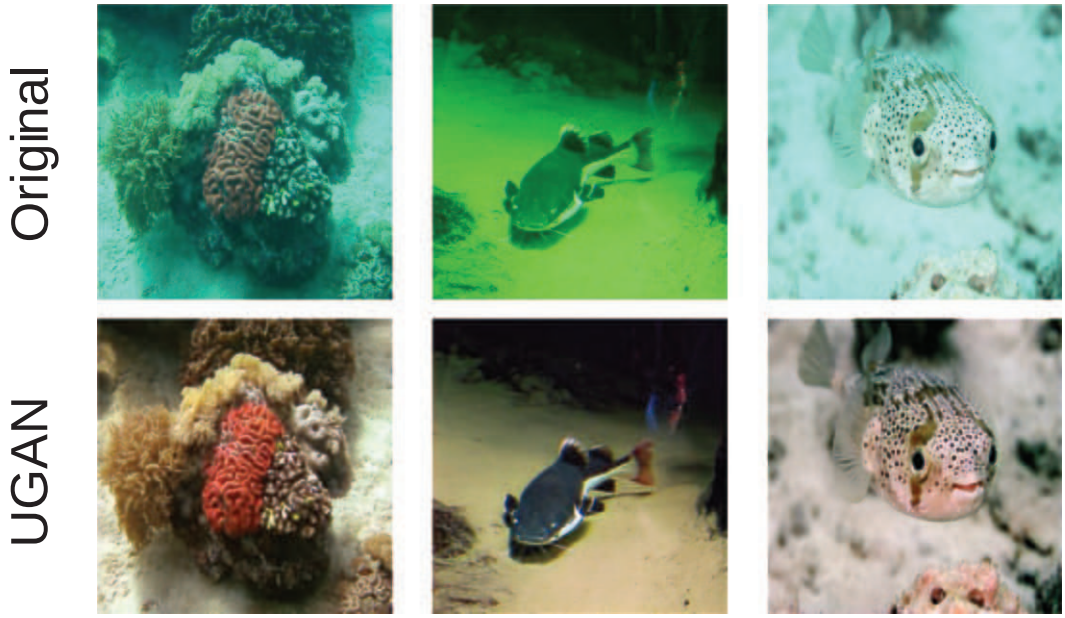

Fig. 6 Original distorted underwater images (top row) and images corrected with an underwater generative adversarial network (UGAN, bottom row). Modified from Fabbri C, Islam MJ, and Sattar J (2018) Enhancing underwater imagery using generative adversarial networks. In *Proceedings—IEEE International Conference on Robotics and Automation*. pp. 7159–7165. IEEE: Brisbane, QLD, doi: 10.1109/ICRA.2018.8460552.

ML methods for detecting data abnormalities primarily follow prediction or distillation pathways and can use a wide variety of model architectures. Supervised prediction methods can be used to predict ("reconstruct") clean datasets with fewer errant measurements. Both random forests and neural networks have been used for this purpose. Autoencoder neural networks are especially suitable because observational outliers are relatively incompressible and are thus greatly altered when the autoencoder compresses and then re-predicts the inputs (Zhou and Paffenroth, 2017). Generative adversarial networks can be used for the same purpose (e.g., for removing distortion from underwater images: Fabbri et al., 2018) (Fig. 6). As an alternative to prediction of clean data, categorical classification and clustering methods can classify data into regimes to enable algorithmic correction for some regimes and targeted expert intervention for others: Supervised classification can group data into modeler-determined regimes such as "clean," "common error pattern," and "needs inspection," while unsupervised clustering can assign data to algorithm-determined groups that the modeler can triage afterward. Both ML and non-ML approaches have been widely used to detect data abnormalities; see Pimentel et al. (2014) for a broad review and Kiran et al. (2018) for tools specific to video and imagery.

Preprocessing data for further modeling

Modern limnological models often ingest complex datasets: imagery from satellites, drones, cameras, or underwater videos, high-frequency observations from mobile or stationary sensors, and multidimensional inputs from rich public databases. Although ML promises a reduced need to simplify the features before building the model (because many ML models can filter the features themselves), this promise is not made for process-based or most statistical models, and in practice even ML models often show improved performance when given inputs that are already distilled to their most informative elements. Fortunately, specialized ML models for preprocessing can provide the link between complex raw datasets and data designed to be used by other models for inputs, training, or testing.

Preprocessor ML models can make use of prediction, inference, and/or distillation to extract information from raw data, reduce dataset complexity, and combine multiple datasets. For example, convolutional neural networks (CNNs) can learn to emulate human interpretations of images, enabling automation of labor-intensive tasks such as identifying fish species from underwater photographs (dos Santos and Gonçalves, 2019), classifying phytoplankton in flow cytometry images (Dunker et al., 2018) (Fig. 7), or estimating flood heights from social media images (Chaudhary et al., 2019). Alternatively, ML models can generate their own rules for data distillation, reducing an extensive time series to a smaller set of information-rich features (CNNs for soil moisture prediction: Feng et al., 2020) or identifying smaller, and thus more interpretable, sets of predictors (self-organizing maps for river salinity predictors: Bowden et al., 2005; feature selection for groundwater nitrate predictors: Rodriguez-Galiano et al., 2018). Some distillation activities make rare use of inference on ML models, learning values of ML parameters that have no *a-priori* meaning to humans but are identified as important by the distilling ML model and can be used effectively by subsequent ML models; for example, Peleato et al. (2018) used the values in the most-compressed layer of an autoencoder as the distillation of results of a multivariate water quality assay. Yet another approach to preprocessing combines multiple datasets in space, either interpolating

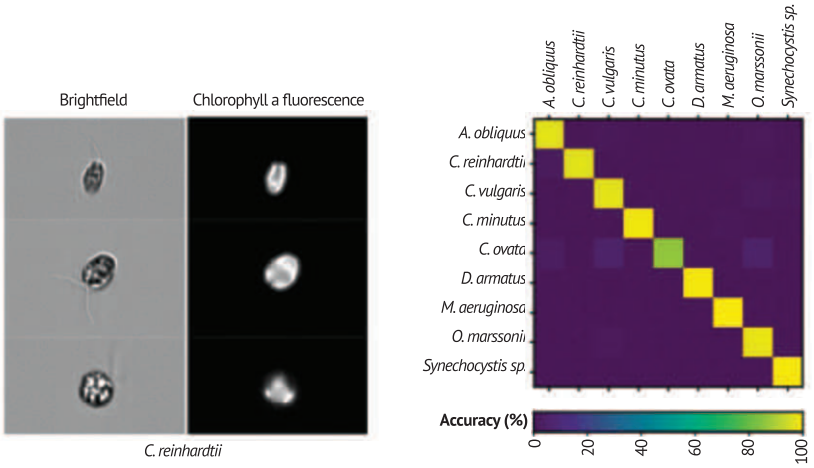

Fig. 7 CNN classifiers can be used to identify phytoplankton species from flow-cytometry images (examples in left panel). In the confusion matrix plot (right panel), rows give the true species, columns give the predicted species, and color indicates the percentage of images in each row that the model assigned to that column, such that a fully yellow diagonal and purple background would indicate perfect accuracy. Modified from Dunker S et al. (2018) Combining high-throughput imaging flow cytometry and deep learning for efficient species and life-cycle stage identification of phytoplankton. *BMC Ecology*, 18(1): 51, doi: 10.1186/s12898-018-0209-5.

from observed to unobserved locations (with random forest prediction: Mital et al., 2020) or combining spatial datasets of varying resolution to downscale a coarse data layer to finer resolution for subsequent modeling (with CNNs: Baño-Medina et al., 2020).

As with other applications, ML models for preprocessing can benefit from injection of limnological design. For example, fish species identification was more accurate when a CNN was trained to predict fish family and order as well as species (dos Santos and Gonçalves, 2019), and distinguishing between land and water pixels in a remote sensing image was more accurate when the classification was tied to estimated bathymetry such that deeper pixels were labeled "water" before shallower pixels (Khandelwal et al., 2016).

Exploring hypotheses

One common modeling goal is to gain insight about the drivers and processes underlying an observed pattern or prediction. With ML models, such insight is often obtained by post-hoc model interpretation techniques, although the use of ML to estimate parameters (next section) can be a complementary way to learn about drivers. ML models are well suited to explore poorly understood relationships between input features and predictions because they are typically robust to high dimensionality and redundant features, and they can capture feature-prediction relationships of any shape. ML interpretation techniques are valuable for generating hypotheses and confronting them with the available data (sometimes even employing formal causal reasoning, e.g., Nauta et al., 2019), thus nudging the field toward understanding of the many complex and hard-to-measure processes in inland waters. Hypotheses generated with ML may even be treated as prior beliefs to be merged quantitatively with the results of other experiments with data or process-based models (Tsai et al., 2020a).

Feature interpretation methods are often used to quantify the importance and effect shapes of features for a wide range of limnological response variables. For example, Worland et al. (2018) used feature importance (FI) to identify primary drivers of annual low stream flows, then used partial dependence plots (PDPs) to visualize the shapes of the effects of each primary driver. Similar approaches have been used to assess the relationships between newly proposed hydrologic metrics and depth to water table (Belitz et al., 2019); regional-to-local lake properties and water quality (Read et al., 2015); and potential drivers of groundwater nitrate concentrations (Ransom et al., 2017), fish reproductive success (Buston and Elith, 2011), and fish species richness (Franceschini et al., 2019). The shapes of relationships in PDPs have also been used to suggest thresholds in stream and watershed disturbance that trigger regime shifts in stream temperatures (Hill et al., 2013).

Neural-network-specific interpretation methods are not yet widely used in studies of water quality or ecology but have been recently embraced in the physical geosciences. Kratzert et al. (2019a) discovered memory nodes in a recurrent neural network whose states correlated over time with water storage states from a process-based hydrologic model; they then used Integrated Gradients to confirm that a node correlated with snow water equivalent was influenced by precipitation and minimum air temperature in early winter, a finding consistent with theory. Barnes et al. (2020) used Layerwise Relevance Propagation to identify those regions of global temperature and precipitation maps that were used by a neural network to predict the year of the maps, i.e., those regions that distinguished the climate in that year from other years (Fig. 8). Identifying the variables, times, and locations that a neural network is relying on for a prediction allows researchers to check for consistency with theory, explain errors, and examine the identified information for additional insights.

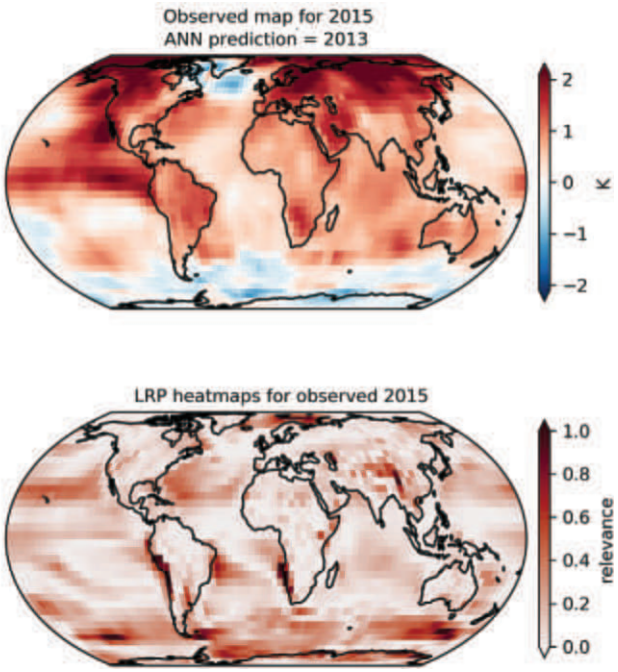

Fig. 8 Layerwise Relevance Propagation (LRP) can be used to propose regions of the globe where air temperature signals are most indicative of the year of an air temperature map. Top: temperature anomalies in 2015 relative to 1979–2099. Bottom: LRP heatmaps show the relevance of each input grid cell to the model's prediction that the map is from 2013, permitting exploration of features that are similar between 2013 and 2015 and different from other years. Modified from Barnes EA et al. (2020) Indicator patterns of forced change learned by an artificial neural network. *Journal of Advances in Modeling Earth Systems* 12(9), doi: 10.1029/2020MS002195, Fig. 10.

Estimating parameters and states

As a way of developing process understanding, modelers often work to refine qualitative descriptions of patterns into process-based or semi-empirical equations that describe relationships among inputs, outputs, and internally represented states. Further process understanding then takes the form of estimated values of the parameters or states used in those equations. ML models can assist in this estimation of parameters and states (collectively termed "variables" in this subsection). However, in contrast to the designed variables of process-based models, ML variables typically lack connection to known process equations, such that ML modelers have turned to creative techniques, either estimating the variables of process-based models or developing process-guided ML models that contain some interpretable variables.

One approach to the use of ML for parameter estimation is to train an ML model to emulate a process-based model, leveraging the quick prediction times of ML models to explore parameter space more rapidly. For example, Gong et al. (2015) experimented with random forests and neural networks as surrogates for a computationally expensive land surface model. They then used the surrogates in a parameter optimization algorithm to find suitable values of soil porosity and other parameters.

As an alternative to emulating a process model, an ML model can also be used to directly predict the values of variables within the process model. For example, Sun (2018) trained a generative adversarial network to predict a map of groundwater hydraulic heads from a map of aquifer hydraulic conductivities or vice versa, where hydraulic heads are more often observed (albeit sparsely) and hydraulic conductivities have historically been solved by inversion of a process-based model, i.e., running that model repeatedly with different conductivities until the predicted hydraulic heads match observations (Fig. 9). ML can also be used to develop transfer functions, i.e., functions that ingest widely measurable predictor variables and output parameter estimates. For mapping river basin characteristics (e.g., soil properties) to hydrologic model parameters (e.g., infiltration curve parameters), Feigl et al. (2020) used a text-generating autoencoder to discover the equation forms and coefficient values of transfer functions, and Tsai et al. (2020b) trained a recurrent neural network to itself act as a transfer function.

Lastly, although the approach is not yet common, ML training strategies and structures can be designed to encourage meaning in otherwise "black-box" states or parameters. For example, Jia et al. (2021) pretrained intermediate states of a neural network on the predictions of streamflow and water temperature from a process-based model, such that the final ML state predictions encoded estimates of these process-relevant state variables.

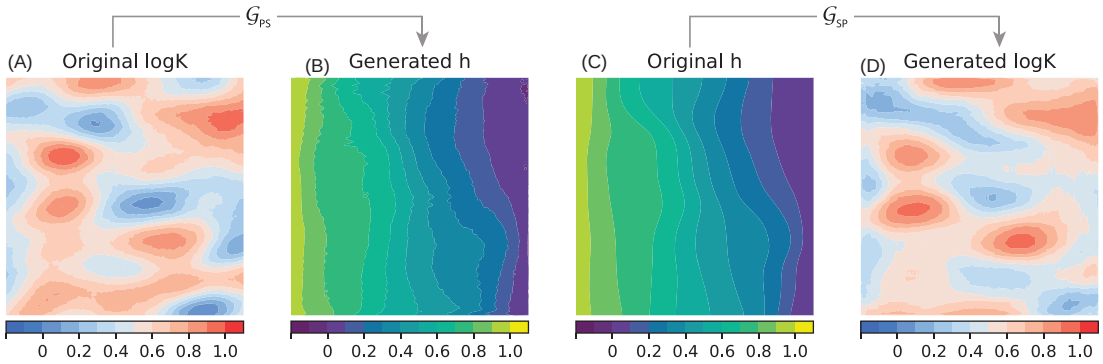

Fig. 9 Example of a generative adversarial network used to predict model parameters and states. There are two competing models in this example: one to predict groundwater hydraulic head states (B) from a set of hydraulic conductivity parameters (A), and one to do the opposite (C and D). Modified from Sun AY (2018) Discovering state-parameter mappings in subsurface models using generative adversarial networks. *Geophysical Research Letters*, 45(20): 11137–11146, doi: 10.1029/2018GL080404. Fig. 2.

Predicting, forecasting, and projecting

ML models are capable of highly accurate predictions and thus have been applied extensively to prediction challenges for inland waters (Maier and Dandy, 2000; Maier et al., 2010). Accurate predictions can fill knowledge gaps in space or time, facilitate scientific hypothesis generation, and support water resources decision-making. An example need for spatial gap filling is that lake water temperature models must usually be trained on a lake-by-lake basis using local observations but would ideally be leveraged for unobserved lakes. Willard et al. (2021) developed a gradient boosting regression model that uses lake features to select a trained lake model to use in predicting temperatures in a new, unobserved lake. For filling gaps in time, Toth and Brath (2007) and Kratzert et al. (2019b) have shown that NNs can predict streamflow with comparable or better accuracy than calibrated process-based models. ML models also excel at capturing nonlinear dynamics, which can be useful in identifying threshold responses; Hansen et al. (2017) fit random forest models of fish abundance and used the resulting nonlinear partial dependence plots to project how fish habitat would change under future climate scenarios (Fig. 10).

In addition to their accuracy, trained ML models also offer relatively fast prediction runtimes, making them efficient choices for generating predictions over large spatial or temporal extents or in real time, for robust uncertainty estimation via large ensembles of predictions, or for decision support applications that explore many potential scenarios. For example, Nolan et al. (2012) used an ML model to emulate a process-based model of the unsaturated zone to predict nitrate losses from agricultural fields throughout a large region of the United States. Fienen et al. (2013) used a Bayesian network model to emulate a large-scale groundwater model for adaptive management on an island threatened by sea level rise. The faster emulator allowed for uncertainty estimation and scenario testing for predicting depth to water table, a metric related to plover foraging habitat and access to freshwater for wild horses.

One concern for prediction using ML models is that they are data hungry and may not generalize well to new inputs such as climate scenarios that have never existed in the past. Incorporation of limnological knowledge can improve prediction accuracy and help ML models earn trust. For example, Franceschini et al. (2019) used knowledge of fish species interactions to develop an NN model that more accurately predicted the occurrence probabilities of a target fish species by including two meaningful intermediate variables, the occurrence probabilities of two secondary fish species. Noori et al. (2020) passed outputs from a process-based water quality model into an ANN to achieve more accurate predictions of riverine nutrient loads in and around Atlanta, Georgia. Read et al. (2019) showed that lake temperature models pretrained with a process-based model, and incorporating physical laws in the loss function, significantly improved performance of an RNN even under sparse data conditions. Recent work has explored real-time data integration into ML models to overcome data sparsity and noise issues and improve near-term forecasts of water resources such as streamflow (Feng et al., 2020).

Summarizing research results

In this age of sensors and powerful computers, it is common for observations and even model outputs to be too detailed for direct human interpretation. ML models can be used to impartially reduce a multidimensional result to two dimensions that can be visualized on a screen or printed page. Autoencoder neural networks are a potentially powerful tool for this application, as evidenced by their usefulness in distilling multivariate or timeseries data during preprocessing (see above), although we have yet to find examples of their use in interpreting water resources research results. Self-organizing maps have been used to summarize the multidimensional relationship between particle size and fluorescence properties in river water feeding to the largest freshwater lake in China (Yan et al., 2018) and to compress aquatic insect (chironomid) community data to a two-dimensional map that enabled (1) further clustering into three general community types and (2) comparison with concentrations of chemical stressors (Milošević et al., 2018).

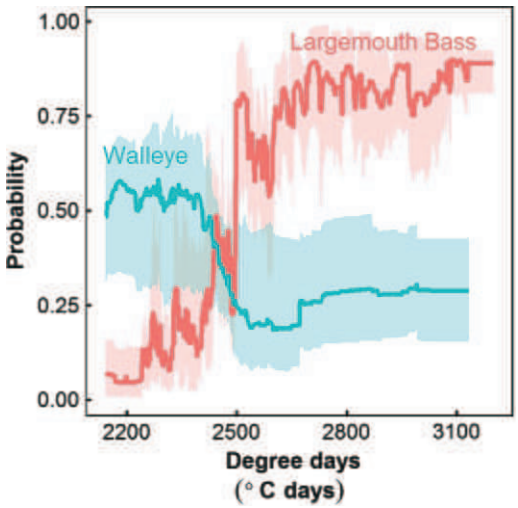

Fig. 10 Random-forest-based partial dependence plot showing the nonlinear relationships between mean lake temperature degree days (horizontal axis) and the probability of walleye (*Sander vitreus*) recruitment or high largemouth bass (*Micropterus salmoides*) abundance (vertical axis). In this plot, solid lines are median responses and ribbons are 25th–75th percentile responses to the degree day value across all possible combinations of the other predictors (lake area, conductivity, and shoreline complexity for walleye; lake order and Secchi depth for largemouth bass). From Hansen GJA et al. (2017) Projected shifts in fish species dominance in Wisconsin lakes under climate change. *Global Change Biology*, 23(4): 1463–1476, doi: 10.1111/gcb.13462. Fig. 1.

We have long organized our understanding into categories such as biomes, aquifer types, aquatic trophic classes, and lake stratification regimes, but the use of discovery rather than design to identify such states has the potential to hasten the development of new intuitions about how to make sense of inland waters and their drivers. For example, Pacheco et al. (2017) used a self-organizing map followed by U-matrix clustering to reduce continuous values in seven water quality dimensions down to six categorical clusters of water quality regimes observed along the Paraíba do Sul River in Brazil, which they then were able to tie to geographic location and local land use (Fig. 11). Savoy et al. (2019) used dynamic time warping to quantify the similarity between pairs of time series of photosynthesis rates in 47 rivers and then used hierarchical agglomerative clustering to identify four common patterns in the annual onset, peak, and decline of photosynthesis. Labels such as "Spring Peak River" or even just "Cluster 6" enable conceptual discussions that would otherwise be mired in numbers.

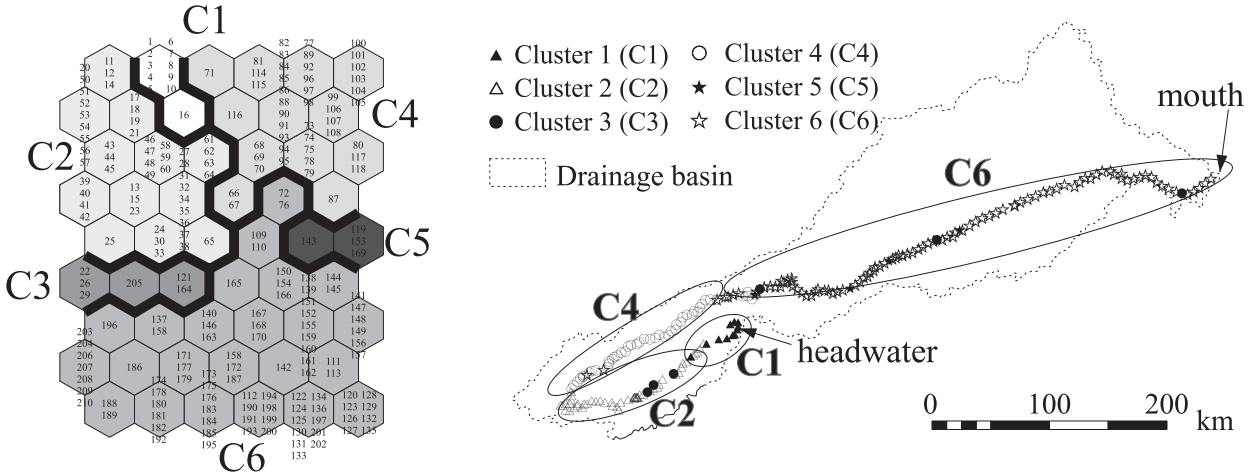

Fig. 11 Example of using a self-organizing map (SOM) to reduce seven continuous water quality parameters to six categorical water quality regimes. Left: Codes in the SOM honeycomb correspond to sampling sites where the number 1 represents the river source, and 210 the river mouth. Right: Map of the catchment and main river channel show the six clusters of the 210 sampling sites. Modified from Pacheco FS et al. (2017) Water quality longitudinal profile of the Paraíba do Sul River, Brazil during an extreme drought event. *Limnology and Oceanography*, 62(S1): S131–S146, doi: 10.1002/lno.10586. Fig. 2A–C.

Conclusion

Water quantity and quality models are central to an increasing number of policy and regulatory decisions, and deliberate selection of the best available ML, process-based, or statistical modeling approaches will be critical to address environmental problems and advance scientific understanding. As described in this chapter, shortcomings of ML models exist but are often overstated and similar to limitations of other approaches. Recognition of ML's value is reflected in the growing proportion of inland waters publications that mention one or more of the tools described in this chapter, although that proportion is still small and indicates room for continued growth (Fig. 12, left panel). Additionally, new research to inject limnological design into ML models is improving predictions and uncovering insights with fewer drawbacks, leading to the rapid recent growth in design-infused ML applications in inland waters and many other domains (Fig. 12, right panels).

The undeniable benefits of ML are creating opportunities for innovation in new dimensions of the aquatic sciences, including assembly and publication of datasets for benchmarking and training, versioned release of model codes for extension and reuse, and model development via interdisciplinary collaborations with computer scientists and technologists. There are also opportunities at the institutional level, where research incentives and resources could be better aligned with the pursuit of machine learning applications and innovation. Given the complementary nature of process-based, statistical, and machine learning modeling, the aquatic sciences are sure to gain by embracing ML models as one set of valuable tools for prediction, inference, and distillation.

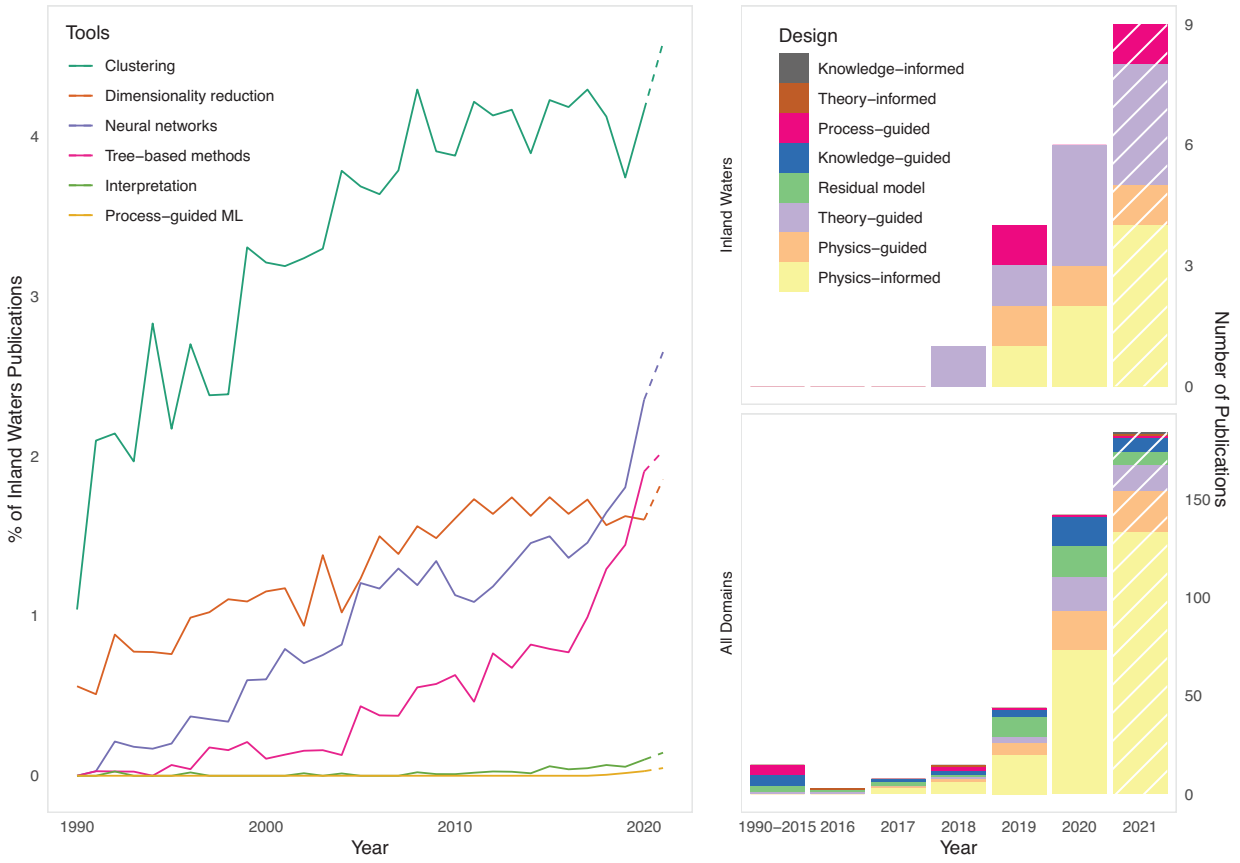

Fig. 12 Publication counts from Web of Science queries for inland waters publications mentioning one of the major tools described in this chapter (left panel) and machine learning (ML) with knowledge-guided design (right panels) for inland waters (top) or all domains (bottom). All major ML tools described in this chapter have become more popular over time, with neural networks, tree-based methods, interpretation, and knowledge-guided machine learning showing the most rapid recent growth. 2021 counts (dotted lines and striped bars) were queried September 5, 2021; counts were multiplied by 365/248 to project the 2021 totals in the left panel and left unmodified in the right panels. Methods in the keys are ordered vertically in the same order as they appear in the figure panels. Exact search terms included many specific approaches within each Tools category (left panel) and required some mention of ML or neural networks along with the text in the Design legend (right panels). Researchers have not yet settled on a consistent term for designed machine learning, hence the diversity of terms in the right panels; "hybrid" yielded many query results but was excluded because it ambiguously describes several methodological and biological concepts. Data from Web of Science, provided by Clarivate.

Knowledge gaps

- Additional core aquatic datasets and baseline performance metrics would support development and comparison of different model architectures, including process-based, statistical, and ML.
- The limnology community would benefit from a general understanding of the conditions under which ML models and process-based models are reliable for extrapolation.
- Establishing common patterns or practices for extracting interpretive insights from ML models would improve model trust and contribute to greater understanding of inland waters.
- Methods to integrate different data types (e.g., single-point data, continuous data, multi-dimensional data, and remotely sensed data) into ML models could improve accuracy and utility.
- Infusion of process knowledge into ML models is a concept in its research infancy, with much left to discover about techniques, potential and limitations, and best practices.
- The limnology community would benefit from a taxonomy by which researchers can communicate the mechanisms and extent to which approaches integrate limnological theory into ML models.
- In contrast to physical processes, biogeochemical and ecological processes can seldom be described with exact equations, such that new techniques may be needed to integrate empirical knowledge about those processes into ML models.

Acknowledgments

Ellen Bechtel transformed rough drafts of the conceptual figures into the polished diagrams we are proud to share here. Critiques by Matt Ross, Phillip Goodling, and Kendra Cheruvelil greatly improved the style and clarity of the text.

Teams, Networks, and Networks of Networks Advancing Our Understanding and Conservation of Inland Waters

Emily K Read[a], Jennifer E Cross[b], Nicole Herman-Mercer[a], Sam K Oliver[a], and Catherine M O'Reilly[c], [a]U.S. Geological Survey, Reston, VA, United States; [b]Colorado State University, Fort Collins, CO, United States; [c]Illinois State University, Normal, IL, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Kendra Cheruvelil.

Glossary

Hydrologic network Interconnected bodies of water, waterways, and stores of water that comprise the hydrologic cycle.
Network of networks A collection of two or more unique networks, each defined by social, geographic, and temporal boundaries and distinct types of connections (e.g., governance, data gathering, information sharing).
Network A group or system of interconnected people or things (adapted from Oxford Language).
Science of team science The study of the processes by which science teams form, behave, communicate, and carry out scientific research.
Social network analysis Mathematical methods used to characterize the structure of networks in terms of edges (connections) and nodes (social actors such as individuals or organizations).
Social network The self-organizing webs of social actors (individuals, groups, or formal organizations) and the relational connections that bind them. In this article, social (human) networks are defined as groups with 12 or more people. Used interchangeably with "network."
Team science Science that is conducted in a collaborative, interdependent manner among individuals with a wide range of backgrounds, skills, and expertise.
Team A group of 3–11 people who interact and influence each other, are mutually accountable for achieving common goals, and perceive themselves as a social entity (adapted from McShane and Von Glinow, 2010).

Introduction and aim

As scientists across the world are working together to answer complex biological and ecological questions, they are forming larger and larger teams. Often, *teams* and *networks* are used interchangeably, but they are fundamentally unique ideas. Distinguishing between the two can help us understand how to improve the performance of increasingly large and complex scientific efforts. In ecological sciences, networks are used to describe more than large teams: a network is "a group or system of interconnected people or things" (Oxford Language Network, 2021). By this definition, inland waters research, management, and conservation is

inherently network-based (Fig. 1), from waterways themselves, to the teams of scientists conducting research, to the policies governing water management. Streams, lakes, wetlands, and groundwater are connected by a network of flowing water as *hydrologic networks*. Human-built infrastructure including drinking water distribution, sewerages, and stormwater management are connected via networks of engineered structures and built infrastructure. Human (social) networks monitor, research, and manage the infrastructure and hydrologic networks. And finally, governance of watersheds, municipalities, states, and nations affect the management function of each of the prior networks (and vice versa).

Consider the Great Lakes basin as a specific example of the network-based aspect of inland waters. Lakes Superior, Michigan, Huron, Erie, and Ontario are connected by a series of waterways including Saint Mary's River, Straits of Mackinac, Niagara River, etc. Built infrastructure such as locks, canals, and water diversions and returns for human use, are distributed across the watershed. Teams at institutions such as Michigan Technological University or the National Oceanic and Atmospheric Administration monitor and research the Great Lakes and connected waterways, and share information through networks such as the Great Lakes Observing System (www.glos.us). Management of the lakes is governed by policy set at the regional, national, or sometimes inter-governmental level. From hydrology to governance, the Great Lakes basin is made up of interacting networks.

Inland waters are inherently *networked*—and the human groups that research and manage them likewise reflect the same network structure. Therefore, these human networks have a particular opportunity to benefit from the understanding of social networks in human collaboration to achieve a goal. Understanding the effective functioning of teams and networks in inland water science will enable the more effective flow of information, resources, coordination, and knowledge creation necessary to address increasingly complex water resources challenges. This article explores the role of teams, networks, and networks of networks in the science of inland waters. Definitions and methods for the development and evaluation of these entities are provided. Case studies from inland waters science are used to illustrate real-world application.

This article sets out to address how to build and maintain *human* networks that can facilitate effective connections between people, knowledge, and data. In recent years, the evidence-based design of collaborative networks and teams in ecological science has increased (Cheruvelil and Soranno, 2018), and the potential effect of this on inland waters is especially great because of the highly networked aspect of inland waters research, management, and conservation. This knowledge must be leveraged to achieve research aims and advancements that would be impossible without crossing disciplinary and institutional boundaries (Fagan et al., 2018).

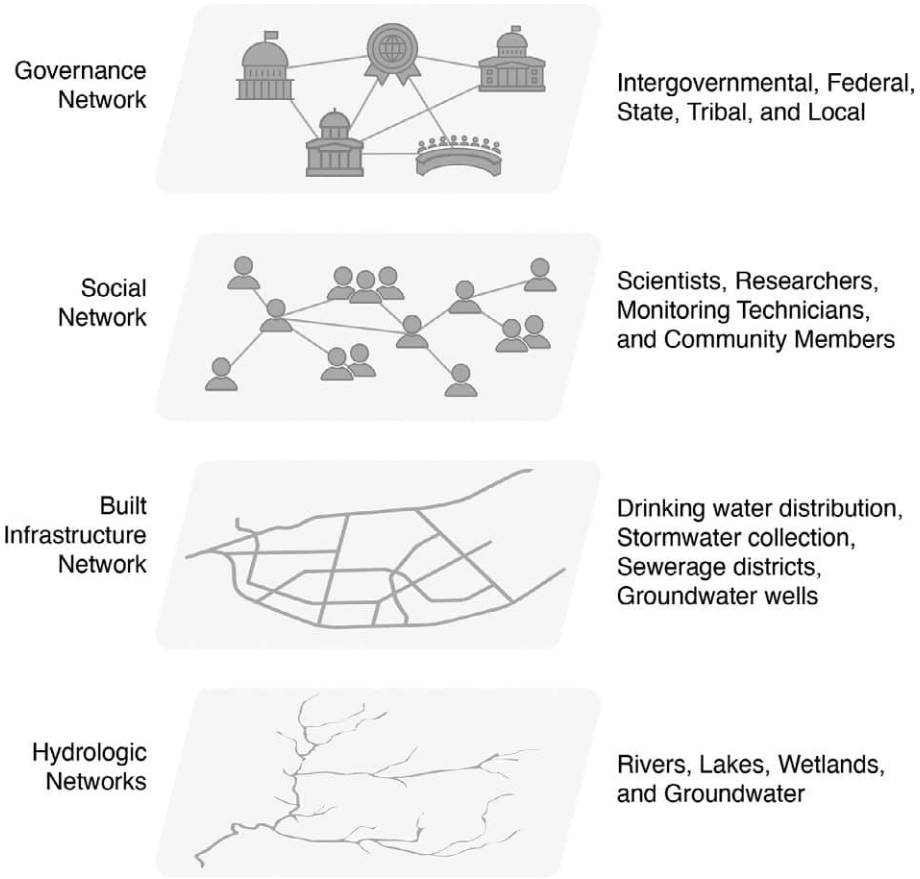

Fig. 1 Network aspects of water, built infrastructure, human (social) networks, and governance networks that relate to them.

The basics of teams, networks, and networks of networks

Before a discussion of the formation, maintenance, and attributes of teams, networks, and networks of networks, it is useful to briefly define these entities and the relationships between them.

Readers will be familiar with the concept of a *team*: a group of people who interact and influence each other, are mutually accountable for achieving common goals, and perceive themselves as a social entity (adapted from McShane and Von Glinow, 2010). In this article, a team is defined as a group of more than 2 and less than approximately 12 people (Box 1). Teams have long been used in the pursuit of science. The *science of team science*-the study of how science teams form and operate-has come out of two primary fields: organizational psychology and translational medicine. The science of team science has been an area of investment and active research since the late 1990s (Stokols et al., 2008; Hall et al., 2018). Although theories and knowledge of teams have developed in parallel in these fields, they agree on this: trust, communication, data and resource sharing, accountability, and cooperation are essential to reaching shared goals.

This article considers networks generally (e.g., interconnected waterways or coordinated data collection systems), but focuses most on *social networks,* within which humans or organizations are connected. Social networks are the self-organizing webs of social actors (individuals, groups, or formal organizations) and the relational connections that bind them. Although the structure of social networks has long been studied by the fields of anthropology and sociology, recent advances in computing have made it possible to study complex social networks in increasing detail and led to the development of more specialized sub-fields and breadth of fields using network analytic methods. Network analysis can be used to measure the formation, structure, performance, and resilience of networks of networks through time (Wang, 2016; Hall et al., 2018).

In practice, entire networks can make connections with other networks by forming new and beneficial connections between individuals across networks. This results in a network of networks, or a collection of two or more unique networks, each defined by social, geographic, and temporal boundaries and distinct types of connections.

Hereafter, teams, networks, and networks of networks are considered entities along a continuum of size (number of individual actors) and structural complexity (connections relating individuals). The value of the relationships between people is determined by the alignment of the connections with the objectives of the team, network, or network of networks.

Teams

What is a team?

Many drivers of change in inland waters-climate warming, pollution, hydrologic modification, and restoration-are large, complex, and interconnected; thus, responding to these changes requires broad interdisciplinary expertise. At the same time, advances in technology and data collection, compilation, and harmonization have given us more information about water than ever before (Cheruvelil and Soranno, 2018). These facts have contributed to the rise of *team science* in limnology-science that is conducted in a collaborative, interdependent manner among individuals with a wide range of backgrounds, skills, and expertise.

The potential for transformative science is maximized in research teams where individuals from different domains integrate their collective knowledge into new ideas and methods that go beyond those of an individual discipline (Stokols et al., 2008). The need for innovation across disciplines and the rise in team science is reflected by the increased funding of multi-principal investigator proposals for centers and research that are inter- or trans-disciplinary (National Science Foundation, 2013).

Sharing and integrating information across disciplines requires an environment of learning, and openness to learning requires trust (Tebes et al., 2014; Salazar et al., 2012). Successful and sustainable teams, therefore, are those teams that foster psychological safety–the shared belief among team members that interpersonal risk (e.g., proposing novel or risky ideas, asking clarifying questions, expressing lack of knowledge) will not come at a price (Edmondson, 1999). Psychological safety and trust are essential for team members to maintain the ability to interact and influence one another, to practice accountability, and to feel a part of a social entity.

Defining a successful scientific team is somewhat elusive, as the number of publications or citations are not holistic measures of success; success includes the effects on *science* and the *individual.* Morale and commitment to the team are additional ways to measure success; team members with high morale are committed to the cause and willing to do the work necessary for successful outcomes (He, 2012). Below are suggestions for how to foster these characteristics in your own science teams.

Methods for effective teams

Trust is the foundation of successful social connections (i.e., human relationships) that foster creativity, information exchange, and scientific advancements. Teams can intentionally build trust over time by creating shared experiences and by offering training in the interpersonal skills required to create positive relationships. Hierarchical relationships are inherent in many science teams, but activities that foster empathy or demonstrate diverse abilities and communication styles can build psychological safety among members with different amounts of power.

The ability of teams to perform a variety of tasks is not related to the maximum or mean individual intelligence, but rather on features like social intelligence (Woolley et al., 2010). Emotional intelligence or social sensitivity can be built through open discussions and recognition of differences in personalities, philosophies, backgrounds (Cheruvelil et al., 2014), and by practicing

Box 1 What differentiates a team from a network?

Everything from a tight-knit group of five scientists to a large, multi-institutional collaboration with hundreds of contributors might be called either a "team" or a "network." We want to distinguish between the two terms and focus our discussion on how viewing large teams as networks can help improve their management and development. All teams can be characterized as a network, but many networks are not teams because they may or may not be striving for a common goal, may not have a shared identity, and the boundaries of membership are less clearly defined. Because of a diversity of meanings and cultural context for the terms "team" and "network," it is important to technically define and distinguish between a team and a network.

Small groups, something less than 12 people, have the advantage of being able to more easily keep all members engaged, maintain communication between all members, and create clear roles and responsibilities for members.

Small work groups (teams) have the maximum number of connections per actor. Every actor has a connection to all other actors. This makes them unique networks because all nodes connect directly to each other.

The ideal size for a work team is 5–7 people because as teams get larger, they require more complex coordination and are more likely to become less productive because of social loafing (Forsyth, 2009). As small groups grow, dynamics begin to shift, and once teams get beyond 5–7, they often break into sub-teams of 3–6 members. As teams grow beyond half a dozen or so, they start to display new patterns, where members begin to work more closely with some members than others, have less frequent communication with the entire group, and have more complex work plans. It is at this stage that the concept of a network and the application of social network analysis to understand structure and function become useful.

Larger work groups (networks) have variation in the number of connections per actor. Actors have connections with one to five other actors. Darker shaded nodes indicates higher degree (number of connections with other nodes).

As the complexity of inland waters science grows, so too does the size and complexity of the groups needed to address them. With greater group size, network patterns begin to appear. In the networks that take on complex projects, much of the actual work tends to get accomplished in smaller work groups (or teams). Even though the social entity is a large network, the work group is likely to be a small team of 3–6 people where all members know each other, interact frequently, and have a well-defined scope of work in which each member has clear roles and responsibilities. The team or work group is a building block of the larger network structure.

Although the threshold at which a group transitions from a team to a network will vary, in this article a specific threshold is given. We distinguish and define *teams as groups of fewer than approximately 12 people and networks as groups of approximately 12 or more people* because increasing group size reduces the ability of individual members to interact with, influence, and hold accountable every other member, and to perceive belonging to the group.

reflexivity through sharing personal experiences and perceptions (Read et al., 2016). Allowing time to build personal connections and interpersonal skills will motivate commitment to the team and foster trust that all members are working toward the success of the team.

Box 2 Social network analysis.

Social network analysis uses mathematical methods to characterize the structure of networks in terms of edges (connections) and nodes (social actors, such as individuals or organizations). Network analysis is also referred to as graph theory (Wasserman and Faust, 1994).

A group of any size greater than three can be analyzed according to the methods below; however, we make a case in this article that more meaningful distinctions in network structure begin to appear when the number of actors in the group exceeds approximately 12.

Average Degree: In any network, degree is the number of edges (connections) that exist for a node (actor). The average degree describes the network as the average number of edges per node, or connections per actor, in the network. Higher levels of average degree are associated with more robust networks (Martin and Niemeyer, 2020).

Centralization: Networks that have a few actors with very high degree (many connections), while most of the network has actors with low degree (few connections), are described as having high centralization. These types of network graphs have a star-like structural pattern.

Closure: One common trait of networks is whether, in any triad, all three possible connections exist (a closed triad). Closure measures the proportion of all closed triads present as compared to all potential closed triads.

Degree Distribution: The degree distribution refers to whether connections among actors are evenly spread across actors in the full network, or whether some actors have very high degree (many connections) while others have very low degree (few connections).

Density: The proportion of connections that exist in a network to all possible connections that could theoretically exist. Smaller networks generally have higher density than larger networks.

Reciprocity: The likelihood of mutuality, or bi-directional, positive actions within a social network. When positive actions occur in both directions between two actors. Reciprocity is an important factor in building and strengthening sustained social connections.

Although diversity in the experiences and information each member brings to the team can foster creativity and interactions among group members that boost team performance (Hoever et al., 2012), diversity in values can create conflict and division of team members that creates an environment of distrust and low team performance (Jehn et al., 1999). Successful teams are both diverse and socially sensitive enough to manage their own diversity. Consider and make efforts to balance diversity in career stage, member incumbency (60–70% incumbent), domain expertise (>1 person per domain), communication mode, and viewpoints (Cheruvelil et al., 2014).

To feel invested in a team, members must have a shared understanding of team purpose and goals, and how they directly contribute to success (Bennett et al., 2018). Successful execution of science by a team depends on clear roles and responsibilities, management of tasks, and a means of accountability. The approaches used to manage and accomplish work can vary greatly within and across disciplines and cultures, and guidance for collaborative scientific management approaches have been defined (e.g., collaborative manuscript management sensu Oliver et al., 2018). The management approach selected will in turn influence how roles and responsibilities are assigned and tracked, which is essential for an accountability.

Effective communication allows the sharing and building of knowledge and trust, but can be difficult to establish and maintain, especially in new teams. Establishing communication includes establishing group norms (e.g., taking turns in group discussion and normalizing disagreement); effective meeting logistics that support all members seeing and hearing one another clearly; and the use of break-out groups to increase participation and engagement. Effective communication also includes having difficult discussions, and which can be enhanced by practicing skills related to recognizing and managing conflict (Read et al., 2016). The combination of shared expectations, optimizing the meeting logistics, and training in facilitation or conflict resolution all support effective communication and increase the likelihood of success of science teams.

Team science in inland water research

The need for team science in inland waters research is becoming more prevalent given an increasing number of disparate data sources, expanding spatial and temporal scales of interest, and new cross-scale and cross-system integrative approaches. Likewise, team science as an explicit research focus within limnology is also growing increasingly common.

Within the lake-centric part of limnology, the science of team science is being practiced and contributed to through graduate student training programs (Read et al., 2016), collaborative approaches to scientific writing (Oliver et al., 2018), the formation and maintenance of high performing science teams (Cheruvelil et al., 2014); recommendations around scientific reward structures (Goring et al., 2014); and around data collection and macrosystems ecology (Soranno et al., 2015).

Within river and wetland research, team science is less prevalent. However, new collaboratives around data sharing, such as a global network of intermittent rivers, have made mention of the importance of team science for accomplishing their goals (Datry et al., 2016). What is evident is that inland water research is moving into an era of being purposeful about the formation of these teams.

Team case study: Projections of climate change effects on Lake Tanganyika (CLEAT)

CLEAT is a transdisciplinary collaborative team with a goal of understanding how climate affects the East African Lake Tanganyika, the fisheries sector, and to make projections and recommendations for long-term sustainability. The project was funded through the Ministry of Foreign Affairs of Denmark. An initial team was formed for the proposal, but the team configuration and membership

evolved through time, which proved both a strength and a challenge to accomplishing project goals. A major challenge was bringing people together from different cultures, most of whom had not worked together, nor on this lake, before.

Structure of the team: *International, multicultural, medium*
- 13 individual members from three countries.
- Small core leadership team of three people.
- 23% early career scientists.
- Limnologists, modelers, fisheries consultant, social scientists.

Rules of the team: *Collaborative, transdisciplinary science*
- Leadership provided by small core of senior scientists.
- The scientific challenges and unique location motivated team participation.
- Project policies were collaboratively developed early and emphasized values, outlined authorship expectations, and had guidelines for data sharing.
- Emphasis was on building community through inclusiveness, communication, flexibility, and transparency.
- Entire team in-person meeting and social activities were important for building trust and social connections at the beginning of the project.

Outcomes of the team: *Publications, new fisheries policies*
- Multiple scientific publications.
- International media coverage of project.
- Engagement with policy makers and local organizations; additional non-project scientists and graduate students became involved directly or with related projects.

Networks

What is a (social) network?

A social network is a self-organizing web of social actors (individuals, groups, or formal organizations) and the relational connections that bind them. Because peer reviewed publications are increasingly produced by larger groups (Wuchty et al., 2007) distributed across more institutions (Jones et al., 2008) and political boundaries (Wagner et al., 2015), it can be useful to consider social network analysis and network properties to understand and improve group function.

The overarching structure of connections in a network determines how easily information or resources can flow or pass through a network, which then influences the ability of the network to accomplish work like creating new knowledge or coordinating collective action (Henry and Vollan, 2014). Network traits are defined by the pattern of connections between social actors (also referred to as nodes), and determine how easy it is for networks to share and create knowledge, adopt new knowledge, and coordinate for collective action (Henry and Vollan, 2014; Krebs and Holley, 2006; Phelps et al., 2012).

Network structures arise out of a variety of constraints, both physical and social, and are determined by the purpose of the network and the actions of individuals comprising it (Phelps et al., 2012; Marin and Wellman, 2011). Network structures are also shaped by individual choices and behaviors: actors may position themselves in a centralized role in order to retain or withhold information or power, or in order to aggregate information for the benefit of the outer actors or groups (Barabási and Albert, 1999; Henry, 2011). Social actors are more likely to form connections with those closer in geographic proximity, to other actors that are similar, and to actors that are connected to other actors (Barabási and Albert, 1999; Guimera et al., 2005; McPherson et al., 2001; Jasny et al., 2019). Network structures are also influenced by the social rules of engagement (e.g., normative expectations to share data freely) or required relationships (e.g., student committee membership), or the knowledge-based tasks networks have formed to achieve (Box 3) (Marin and Wellman, 2011). For example, when funders require a memorandum of understanding among a group of local agencies in order to be eligible to receive funding, the funder is making an intentional play to create network connections between a diverse set of actors. Individuals and organizations are only able to maintain a limited number of connections, and therefore, as new members join, existing connections may drop off or become less frequent connections, thus changing the patterns of connections in the network.

Box 3 Knowledge-based tasks for networks.

Network structures have differential effects on the ability of the network to accomplish various *knowledge-based tasks*:

- Flow of information or resources across the network
- Adoption of knowledge from one field of practice to another
- Integration of knowledge across fields
- Creation of new knowledge or innovation
- Solving complex problems
- Engaging in coordinated action
- Building capacity to mobilize for and engage in collective action

Table 1 illustrates how network structures change based on degree, density, centralization, closure, and modularity. These structures have varying opportunities and challenges for collaboration, knowledge sharing, and team performance (Table 1). See *Further Reading* for more detailed descriptions of how network structures enable or hinder creation, transfer, and adoption of knowledge and build capacity for coordinated or collective action.

Methods for effective networks

The considerations for forming effective teams also apply to forming effective networks. As in teams, trust is the foundation of network connections and plays a central role in the formation of relationships in a network, thus influencing the network structure (Phelps et al., 2012). Trust is the basis for the formation of individual connections, larger subgroups, as well as how knowledge and resources flow through a network (Levin and Cross, 2004). In addition, social network analysis can be used to help networks evaluate their capacity for knowledge-based tasks (Box 3) over time and understand how established processes and norms are supporting or degrading the intended network structure and achieving network tasks.

Some tasks are well suited to be parallelized and performed simultaneously, and in this case, the network structure and the assignment of work can be optimized to support this work. Research tasks such as data collection, data aggregation, modeling, and writing tasks may be best completed by a number of sub-groups (or *teams*) within the network and coordinated by a few lead scientists. Mapped as a network, this would resemble the hub-and-spoke network, where the lead scientists are acting as the hubs between teams.

When the goal of a network is to share and integrate knowledge, or create new knowledge and innovations, then a higher density core-periphery network may be more suitable. Consider the intensive, multi-day scientific events known as "annual retreats" or "workshops," where the goal is to integrate past work, iterate on knowledge, and create or revise a group vision that might be held by dozens of participants. These multi-day events could be used to cultivate greater density in the network and cultivate trust and team identity, by maximizing the opportunities for all network members to share information and to encourage the formation of social connections among participants.

When networks seek to make progress with specific tasks such as modeling or data analysis, while simultaneously advancing knowledge and innovation, then the network communication structure should allow for frequent within-team communication, with less frequent (but regular) opportunities to seek advice and share preliminary results. The corresponding network structure that optimizes both for accomplishing independent, parallelized, or sequential tasks, while advancing knowledge generation, is a multi-hub network.

Social network analysis can be used to strategically intervene when parts of a network—or single actors—fail. If a single actor becomes overwhelmed with requests for time or advice and is unable to perform their tasks because of collaboration overload (Cross et al., 2016), then that actor may become a limiting factor to achieving shared goals. In network structure, this would appear as high centralization, and the solution to this would be to encourage new connections to form to reduce the degree (number of connections) that are reliant on a single actor in order to accomplish their work.

Networks in inland waters research

As the scale and scope of scientific research has expanded, so too have a variety of networks that focus on aquatic systems. Many of these networks share overarching research objectives but vary in their approach to accomplish knowledge-based tasks, which is in turn reflected in the network structure. Three tasks that aquatic networks appear to focus on singularly or in combination include (1) coordinated data collection and flow of information, (2) creation of new knowledge, and (3) building and engaging in collective action.

Networks designed around consistent data collection tend toward a decentralized hub-and-spoke model (Table 1), in which data sharing is the primary connection between actors, and governance and resource sharing from a central actor sustains the network. Government-sponsored inland waters networks in the United States that are designed for coordinated data collection and information flow include the National Ecological Observatory Network; U.S. Environmental Protection Agency National Aquatic Resources Assessments of lakes, streams, and wetlands; and the U.S. Geological Survey (USGS) National Streamgage Network. Information flow and communication occurs in support of the task of data collection. Information content from data collection flows from the less connected, outer actors toward the central actors, and governance (e.g., protocols, standards) tends to flow from the central actors to the outer actors. These networks have a strong emphasis on gathering data rather than on knowledge integration or new knowledge creation. Highly managed protocols and coordinated sampling lead to high quality datasets that are comparable across space and time, which facilitates data analyses by users of the network data.

In contrast, networks focused on creation of new knowledge tend to have core-periphery structures (Table 1), and the connections that bind the actors exist to optimize communication and resource sharing. An example of such a network is the Global Lake Ecological Observatory Network (GLEON; see case study below). These networks have more emphasis on bringing people together to integrate knowledge globally and for the creation of innovations in aquatic science and technology. The structure of the network, for which connections between actors are based on voluntary and non-standardized communication and resource sharing, heavily relies on trust. Knowledge networks with core-periphery structure may evolve more rapidly through time as compared to data collection networks, as new teams are created, new social connections are formed, and others senesce. Community-built tools and open science approaches are complementary to the core-periphery network structure and are a hallmark

Table 1 Definitions, idealized example structures, attributes, and real-world examples of teams, networks, and networks of networks. Darker shaded nodes have higher degree (number of connections with other nodes), while lighter shaded nodes have lower degree.

Name, size, and description, idealized structure	*Traits and ideal uses (see Box 2 for definitions of traits)*	*Examples*
Team: 3–11 people; small, tight knit collaborative group. 	Average Degree: Moderate (3–6) Density: Moderate (>0.50) Closure: High (>0.60) Reciprocity: High (>0.50) Centralization: Low Modularity: Low Well-defined scope and objectives that can be accomplished by a small group	Projections of Climate Change Effects on Lake Tanganyika Team (CLEAT, see case study below)
Isolated Teams: More than 12, collection of small teams of variable size. No ties or very weak connections across teams. 	Average Degree: Low-moderate (1–3) Density: High within teams, low across full network Closure: High within teams, low across network Reciprocity: High within teams, low across network Centralization: Low within teams Modularity: High Work completed by separate teams, requires little coordination	Co-author teams contributing separate articles to a journal issue

Small Network: A single network including12–24 members in which all individuals have at least one connection. 	Average Degree: Low-moderate (1–3) Density: Low Closure: Low Reciprocity: Low Centralization: Moderate Modularity: Low-moderate	Grant-funded team with several co-investigators and their labs, requiring strong integration between groups
Centralized Network (Baran, 1964). Variable size, larger than 12 Also known as a *hub-and-spoke network* (Krebs and Holley, 2006). 	Average Degree: Low Density: Low Closure: Low Reciprocity: Low Centralization: High Modularity: High Used when a high level of coordination or standardization between actors is needed. The key feature of this network is the power held by the two key actors and the lack of connectivity among other actors. The hubs control information flow out to the edges of the network. This is an efficient network (e.g., emergency response) but vulnerable if either of the hubs is taken out of the network or intentionally limits information flow	U.S. Geological Survey National Streamgage Network National Science Foundation National Ecological Observatory Network U.S. Environmental Protection Agency National Lakes Assessment

(*Continued*)

Table 1 (Continued)

Name, size, and description, idealized structure	*Traits and ideal uses (see for definitions of traits)*	*Examples*
Decentralized Network: Variable size, larger than 12 Also known as a *multi-hub network* (Krebs and Holley, 2006) 	Average Degree: Low Density: Low Closure: Low-moderate Reciprocity: Low Centralization: High Modularity: Moderate This kind of network may be formed initially for data collection or a more centralized, standardized purpose, but evolves to decrease centrality and increase density and closure. This network has a higher capacity to share knowledge and resources and be more resilient to loss of one of the hubs because there is more closure and less centralization (Baran, 1964)	National Science Foundation Long Term Ecological Research
Core-periphery: Typically two dozen or more, tightly connected core with sparse connections to the outside members (Borgatti and Everett, 2000). 	Average Degree: Low in periphery too high in core Density: High in core, low in periphery Closure: High in core, low in periphery Reciprocity: High in core, low in periphery Centralization: Moderate-high Modularity: Variable These networks are more resilient (due to the dense connections in the core), represent network maturity, and may improve the coordination capacity of the network (Krebs and Holley, 2006; Csermely et al., 2013) Useful for knowledge generation and innovation. Due to the centralization and density in the core, this type of network has increased capacity to move knowledge and resources across the network, coordinate collective action, and be resilient to change (Csermely et al., 2013)	Global Lake Ecological Observatory Network

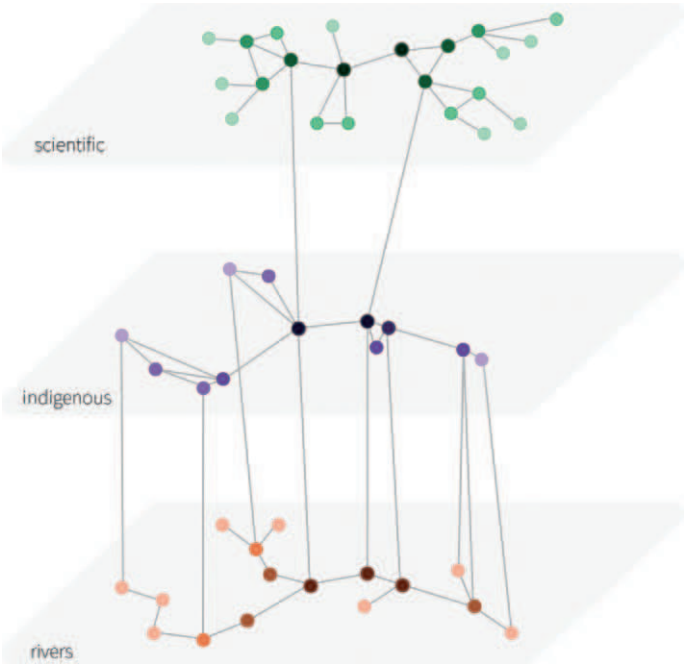
Small world networks: Small, densely connected groups with sparse connections between groups.		Average Degree: Moderate (especially within sub-groups) Density: Low across full network, high within clusters Closure: Low across full network, high within clusters Reciprocity: Low across full network, high within clusters Centralization: Moderate-high Modularity: High Used to coordinate and share information across sparsely connected teams or communities. Weak ties connect the groups to each other	American Society of Limnology and Oceanography

(*Continued*)

Table 1 (Continued)

Name, size, and description, idealized structure	*Traits and ideal uses (see for definitions of traits)*	*Examples*
Multi-team systems: A few dozen to hundreds of members, teams operate in parallel, and each has a unique focus and scope, but are all contributing to common overarching scope. Teams may be doing work that is dependent on the results from other teams, as indicated by the arrow 	Average Degree: Moderate (especially within sub-groups) Density: Low across full network, high within clusters Closure: Low across full network, high within clusters Reciprocity: Low across full network, high within clusters Centralization: High Modularity: High Used with a large and complex scope of work, requiring either specialization within small teams, or distribution of a large scope of work over many teams. The work of all teams contributes to a larger goal than the scope of each individual team. We define a multi-team system as a *network of networks* because of the separation of teams which may vary in size, network structure, and coordination with the larger goals of the network	Human Genome Project

Multi-level networks: Layers or levels represent unique types of network connections.	All network metrics (average degree, density, closure, reciprocity, centralization, and modularity) vary across the layers. Typically, contacts between layers are highly centralized and not highly dense, but this too varies by the purpose of the network connections across layers. Used to connect existing networks to each other. Each network has a unique purpose and types of ties (e.g., monitoring, governance, ecological). The structure of each layer is determined by its mission and context, ties are formed between layers to facilitate creation of something no layer can accomplish alone	Indigenous Observation Network



of some inland waters networks (Read et al., 2018). New connections built within this type of network are critical to developing new users of data and tools.

Finally, there are networks that focus on data collection, knowledge creation, and building capacity for collective action. The National Phenology Network has a focus on data collection and information sharing, but also on building the capacity to mobilize community scientists for collective action in support of the network's goals. Quality control of data is less emphasized as compared to the hub-and-spoke model described above. In contrast, the Long Term Ecological Research (LTER) network model not only functions as a hub-and-spoke network, but also incentivizes connections between different actors (LTER sites) via targeted cross-site funding. In this model, distributed place-based research stations collect high-quality, standardized data that are used primarily for pre-identified locally scaled research questions but the data are also publicly accessible. Within each location, knowledge creation, communication, and trusting social connections comprise the network connections.

Network case study: Global Lake Ecological Observatory Network

The Global Lake Ecological Observatory Network (GLEON) is a grassroots network of scientists, sensors, and data. The network has been funded by the U.S. National Science Foundation and various private foundations over time. GLEON is a core-periphery network that seeks to integrate knowledge across fields, create new aquatic science knowledge and innovations, and provide an optional platform for data sharing. GLEON seeks to enable connections between as many members as possible; however, also has a more sustained core of members with higher density, and with more sustained participation in the network through time.

Structure of the network: *Core-periphery*

- 500 individual members from 49 countries.
- 30% students.
- 60 member *lakes* from 34 countries on six continents.
- Members from academic, public, non-governmental and private institutions.

Rules of the network (excerpted from https://gleon.org/about/vision-and-mission): *Educational, collaborative, scientific*

- Steering Committee, Student Association, and Collaborative Climate Committee guide the long-term strategy, student services, and collaborative culture and practices of the network.
- Annual meetings rotate geographically to encourage new membership.
- Interdisciplinary lake science.
- Foster an empowered, diverse membership and facilitate informality, collegiality, and collaboration.
- Spark curiosity and share ideas, expertise, and data.
- Use transparency in decision-making, communication of results, tools, and products.
- Prioritize professional development of members.

Outcomes of the network: *Global lake research, technical and scientific advances, team-science fluent membership*

- Open data and community-built tools (Read et al., 2018).
- Effective pipeline for student training and career opportunities.
- 329 publications attributable to network collaborations between 2005 and 2020.
- Technical innovation resulting from GLEON-based collaboration between private sector and academia, driven by research needs.
- Training in team science (Read et al., 2016), sensor technology, data processing, and modeling skills.
- International networks for future opportunities (jobs, research collaborations).
- Appreciation for different cultures.

Networks of networks

What is a network of networks?

Beyond teams and networks, science frequently requires building connections between networks with different purposes and disciplinary alignment (e.g., monitoring, governance, analysis). These are networks of networks: interconnected networks where each layer is a unique network defined by social, geographic, and temporal boundaries and distinct purposes, e.g., governance, data gathering, information sharing. Networks of networks are often called multilevel networks (Lazega and Snijders, 2015; and see Table 1).

All of the knowledge about teams and networks described in previous sections also applies to the structure of networks of networks, but networks of networks are recognized to have uniquely transformative capabilities, and are being invested in by scientific agencies as a growth area (e.g., National Science Foundation AccelNET program).

By definition, networks of networks are interconnected by a small number of connections across networks; this structure makes them more vulnerable to the loss of those cross-network connections.

Methods for effective networks of networks

The process of forming networks of networks varies greatly depending on the networks that need connections to each other. Because networks of networks are composed of networks and teams, and rely on connections between actors through which knowledge and resources are shared, we speculate that the best practices for teams and networks also apply to networks of networks. However, in addition to the previous guidance, we hypothesize that the time needed for leadership and maintenance of key connects (cross-team, cross-network) scales proportionally with the complexity of the network.

Small world networks are an emergent property of human communities: because no explicit effort or design is required to build a small world network, the only prerequisite is a minimum number of individuals with opportunities to interact and form connections. In contrast, multi-team systems are used under moderate to highly organized circumstances, and in some cases to achieve very specific, coordinated outcomes where the work of one team is dependent on the previous work of another (see Table 1).

Multilevel networks form when independently-created networks become connected by relationships between individuals *across* networks; thus, these network of networks structures can be formed only when two or more networks already exist, and then become connected. The way that meaningful connections across networks are made and sustained are studied most frequently in the fields of environmental governance and resilience (Hahn et al., 2008; Hileman and Lubell, 2018). Thus, theories and applied knowledge about how best to design, manage, and study networks of networks are just beginning to appear in the literature (Brass and Borgatti, 2019; McGee et al., 2019). One of the unique features of networks of networks is that where any individual network structure might be resilient, the dependency of networks of networks on a small number of inter-network connections can make them vulnerable (Das et al., 2017). Because networks of networks are connected by actors, the loss of key actors or a connection can create a cascading failure. Networks of networks that have strong interdependent coupling may be less resilient than individual networks.

Support and training for the development of networks of networks can be found through organizations sponsoring inland waters research, including the National Socio-Environmental Synthesis Center or the USGS Powell Center.

Networks of networks in inland water research

Multi-team systems may be the most common form of networks of networks found in inland waters research. At this time, direct study of multi-team systems pursuing inland waters research objectives is not available, but it is likely that this network of network structure is present in the aquatic sciences: most natural science researchers in Norway conduct about 20% of their work in what would be described at least as multi-team systems (Kyvik and Reymert, 2017).

Multi-level networks can also be found in the field of inland waters. As a Federal agency, the USGS is a model of a national network of networks, as it incorporates a diverse set of networks including the National Water Quality Monitoring Network, the National Streamgage Network, the National Phenology Network, and others which have direct relevance for aquatic science; but the network of networks also features looser affiliation with other networks within USGS including volcano and earthquakes observatories. These networks within a network have been created within a bureaucratic framework and under an earth-science mission; largely, connections between the network are informal and consist of information sharing between a small number of individuals each embedded within one of the networks.

In contrast, the Indigenous Observation Network (ION; see case study below) is a multi-level network that has been created under a less formal setting: ION links an intertribal watershed council with a standardized community-based monitoring network and an indigenous knowledge network; this network of networks is designed for the co-production of new scientific knowledge. This multi-level network relies heavily on social relationships between a small number of individuals who span the three network layers.

The Consortium of Universities for the Advancement of Hydrologic Sciences, Inc. (CUASHI) is a network of networks that incorporates international partners and emphasizes integration of knowledge, creation of new knowledge, and data sharing. CUASHI's goal is to catalyze water-related research across institutions and disciplines. Institutions, rather than individuals, are members; currently there are more than 140 member institutions, with 20% from outside the United States. CUASHI primarily maintains infrastructure to support collaborative research and data sharing, but also provides training opportunities and hosts an annual meeting.

In the aquatic sciences, there is a growing demand for the creation of networks of networks beyond the naturally occurring small world networks, to multi-level networks in which layers are connected through formal linkages that can serve as "force multipliers and connectors to advance science." Recent investments by the NSF (e.g., the U.S. National Science Foundation's AccelNet Program and Coastlines and People Program) focus on connecting people, rather than infrastructure, in recognition of the importance of human relationships for creating networks of networks. The goal is to bring together networks that might not normally interact because the scientific context differs substantially. This approach is gaining ground within the aquatic sciences, with calls to strengthen connections between remote sensing scientists and limnologists to better understand lake ice dynamics, for example (Sharma et al., 2020).

Network of networks case study: Indigenous Observation Network

The Indigenous Observation Network (ION) is a multi-level network of networks that connects scientists, community monitoring groups, and indigenous knowledge networks. The ION links community-based water-quality and permafrost monitoring programs

that produce data from the Yukon River Basin in the United States and Canada. The Yukon River Inter-Tribal Watershed Council (YRITWC), an Indigenous non-profit organization, collaborates with the USGS, and the University of Alaska-Fairbanks to implement the ION. The ION was first established in 2006 to measure baseline water quality in the Yukon River Basin and has continued to collect hundreds of surface water samples annually to track effects from changing climate and land use. Today, ION has sampled >200 sites across the Yukon River Basin spanning the United States and Canada.

Structure of the network of networks: *Multi-level*

- Yukon River Inter-Tribal Watershed Council represents 76 Tribes and First Nations located in the Yukon River Basin that have signed the inter-tribal accord.
- USGS and YRITWC have agreed to collaborate on monitoring and science activities through a memorandum of understanding.
- U.S. Environmental Protection Agency—Indian General Assistance Program (EPA-IGAP) funds the surface water sampling of community members in the United States that participate in the program.

Rules of the network of networks: *Quality and conservation*

- Tribes and First Nation members of the YRITWC are the governing body committed to preserving and protecting the environmental quality of the Yukon River.
- Standardized training, field methods, quality assurance, lab analysis, and data publication is practiced across sites and by all community technicians.
- YRITWC consults with participating members on new site selection.
- Outside access to community members and collaborators is restricted by USGS and YRITWC project personnel so as to avoid stakeholder fatigue.

Outcomes of the network of networks: *Co-production of knowledge, conservation, and community engagement.*

- Research on long term water quality trends and other climate change effects experienced by Indigenous communities (Toohey et al., 2016).
- Demonstrated the generation of accurate, precise, and reliable water quality data by Indigenous community-based monitoring network.
- Provides rich opportunities for USGS engagement with Indigenous stakeholders.
- Provides opportunities for students and community members from traditionally underrepresented groups to engage in science, technology, engineering, and math (STEM) activities.
- Communities have greater trust in ION data than that collected by other entities because it is being collected by community members (Wilson, 2017).
- The ION allowed for deeper integration of Indigenous Knowledge with western science to understand climate change effects on this relatively under-studied (from a scientific perspective) region (Herman-Mercer and Schuster, 2014) by building long term trusting relationships.
- Communities have used the ION program to establish baseline monitoring and assessment required to establish conservation districts that further the YRITWC goal of preserving the environmental quality of the Yukon River.

Conclusion and synthesis

Trust is essential to the formation of human relationships, and these relationships in turn are the basis of meaningful connections in teams, networks, and networks of networks. Communication, data sharing, resource sharing, and coordination are impossible without trust; and without those functions, groups at all levels of organization cannot accomplish knowledge-based tasks including sharing and integration of knowledge, innovation, collective action, and more. The intentional formation of teams and networks, informed by the literature on the science of team science and social network analysis, can result in more productive and sustained performance. Creating and maintaining successful teams, networks, and networks of networks is dependent on both the structure and the culture of the entity.

Increasing the commonly-understood attributes of high performing teams and the ideal uses of various network structures will allow societies, universities, government agencies, and funders to improve team science and network building. A reward structure that recognizes and values the successful creation of teams and networks to accomplish inland waters research can incentivize more emphasis of team and network development in inland waters research. Because many reward structures focus on the products rather than the processes of team science, training for the social-emotional skills required to lead or participate in successful teams, networks, and networks of networks are not commonplace in natural and physical sciences graduate programs, and there are multiple generations of inland water science professionals working in teams or networks without such training. Outside of a few specialized graduate training programs that are limited in size and offered irregularly (e.g., NSF Research Traineeship program, GLEON), there are no common pathways for inland water professionals (particularly those outside of graduate school) to receive training geared toward improving team science outcomes.

At the writing of this article, networks of networks remain the least understood of the entities examined in this article. However, as humans face ever increasing global-scale environmental challenges related to water quality and availability, new connections across communities, research, governance, and management groups could help minimize the societal and environmental effects.

An understanding of the basis of teams, networks, and networks of networks, which all rely on robust, trusting human connections, will be essential to adapting to a changing planet. Inland waters research—and geosciences more broadly—can benefit from the knowledge acquired through social science research, and the integration of this to team and network formation; and we hope that this knowledge will contribute to meeting the global environmental challenges facing inland waters today.

Knowledge gaps

- Methods for developing and maintaining specific network structures and rules of engagement to accomplish various knowledge-based tasks.
- The effect of transdisciplinarity and convergent science on teams, networks, and networks of network structure and function.
- Methods for development and maintenance of multi-level networks and networks of networks.
- Rules of engagement for networks and networks of networks of various structures and purposes.
- Best practices for evaluating the success of teams, networks, and networks of networks outside of product-based metrics.

Glossary

Citizen science Participation of non-scientists in the process of scientific research, which may include the development of research questions and data-collection protocols; data collection, processing, and analysis; and interpretation and application of results. The term "citizen" here does not refer to the legal citizenship status of participants, but rather that participants are not professional scientists. Alternative terms include community science, participatory science, lay science, and public participation in science.

Crowdsourcing Leveraging a large unidentified group of people to perform predetermined tasks; a type of citizen science.

Social media Internet applications that allow users to create and share media and build connections with one another.

Introduction

Scientists and managers working on inland waters are increasingly recognizing the value of engaging diverse audiences. Participation of non-scientists from a variety of perspectives, places, and backgrounds in conservation research and implementation has been shown to have several benefits. For example, public participation in conservation research can result in more relevant research questions, can produce a richer set of data and knowledge, and generate innovative solutions to complex conservation problems. Further, public participation can increase scientific literacy and public support for research and conservation work.

Engaging broad and diverse audiences in conservation research and implementation requires the use of innovative communication and engagement strategies. Presently, funding agencies and foundations expect researchers and managers to incorporate public engagement into their work (National Science Foundation, 2015). Improvements in public access to, and comfort with, the necessary technology required for public engagement is also contributing to the growth in public participation. This is because technologies such as smart phones, web applications, and widely available access to the internet allow efficient data collection and transmission, validation of public observations, and integration of electronic sensor data, such as stream flow trackers, that can be collected and uploaded by public participants (Catlin-Groves, 2012; Dickinson et al., 2012). Rapidly expanding methods for public engagement in inland water research and conservation include citizen science, crowdsourcing, and the use of social media.

In this chapter, we explore the application, potential, and best practices for using citizen science, crowdsourcing, and social media to advance our understanding and conservation of inland waters.

Citizen science

Citizen science defined

Citizen science can be defined as "participation by the public in a scientific project" (McKinley et al., 2015). More descriptively, citizen science generally involves the participation of non-scientists in the process of scientific research, which may include the development of research questions and data-collection protocols; data collection, processing, and analysis; and interpretation and application of results (Silvertown, 2009; Miller-Rushing et al., 2012; Crain et al., 2014; Sanz et al., 2014; Thornhill et al., 2016). Science-based activities that do not result in new scientific knowledge, or those where results are not shared beyond the participants, are not typically considered citizen science. Such activities include educational or teaching activities where the outcome is known (Miller-Rushing et al., 2012).

Of important note are recent concerns raised about the implications of the term "citizen science," in that it can be interpreted as limiting participation to those holding legal citizenship in the country where the project is based (Eitzel et al., 2017). The word "citizen" in the case of citizen science is meant to distinguish amateur or non-professional participants from professional scientists, rather than the legal definition; however, some programs have chosen alternative labels, including community science, public-engaged science, participatory sensing, or lay monitoring.

History of citizen science

Amateurs (defined here as anyone who is not a professional scientist, regardless of level of expertise, Miller-Rushing et al., 2012) have long contributed to scientific endeavors. Throughout recorded history, people have asked questions and cataloged observations of the world around them (Miller-Rushing et al., 2012). As recently as just two centuries ago, nearly all science was conducted by people who made their living in some other way (Silvertown, 2009). As science professionalized, fields such as ornithology, archeology, and astronomy, where observational skills are equally or more important than access to expensive equipment, continued to benefit from amateur contributions (Silvertown, 2009; Dickinson et al., 2010). For example, public monitoring of bird populations can be traced back to the eighteenth century in Europe (Greenwood, 2007), and the Christmas Bird Count run by the National Audubon Society in the US has taken place every year since 1900, providing a vital source of ornithological data that allows conservationists to study the long-term status and health of bird populations (National Audubon Society, 2020, Fig. 1).

Citizen science has grown rapidly since the mid-twentieth century, an expansion that may be attributed to a combination of factors, including "environmental tragedies, shifts in policy making structures, affluence in society, governmental budgets, and expanded interests in partnerships" (Stepenuck and Genskow, 2018). The term "citizen science" came into broad use in the mid-1990s (See et al., 2016), including publication of a book of the same name (Irwin, 1995) that discussed the integration of citizen knowledge and scientific knowledge, and the use of the term by Cornell's Laboratory of Ornithology as an alternative to the phrase "public participation in scientific research" (Bonney, 1996). This growth of citizen science can also be observed in citizen science supported peer-reviewed scientific literature (Follett and Strezov, 2015).

Citizen science on inland waters

Volunteer monitoring of inland water quality has a strong tradition around the globe. Water-focused citizen science programs (often called volunteer monitoring programs) have a long history and are among the most common types of citizen science programs. For example, a national directory of US volunteer environmental monitoring programs published in 1998 included 772 programs, the vast majority of which focused on inland waters (Ely and Hamingson, 1998). These numbers continued to grow through the years; by 2013, 1676 volunteer water monitoring programs were in existence in the US, more than doubling the number of water-focused citizen science programs in just 15 years (Stepenuck and Genskow, 2018).

Among citizen science programs on inland waters, the most common focus is on rivers and streams (Fig. 2). In the earlier report, 76% of programs monitored rivers and streams, 34% monitored lakes and ponds, 22% monitored wetlands, and 11% monitored reservoirs (Ely and Hamingson, 1998). By 2013, volunteer water monitoring programs reported that 86% of responding programs monitored rivers and streams, while 43% monitored lakes and ponds. This focus on rivers and streams may be because public access at road crossings facilitates monitoring and makes boats typically unnecessary. Lake monitoring programs benefit from the presence

Fig. 1 Amateur birdwatchers have contributed data on bird populations and seasonality for centuries. Credit: Jen Owen.

Fig. 2 Streams are commonly monitored by citizen scientists due to their accessibility at road crossings and volunteer-friendly protocols to use aquatic invertebrates, primarily insects, as indicators of stream health. Credit: Jo Latimore.

of interested homeowners and homeowners' associations who have easy access to their lakes and an interest in maintaining lake health and associated property values (Stepenuck and Genskow, 2018).

Citizen science programs on inland waters in North America are led by local conservation groups, such as lake associations and watershed councils, as well as regional and national organizations like Trout Unlimited. Government agencies (local, state, federal, and tribal) are frequent sponsors of citizen science programs. Native American tribes have embraced citizen science approaches to combine indigenous knowledge and western science in projects like Indigenous Observation Network located in the Yukon River watershed in northwest Canada and Alaska (https://yukon.next.fieldscope.org/) and a program to detect aquatic invasive species on the Blackfeet Reservation in Montana (Hedin et al., 2021). Schools and universities also often support inland water citizen science programs, such as the Alliance for Aquatic Resource Monitoring (ALLARM, https://www.dickinson.edu/allarm) based at Dickinson College in Pennsylvania.

Types of citizen science programs

A key characteristic of modern citizen science is that participation is open to all interested participants, and not just those with the time and resources to pursue science as a hobby (Silvertown, 2009). This accessibility is due partly to the wide variety of participant roles along a spectrum of engagement, which can range from recording observations around one's backyard (e.g., The Great Sunflower Project, Domroese and Johnson, 2017) or within imagery accessed on one's computer (e.g., Zooniverse; Jones et al., 2018), to long-term engagement within a team of scientists and amateurs to develop a scientific project and apply its results. In fact, the multiple models for citizen science projects facilitate a variety of roles and a diversity of participants. Bonney et al. (2009) categorize citizen science projects into three broad categories: contributory, collaborative, and co-created (Table 1).

Examples of contributory citizen science projects on inland waters include using non-scientists to record water level data (e.g. CrowdHydrology; Lowry and Fienen, 2013), identify ephemeral streams (e.g. Stream Tracker; Kampf et al., 2018), monitor water clarity (Lottig et al., 2014), and submit samples or observations as part of the many lake and stream monitoring programs that are designed and led by professionals but engage the public (e.g., Michigan Clean Water Corps (MiCorps) Volunteer Stream Monitoring Program; Latimore and Steen, 2014). Collaborative citizen science projects involve the public in ways beyond data contribution; an example is the Michigan Clean Water Corps (MiCorps) Score the Shore program, which was designed by scientists with input from interested members of the public who expressed a need for nearshore lake habitat data to support lake conservation and management actions at the community level. These citizen scientists analyze their Score the Shore data with guidance from program scientists and many disseminate the findings to their homeowner associations and local decision makers (Fig. 3; http://www.micorps.net). Co-created programs are the least common, and examples of truly co-created citizen science programs focused on inland waters are not well-represented in the literature.

While citizen science projects can range from local to multinational levels, there are several clearinghouses where project information can be found that facilitate some analysis of participation. Within the United States, the three main clearing houses of citizen science projects are SciStarter.org, CitSci.org, and CitizenScience.gov. Databases within these organizations provide a

Table 1 Categories of citizen science projects, as defined by Bonney et al. (2009).

Category	*Description*
Contributory	Designed by scientists, members of the public contribute data
Collaborative	Designed by scientists; members of the public contribute data, may help refine project design, analyze data, or disseminate findings
Co-created	Designed by scientists alongside members of the public; at least some of the public participants are involved in most or all steps of the scientific process

Fig. 3 A volunteer in the MiCorps Score the Shore program records observations about lakeshore habitat conditions while boating around her lake. Credit: Jo Latimore.

starting point to analyze participation both within and across projects. By collecting information on the roles of staff, volunteers, and external scientists in nearly 300 US volunteer water monitoring programs, Stepenuck and Genskow (2018) determined that over half (53%) of the programs are collaborative; 29% contributory; and 14% co-created. An additional 2% were categorized as "collegial," operating without engaging professional scientists.

Goals and outcomes of citizen science projects

Just as the roles of participants in citizen science programs vary, so do the program goals and outcomes. The most common goals of citizen science programs in inland waters include community involvement, participant education, and collection of data (Table 2; Stepenuck and Genskow, 2018). To be successful, citizen science projects must have a sound scientific design and align with program goals.

An important scientific outcome of inland waters citizen science programs is the generation of an abundance of high-quality data. In a review of available lake data from seven US states, over half of the measurements of common water-quality parameters (water clarity, nutrients, and algal biomass) were provided by citizen science programs, and overall, 82% of all data over a 31-year period was collected by citizen scientists (Poisson et al., 2019). Citizen science programs also increase both the temporal and spatial scales at which scientific projects can occur (McKinley et al., 2015; Poisson et al., 2019). Participants often have access to private lands and water bodies that a research team may struggle to reach, and because participants often live near the study sites, they can collect data more frequently. Engaging participants who live near study sites allows for more frequent data collection over a larger geographic area than logistically feasible for a professional research team (Dickinson et al., 2012; Miller-Rushing et al., 2012; Latimore and Steen, 2014).

Because of the large number of observers across temporal and spatial scales, relative to professional monitoring, citizen science programs can be very effective in early detection of invasive species (McKinley et al., 2015; Johnson et al., 2020; Larson et al., 2020), environmental and phenological changes, issues that require management response, and the effectiveness of management actions (McKinley et al., 2015). Additionally, citizen science projects can be a cost-effective (though not cost-free) means for collecting data (Aceves-Bueno et al., 2015), an important factor when budgets and staff for environmental monitoring are limited. Further, engaging the public can help refine research questions by improving local relevancy and better incorporating human dimensions and the social aspects of ecosystem management (McKinley et al., 2015). Citizen engagement in environmental monitoring also influences the relationship between scientists and the public (Dickinson et al., 2010), potentially improving public support and funding for science-based management actions (Latimore and Steen, 2014).

Outcomes of citizen science programs can extend far beyond data collection. Citizen science programs can also benefit the participants and their communities, depending on program design, goals, and implementation. Participant outcomes may include increased personal knowledge (particularly about the scientific issue at hand, and about the scientific process generally), changed attitudes, and changed behaviors (Danielsen et al., 2005; Conrad and Hilchey, 2011; Jordan et al., 2012; Stepenuck and Green, 2015). While not a tangible outcome (Overdevest et al., 2004), personal knowledge gain tends to be the most reported benefit for citizen scientists. However, education is a very common goal among citizen science programs, so this is a positive finding (Stepenuck and Genskow, 2018). Among the most reported community outcomes is increased social capital; that is, improved networks of relationships among community members that enhance community functions. Other reported community outcomes include increased community awareness of environmental issues, increased citizen engagement in decision-making processes around environmental management and policy, improved adherence to natural resource regulations, and job creation (Overdevest et al., 2004; Danielsen et al., 2005; Conrad and Hilchey, 2011; Jordan et al., 2012; Aceves-Bueno et al., 2015; McKinley et al., 2015; Stepenuck and Green, 2015).

Table 2 Goals of US volunteer water monitoring programs, as reported by Stepenuck and Genskow (2018). Note that the percentages do not sum to 100 since each program can have multiple goals.

Program goal	*% of Programs reporting*
Involve community	91%
Educate the public	82%
Create a long-term data set	76%
Address lack of data	71%
Identify pollution problems	69%
Educate youth	65%
Create consistency in methods	56%
Obtain data to affect natural resource policy	51%
Study restoration outcomes	47%
Provide data for state/tribal water quality reports	43%
Address environmental crisis	27%
Answer a research question	17%

Challenges: Is citizen science right for your project?

While citizen science projects can be an effective approach to answering questions about inland waters, they are not without challenges. As noted above, citizen science projects can be cost-effective, but they are not cost-free. Depending on the program, necessary investments in staff and volunteers, data management tools, technology and equipment can be significant. Further, establishing organizational culture and policies that support citizen science may be needed (McKinley et al., 2015). Privacy can also be a concern in citizen science programs, especially those sponsored by or in partnership with federal agencies. For example, in the US, the Privacy Act applies to personal and location-based information, photographs, videos, and audio content. To comply, federal agencies must plan to either avoid collecting or storing personally identifiable information or develop an approved process for managing it (McKinley et al., 2015).

Volunteer recruitment and retention (i.e., keeping volunteers engaged after their initial participation and, if applicable, training) are critical to successful citizen science projects. Not all projects attract public interest. For example, projects involving charismatic animals or pleasant environments will draw more interest from participants than will opportunities to collect data in mucky swamps. Water bodies near college campuses or tourist destinations also attract more public interest than those in industrial areas, and in rural areas, the population of potential participants can be small (McKinley et al., 2015). To maintain volunteer interest, effort must be made to communicate project results and outcomes, respond to volunteer questions, and offer opportunities for future engagement that appeal to participants. For example, project results and outcomes can be shared in plain-language reports and presentations by project leaders at community gatherings provide opportunities for discussion. Such reports and presentations can also be used to recruit new volunteers and retain existing volunteers for future participation.

Data collected by citizen science programs is often subject to stronger scrutiny than that generated by professionals. Critics of citizen science data point to the lack of professional credentials held by the volunteers collecting the data, suggesting that they may be more likely to make procedural errors. Another common criticism is that volunteers are more likely to introduce personal bias into data collection and interpretation than professionals and have not been trained to avoid it (Latimore and Lawson, 2007; Cohn, 2011; Kremen et al., 2011). Although several studies have shown that volunteer monitoring assessments of inland waters are highly valuable and similarly reliable as professional assessments when volunteers are trained, protocols are clear, and quality assurance project plans are followed (Albus et al., 2020; Krabbenhoft and Kashian, 2020), demonstration of data quality and validity is a critical need for volunteer-based projects.

The strongest citizen science programs - those most likely to generate reliable data - are designed, implemented, and evaluated as rigorously as conventional science programs (McKinley et al., 2015). A range of methods can be used to certify data validity, with the most common reported as expert review (Wiggins et al., 2011). Development and adherence to a federally- or state-approved Quality Assurance Project Plan (QAPP) has been shown to increase the confidence that sponsoring agencies and external decision makers have in data generated by citizen science programs (Stepenuck and Genskow, 2018). However, QAPP development may be time-consuming and onerous since a QAPP lays out the goals of the project, field and lab protocols, and data handling, analysis, and reporting procedures. For each procedural step, the QAPP describes how volunteer compliance will be ensured, procedures for guarding against bias, and the process for resampling or rejecting problem data. The QAPP provides a procedural framework for program staff and reassurance to potential data users that these data are accurate and valid. The US Environmental Protection Agency provides QAPP guidance for volunteer water monitoring programs (USEPA, 2019).

The process of thinking through the necessary volunteer protocols and quality assurance steps "forces the program manager to carefully consider the reasons for collecting the data; the objectives for using the data; the needs and limitations of the methods, equipment, and personnel; and the need for contingency plans" (Latimore and Lawson, 2007), and for a particular question, may reveal that a citizen science approach is not a good fit. Projects that require specialized knowledge or training, expensive or complex equipment, great time commitments, or that take place in potentially hazardous conditions may not be suitable for citizen science (McKinley et al., 2015). Although citizen science projects can result in improved public participation in environmental stewardship and decision making, it is not always the most effective path to engagement. In fact, McKinley et al. (2015) argue that direct outreach can be more efficient and effective in stimulating engagement than citizen science projects.

Citizen science best practices

The current surge in interest in citizen science across many scientific disciplines has led to growth in associated scholarship supporting best practices, as well as many successful programs that serve as models. Several "toolkits" that compile resources and best practices for citizen science programs also exist (See Relevant Websites).

As with any scientific endeavor, a clear statement of the question or need to be addressed by the project is critical, as is the definition of goals and objectives. This framework guides the choice and development of data collection and handling protocols, project scale, and "job descriptions" for volunteer participants, program staff, and professional scientists. Clarity in project goals and objectives also supports development of an evaluation process through which realistic expectations can be set and the program can be regularly assessed and adapted, if necessary.

Resources and, in most cases, training of program participants are critical to ensure volunteer confidence in their roles and to ensure accurate, credible data and participant safety (Fig. 4). While some contributory programs may require no more than clear and concise instructions for submitting observations or reviewing imagery, many citizen science programs include classroom and field training programs, or pair inexperienced participants with seasoned, trained volunteers or staff who can guide and supervise

Fig. 4 MiCorps volunteers learn to identify aquatic plants during an in-person training session. Training is also offered online to increase accessibility and participation. Credit: Jo Latimore.

activities. If improved public capacity to engage in water resource management is a program goal, then resources or training in sharing program results should be provided, in addition to the training needed to collect or analyze data (Stepenuck and Genskow, 2018).

Assurance of data credibility is important for all citizen science programs, so methods for certifying data validity should be incorporated into program design. The most common approach for volunteer water monitoring programs is development of and adherence to a Quality Assurance Project Plan that is approved by a federal or state agency (see discussion above).

Attention must be paid to volunteer recruitment and retention throughout the project. Clear "job descriptions" for potential participants provide clarity of task and time commitment expectations. Offering a range of activities suited to different interests, abilities, availabilities, and levels of expertise allows a program to tap into a broad pool of potential participants; the option of one-time, low-effort participation can be an attractive option for participants who may then be inspired to commit to a more significant role in the program (Latimore and Lawson, 2007).

Understanding of the interests, availability, and motivation of current and potential project participants is valuable to match to program expectations. Helping the environment (Domroese and Johnson, 2017) and providing water resource information (Alender, 2016) motivate many participants in citizen science programs, perhaps less so than increasing personal knowledge (Nerbonne and Vondracek, 2003). Thus, it is important for programs to share with their participants specifically how results are being used to protect water resources or provide them with training and resources to use the results themselves. A review of eight US volunteer water quality monitoring programs revealed that volunteers are less interested in rewards or recognition for their participation, and more interested in hearing about the tangible results of their efforts (Alender, 2016).

Case study: Example of citizen science on inland waters: The Michigan Clean Water Corps

The Michigan Clean Water Corps (MiCorps) is the State of Michigan's volunteer lake and stream monitoring program. Formed in 2003, MiCorps incorporated two previously established citizen science programs: the Volunteer Stream Monitoring Program, launched in 1998, and the Cooperative Lakes Monitoring Program begun in 1974 that is the second-oldest statewide volunteer lake monitoring program in the US.

MiCorps is overseen by the Michigan Department of Environment, Great Lakes, and Energy, which has long recognized the value of public participation in collecting water quality data and engagement in the assessment and management of Michigan's lakes and streams. The MiCorps program is administered by a team of partner organizations, including academic and environmental stewardship organizations, which together bring the scientific, technological, and public engagement skills needed to run a successful, large-scale volunteer water monitoring program.

MiCorps mission

The mission of MiCorps is to network and expand volunteer water quality monitoring organizations statewide for the purpose of collecting, sharing, and using reliable data; educate and inform the public about water quality issues; and foster water resources stewardship to facilitate the preservation and protection of Michigan's water resources (MiCorps, 2021).

MiCorps goals

- Establish a volunteer monitoring network to facilitate communication, data and information sharing, common methods, and quality assurance practices.
- Promote and expand the volunteer monitoring network by identifying and assisting the development of new volunteer monitors and volunteer monitoring programs statewide.
- Educate the public about water quality issues and foster exemplary environmental stewardship.
- Gather and exchange reliable and meaningful water quality data for water resources management and protection programs at the state and local level.

- Establish an Internet-based program, including an enrollment registry, directory of member organizations, a data exchange platform, volunteer monitoring resources, training aids, and a newsletter.
- *Include a volunteer monitoring recognition program with a Certification of Recognition for each member organization and a Certificate of Participation for each volunteer member* (MiCorps, 2021).

All data collected by MiCorps volunteers, current and historic, is publicly available in the MiCorps Data Exchange online (https://micorps.net/about-data-exchange/). Program outcomes are shared with volunteers via written reports and regular communications.

The MiCorps Cooperative Lakes Monitoring Program (CLMP)

The CLMP offers participants a suite of parameters to monitor in their lake, including:

- Water transparency (Secchi depth)
- Total phosphorus (a productivity-limiting nutrient in Michigan lakes)
- Chlorophyll-a (indicator of algal biomass)
- Dissolved oxygen and temperature (determinants of many biotic species)
- Score the Shore (nearshore habitat assessment)
- Exotic Aquatic Plant Watch (aquatic invasive plant survey)
- Aquatic Plant Identification and Mapping (quantitative assessment and mapping of the entire aquatic plant community)

Participation in the CLMP is open to all. Most volunteers are lakefront property owners and learn of the program through direct outreach efforts through lake homeowner associations. Participants pay a small enrollment fee for each parameter they monitor, to partly cover program costs. The remaining costs are covered by state funds.

Quality assurance measures include participant training, volunteer-friendly protocols and equipment, and post-data collection handling techniques. Volunteers are trained directly by MiCorps program staff. A Quality Assurance Project Plan is adhered to and updated as needed.

The MiCorps Volunteer Stream Monitoring Program (VSMP)

The VSMP focuses on collections of macroinvertebrates as indicators of stream health, augmented by periodic physical habitat assessments. Participation in the Volunteer Stream Monitoring Program is open to all. Volunteer demographics vary widely. State funding allows for a competitive grant program open to non-profit organizations to launch and maintain their own programs. Training follows a "train-the-trainer" model, where MiCorps staff provide training to staff of participating organizations, who then recruit and train their own volunteers. Each participating organization develops their own Quality Assurance Project Plan, which is reviewed and approved by MICorps program staff.

MiCorps outcomes

MiCorps lakes and stream monitoring has advanced public understanding of inland waters, built public support for lake and stream research and management, and informed local management and conservation projects. Communities regularly turn to MiCorps data to assess status and trends in their local water bodies, researchers incorporate the data into regional and national assessments (Fuller and Jodoin, 2016; Poisson et al., 2019), and researchers cooperate with MiCorps volunteers on specialized research projects (Sarnelle et al., 2010). Both state natural resource agencies (the Michigan Department of Natural Resources and the Michigan Department of Environment, Great Lakes, and Energy) use MiCorps volunteer monitoring data to meet their planning and reporting responsibilities. MiCorps data regularly supports management decisions ranging from nuisance aquatic plant control to land use planning and assess the impacts of past changes to lakes and streams, including non-native species invasions and sewer system installations.

Crowdsourcing

Crowdsourcing defined

Citizen science can include crowdsourcing, which is a method of leveraging a large unidentified group of people to perform predetermined tasks (Dickinson et al., 2012). Within the context of citizen science, crowdsourcing is a way of outsourcing, in the most basic cases, tasks such as data collection, classification, and analysis to the community. The concept of crowdsourcing was first defined as a business practice to outsource a specific task to groups of people via the internet (Howe, 2006). In the hierarchical classifications of citizen science, crowdsourcing is considered a lower order method where participants come to the task pre-trained or needing little training. In many applications, crowdsourcing is anonymous citizen science where participants are not individually recruited to participate. While this anonymity can cause problems such as recurring issues of confidence in data quality, it can also be a strength as it is easy to upscale citizen science projects as there is no need for individual recruitment and training.

The original concept of crowdsourcing can lead to problems of training. Not fully knowing your participants makes it more difficult to design training and instruction platforms for crowdsourced citizen science. However, many crowdsourcing projects design research questions that are less complex, such as asking participants to compare observations to training images or report common observations like temperature. This approach allows citizen scientists to draw on their previous knowledge more than

learning new skills. When formal training is conducted in crowdsourcing, the training is typically performed through pre-recorded videos (e.g., CoCoRaHS; Reges et al., 2016) or through some sort of training exercise or games (e.g., CrowdWater; Strobl et al., 2019).

Benefits of crowdsourcing

The biggest benefit of crowdsourcing is the scalability in both space and time. With appropriate design and research objectives, crowdsourcing can open data collection to millions of participants at the continental or even global scale. This method also allows for multiple observations at a single location from multiple users, which provides repeatability that many other citizen science methods lack. Distributing the observations among multiple users at a single location also facilitates error analysis and allows a qualitative measure of each participant's accuracy as compared to the crowd. Based on the type of data collection, for example the use of mobile phones, it is possible to have users collect data at locations even professional scientists who may be conducting the research have not visited.

Crowdsourcing best practices

Crowdsourcing works best with well-defined research questions and simple sampling protocols. Complicated and multi-step observations can create barriers of entry that prevent participation from the crowd. This does not mean that specialized equipment (such as mobile phones or computers) cannot be used, but that this equipment needs to be accessible and familiar to the participants. Examples of situations where crowdsourcing works best include collecting images of streams (e.g., Crowd Water, crowdwater.ch) or cloud cover (e.g., Globe Clouds, observer.globe.gov) using mobile phones through web-based applications.

One concern when using a crowdsourcing approach is the quality control of collected data. Some methods use an oversampling approach for quality control, such as the example of image processing where more than one participant classifies an image (Hennon et al., 2015). If all participants agree on an image classification, it is deemed acceptable, whereas if participants disagree on an image, it is sent to an expert for further classification. This same quality control approach can be adapted to data entry. In the case of field measurements, traditional instruments such as weather stations or pressure transducers can be co-located in selected areas to allow for quality control. It is also possible to use a statistical approach to flag observations that may be erroneous based on related data (Wu et al., 2021). An example would be to flag measurements of stream turbidity if those observations were reported to have been collected at 2:00 AM. Quality control is a much bigger issue with field observations than image processing because experts cannot check the results. This highlights the usefulness of asking participants to take photos of field observations to help professional scientists verify these data.

Crowdsourcing of inland waters

Crowdsourcing of inland water represent a range of methodologies that can use existing or new infrastructure through passive and active participant recruitment. Passive participation can include data mining of existing social networks, describe in more detail below, to quantify human-nature interactions and prioritization of ecosystem function (Ghermandi et al., 2020; Angradi et al., 2018). Active participation can include crowdsourcing of water levels accomplished using physical water level stations at fixed locations (e.g., CrowdHydrology, Fig. 5; Lowry and Fienen, 2013) or virtual water level station at flexible locations (Seibert et al., 2019). The proliferation of mobile phones has exponentially increased the ability to monitor inland waters (Kampf et al., 2018; Malthus et al., 2020). However, it is more common that examples of crowdsourcing of inland waters are community-based projects

Fig. 5 Citizen scientist reporting water levels via text message on Amity Creek in Duluth, Minnesota. Credit: Andrea B. Crouse.

not necessarily reflected in the peer-reviewed literature. Examples include monitoring water clarity and quality (EyeOnWater.org; LakeForecast.org; lakeobserver.org), locating cyanobacteria blooms (cyanos.org/bloomwatch/), identifying river obstructions (river-obstacles.org), and image processing of invasive species (Zooniverse: Deep Lake Explorer). These examples highlight the richness and rapid growth of opportunities to monitor inland waters.

Social media

Social media defined

Another method used in citizen science and to broaden the impact of science is social media, which refers to internet applications that allow users to create and share content and build connections with one another, such as Twitter, Facebook, and Instagram. As of 2021, 72% of US adults used at least one social media platform (Pew Research Center, 2021). Social media is a growing tool for gathering and sharing scientific information, as well as engagement among professional scientists and with the public (Howell et al., 2019). Increasingly, citizen science programs use social media to raise awareness of their programs, recruit participants, and share outcomes (Catlin-Groves, 2012). More broadly, many scientists and members of the interested public are taking to social media to discuss scientific topics.

Benefits of social media

Wilson (2016) discusses several benefits of social media as a communications tool for professional scientists, including:

- Improved science communication - social media platforms require scientists to distill ideas concisely and clearly, in audience-appropriate ways
- Frequent and fast communication of results
- Broader awareness of scientific work and outcomes, which may lead to funding and other forms of public and private support for projects; innovation; and individual career advancement

Social media can provide a platform for two-way engagement between scientists and the public, opening pathways to explore and refine research questions, gather information and data, and share perspectives and experiences. This two-way engagement can advance research and add social relevance to scientific endeavors. A recent exploration of graduate student and faculty attitudes revealed a shared view that the public has valuable insights to contribute to their scientific fields, and that social media provides an opportunity for engagement (Howell et al., 2019).

Social media best practices

Recommended approaches and guidelines for scientific communication on social media coincide with those recommended for all types of science communication, with a few nuances. The approaches include: (i) Be clear and concise - some social media platforms limit the length of posts, so brevity is required. (ii) Include visuals - social media posts that include images or video show greater engagement (Ulloa et al., 2015). (iii) Communicate with integrity, respect, transparency, and honesty (Shiffman, 2019). (iv) Focus on quality messaging rather than social trends. Jumping on social media trends (e.g., popular hashtags, jokes, or memes) can help increase user engagement but should not be prioritized at the expense of delivering substantive and accurate content that is true to your science communication goals. (v) Share others' information when aligned with your (and your organization's) mission and goals (Wilson, 2016). (vi) Consider your audience. What are their interests and values? Why do they (or should they) follow you? Tailor your communication to suit your desired audience(s). (vii) Be open to respectful engagement with scientific peers (within and among disciplines) and non-scientists. Even the best-constructed social media post is only one-way communication of information until others comment – then it can become a truly social opportunity for rich discussion and exchange of ideas.

Practices for mining social media sites for scientifically relevant data are still relatively novel. A critical consideration for researchers in using these approaches is bias. For example, because not all people use social media and the preferred social media platforms vary by demographic (Pew Research Center, 2021), data mined from these platforms will be specific to the populations using the platform. For example, photos posted by Flickr users may not be representative of the locations visited by people who do not use Flickr (Keeler et al., 2015). Further, social media users may only post photographs or information about exceptional events (e.g., extreme floods, large fish caught), leaving researchers to resort to other means of collecting data about "normal" conditions.

Social media of inland waters

There are many ways social media is being used to further understanding and management of inland waters. For example, social media posts can be a rich source of data. Photographs and videos of organisms or environmental phenomena that are publicly shared on social media can be "mined" for information (Catlin-Groves, 2012). For example, Michelsen et al. (2016) analyzed YouTube videos of a cave popular with diving tourists to assess changes in water levels in the cave, leading to better understanding of hydrological changes in the region. Another study assessed the recreational and tourism benefits of improved water quality using

Fig. 6 Water Rangers uses social media platforms, including Facebook and Twitter, to create community and engage with their volunteers.

geotagged photographs shared by travelers on the photo-sharing site Flickr. By using the photographs as a proxy for lake visits, they were able to determine that people are willing to travel significantly farther, and thus spend more money, to visit clearer lakes (Keeler et al., 2015). Social media is also regularly used to promote participation and create community around citizen science and crowdsourcing programs. For example, the Canada-based Water Rangers program (https://waterrangers.ca/) uses Facebook, Twitter, and Instagram to promote participation opportunities, celebrate volunteer contributions, and share success stories (Fig. 6).

Social media can also be used effectively to increase public appreciation and understanding of inland water systems and their components. For example, a fisheries scientist created an annual Twitter campaign, #25DaysofFishmas, with the goal of increasing awareness about aquatic biodiversity in the Great Lakes of the US, using humor. The campaign has become an interactive forum for learning and sharing, with posts retweeted more than 8000 times and liked more than 25,000 times (Burdett et al., 2021).

Conclusion/synthesis

Application of citizen science, crowdsourcing, and social media approaches represent powerful opportunities for advancing understanding and conservation of inland waters. These approaches engage the public in dynamic and meaningful ways and generate an abundance of valuable data and information and can be used to address questions that may be unanswerable by traditional scientific means. The public and transparent nature of well-designed citizen science, crowdsourcing, and social media projects fit well into "open science" culture and practices, which are increasingly being recognized as beneficial to advancement of science and conservation. Most citizen science and crowdsourcing programs provide open access to data as a conscious choice and encourage engagement of both scientists and the public in at least some, if not most or all, stages of the scientific process.

The recent growth of citizen science, crowdsourcing, and social media approaches has also resulted in an expansion of the scholarship around practices and impacts, which, combined with examples of existing programs, provide a solid foundation for new and growing programs to emulate. This scholarship confirms that these approaches can result in accurate, reliable data about inland waters. Further, participants can become more knowledgeable about the issues facing inland water ecosystems and become more likely to engage effectively in public decision-making processes on water policy and management.

Knowledge gaps and opportunities for future research

- How extensively are citizen science and crowdsourced data used for the understanding and conservation of inland waters? Is there a significant gap between the collection of data and its use, and if so, what strategies could close that gap?
- What changes need to be made or metrics achieved for citizen science participation to become main stream in the professional science community? If transformative research and boarder impact have equal weight, why has citizen science not become the gold standard in our current research community?
- What characteristics of data-sharing platforms or structures best facilitate access to and use of citizen science and crowdsourced data?
- What are the primary motivations for citizen scientists to participate in the scientific process and how can professional scientists and managers build stronger participatory communities?
- What approaches of engaging nonscientists with scientific information on social media platforms are most effective in leading to knowledge gain and behavior change?

Dust and Fog Effects on Inland Waters

J Brahney[a], KC Weathers[b], and I Reche[c], [a]Department of Watershed Science and Ecology Center, Utah State University, Logan, UT, United States; [b]Cary Institute of Ecosystem Studies, Millbrook, NY, United States; [c]Departamento de Ecología, Universidad de Granada, Granada, Spain

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Kendra Cheruvelil.

Glossary

Acid neutralizing capacity (ANC) A measure of the overall buffering capacity of a solution against acidification.
Aerosols A suspension of solid, liquid, or gas particles in the atmosphere.
Dry deposition The deposition of dust and other aerosols by gravity.
Orographic Relating to the topographical relief of mountains. Orographic precipitation occurs when an air mass is forced to higher altitudes due to the presence of mountains, leading to condensation.
Persistent organic pollutants Toxic organic compounds that are resistant to degradation within the environment.
Wet deposition The deposition of chemicals via precipitation (rain, snow).
Xenobiotics Synthetic chemicals that is foreign to the body or to ecological systems.

Introduction

The atmospheric deposition of aerosols can occur in sufficient quantities to influence the water chemistry and aquatic communities of receiving inland waters. Although both dust and fog are natural phenomena, human activities have greatly influenced the production, composition, and distribution of these aerosols. For example, any activity that destabilizes soils can increase dust entrainment and influence dust composition. Some examples of land use activities that exacerbate soil erosion include agriculture, animal husbandry, and construction (e.g., Fig. 1). The chemical and aerosol composition of clouds and fog (hereafter fog) is usually more concentrated than rain and is influenced by urbanization and other sources of combustion products. Therefore, fog can play a role in the transportation to or removal of aerosols and soluble gasses from ecosystems.

The composition of dust and fog is influenced by both the composition of the generating source (e.g., the soil or water body composition) as well as chemical reactions that may occur along the transport path including sorting, adsorption, coagulation, nucleation, dissolution, precipitation, and in the case of fog, photochemical reactions. These atmospheric vectors have the potential to transport or export other constituents that may influence aquatic ecology, including metals, microorganisms, pathogens, plastics, and persistent organic pollutants. Both dust and fog can effectively transport nutrients but are likely to differ in their influence on aquatic chemistry. Because dust constituents are frequently alkaline, dust deposition will tend to increase the pH of receiving ecosystems. When downwind of pollution sources, fog can transport significant concentrations of airborne acids, which are

Fig. 1 Dust plumes arising from a tractor in Cache Valley, UT, US. Photo Credit: Patrick Strong.

Fig. 2 Fog in the Bitterroot Mountains, US. Fog can deposit nutrients and other constituents onto catchment surfaces. Source: Flickr.

deposited on surfaces within a catchment and can be subsequently transported to lake systems (Fig. 2). In the case of fog, water droplets generated from a lake surface can also be a vector for moving constituents out of the waterbody and into atmospheric systems.

Defining the minimum deposition rate of dust or other aerosols that could negatively influence an aquatic ecosystem, often described as a 'critical load', would be useful for land managers wishing to identify targets and/or predict whether a system may be affected by upwind activities. However, deposition rates of particulate aerosols onto catchments or lake surfaces may not be sufficient to predict the aquatic response. This is because catchment properties and antecedent lake conditions will also play a role in how an aquatic system responds. Catchment properties can either exacerbate or mollify the effect of deposition by either taking up the deposited nutrients/constituents or facilitating the transport to its aquatic systems. The antecedent lake conditions will also dictate the biological and/or chemical response to changes in atmospheric deposition.

Though the importance of dust in fertilizing soils and oceans over millennial times scales is well understood, only recently have scientists become aware that dust can meaningfully impact freshwater aquatic systems over annual to decadal time scales. This new awareness is in part due to the more recent decadal increases in regional dust emissions associated with land use. Globally, there are comprehensive networks aimed at measuring and monitoring atmospheric concentrations of particulates smaller than 10 μm as these are the sizes that influence human health. However, the bulk of the mass of particulates in local to regional dust sources is found in large size classes. Thus, we still know very little about the composition of atmospheric materials and their influence on receiving aquatic waterbodies. Below, we describe how dust and fog are generated, the controls on composition, the influence to aquatic systems, the role of catchment properties using the special case of mountain lakes, and we point to current knowledge gaps.

Dust generation and sampling

Atmospheric or eolian dust generally refers to mineral particulates that have been eroded from the Earth's surface and subsequently transported through the atmosphere. In contrast, particulate aerosols may refer to both dust and particulates that have formed within the atmosphere itself (e.g., photochemical smog). Dust particles are generated from a number of natural and human sources including soil erosion, industrial emissions (e.g., mining, fossil fuel burning, cement production), transportation, construction sites, biomass burning, residential heating sources, plant products (e.g., pollen), volcanic emissions, and synthetic particles like plastics (Piketh et al., 1999; Mahowald et al., 2008; Gesierich and Rott, 2012; Langmann, 2013; Allen et al., 2019; Brahney et al., 2020a) (Fig. 3). Because dust generated from such sources is transported through the atmosphere to aquatic ecosystems, for the purpose of this chapter, all particulate aerosols will be considered as atmospheric dust, regardless of source.

The production of dust from arid and semi-arid landscapes is a natural phenomenon and is controlled by two primary factors (Field et al., 2010). First, the soil surface must be exposed to erosive forces such as wind. Factors that limit soil exposure to wind include vegetation cover or other surface protectors such as cryptobiotic crust (Belnap and Gillette, 1998; Leys and Eldridge, 1998). Second, there must be sufficient wind energy for soil erosion and subsequent entrainment (Fig. 4). These biogeoclimatic drivers of dust production can be influenced by year to year variation in rainfall, storm tracks, and decadal drought (Prospero and Nees, 1986; Goudie and Middleton, 1992; Qian et al., 2002; Flagg et al., 2014). For example, in the semi-arid regions of the southwestern US, La Niña years lead to decreased precipitation, which suppresses the growth of grasses during the growing season. The loss of the stabilizing vegetation causes the soil to be more susceptible to erosion the following spring when storms and strong winds travel through the region (Okin and Reheis, 2002).

Human activities can exacerbate natural dust production in dust-producing regions and create new dust source areas by removing vegetation cover, water, and/or destabilizing surface soils (Neff et al., 2008; Mulitza et al., 2010; Munson et al., 2011;

Duniway et al., 2019; Brahney et al., 2019). Recent centennial and decadal increases in dust deposition have been linked to both drought and human activities (Neff et al., 2008; Brahney et al., 2013; Aarons et al., 2019; Arcusa et al., 2020). Human land-use activities that can aggravate dust production include agriculture and pastoralism (Neff et al., 2008; Lee et al., 2012; Brahney et al., 2019), water diversions (Saint-Armand et al., 1986; AghaKouchak et al., 2015; Indoitu et al., 2015), industry, roads, and construction (Morishita et al., 2006; Neitlich et al., 2017), oil and gas operations (Brahney et al., 2015a), biomass burning (Andreae et al., 1988), and recreation (Goossens and Buck, 2009) (Fig. 5).

The extent of the human fingerprint on Earth is enormous as more than 95% of the Earth's surface has been appropriated for the variety of land-uses listed above (Kennedy et al., 2019). Impacts of this human fingerprint are highlighted by a 50% diversion of the global runoff (Abbott et al., 2019). These diversions can lead to desertification and the complete or near-complete loss of large lake ecosystems whose lakebeds are then susceptible to wind erosion (Reheis, 1997; Larsen, 2014; Wurtsbaugh et al., 2017). Approximately 40% of the Earth's surface has been appropriated for pasture and crop production (Foley et al., 2005), which can exacerbate soil erosion through tillage or by reducing the threshold wind velocity required for soil entrainment (Leys and Eldridge, 1998; Goossens, 2004; Neff et al., 2005). The widespread fingerprint of human activity on the Earth's surface, combined with persistent and intensified droughts, led to an increase in global atmospheric dust generation in the 20th century (Mahowald et al., 2010). It is estimated that human sources make up 25% of the global 21st century dust production (Ginoux et al., 2012). This increase in the movement of material through the atmosphere has the capacity to significantly alter the natural biogeochemistry of receiving aquatic ecosystems.

Although dust emissions caused by humans have increased in recent centuries and decades, natural dust generation events are episodic and controlled by stochastic and climatic factors (Moulin et al., 1997; Prospero and Lamb, 2003). As a result, dust deposition rates in inland aquatic ecosystems are highly variable across space and time, which poses challenges to sampling efforts. To illustrate, 15 years of dust on snow data from the intermountain west has shown as few as three to as many as 12 dust events during the winter season with corresponding mass deposition rates ranging from 1.65 to 64.3 g m^{-2} $year^{-1}$ (CODOS, 2019). At a global scale, dust deposition rates range from 0 to 450 g m^{-2} $year^{-1}$ with the highest deposition rates influenced by proximal (<10 km) sources (Lawrence and Neff, 2009).

Dust sources are divided into three broad categories based on their proximity to dust deposition sites, namely "Local" dust sources originating from 0 to 10 km away, "Regional" from 10 to 1000 km, and "Global" from greater than 1000 km (Lawrence and Neff, 2009). Dust source distance influences the deposition rate and the spatial heterogeneity in deposition, the chemical composition, and the particle size distribution. Whether or not a researcher is interested in quantifying the effect of local, regional, or globally sourced dust will influence the types of samplers used and where they are placed on the landscape. Dust derived from local sources tends to have larger particles sizes and is likely transported closer to the ground surface than aerosols sourced from long distances. For example, Asian dust over North America is typically less than 2.5 μm in size and found between 500 and 3000 m asl (VanCuren and Cahill, 2002).

Fig. 6 Field deployed active (left) and passive deposition samplers. Photo credits: Jeff Perala-Dewey and Molly Blakowski.

Methods for sampling dust fall into two categories, namely passive and active sampling (Fig. 6). Passive sampling techniques rely on the gravitational deposition of particulates into the sampling apparatus (e.g., Reheis and Kihl, 1995). Bulk passive samplers collect particulates deposited both dry and with rain, whereas some samplers are designed to capture dry and wet deposition separately (Reche et al., 2018; Brahney et al., 2020b). Active sampling techniques use a vacuum to draw air through a filter and/or foam to capture gasses, aerosols, and dust (Hart et al., 1992). One advantage of active sampling techniques is that it allows for the separation of aerosols by their size (Büttner, 1988). A disadvantage is that active sampling methods provide atmospheric concentrations, not deposition rates. Concentrations may be more important for understanding atmospheric chemistry and the impacts to human health, but deposition is more relevant for quantifying and understanding the ecological implications of dust deposition.

Fog formation and sampling

Fog, or ground-based cloud, is comprised of water droplets whose size usually ranges from a micron to ~50 μm. These droplets, which are suspended in the atmosphere (Gultepe et al., 2007), are often referred to as occult precipitation (Weathers, 1999; Weathers et al., 2020). Occult precipitation is an apt description of fog behavior—fog hangs in the atmosphere—and also an indication of the complexities inherent to quantifying its deposition since it does not fall vertically like rain. Fog is formed via radiative cooling of moist air either as a result of advection over land from large water bodies or adiabatic expansion (e.g., upslope fog formation).

Of the three primary forms of atmospheric deposition—wet (rain, snow), dry (aerosols and gasses) and fog—fog sits between wet and dry: it is liquid, but because its droplets are suspended, its deposition is governed by meteorological conditions (e.g., windspeed) and receptor surface (i.e., vegetation) (Weathers and Ponette-González, 2011). Because of this, it is unlikely that direct deposition of fog to inland water surfaces is significant. Collection of fog water is usually accomplished via passive or active collection devices (Fig. 7). Passive collectors rely on wind to drive droplets onto collection surfaces, which are often inert strands or mesh, after which the droplets run down the surface into a collection bottle. Active collectors pull air into an opening and across a collection surface at constant speed. Advantages of using an active collector include that high windspeeds are not necessary to collect a sample of sufficient volume, and liquid water content of the sample can be calculated easily.

Dust and fog composition

Dust and fog composition are determined by the biophysical environment of the source region as well as other factors that alter its reactivity during transportation to deposition sites. The primary controls on dust composition are the parent geology and degree of soil development of the source region, as well as human land use activities. To illustrate, dust from arid regions such as the Sahara are typically poor in organic content comprising less than 1% of the dry mass (Eglinton et al., 2002), while dust generated from agricultural regions can contain much larger fractions of organic and nutrient-rich material, up to 67% (Malm et al., 2004). Dust may also change appreciably in composition during travel through the atmosphere due to sorting, scavenging, and chemical

Fig. 7 Passive (top) and active sampling of fog. Photo credit: Kathleen Weathers (top), Collett research group (bottom).

reactions. For example, the progressive loss of the larger size fractions due to sorting may lead to a loss of heavier and larger minerals such as zircons and silicates. Various gaseous and particulate emissions may also be scavenged by dust during transport through adsorption, coagulation, nucleation, dissolution, and precipitation reactions. As a result, dust produced in or passing through urban centers will have a composition influenced by combustion sources (fossil fuels, incinerators), volatile metals, and organic contaminants (Han et al., 2004; Marx et al., 2008; Xiong et al., 2017; Goodman et al., 2019) (Fig. 8). The chemical and biological composition of fog is often reflective of its regional environment (Weathers et al., 1988, 2020; Evans et al., 2019; Gultepe et al., 2007). Fog has been recorded to have up to a 100-fold higher chemical concentration than rain collected from the same location (Kimball et al., 1988; Weathers et al., 2020) (Fig. 9). Dust and fog can also contain synthetic compounds such as pesticides, fertilizers, or even plastics (Glotfelty et al., 1987; Allen et al., 2019; Brahney et al., 2020a). Finally, dust and fog can act as a vector for the transport of microorganisms including pathogens that can affect human and ecosystem health and functioning (Hervàs et al., 2009; Metcalf et al., 2012; CDC, 2013; Reche et al., 2018).

Dust and fog influences on aquatic system pH

The acid neutralizing capacity (ANC) references the ability of water body to resist, or buffer, changes in pH. Most natural waterbodies have pH ranges between 6.0 and 9.0 pH units and deviations higher or lower can fundamentally alter the ecology and chemistry of the waterbodies. Lakes with low natural ANC are sensitive to external inputs, like acid rain. Because dust is often, but not always, generated from sedimentary basins, dust often includes carbonate minerals and can therefor affect receiving water ANC.

Carbonate minerals such as $CaCO_3$ are readily soluble in even slightly acidic waters contributing ANC to both precipitation (Loye-Pilot et al., 1986; Rogora et al., 2004, 2016; Brahney et al., 2013; Kopáček et al., 2016) and aquatic ecosystems through the addition of the bicarbonate ion (Psenner, 1999; Tait and Thaler, 2000; Rogora et al., 2004). Fig. 10A shows a tight correlation

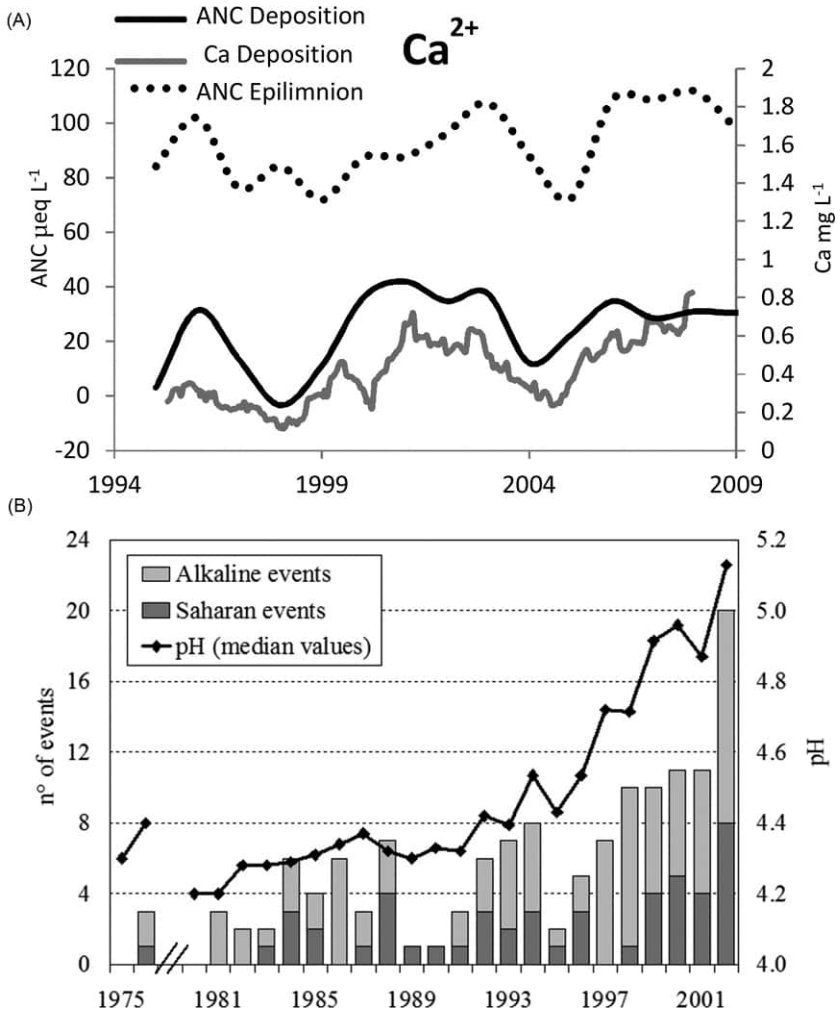

Fig. 10 (A) Temporal correlation between the Acid Neutralizing Capacity (ANC) in the Epilimnion of Blake Joe Lake, Wyoming with the dust (Ca^{2+}) and ANC in deposition (Brahney et al., 2014). (B) Temporal trends in Saharan dust events and the pH and alkalinity of precipitation in the Lake Maggiore region of Italy and Switzerland (Rogora et al., 2004).

between dust deposition, precipitation ANC, and the ANC of Black Joe Lake, Wyoming, illustrating the relationship between dust contributions and the buffer capacity of lake systems. Alkalinity contributions from dust may counteract acid deposition from other human activities. For example, the quartzite bedrock of the Uinta Mountains is naturally poor in ANC, yet these mountain waters have not experienced acidification despite their proximity to acid emissions. It has been speculated that dust contributions have buffered these aquatic systems that remain neutral to alkaline (Messer et al., 1982; Ellis et al., 2015). The effect of dust on lake recovery from acidification is illustrated in Fig. 10B. Elevated Saharan dust deposition from the 1990s onward is thought to have aided in the recovery of Lake Maggiore from acidification (Rogora et al., 2004).

The calcium carbonate content of dust ranges from 0% to 33% worldwide (Lawrence and Neff, 2009). However, due to its high solubility in water in some regions, the calcite content may rapidly disappear during transport, particularly if airborne acid concentrations are high (Jacobson and Holmden, 2006). Thus, the dust source composition, the distance traveled, and the presence of acid precursors in the atmosphere will influence the extent to which dust may neutralize acids in freshwater systems.

Dust and fog delivery of nutrients and metals to aquatic ecosystems

The transport of the key limiting nutrients such as nitrogen (in dust and fog) and phosphorus, carbon, and calcium to ecosystems may occur in both the organic and inorganic forms. Dust and fog may also be vectors for metals to ecosystems, some of which may be necessary micronutrients while others are considered toxins. Because it is aqueous, fog can effectively transport ions such as nitrates (NO_3^-) and ammonium (NH_4^+), and can trap and move particulates such as pollen, or particulate organic carbon from atmosphere to ecosystem (e.g., Fuzzi et al., 1997; Fenn et al., 2000). The bioavailability of nutrients, and thus their capacity to

influence inland waters, will vary with the composition of the particulate aerosols. For example, the water-soluble fractions of nutrients are immediately available for biological uptake whereas the organic or mineral bound fractions may become available over longer time periods. Dust can directly deposit nutrient and metals onto lake surfaces and some portion of the dust deposited within the catchment will be mobilized to the lake basin (Brahney et al., 2015a). Though fog is often enriched in elements (N, P, Ca, C) relative to rain (Fig. 9), direct deposition to lake surfaces is unlikely and it is not clear how efficiently fog deposition is transported into lake systems.

At present, a critical unknown is how the antecedent lake conditions will influence the response and bioavailability of deposited dust. Both pH and nutrient limitation can theoretically influence the efficiency of nutrient acquisition from dust particulates based on enzyme production and activation. Regardless, the atmospheric deposition of bioavailable nutrients will not only increase primary production but can also influence community composition through the alteration of N:P ratios (Elser et al., 2009a,b, Camarero and Catalán, 2012). For example, there is a strong linear relationship between the stoichiometry of nutrient deposition and that found in mountain lake systems (Fig. 11). These data suggest that direct atmospheric deposition is a primary control on mountain lake nutrient availability, which in turn influences production and species composition.

Nitrogen

Nitrogen deposition via rain and gaseous aerosols is well monitored and modeled around most areas of the world (Holland et al., 2005; Lü and Tian, 2007; NADP, 2019). Less is known about the contributions of nitrogen to receiving ecosystems from dry dust material as this fraction is rarely analyzed, although it is often modeled (Jia et al., 2016; TDep, 2019). Likewise, while fog has been shown to deliver proportionally large quantities of nitrogen to fog-dominated terrestrial ecosystems (e.g., Weathers et al., 2000a,b, 2020), little sustained, coordinated fog monitoring has been conducted. Furthermore, as noted earlier, while fog is chemically concentrated when compared to rain, direct deposition to inland waters is likely to be very limited.

In some areas, the dry fraction could potentially be an underappreciated component of the atmospheric nitrogen deposition (Neff et al., 2002; Cornell, 2011). The water-soluble organic nitrogen fraction has been shown to contribute approximately 25% of the flux of total nitrogen to Europe (Mace et al., 2003b; Cornell, 2011), 66% of the flux to North America (Neff et al., 2002), and up to 45% of the total nitrogen flux in the Amazon basin (Mace et al., 2003a; Cornell, 2011). Morales-Baquero et al. (2013) quantified wet and dry deposition of nitrogen associated with Saharan dust events, and found that wet deposition accounted for a larger fraction, with a Dry:Wet ratio of NO_3^--N at 0.56 and TN at 0.78. The bioavailability of particulate nitrogen is likely to vary according to dust composition, which is largely influenced by the climate and human land use patterns of the source area. For example, biomass burning and agriculture may contribute to the particulate nitrogen flux in areas where these practices occur, whereas, in the Mediterranean region, the organic nitrogen fraction has been linked to soil and dust sources (Mace et al., 2003b). Because dry deposition rates of nitrogen are generally modeled rather than measured and the spatial variability in deposition is high, overall uncertainties in the deposition rate of organic nitrogen and its waters soluble fraction can be large (Cornell et al., 2003).

Phosphorus

In contrast to atmospheric nitrogen, phosphorus has no stable gaseous form and thus atmospheric transport largely occurs as particulates. Important sources of atmospheric phosphorus include soils, biomass burning, and industrial emissions (Mahowald et al., 2008). Owing to the erodibility of the fine-grained, nutrient-rich fractions of soil, on average, dusts are enriched in

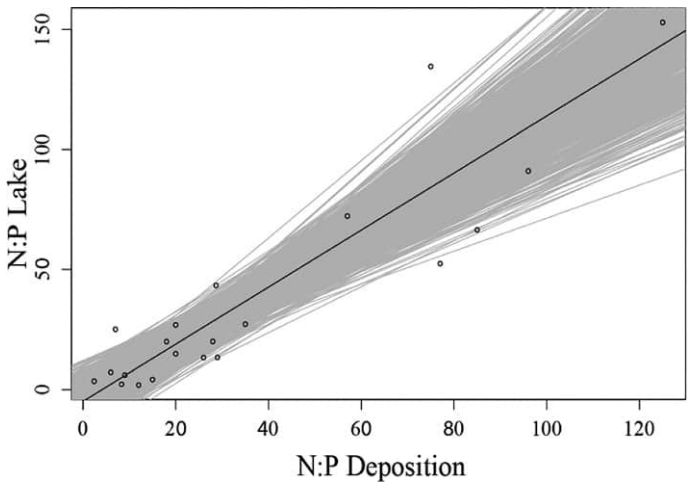

Fig. 11 The global relationship between the N:P ratio in atmospheric deposition and the N:P ratio in co-located mountain lakes. Each point represents the average within a mountain region spanning four continents (Brahney et al., 2015b).

phosphorus over average crustal concentrations by a factor of 1.6 (Lawrence and Neff, 2009). Thus, dust generally has the capacity to fertilize receiving ecosystems. Because fog can effectively scavenge and transport particles, total phosphorus concentrations measured in fog can be enriched compared to rain, and account for a sizeable portion of the mass flux of the nutrient to leaf surfaces in some areas (Vandecar et al., 2015).

Phosphorus concentrations in dust range from <1 mg g^{-1} to 5 mg g^{-1} (Tipping et al., 2014; Brahney et al., 2015b) but the form of particulate phosphorus will greatly influence the bioavailability of deposited phosphorus. Exchangeable and water-soluble phosphorus are the most bioavailable, while phosphorus bound in organic matter can be released in the water column when broken down by free enzymes and microbes. Phosphate bound to Iron (Fe) or Aluminum (Al) oxides or phosphorus locked up in the mineral apatite may not be biologically relevant over seasonal timescales but may become available through longer time scales.

The source of atmospheric particulates influences the forms of particulate phosphorus. For example, dust originating from the Sahara are dominantly minerogenic, with the organic fraction making up just 1% of the dry mass (Eglinton et al., 2002). Much of the phosphorus in this dust is tied up in apatite and iron minerals (Clausnitzer and Singer, 1996; Eijsink et al., 2000). Nevertheless, studies have shown that approximately 10% of the phosphorus in the Saharan dust becomes available within one hour, and an additional 30–40% within just 16 hours (Herut et al., 1999; Ridame and Guieu, 2002). Dust originating from agricultural or semi-arid soils, in contrast, can have organic concentrations that range from 15% to 67% by weight of dry mass (Dahms and Rawlins, 1996; Malm et al., 2004; Lawrence and Neff, 2009). Particulates from biomass burning may also be enriched in phosphorus (Newman, 1995; Boy et al., 2008; Ponette-Gonzalez et al., 2016). However, the concentration of P in emitted ash may vary with both the type of vegetation burning and the intensity of the fire (Maenhaut et al., 1996; Vicars et al., 2010; Vicars and Sickman, 2011).

Because phosphorus is a key limiting nutrient in aquatic ecosystems, the atmospheric deposition of this nutrient to remote sensitive aquatic ecosystems is of concern. The capacity for dust to affect phosphorus nutrient subsidies in mountain lake systems was first identified in the Austrian Alps (Psenner, 1999). Since then, other studies elsewhere in mountain regions of Europe, Asia, and the US have shown the effects of dust associated phosphorus deposition on controlling lake water nutrient chemistry, productivity, and species composition (Sickman and Melack, 2003; Morales-Baquero et al., 2006; Pulido-Villena et al., 2008; Tsugeki et al., 2012; Brahney et al., 2014). A 2016 study showed that oligotrophic (low phosphorus) lakes and streams in the continental US may be becoming higher in nutrients and the sites most affected were the most remote with the least amount of human influence within the catchment (Stoddard et al., 2016). This result suggests that phosphorus is likely entering these catchments via the atmosphere, potentially as dust. Lowland lakes are not exempt from the influence. For example, in regions with intense burning, even large lakes have been enriched in nutrients due to large atmospheric contributions (Tamatamah et al., 2005; Boy et al., 2008).

Research in the Wind River Range of Wyoming, US has provided strong correlational evidence that even at low deposition rates (e.g., <4 g m^{-2} $year^{-2}$), dust can transport phosphorus in sufficient quantities to affect lake systems. Because the dominant dust source to the Wind River Range is the nearby Green River Valley, a gradient in dust deposition across the range exists (Dahms, 1993; Dahms and Rawlins, 1996; Brahney et al., 2014). Dust affected lakes in the range had higher total phosphorus (TP) concentrations and up to two orders of magnitude greater primary and secondary production than nearby non-dust affected lakes (Brahney et al., 2014). Sediment core analyzes corroborated the spatial analyzes and showed temporal relationships between dust deposition and the diatom-inferred phosphorus concentrations in lakes (Fig. 12). This research highlights that while large dust storms or haboobs may generate public interest, smaller chronic emissions, which may not be visible via satellite, may lead to significant cumulative consequence in receiving water bodies.

There is a growing body of evidence that dust phosphorus can have measurable consequences in lake ecosystems Sickman and Melack, 2003; Reche et al., 2009; Vicars et al., 2010; Ballantyne et al., 2011; Camarero and Catalán, 2012; Brahney et al., 2014, 2015a,b). However, all but one of these studies (Reche et al., 2009) relied on correlational rather than experimental analyzes. Therefore, more research on the role of dust phosphorus is required to fully understand ecosystem impacts.

Calcium

Calcium is an important nutrient for many organisms in lake systems, but in particular for invertebrates, where the element makes up a key component of their shells and carapaces (Tessier and Horwitz, 1990; Wærvågen et al., 2002). Calcium leached from dusts into aquatic systems may be derived from a variety of minerals including feldspars, phyllosilicates, gypsum, dolomite, and calcium carbonate ($CaCO_3$). The dissolution of calcium carbonate and other dust minerals either in precipitation or in depositional water bodies can provide readily available calcium ions (Ca^{2+}) to remote mountain lakes (Pulido-Villena et al., 2006). For regions with catchments having low natural calcium abundance, this contribution may be a critical source of calcium to aquatic organisms with relatively high calcium requirements. Measured calcium carbonate concentrations from Chinese dust sources have ranged from 2% to 10% (Jacobson and Holmden, 2006), African sources from 2% to 20% (Guieu et al., 2002), U.S. sources from 1% to 25%, and up to 33% in parts of the Middle East (Singer et al., 2003). For example, in the Sierra Nevada Mountains in Spain, paleolimnological research showed that in the last ~50 years there has been an intensification of dust and Ca^{2+} inputs from the Sahara (Jiménez et al., 2018). This, combined with the effects of climate change, resulted in increased Ca^{2+} concentrations, which in turn, led to an increase in *Daphnia*, a Cladocera taxon, whose growth and reproduction can be impaired by low Ca^{2+} (Jeziorski et al., 2008). *Daphnia* is a keystone genus, and the expansion of their populations is an indication of significant environmental changes in this region, illustrating the role dusts may have in shaping community composition.

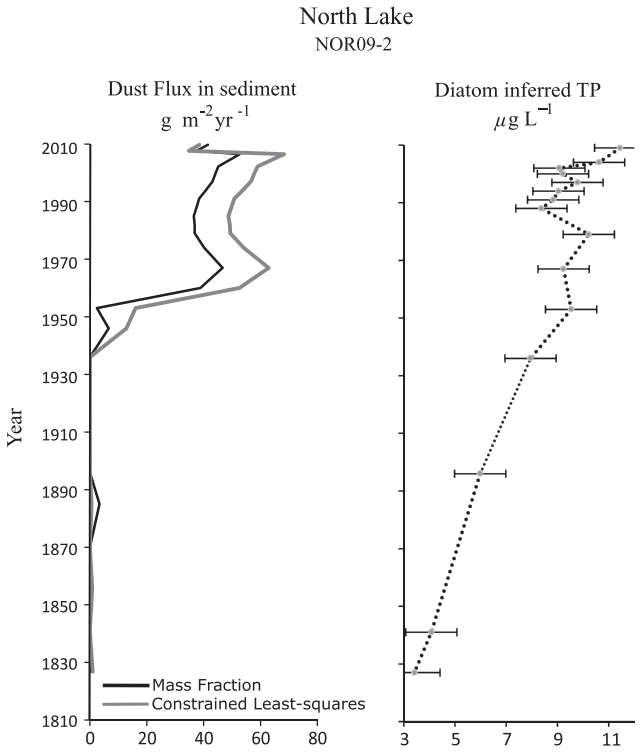

Fig. 12 Historical dust deposition rates to North Lake in Wyoming paired with diatom-inferred total dissolved phosphorus (TDP) concentrations.

Carbon

Dissolved organic carbon (DOC) concentrations in high-elevation lakes has been associated with the water-soluble organic carbon fraction of dust (Reche et al., 2009; Mladenov et al., 2011). Because alpine lakes are above tree line, terrestrial production and export of dissolved organic matter (DOM) is generally low and alpine lake transparency high. DOC not only serves as a substrate for microbial metabolism, but also adsorbs harmful ultraviolet radiation (UVR) that would otherwise act to suppress production. Thus, the dust-mediated transport of water soluble organic carbon (WSOC) can have both physical and biotic implications. A study in the Mediterranean reservoirs showed that dust transport of DOC into waterbodies reduced transparency and (UVR) penetration, and was associated with shallower mixing depths (de Vicente et al., 2012). Nutrient and DOC inputs from dust likely also support microbial growth in receiving water bodies (Pulido-Villena et al., 2008; Reche et al., 2009; de Vicente et al., 2012).

Metals

Along with macro nutrients (N, P, C, Ca) dust can transport trace elements that can act as either nutrients or toxins, depending on the concentration. Although several studies have quantified the metal concentrations within dust and the role of dust in transporting heavy metals such as As, Cd, Cr, Cu, Fe, Ni, Pb, Sb, Se, and Zn to aquatic systems (Sweet et al., 1998; Reynolds et al., 2014; Brahney et al., 2015a), there are no studies to date that directly examine the influence of dust-metal deposition on the ecology of lake systems. However, Goldman et al. (1990) attributed an increase in Lake Tahoe production during forest fires to nutrient and trace metal additions via ash deposition. Iron is critical for biological processes, including photosynthesis and nitrogen fixation, and may be limiting in some oligotrophic lakes systems (Vrede and Tranvik, 2006; North et al., 2007). Bhattachan et al. (2016) showed that dust iron (Fe) is more soluble than soil Fe and provided evidence that Fe in dust becomes more soluble through atmospheric processing, thus atmospheric processes may increase the bioavailability of soil macro and micronutrients. Future work might focus on quantifying the bioavailability of dust metal deposition to inland, oligotrophic systems, and the role of multi-element nutrient limitation on community composition and production.

Microorganism deposition to and export from inland waters

Dust and fog transport may represent a significant mechanism for the dispersal of microbes ranging from viruses to fungi across ecosystems, which have the potential to alter the function of resident communities (Kellogg and Griffin, 2006; Lindström and Östman, 2011; Yamaguchi et al., 2012; Reche et al., 2018). Microhabitats within dust and in situ sediment particles have been shown to enhance the survival of pathogens extending their range of influence (LaBelle and Gerba, 1982; Rao et al., 1984; Reche

et al., 2018). Further, microbes in coastal fog have been shown to resemble aquatic and terrestrial genera (Dueker et al., 2012; Evans et al., 2019), demonstrating that fog can be a vector of microbes from aquatic to adjacent terrestrial ecosystems.

Experiments in the Sierra Nevada and Pyrenees Mountains of Spain demonstrated the viability of transported taxa in laboratory experiments (Hervàs et al., 2009; Reche et al., 2009). However, the likelihood of establishment in a recipient habitat will relate to seeding pressure and the resident community composition (Jones et al., 2017). This microbe seeding may be particularly influential in mountain regions where the losses of perennial snowpack and glaciers have exposed new terrain and established new terrestrial and aquatic systems. Although atmospheric deposition of dust is likely to result in dispersal of microbes to inland waters (Peter et al. 2014), recent research suggests that fog may be a vector for microbial export from inland waters to adjacent terrestrial systems (e.g., Dueker et al., 2012; Weathers et al., 2020). Aerosols generated from lake surfaces have also been shown to contain cyanobacteria and associated toxins (Cheng et al., 2007; Banack et al., 2015; Olsen et al., 2018). The export and import of microbes to lakes and the ecological relevance of these processes are currently not well understood.

Aerosol effects on solar radiation

Dust and fog also have the ability to affect photosynthetically active radiation (PAR) in aquatic ecosystems. In fact, the greatest impact of fog on inland waters is likely to be indirect through its effect on PAR. Fog has been shown to reduce PAR and affect photosynthesis in terrestrial systems (Weathers et al., 2020). However, in terrestrial systems that are enveloped in fog, there is a counterbalancing effect on plant productivity through hydrologic modulation by fog: trees transpire less. In a similar way, dust can absorb PAR and it is likely that during periods of intense biomass burning, lakes experience diminished solar irradiance to a point where primary production is altered (Scordo et al., 2021) (Fig. 13).

Dust and fog effects vary by lake and catchment characteristics

The effect of dust and fog on water chemistry and biology in aquatic ecosystems will vary with catchment and lake characteristics. Geology, aspect, slope, catchment morphometry, and vegetation type and cover can all act to either mollify or exacerbate the influence of atmospheric deposition on receiving water bodies (Morales-Baquero et al., 1999). Steep, rocky slopes with poor vegetation cover can be very effective at delivering atmospherically deposited nutrients to waterbodies, whereas vegetation and soils can take up nutrients either effectively delaying the transport to the waterbody or preventing it altogether.

In steep mountain catchments, dust material can be mechanically focused into lake basins by either wind redistribution, or overland flow. However, catchment geology will play a role in the transport of phosphate as it binds tightly to available Al and Fe-oxide minerals, even when vegetation is poor. An abundance of these minerals within catchments may effectively immobilize phosphorus on the landscape (Vicars et al., 2010; Kopáček et al., 2011, 2015). Conversely, watersheds with poor soil development and a low abundance of Aluminum (Al) and Fe bearing minerals may allow for the effective transport of dust–phosphorus to lake basins (Tsugeki et al., 2012; Brahney et al., 2014).

Lake morphometry, including area, depth, volume, and fetch can influence whether lakes are more or less susceptible to the effects of atmospheric deposition. The addition of nutrients and other compounds can be diluted if the volume of the upper mixed layer of a lake (epilimnion) is relatively large, for example. Pre-existing lake conditions are also likely to influence the role of atmospheric nutrient deposition. Acidified lakes are likely to respond to a greater degree to dust alkalinity contributions and phosphorus limited lakes may see a greater increase in production than lakes that are predominantly nitrogen limited. Those hypotheses have yet to be explicitly tested.

Fig. 13 A lake enshrouded in fog to the extent that solar radiation reaching the lake surface is diminished. Similar effects may occur with excessive particulates in the air from smoke or inversions. Peter Dasilva/EPA, via Shutterstock.

A special case: Mountain lakes

Mountain lakes and their catchments are highly varied in their composition (Fig. 14). Thus, the response of any one lake to similar dust composition and deposition rates are likely to vary. Mountain ranges act as natural barriers to the atmospheric transport of material and orographic precipitation on windward slopes that may produce fog and effectively scrub the atmosphere of particulates. Mountain lakes tend to be particularly sensitive to atmospheric deposition due to their small, steep, and poorly vegetated catchments. These types of lakes are also excellent recorders of dust deposition due to enhanced mechanical transport of dust to lake basins. Further, a uniform and simplified geology of small catchments allows for the geochemical tracking of dust deposition rates in sediment core studies (Neff et al., 2008; Reynolds et al., 2010; Brahney et al., 2015a; Routson et al., 2016). Researchers can use the geochemical composition of dust and catchment bedrock as fingerprints and the relative amount of bedrock versus dust material that accumulates in a lake's sediment can be used to reconstruct historical dust loading. As such, mountain lakes provide an excellent context for studying changes in dust deposition and any associated effects on mountain lake chemistry and biology. Contemporary and paleolimnological analyzes in mountain lakes worldwide have shed light on long- and short-term dust histories as well as the variation in chemical composition, and influence on aquatic ecosystems through the atmospheric addition of alkalinity, nutrients, trace elements, contaminants, and organisms.

Research on the dust-mediated transfer of phosphorus to aquatic systems has primarily focused on oligotrophic mountain lake systems as they have few alternative watershed sources of nutrients (Morales-Baquero et al., 2006; Vicars and Sickman, 2011; Camarero and Catalán, 2012; Brahney et al., 2014). Similarly, the atmospheric deposition of N and its effect on aquatic systems is pronounced in mountain watersheds where natural concentrations are low and abatement through catchment uptake is limited (Baron et al., 2000, 2011; Wolfe et al., 2001; Nydick et al., 2003; Elser et al., 2009a). Thus, in mountain systems, a small change in atmospheric loads can result in a large change in absolute nutrient concentrations, causing mountain lakes to be more susceptible to the influence of atmospheric deposition than lowland lakes and those with large watersheds (Moser et al., 2019). For example, in the Sierra-Nevada Mountains of Spain, dust associated P deposition ranged from 24 to 38 $\mu g\ P\ m^{-2}\ day^{-1}$, a seemingly small contribution, yet this deposition rate had measurable effects on productivity, nutrient ratios, bacterial abundance, and plankton diversity (Morales-Baquero et al., 2006; Pulido-Villena et al., 2008; Reche et al., 2009). In fact, there is evidence suggesting mountain lakes may experience reduced functional diversity and a diminished efficiency in the trophic transfer of energy up the food web as a consequence of dust deposition (González-Olalla et al., 2018). Because mountain lakes are sensitive to such perturbations, a warmer dustier future may fundamentally alter mountain lake community composition.

Summary

Dust and fog have the capacity to influence the physical, biogeochemical, and biotic components of inland waters both directly and indirectly. Paleolimnological, modeling, and monitoring studies have shown that soil and biomass emissions have increased across large regions of the globe (Neff et al., 2008; Mulitza et al., 2010) and the resulting deposition has led to ecosystem shifts, such as elevated production, changes in pH, and associated changes in community composition. Because particulate emissions are tied to human land-use changes from pastoralism, food production, biomass burning, and the frequency and severity of drought, it is reasonable to conclude that with human population growth and climate change, eolian dust may become more important to aquatic ecosystems in the near future (Foley et al., 2005; Hudson, 2011; Trenberth et al., 2014). Fog is more likely to have indirect impacts on inland waters through scattering and absorption of incoming light, and hydrologic and biogeochemical impacts to adjacent catchments. However, in some systems and under certain conditions, inland waters may be a source of condensation nuclei for fog and thus result in an export of biotic or abiotic materials from inland waters to surrounding terrestrial systems.

Knowledge gaps

There are many knowledge gaps in our understanding of dust and fog deposition and subsequent direct and indirect effects on inland water ecology and ecosystem processes. Here we outline a few. While we know that what goes up into the atmosphere must come down, we know less about what is emitted, transported, and deposited when it comes to dust and fog. For example, there are few studies that have examined novel pollutants, pesticides (xenobiotics), nanoplastic, metals, or ash in either dust or fog, or what quantities of these chemicals make their way into aquatic ecosystems. Whether the aerosols and chemicals that are transported are also bioavailable to aquatic systems is also a major question. We know that dust can contain relatively high concentrations of nutrients, like phosphorus. However, phosphorus in dust can be found at mineral or organic exchange sites, bound within organic matter, or locked up in minerals. The ability for an aquatic organism to acquire dust-derived nutrients may also vary with antecedent lake properties, like pH and nutrient limitation. At present, the variability in dust composition and thus the bioavailability of dust-nutrients is not well quantified and there are limited studies evaluating how aquatic organisms respond directly to dust deposition in either controlled or in-lake experiments.

In recent years there has been an increasing interest in understanding to what extent materials move from inland waters to adjacent ecosystems via atmospheric transport. Of particular interest and concern is the transport of potentially toxic substances such as cyanotoxins. Further, several studies have shown that dust, and sometimes fog, can transport viable microbes to distal locations, and that the composite microbial community reflects the particle source area. However, whether or not the deposited microbes influence or shape the resident microbial community has not yet been addressed in the literature.

Finally, along with climate warming, dust on snow can change albedo and accelerate snowmelt (Skiles et al., 2018) leading to shifts in the pulse of water and nutrients to receiving water bodies. Changes in the timing snowmelt has led to shifts in periphyton communities in river systems. It is possible that dust-induced earlier runoff and nutrient delivery could impact lake ecosystems as well, but to date we are unaware of any research targeting this specific question.

Glossary

Automatic call recognizer An application that uses various techniques (often machine learning or artificial intelligence) to automatically find acoustic events.
Autonomous Recording Unit A self-contained audio recording device that is deployed in marine or terrestrial environments for bioacoustical monitoring.
Bioacoustics The branch of acoustics concerned with sounds produced by or affecting living organisms, especially as relating to communication.
Ecoacoustics An interdisciplinary science that investigates natural and anthropogenic sounds and their relationship with the environment over a wide range of study scales, both spatial and temporal, including populations, communities, and landscapes. Ecoacoustics operates in all types of terrestrial and aquatic (freshwater and marine) ecosystems extending the scope of acoustics and bioacoustics.
Hydrophone A microphone designed to be used underwater for recording or listening to underwater sound. Most hydrophones are based on a piezoelectric transducer that generates an electric potential when subjected to a pressure change, such as a sound wave.
Passive acoustic monitoring (PAM) Is used to measure and monitor sounds emitted by organisms or ecosystems. It differs from active acoustic monitoring which often manifests itself by sonar emissions from research vessels.
Soundscape The acoustic environment as perceived by humans.

Introduction to aquatic bioacoustics and ecoacoustics

Environmental changes—both natural and human-induced—can be very difficult to monitor. Often remote locations can be only reached infrequently so changes in the environment that occur between sampling events can be hard to detect. Ability to detect change is also exacerbated in freshwater systems, for which specialized equipment and expertise are often needed. Freshwater species are about three times more likely to be endangered by extinction than terrestrial taxa, making it crucial to properly monitor these species (Almond et al., 2020). Bioacoustics and its sister discipline ecoacoustics are emerging non-invasive and real-time monitoring techniques that have been used to survey rare and endangered species' population trajectories and the impact of human activities on ecosystems (Sueur and Farina, 2015; Farina and Gage, 2017). Bioacoustics is analogous to biology—i.e., studying single species and the sounds they produce, including production mechanisms. Ecoacoustics is an interdisciplinary science that investigates natural and anthropogenic sounds and their relationship with the environment over a wide range of study scales, both spatial and temporal, including populations, communities, and landscapes.

Problem 1: Risks to fish health and habitat integrity. Classic techniques like netting and electrofishing can cause injury or even death in fish. This is inappropriate for sensitive or threatened species.

Problem 2: Bias. While all sampling methods are biased to varying degrees, a key source of bias is the act of sampling itself. It often causes fright responses of the target fish, making detection difficult.

Problem 3: Temporal variation. Usually single survey events are used to estimate ecosystem health and monitor population. This can only deliver a snapshot of the population at a single sampling time.

Fig. 1 Three key problems with traditional monitoring that ecoacoustics solves.

Ecoacoustics addresses three problems with more traditional sampling methods (Fig. 1). Apart from mitigating sampling-induced risk of damage to species and ecosystems as well as certain sampling biases, acoustic monitoring is able to autonomously detect continuous environmental change in an ecosystem. This is a major improvement on classic sampling techniques which often only entail annual or quarterly sampling.

In terrestrial systems, acoustic monitoring has been used to monitor wildlife populations for many decades. Historically, tape recorders were used to capture the sounds of nature by researchers like Aldo Leopold and Rachel Carson who used acoustics in behavioral and ecological studies. Sounds have been used to survey birds and amphibians since the 1960s, formalized in the Breeding Bird Survey of North America (Peterjohn and Sauer, 1999). These surveys were then manually processed by listening to the recordings to tally call types and frequencies. These manual survey processing techniques that resulted in studies optimizing call detection continued until the 21st century. The first auto-detection algorithms were developed between 1996 and 2005 with increased and accessible computational power as research computing moved from centralized clusters to home computers and laptops. Automatic processing revolutionized both bioacoustics and ecoacoustics as much larger data volumes could be processed.

Ecoacoustics is an emerging discipline studying the ecological relevance of environmental sounds (Sueur and Farina, 2015; Farina and Gage, 2017). It studies sounds at ecologically relevant scales including the individual, population, community and landscape (or soundscape). An acoustic population is composed of the songs of one species. An acoustic community is made up of different species producing sounds. Finally, a soundscape not only includes the acoustic community (biophony) but also geological sounds (geophony) such as wind or rain and anthropogenic noises (anthropophony) such as airplane or car sounds (Pijanowski et al., 2011). In this chapter, we discuss the history of bioacoustics in freshwater systems, as used to study both fish and invertebrates. We then describe abiotic sounds and introduce the holistic field of ecoacoustics. After a short primer on analysis techniques, we cover current challenges and recent frontiers in the field, before closing with a discussion of ecoacoustics as an engagement tool.

History of bioacoustics in inland waters

While even experienced freshwater ecologists are often unaware of the diversity in underwater sounds, the field of bioacoustics has a long tradition. In his Historia Animalium, Aristotle described the two key methods of sound production in fish in close to correct anatomical detail (Aristotle, 1910). Aristotle mentioned both stridulation ("rubbing motion of the gills"), as well as the use of the swim bladder ("an organ with air inside it") as sound producing mechanisms. In the 17th century, Izaak Walton noted that fish could hear and in the middle of 19th century sound production in fishes was also mentioned in communications to Charles Darwin by Fritz Mueller (https://www.darwinproject.ac.uk/fritz-m-ller). Mueller described sound production in 10 families, both by stridulation and vibration of the swimbladder. Ralph W. Tower—a professor at Brown University—in 1908 described the sound production mechanism of three drumfishes, as well as the sea-robin and toadfish in a groundbreaking and anatomically detailed study, paving the way towards an expanding field of research and on-ground applications (Tower, 1908).

The abundance of reference calls for fish is still greatly lagging behind reference calls for birds or anurans, despite a large effort by two researchers in the 1970s, Marie Fish and William Mowbray (Fish and Mowbray, 1970). The entire archive was digitized and is currently still shaping the backbone of the fish section within the Cornell's Macaulay Library sound archive. That said, the library still only harbors ~900 fish calls, as opposed to ~1.2 million bird calls, although this is hard to quantify as the taxonomic backbone for 'Actinopterygii' has recently disappeared from the library. Currently, a major drive to catalogue fish sounds is underway—on the aptly named 'FishSounds' platform (https://fishsounds.net/).

The science of behavioral aspects of fish sound and communication was driven forward by academics in North America and Europe including Arthur Popper, Michael Fine, Friedrich Ladich and Eric Parmentier, among many others (Ladich and Fine, 2006; Fine and Parmentier, 2015). In the early 2000s, a group of researchers led by Rodney Rountree and Joseph Luczkovich led the charge to drive an expansion of the field of applied ecoacoustics, especially of fish (Luczkovich et al., 2008). In recent years, researchers in the freshwater realm started to document calls, but also began to use acoustic data in behavioral and general ecological studies. For example a research group led by Rodney Rountree started cataloguing the sounds of six piranha species in the Amazon

(Rountree and Juanes, 2020) and a few Canadian studies looked at behavioral aspects of burbot (*Lota lota*) under arctic winter ice using acoustics (Grabowski et al., 2020). The science of building automatic recognizers and other processing options has also greatly progressed, starting with an automatic signal processing workflow for river redhorse (*Moxostoma carinatum*) spawning by a group of American researchers from the University of Georgia (Straight et al., 2014).

Fish bioacoustics

Fish have one of the highest diversities of vocal organs of any animal group, with many sounds made by the swim bladder—a gas filled organ that is mainly used to regulate buoyancy in the water column (Fig. 2). Similar to a plastic air balloon or a drum skin, the

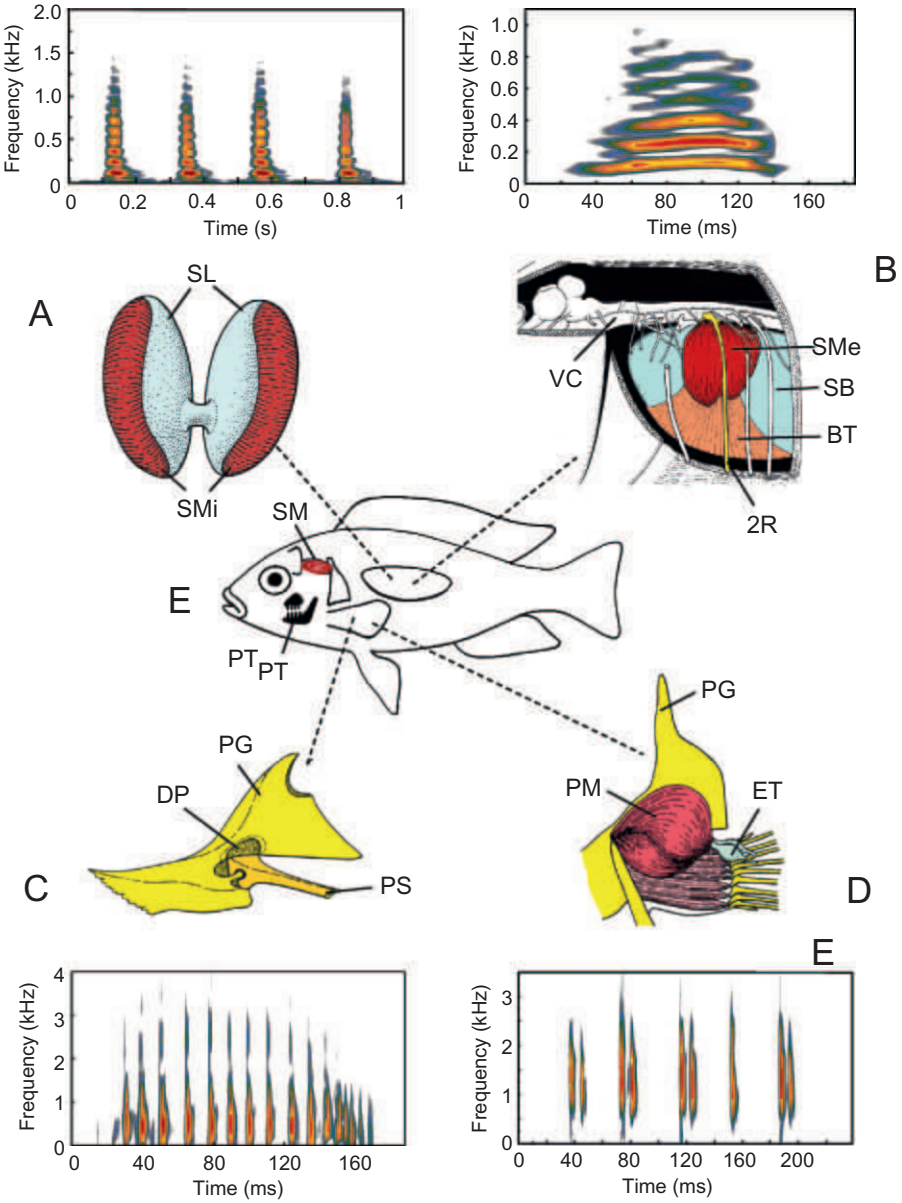

Fig. 2 Diversity of sound generating mechanisms in fishes and sonagrams of sounds produced by these mechanisms. (A) Intrinsic sonic muscles (SMi) attached to both swim bladder lobes (SL) in the Lusitanian toadfish *Halobatrachus didactylus*, (B) extrinsic sonic muscles (SMe) originating at the second rib (2R) and inserting on a broad tendon (BT) ventrally of the swim bladder in the black piranha *Serrasalmus rhombeus*, (C) in the stridulatory mechanism in catfish a ridged dorsal process (DP) of the pectoral spine (PS) rubs in a groove of the shoulder girdle (SG), (D) enhanced pectoral fin tendons (ETs) are plucked similar to guitar strings in the croaking gourami *Trichopsis vittata*, (E) Pharyngeal teeth (PT) stridulation in damselfish, sunfish, among others, and pectoral girdle vibration in sculpins by a sonic muscle (SM) originating at the skull and inserting at the dorsal part of the pectoral girdle. 2R: second rib, BT: broad tendon, DP: dorsal process of pectoral spine, ET: enhanced tendons, PG: pectoral girdle, PM: pectoral adductor muscle, PT: pharyngeal teeth, PS: pectoral spine, SL: swim bladder lobes, SM: sonic muscle, VC: vertebral column. All sonagrams show sounds produced in agonistic contexts. With permission from Ladich (2014).

vibrations of the swim bladder produce harmonic sounds, allowing it to be used as a resonator in sound production (Ladich, 2014). Sound production using the swim bladder includes a variety of mechanisms—hinting at convergent evolution—with the common feature being the perfect resonator of the swim bladder itself (Ladich and Fine, 2006). Some fish—toadfishes (Family: Batrachoididae) for example—have intrinsic muscles that trigger the vibration of the swim bladder to produce sound. Other taxonomic groups trigger the vibrations in the swim bladder by external muscles (Ladich, 2014). These muscles can be either directly attached to the swim bladder—for example in the family Terapontidae, a common family of freshwater grunters in Australia. The second mechanism, observed in Piranhas is an indirect connection via tendons or bony plates (Rountree and Juanes, 2020).

Not all sound production mechanisms involve the swim bladder. Catfish (multiple families in the order Siluriformes) rub a spine against the pectoral girdle—located under the pectoral fin—to produce a sound by stridulation (Ladich, 2014). The nature of this sound means that catfish can be heard above water as the production mechanism is not associated with the airfilled resonator that collapses above water. Other sound producing mechanisms around the pectoral fin are tendon vibration—often compared to plucking a guitar string, as well as vibration of the entire pectoral girdle in sculpins (Superfamily: Cottidae). Last, stridulation sounds can also be produced by grinding pharyngeal teeth, a second mechanism of piranha sound production, but also observed in damselfish (Family: Pomacentridae) and sunfish (Family: Molidae) (Fig. 2; Ladich, 2014).

Invertebrate bioacoustics

Aquatic invertebrates—especially insects—are one of the major components of the freshwater orchestra (Linke et al., 2018; Desjonquères et al., 2020). A wide diversity of insects and a few freshwater crustaceans are known to produce sounds underwater. This includes four orders of insects—Coleoptera, Heteroptera, Odonata and Trichoptera (Desjonquères et al., 2015). Sound production has been reported in one family of Asian Odonata larvae, one family of Trichoptera larvae, and two Coleoptera larvae species. Sound production in larvae is relatively anecdotal in contrast with sound production in Coleoptera and Heteroptera adults. Six families of Coleoptera and seven families of Heteroptera are known or suspected to produce sounds (Aiken, 1985).

Most insects and Crustaceans stridulate: they rub a tough ridge—the scraper—against a finely striated surface—the file. Most people are familiar with crickets producing sounds by rubbing their hind legs against their elytras; in the case of aquatic insects, a variety of body parts are involved. Most Corixidae produce sounds by rubbing a striated area of their front legs on the ridge of their head (Aiken, 1985). Other body parts involved in insect sound production include the abdomen, wings, various leg segments, and genitalia (in *Micronecta* sp. for example). Although stridulation is the most common mechanism of sound production in insects, some species produce sounds in other ways including muscle contraction (e.g., in a lesser diving beetle, *Acilius sulcatus*), or air expulsion (e.g., in the larvae of the great silver water beetle *Hydrophilus piceus* or the diving beetle *Cybister confusus*).

Aquatic invertebrates produce sounds for reasons similar to their terrestrial counterparts: sex, fear and food. Many insect signals are associated with reproduction. For example males produce signals to attract females and repel male competitors. Such is the case with water boatman males, *Palmacorixa nana*, which produce courtship signals to attract females. Females are attracted to the densest aggregations of calling males while males avoid those dense aggregations where they experience more antagonistic interactions. Some insect larvae and adults such as *Hygrobia* beetles produce antipredator squeaks when handled. *Hygrobia* beetles were even sold as 'squeakers' in London's Covent Garden Market (Aiken, 1985). Finally, some caddisflies in the family Hydropsychidae emit ultrasounds when fighting for their retreat and feeding territory (Vuoristo and Jansson, 1979).

Although invertebrates are one of the major components of the underwater orchestra, they remain a neglected focus of freshwater bioacoustic and ecoacoustic studies. A recent review of the literature highlights that they represent the focus of only a quarter of the freshwater acoustic studies while they are estimated to constitute almost 90% of the sound producers(Greenhalgh et al., 2020). This neglect is likely the source of our limited knowledge about the mechanisms and functions of sounds produced by invertebrates.

The sound of physico-chemical processes

Various physico-chemical processes produce sounds including flow turbulence, sediment transport and gas emissions (Linke et al., 2018). First, similar to wind in terrestrial environments, the water current in rivers and streams is an important source of sounds. Some may consider it as noise concealing animal sounds. Yet flow sounds can be rich and informative. These sounds result from flow turbulence and sediment transport and are thus indicative of geomorphological characteristics of the study locations (Tonolla et al., 2011; Lumsdon et al., 2018). Such sounds have enabled researchers to classify different river segments and habitat types, differentiate rivers with and without hydropeaking, and quantify water reaeration.

Another important component of freshwater soundscape comes from gas emitted by ecological processes such as organic matter decomposition, plant respiration and photosynthesis. Anaerobic decomposition of organic matter by micro-organisms may create methane pockets in the sediment that when released produce diverse bubbling sounds in standing water environments such as ponds and lakes (Linke et al., 2018). These decomposition sounds often co-occur with the sound of photosynthesis. Aquatic plants and algae release oxygen bubbles when photosynthesizing. These bubbles may produce ticking and whistling sounds when expelled in specific conditions (Freeman et al., 2018). Recent soundscape research shows that soundscape daily variation was related to oxygen daily variation, suggesting that such sounds may constitute important drivers of the soundscape (van der Lee et al., 2020).

Researchers are starting to uncover sounds related to physico-chemical processes. But this area requires extended research to better understand these sounds. Do different plant species produce different sounds? Do environmental conditions influence these sounds? Monitoring these sounds is likely to provide valuable insights towards the understanding of dynamics of ecological processes in freshwater environments.

Anthropogenic noises

In addition to being a tool for monitoring and assessment of natural components of ecosystem health, the soundscape can also assess the amount of anthropogenic noise present. As vocalizations have a communicative role for many soniferous animals, the incursion of human-induced noise can interfere with the normal functioning of an ecosystem. As with other aspects of freshwater ecoacoustics, knowledge regarding the impact of noise on freshwater ecosystems is sparse compared to terrestrial and marine environments, for which there is an abundance of evidence that noise has often deleterious effects.

In freshwater environments, anthropogenic noise comes from various sources including transport (boats but also cars on nearby roads and bridges), recreation (water parks), extraction (gravel pits) and construction activities. These noises can be present in a wide range of environments, including lakes, rivers and ponds. For example, in Irish lakes surveyed by Marta Bolgan and her colleagues, anthropogenic noise reaches sound pressure levels as high as 135 dB re 1 μPa (Bolgan et al., 2016).

Freshwater taxa suggested to be negatively impacted by noise include various species of fishes, invertebrates, and river dolphins (Celi et al., 2013; Popper and Hawkins, 2019). Mechanisms of disruption include interference with the communicative functions of animal calls; behavioral change in response to sound, for example provoking fear responses; physical damage to hearing mechanisms in the case of loud sounds such as pile driving, and possibly interference in echolocation function. Recent research has also investigated the effect of noise on feeding behavior of freshwater fish and has showed that immediate effects of noise include less efficient prey capture (Purser and Radford, 2011). Noise could thus impose disruptions on the whole trophic chain.

For suitable conservation policies to be developed, much more work needs to be done to assess and quantify the impact of noise on freshwater environments. Whilst there is widespread recognition of 'noise pollution' as a policy issue in marine environments (although virtually no binding regulations to address it), there has been little corresponding governmental attention in freshwater environments.

Ecoacoustics—Theory and analysis methods

Until recently, the study of animal sounds has focused on single species in controlled experimental settings. Lately, researchers are starting to adopt a more integrative approach to understand the importance of environmental factors in influencing acoustic behaviors (Short et al., 2020). For example, the presence of noise, other species, or rain may result in variation in acoustic behavior. Concurrently, recording the sound emanating from the environment has become technically easier with the advent of autonomous recorders. Ecoacoustics has resulted from these two paradigm shifts (Sugai et al., 2019).

The ecoacoustic understanding of acoustic communities is currently based on two main theories: the acoustic niche hypothesis and the acoustic adaptation hypothesis (Krause, 1993). According to the acoustic niche hypothesis, each species occupies a specific acoustic niche and this pattern is driven by the cost of overlapping with other species. Species sharing the same vocalizing environment, timing and frequency band, are thus expected to diverge in at least one of those dimensions (time, space or frequency; Krause, 1993). The acoustic adaptation hypothesis posits that animals vocalizing should optimize their signal such that it propagates well in their environment. Thus, animals vocalizing in the same habitat should acoustically converge towards optimal propagation. These two hypotheses are expected to result in two different patterns of signal co-existence (Morton, 1975). This question of constraints in acoustic community assemblage has generated much interest and tests for these hypotheses reveal conflicting evidence. Novel theoretical development suggests that the two predicted patterns (divergence or convergence) may result from a variety of other ecological and historical processes and should thus be interpreted with care just as any other ecological community pattern.

Ecoacoustics relies heavily on data collected by autonomous recorders over several days, months and sometimes even years. Data volumes are usually too large to be processed manually by listening. For example, the Australian Acoustic Observatory—an Australian-wide passive acoustic monitoring scheme—will collect recordings equivalent to a duration of 2000 years of recordings over 5 years (Roe et al., 2021). Ecoacousticians thus need to use automatic or semi-automatic analysis methods. There are two main approaches: acoustic indices and signal classification.

Acoustic indices are mathematical functions allowing quantification of certain characteristics of the spectrogram thought to be related to some aspect of bio- or acoustic diversity (Sueur et al., 2014). They are cost-effective tools to characterize the variation in animal sound production in recordings. There are more than 60 acoustic indices available. They have been applied successfully to detect acoustic and biological diversity; to distinguish soundscapes in different environmental conditions including different time (Linke et al., 2020a), different habitats (Fuller et al., 2015) and land management types; or to estimate population abundance (Borker et al., 2014). The efficiency of acoustic indices as indicators of biological diversity is under a lot of scrutiny. In aquatic environments, this scrutiny has different stakes. Most acoustic indices were developed with bird songs in mind and thus may not be the best tools to characterize acoustic diversity in freshwater environments composed mostly of rhythmic, non-tonal sounds from insects and fish. Yet, acoustic indices allow us to detect spatio-temporal differences in freshwater environments (Linke et al., 2020a).

Another approach to automatically process recordings is the use of automatic signal detection and classification. This approach usually relies on machine learning techniques to detect and classify acoustic signals. These methods can require a labelled training dataset in the case of supervised learning or be based on clustering methods that do not require labelled data (Ulloa et al., 2018). Such approaches are particularly efficient to detect specific signals emitted by single species. Machine learning techniques can also be used similarly to acoustic indices to classify different types of sound recordings and detect acoustic anomalies in a dataset (Sethi et al., 2020).

Recent developments in applied freshwater ecoacoustics

Automatic processing

Driven by a thriving research community and easier access to both computational resources and reference calls, recent years saw exponential growth in the development of automatic processing in ecoacoustic applications. Automatic call recognizers are a key technique for automatic processing. The term 'call recognizer' is an umbrella term for a number of auto-detection techniques, ranging from hand-coded custom algorithms to even 'point-and-click' windows in applications like Kaleidoscope (Wildlife Acoustics, 2019) or Raven (Cornell Bioacoustics Research Program, 2011). Many applied studies in ecoacoustics currently choose an intermediate path in which algorithms are implemented in a larger statistical or mathematical framework, such as Matlab, R or Python libraries (for example Katz et al., 2016).

An example of a hybrid approach is a recent study in which our lab developed call recognizers for eight frog species (within the genera *Litoria, Limnodynastes, Crinia and Neobatrachus*) to monitor environmental water allocations. We used an algorithm 'binary point matching' delivered via the R package monitoR (Katz et al., 2016). The algorithm develops a template by transforming a spectrogram into a binary representation. It then searches for a matching pattern in the dataset the operator wants to find the sound in. The core algorithm is coded in R and the user can optimize three parameters:

- The call template, which is the actual call that is used to develop the recognizer.
- The amplification—if the call is too quiet this can lead to a lack of detections, if it is too loud it can confuse the algorithm.
- The threshold, which triggers a detection.

For the frog study, we optimized these three parameters, which was the manual part building the recognizer. This is just one potential avenue; recent developments have also increasingly used AI and machine learning techniques that automatically classify all acoustic events.

In freshwater science, the first automatic recognizer was a simple pattern matching algorithm to analyze and monitor spawning noises in river redhorse in Georgia (Straight et al., 2014). Lately, underwater recordings from the endangered spadefoot toad (*Pelobates fuscus*) have been used to develop a call recognizer and give insight into the anuran species' ecology, especially in regard to the breeding season (Dutilleux and Curé, 2020). With improvements in technology, we predict that further call recognizers will follow soon, as clear call characterizations have recently been published for a range of fish taxa, for example piranhas and burbot (Grabowski et al., 2020; Rountree and Juanes, 2020).

Ecoacoustic analysis

Ecoacoustics usually researches the ecology of acoustic signals as organisms interact with each other, as well as their environment. Ecoacoustics has been developed by and for ecological practitioners. Summary indices are often used to simplify complex acoustic data, including the amplitude of the signal (M)—which is analogous to species abundance, or an acoustic complexity index (ACI), analogous to species richness, as well as an entropy index (H) which is analogous to Shannon's diversity index (Sueur et al., 2014). These acoustic indices have been used extensively in terrestrial applications, including studies monitoring ecological responses to environmental water allocations (Linke and Deretic, 2020).

Acoustic indices have been deemed good surrogates for acoustic events in underwater environments. Utility of different indices seems to be varying—depending on the signal and the system. The first study in freshwater systems (Desjonquères et al., 2015) found that the acoustic richness index (which is a combined index of acoustic entropy and overall sound pressure) best described 48 sounds in 3 ponds. In a similar study in British ponds, a whole suite of indices, including M, H and ACI were found significant in representing sound types (Greenhalgh et al., 2021). A study in waterholes from Australia (Linke et al., 2020a) found that ACI, filtered by frequencies can be related to a suite of signals, including a nocturnal insect chorus, diurnal variation in creek flow, as well as fish choruses that mainly occurred in the mornings. In flowing waters, Decker et al. (2020) combined these indices to describe acoustic variation in 12 Queensland rivers.

A new visual analysis method involves the use of false-color spectrograms, which are constructed from multiple acoustic indices (Fig. 3; Linke et al., 2020a). While summary indices could depict insect choruses, flow and fish calls, false-color spectrograms are also able to detect variation within these events. The nocturnal hemipteran choruses for example display complex interaction patterns between multiple species of hemiptera, but also rise and fall in diurnal creek flow (Fig. 3).

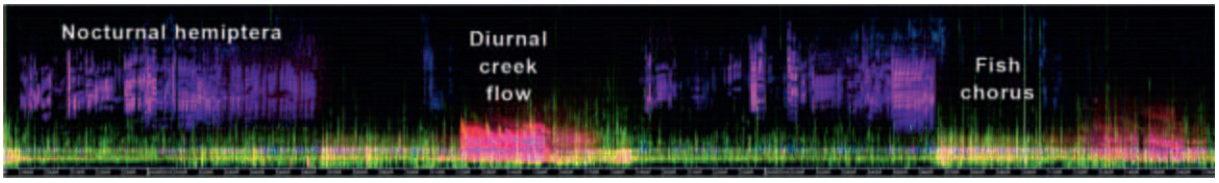

Fig. 3 False-color spectrogram of the diel variation in the Einasleigh River, Northern Australia described by Linke, Decker et al. (2020).

Linking sound to environmental condition

A limited number of studies have drawn links between frog and bird sounds and ecosystem condition in terrestrial and wetland settings (Linke and Deretic, 2020). However, a change in soundscapes does not automatically indicate the direction of change in an ecosystem. Soundscapes in degraded ecosystems for example, can become richer as ecological condition worsens, e.g., when pollution tolerant 'noisy' taxa start dominating the soundscape. Similarly, invasive species can increase soundscape complexity, while impeding ecological function. Previously, studies have investigated the response of bird and frog communities to disturbances (Fuller et al., 2015). This concept has even been extended to water-dependent terrestrial ecological communities in the United States and the Murray-Darling Basin. For example, in Australia, summary acoustic indices were utilized to track recovery of ecological communities in response to environmental water delivery as a restoration measure (Linke and Deretic, 2020). If we assume that an increased gradient of landscape complexity and good ecological condition will harbor higher species richness, it follows that the acoustic signal is enhanced by diverse complex communities.

The difference between aquatic and terrestrial applications of ecoacoustics is that only 20% of fish species and not all invertebrates are soniferous. Shifts in sonic activity will likely depend on the group of fishes. For example, an increase of the more pollution-tolerant Ariid catfish taxa will add to soundscape complexity, whereas displacement of more sensitive Terapontidae can reduce sonic activity. Therefore, an improvement in water quality is not directly related to an increase in sonic activity. Macroinvertebrates are important indicators of river health, but not all invertebrates produce sounds. While some sensitive taxa, e.g., caddisfly larvae, can be soniferous, the main classes of sound-producing organisms are aquatic hemiptera and beetles that have higher tolerances to warm water, low dissolved oxygen and mild organic pollution (Fig. 4). That said, dominance of very tolerant taxa e.g., chironomids and oligochaetes, will lead to a quieter soundscape. Thus, the most diverse soundscapes may be found at intermediate environmental conditions.

So far, few studies have linked acoustic measures to ecological condition in freshwater systems. A geomorphic link was established when comparing the sounds of pristine streams to streams that were impacted by sedimentation—mainly caused by grazing (Tonolla et al., 2011). Through the increased sediment input, gravel beds turned into sand beds and consecutively, the soundscapes were a lot quieter. Recently, a study from Holland related dissolved oxygen levels to underwater soundscapes. The change in soundscape was expressed not only by the proximate cause (i.e., roughness of the riverbed) but there was also a relation between sonic activity and dissolved oxygen (van der Lee et al., 2020). Listening to the invertebrate community, therefore demonstrated a first hint towards the validity of our theory of intermediate disturbance.

Knowledge gaps

Automated analysis of freshwater recordings is complicated by our general lack of knowledge regarding inland water soundscapes. Compared with terrestrial and marine environments, there has been relatively little history of freshwater acoustic analysis. In order to advance the field to the point of practical widespread application for conservation, a concerted global effort in recording, cataloguing, analyzing and sharing freshwater soundscapes is needed.

Over the last 5 years or so, automated analysis of data by computer algorithms has been revolutionized by a technique known as deep learning—a type of machine learning that leverages the increasing power of highly parallel computer graphics cards. Deep learning has been successfully applied to finding structure in complex data in a number of application domains, both supervised (with the help of human annotations) and unsupervised (without annotations). Deep learning has been recently applied in ecoacoustics for unsupervised learning in terrestrial and marine environments (Sethi et al., 2020), and supervised learning in freshwater environments (Guyot et al., 2021). The possibility of further using unsupervised automated analysis techniques in freshwater ecoacoustics is tantalizing, as it would facilitate a step-change in the volume of data analysis feasible.

Ecoacoustic monitoring generates high volumes of data. The logistical benefits of passive acoustic monitoring—namely the relative ease of long-term remote multi-site observation—tends to result in datasets much larger than typically encountered in ecology, sometimes of the order of PetaBytes. The storage and processing of such large datasets is a key challenge in ecoacoustic work

Fig. 4 Pollution tolerant taxa are responsible for key changes in aquatic soundscapes.

in any environment. Typically, studies will employ temporal sampling regimes (for example recording 1 min of every 10 min) and impose audio quality constraints by recording at low sample rates (for example 16,000 samples per second) to reduce data capture volumes. There is a trade-off, however, as such sampling regimes may miss rare but important events, the serial correlation patterns in acoustic indices are not generally known which confounds statistical inference, and high frequency sounds may be missed (Linke et al., 2020b).

The importance of spatial replication is increasingly being recognized in ecoacoustics generally. However, freshwater environments place greater demands in this regard, particularly in comparison to marine ecoacoustics. A foundational tenet of marine ecoacoustics is that sound travels far underwater, however this is not generally true in freshwater, particularly in shallow environments. On the contrary, sound there can be attenuated much more sharply than in terrestrial environments (Karaconstantis et al., 2020). Consequently, freshwater ecoacoustics can demand higher spatial replication and concomitant data storage and recording equipment requirements.

Because of the difficulties associated with data storage (Barclay et al., 2018), processing audio data in situ (i.e., at the recording site) is an attractive alternative where feasible. Running machine learning algorithms in real-time is sometimes possible, obviating the need to store all of the recorded audio. Instead, storing much smaller volumes of meta-data for species detection events and counts (for example) may be sufficient. Alternatively, processing may act as a filter to store audio only for periods of time deemed interesting. Algorithms for creating detection events and/or marking periods of time as interesting may include specialized species recognizers or more general anomaly detection approaches. Despite the steady increase in computational power of low-cost edge devices, processing on site remains challenging, as the machine learning algorithms typically employed push the capacity of these devices and add to the difficulty of providing power to long-term remote recording setups.

The sparsity of catalogued reference calls is a key obstacle to the practical application of freshwater ecoacoustic studies. In contrast to the rich catalogues of bird calls, freshwater acoustics has seen little representation in the leading international sound archives. The Cornell Lab of Ornithology's Macaulay Library does have some fish sounds (982, which represents 0.25% of the library, Linke et al., 2020b), however these are mainly from marine environments. This lack of reference material is challenging for researchers entering the field, as the emitter of an underwater sound is not obvious. In order for the field of freshwater ecoacoustics to advance, the international community should submit their documented and validated calls to the Macaulay Library, the Berlin Animal Sound Archive, the Paris sonothèque or other central bioacoustics repositories.

Ecoacoustics as a communications and engagement tool

The integrated nature of ecoacoustics calls for greater collaboration with other disciplines, including electronics, remote sensing, data science, humanities, and social sciences (Sueur and Farina, 2015). Collaborations between scientists and artists have become increasingly popular as environmental research calls for more effective methods to engage communities in the scientific process and its outcomes. Many of these collaborations can be categorized broadly as science communication, where artists are engaged to translate resulting data for accessible public dissemination. However, there is evident value in interdisciplinary research that brings together creative and scientific knowledge and perspectives to inform field work methods, analysis and outcomes. Freshwater ecoacoustics has benefited from various art science collaborations that have contributed to advancing the discipline and engaging communities in the process.

The rapid advancements of accessible and affordable digital technologies have resulted in numerous pathways for communities to directly engage with the emerging field of freshwater ecoacoustics. Creative projects, mobile applications and interactive experiences that engage communities in river soundscapes have the capacity to encourage environmental stewardship and inspire freshwater conservation (Gilmurray, 2017). Hydrophones capturing rich and immersive underwater soundscapes have been used in the context of creative work since the 1970s, with composers including Maggi Payne, Jana Winderen, Douglas Quin, Chris Watson, David Monacchi and Ros Bandt, all renowned for their creative projects that draw listeners beneath the surface of rivers, lakes and oceans. The resulting creative experiences have been a catalyst for communities to engage with freshwater ecoacoustics and facilitate local citizen science initiatives.

These interdisciplinary efforts have also strengthened engagement from those in the arts and humanities to promote the emerging discipline of freshwater ecoacoustics. Composer Rob Mackay has developed many creative projects and community engagement initiatives around hydrophones with recent examples including 'Red River: Listening to a Polluted River' (https://redriverpoetry.com/). This 18-month research project was funded by the United Kingdom Arts and Humanities Research Council and led by Dr. John Wedgwood Clarke. This project has included soundscapes, poetry, community events, workshops and showcases at conferences including COP26 in Glasgow. Another example is 'The Secret Sound of Ponds' presented at the Science Gallery Detroit, which is a collaboration between Benjamin Gottesman, David Rothenberg and Camille Desjonquères (https://detroit.sciencegallery.com/depth-exhibits/the-secret-sound-of-ponds). This project features an immersive sonic sculpture installation that was accompanied by a hydrophone building and recording workshop, freshwater soundscape data collection in the Detroit River and a live performance designed to connect people to the hidden life of freshwater environments through sound. The subsequent increased engagement in freshwater ecoacoustics has prompted students engaging in interdisciplinary pathways including science students creating podcasts with aquatic soundscapes and emerging sound artists such as David de la Haye who are using sound to raise awareness and cultural value of freshwater habitats.

Listening to rivers with hydrophones can help local communities understand freshwater biodiversity in accessible and engaging ways (Barclay et al., 2018). For example, the project 'River Listening' has developed new approaches for citizen science engagement with freshwater ecoacoustics that have inspired various communities to engage with hydrophone recording (Barclay et al., 2018). The project developed noninvasive recording techniques with accessible hydrophone kits and participatory workshops to engage local communities in the process and outcomes. Preliminary work in community engagement with freshwater ecoacoustics explored the possibilities of hydrophone recording through interactive workshops, recording expeditions, and art installations designed to draw attention to the sounds beneath the surface of rivers. The workshops explored methods for using acoustics to understand aquatic biodiversity and involved extensive experimentation with recording techniques, new technologies, and community collaborations to compare aquatic soundscapes and the most effective methods for recording in freshwater ecosystems. The resulting database of hydrophone recordings have informed the scientific research and a diversity of community events and creative projects disseminated the outcomes worldwide.

Various endeavors have been established within River Listening to encourage ongoing community engagement outside of scheduled workshops. These efforts include a customized digital platform, virtual sound maps with live streaming hydrophones, and a mobile application that allows communities to record, upload, and compare sounds in a global database (Barclay et al., 2020). These digital outcomes underpin the major creative projects and facilitate the collection of recordings for scientific monitoring. The central tools for public engagement around River Listening have been creative outcomes, including site-specific performances and installations that have toured internationally. The most effective tool for public engagement has been the River Listening Sound Walks, which require audiences to visit their river to experience the work. The sound walks involve a custom built mobile application that transforms the listener's phone into a sonic compass to guide them along the riverbank and explore the cultural and biological diversity of the river through sound (Barclay et al., 2018). The installation triggers geo-located soundscapes that are accompanied by images and text identifying the sounds that are drawn from a local database of hydrophone recordings.

Perhaps most importantly, the community engagement processes surrounding River Listening have acted as a catalyst to amplify First Nations voices and facilitate opportunities for Indigenous knowledge holders to take a leadership role in the projects. The River Listening project has had the great privilege of learning from Indigenous leaders such as Lyndon Davis, Brendan Kennedy and Anne Poelina in Australia (https://www.riverlistening.com/). In 2017, the Whanganui River in Aotearoa (New Zealand) was the first river in the world to be granted personhood and recognized as a living being. Anne Poelina has been leading the conservation and protection of the Mardoowarra (Fitzroy River) in Western Australia and has advocated for the river to be recognized as a living ancestral being. Poelina argues that healthy rivers are culturally located and there are Indigenous ways of knowing, being and doing based on nonlinear time, a located temporality, which connects people, rivers and place (Martuwarra et al., 2021). She believes that healing river ecosystems is a cultural endeavor and that listening, hearing and voicing rivers is a first, Indigenous step. Poelina, along with many First Nations leaders in Australia and beyond, believe that water management requires Indigenous-led restorative research and practices to ensure Indigenous values are recognized (Martuwarra et al., 2021).

Listening to rivers provides unique methods for bridging traditional knowledge systems, emerging science and creative practice when working directly with communities in freshwater management. The methods of engaging with freshwater ecoacoustics in the field can embrace Indigenous leadership and traditional knowledge, and the ongoing monitoring of acoustic sensors can be managed by local communities. The interdisciplinary pathways that continue to emerge in the field of freshwater ecoacoustics indicate that interdisciplinary collaborations are vital in engaging communities in listening to rivers and inspiring freshwater conservation.

Glossary

Aero-aquatic fungi Fungi that need air exposure for sporulation to complete their life cycle. Consequently, they spend one stage of their life cycle underwater and another stage dispersed in the air-water boundaries.
Allochthonous organic matter Organic matter that is introduced into aquatic ecosystems from the terrestrial surrounding, e.g., plant debris, pollen, and leaves.
Anamorphic Asexual state of a fungus, which refers to the asexual morphotype of a fungus, also mitosporic state, i.e., a morphotype that forms spores only by mitosis.
Anthropocene The geological period during which humans have had a significant impact on the planet's climate and ecosystems. Most researchers state that it began at the start of the Industrial Revolution of the 1800s, when—for the first time—human activity had a significant large scale impact on carbon dioxide and methane in Earth's atmosphere.
Autochthonous organic matter Organic matter produced inside aquatic ecosystems, e.g., by algal photosynthesis and organismic biomass production.
Benthic shunt Fungal pathway in which (mainly terrestrial) organic matter is channeled by aquatic fungi in benthic biofilms to higher trophic levels of the aquatic food web.
Conidia Asexual reproductive units that formed from special cell (conidiogenous cells) developed from conidiophore.
Dark matter fungi Group of fungi that has been mainly characterized by sequence-based methods, related mostly to the early branches of the fungal tree, i.e., Aphelida, Rozellomycota, and Chytridiomycota (Grossart et al., 2016).
Emerging pollutants Synthetic or naturally occurring chemicals that are generally not controlled but could have adverse effects on human and ecosystem health.
Fungi-like organisms Represents all microorganisms in Oomycota phylum. They are morphologically very similar to fungi. However, molecular studies has revealed their vast evolutionary distance to fungi. While fungi are more related to animals, they are plant's close relative.
Hyphomycetes Fungi with long, branching filamentous structures called hyphae and that represent the main mode of vegetative growth in the form of mycelia.
Ingoldian fungi A fungal group honored for Ingold (1942) that is characterized by their ability for sporulation on plant materials underwater.
Microplastics Generally defined as plastic particles equal or smaller than 5 mm in length that result from both commercial product development (primary) and the breakdown of larger plastics (secondary microplastics). As a pollutant, microplastics can exert harmful effects on the environment, animal, and human health.
Mycoflux Fungal pathway in the pelagic zone of water bodies in which fungi lead to changes in organic matter aggregation or disintegration and thus affect organic matter cycling and sequestration.

Mycology Scientific field studying all aspects of fungi and fungi-like organisms.
Mycoloop A fungal pathway in the pelagic zone of water bodies in which parasitic fungi transfer inedible phytoplankton or pollen to higher trophic levels either via edible fungal zoospores of cell fragmentation and/or lysis.
Mycovirology Scientific discipline studying virus infecting fungi, i.e., mycovirus.
Mycovirus A virus that infects fungi.
OMICS era Phrase that relates to the current time period when the use of new molecular and biochemical tools such as metagenomics, metatranscriptomics, metaproteomics and metabolomics, arose to study organisms in the lab and field.
Plastisphere Term to describe a newly emerging microbial habitat created by the massive, anthropogenic introduction of microplastics to practically all environments.
Teleomorphic Sexual state of a fungus, in which two fungal nuclei unite and undergo meiosis, forming offspring with new genetic information.
Transient fungi Group of fungi that is passively introduced into water via high loads of fungal propagules from inflowing streams, rainwater runoff, and wind. These fungi exhibit no activity in the water, presumably due to unfavorable aquatic conditions or interactions with organisms.
Zoosporic fungi Synonym for chytrids and other basal fungi that possess a zoosporic stage during their life cycle.

Introduction

Fungi and fungi-like organisms (such as oomycetes) are key components of aquatic ecosystems, with parasitic and/or saprophytic lifestyles that influence biodiversity, food web dynamics, and the cycling of organic matter, nutrients, and energy within ecosystems. Yet, they represent an understudied group of aquatic microorganisms, largely neglected by aquatic microbial ecologists. In fact, historically *mycology* was separated from microbial ecology in all aquatic sciences. Studies of fungi are of great ecological and biotechnological interest because fungi have a large variety of polymer-degrading enzymes and detoxification mechanisms. However, the dramatic increase in the human population worldwide and subsequent increasing urban development and anthropogenic pollution has led to a severe modification of inland waters, with adverse effects on fungi. In this article, we highlight the multiple metabolic capacities and adaptive behavior of aquatic fungi to cope with these rapid environmental changes in the **Anthropocene**. We provide an overview of emerging topics in the field of aquatic **mycology** that are, to a great extent, related to the anthropogenic modification of inland waters, in particular **emerging pollutants**, including microplastics.

Diversity and ecology of aquatic fungi and fungi-like organisms

In general, fungi and fungi-like organisms (not necessarily the aquatic ones) have been phylogenetically and taxonomically separated (Fig. 1). However, several basic differences make it hard to treat all fungi the same. Therefore, the formal taxonomy-based classification system coexists with the "informal" ecology-based system which is polyphyletic. Thus, many classifications of aquatic fungi have been adopted (Goh and Hyde, 1996; Shearer et al., 2007).

Aquatic fungi

A recent estimate based on molecular evidence suggests a global fungal diversity of about 1.5 million species (Hawksworth and Lücking, 2017). Aquatic fungi form a taxonomically and morphologically diverse group in freshwater, brackish, and marine habitats. In parallel to their diverse lifestyles, community composition and abundance of fungi vary considerably with their aquatic habitats (Wurzbacher et al., 2010). Interestingly, about 96% of all fungal taxa have been recorded in temperate regions and fewer in tropical and subtropical regions (Rossman, 1994; Hawksworth, 2001; Duarte et al., 2016; Hyde et al., 2016). Therefore, the "true" number of fungi should be much higher, i.e., 2.2–3.8 million species, because a substantial fraction of the global fungal diversity has not been explored in-depth (Grossart et al., 2019).

The number of isolated and described fungal taxa is much lower than global estimates, including only 120,000–143,273 species (Fungorum, 2018; Wijayawardene et al., 2017). The majority of fungal species are related to the two phyla Ascomycota and Basidiomycota (ca. 96,000 species), which form the subkingdom Dikarya. Our current knowledge of fungal diversity is quite limited (Tedersoo et al., 2014), particularly in aquatic systems where the number of described species is low (ca. 3000–4000 species) as compared to terrestrial fungi (Jones et al., 2014). Consequently, the number of newly discovered fungal species in aquatic systems is predicted to increase (Voigt and Kirk, 2011).

Gessner and Van Ryckegem (2003) suggested that there are ca. 20,000 different species of freshwater fungi, yet only ~5% of the estimated fungal species have been described. The estimated number of species documented from different habitats and substrates include 622 fungal species of ascomycetes, 600 hyphomycetous fungal species from *Phragmites* litter (Gessner and Van Ryckegem, 2003), 531 asexual fungal species, 317 species on peat swamp (Tsui et al., 2001; Sivichai et al. 2002), and 183 trichomycetes. Also, zoosporic fungi comprise more than 500 species of chytrids and members of fungal-like organisms (Jones et al., 2014). All other

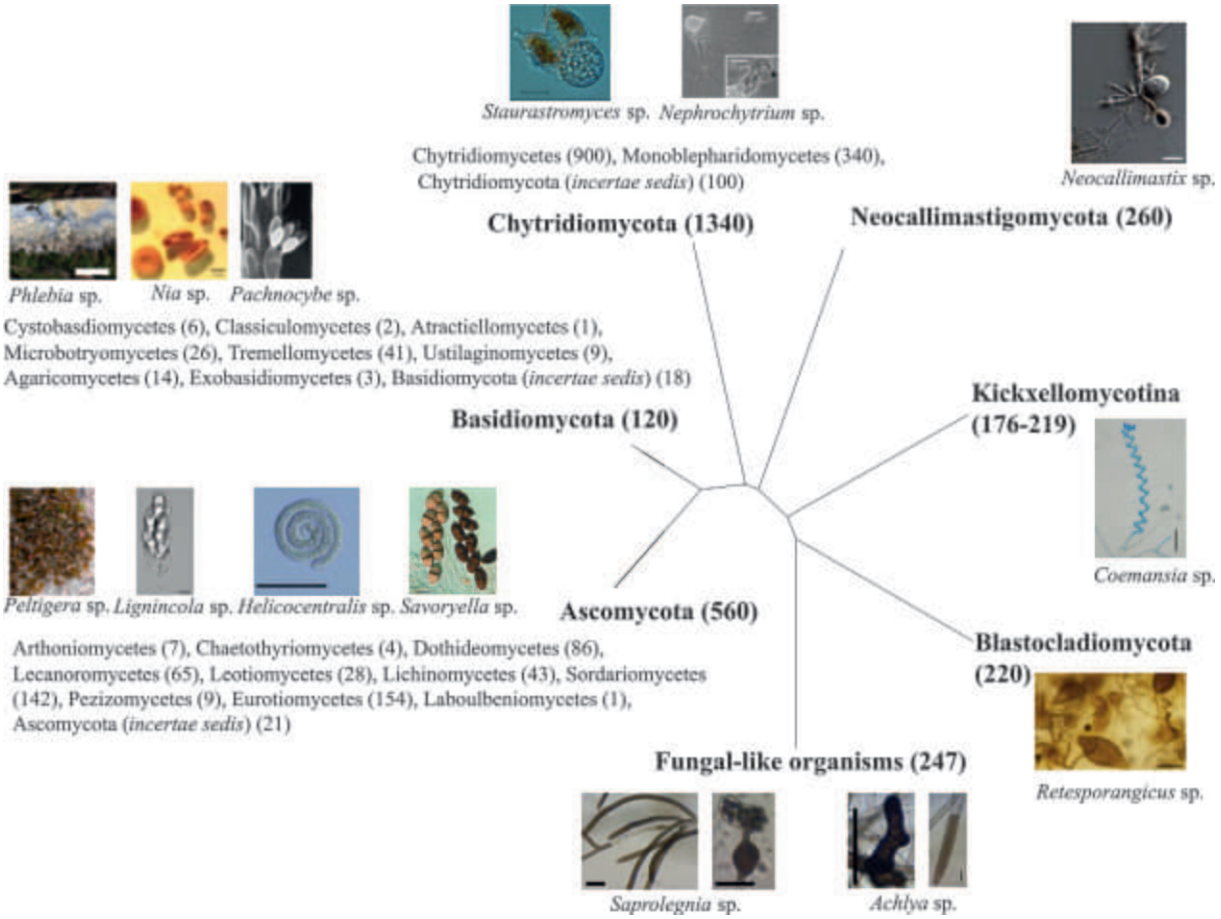

Fig. 1 Phylogeny of freshwater fungi and fungi-like organisms. The morphological and phylogenetic diversity of freshwater fungi and fungi-like organisms is illustrated. The numbers in parentheses stand for the currently identified species within each taxon. Ascomycetes are associated with dead stems and leaves of herbaceous and woody plants. They are mainly responsible for breaking down the lignocellulose constituents of plant cell walls. In contrast to their terrestrial diversity, freshwater Basidiomycota are less abundant. They colonize leaves and twigs in streams and rivers. They are known for basidiomata reduction, the passive release of basidiospores, and the production of branched conidia. Recently, the importance of true zoosporic fungi, including Chytridiomycota, Neocallimastigomycota, Kickxellomycotina, and Blastocladiomycota, has been highlighted. This is mainly due to increased awareness (both in morphology and phylogeny) for yet undescribed taxa (**dark matter fungi**). Many species are parasites and influence food web structure in freshwater ecosystems. Finally, fungi-like organisms, also known as "water molds," are some of the most devastating aquatic animal pathogens, responsible for massive mortalities of crabs, fishes, amphibians, etc.

fungal groups, however, are poorly described, including freshwater lichens with about 270 lichenicolous fungi and lichens, 226 fungal species on aquatic plants described as dark septate endophytes or endomycorrhizae, and 40 species of parasitic fungi. In particular, basidiomycetes are poorly documented in freshwater ecosystems, with only 41 non-yeast basidiomycetes and 74 basidiomycetous yeasts. The overall documented species richness of freshwater fungi (<4200 species) suggests that there are still many freshwater habitats and substrates to be surveyed (Jones et al., 2014).

In aquatic systems, three major types of fungi can be found depending on their growth and adaptation abilities in aquatic ecosystems: (I) terrestrial fungi that are often passively introduced into the water via high loads of fungal propagules from inflowing streams, rainwater runoff, and wind. This fungal group is known as **transient fungi** (versatile immigrants), which exhibit no activity in water - presumably due to unfavorable aquatic conditions or interactions with organisms (Dix and Webster, 1995; Voronin, 2014). (II) Partially adapted aquatic fungi that may be amphibious with one stage of their life cycle underwater and another stage dispersed in air-water boundaries (**aero-aquatic hyphomycetes;** Dix and Webster, 1995; Park, 1972 or periodic immigrants). (III) Fully adapted aquatic fungi (indwellers including Ingoldian fungi; Ingold, 1942) that can maintain their biomass in aquatic ecosystems with constant activity from year to year. They utilize substrates and nutrients available in water bodies, and most are capable of sporulating directly in water (Grossart et al., 2019).

Based on their morphology and lifestyle including different functional behaviors (independent of phylogeny), aquatic fungi are further separated into six major groups (Wurzbacher et al., 2010):

1. *Aquatic hyphomycetes* are recorded on decaying leaves and lignocellulosic debris in freshwater ecosystems worldwide. Aquatic **hyphomycetes** (Nilsson, 1964), also known as amphibious **hyphomycetes** (Michaelides and Kendrick, 1978), comprise **anamorphic** fungal taxa of ascomycetes and basidiomycetes (Shearer et al., 2007) that are specifically adapted to aquatic habitats via their reproductive systems by producing their spores in relatively large multiradiate (often tetraradiate), sigmoid or spherical conidia with tips usually covered with sticky mucilage (Read et al., 1992) to facilitate attachment to and colonization of a specific substrate. Aquatic **hyphomycetes** are categorized into two ecological groups according to their reproductive behavior (Goh and Hyde, 1996): (a) the **Ingoldian fungi** (Ingold, 1942) are characterized by their ability for sporulation on plant materials underwater and (b) the **aero-aquatic fungi** that do not sporulate underwater but need air exposure for sporulation to complete their life cycle (Wurzbacher et al., 2010). On the other hand, Goh (2003) provides another common group of aquatic hyphomycetes, i.e., transparent fungi with asexual reproduction (mitosporic) and dark conidia (coelomycetes) that have been recorded from various freshwater habitats. However, their conidial structure is not as well adapted for the aquatic ecosystems as the **Ingoldian** and **aero-aquatic hyphomycetes** (Goh and Hyde, 1996). These fungi include two ecological groups, namely, indwellers that are present only in freshwater environments (e.g., *Aquaphila*, *Canalisporum*, *Camposporidium*) and immigrants that occur in both terrestrial and freshwater environments (e.g., *Acrodictys*, *Acrogenospora*, *Arthrobotrys*) (Park, 1972).
2. *True zoosporic fungi* currently include phyla Chytridiomycota, Neocallimastigomycota, Kickxellomycotina, and Blastocladiomycota. They commonly occur as saprobes in the degradation of particulate organic matter of dead animals, pollen grains and plant litter as well as parasites of vertebrate animals, e.g., frogs, zooplankton and phytoplankton, or as symbionts in the mammalian digestive system. Consequently, zoosporic fungi have significant ecological roles in nutrient cycling and regulation of the populations of phytoplankton in aquatic ecosystems and also cause some economically important plant and animal diseases (Gleason et al., 2017). True zoosporic fungi typically occur in the pelagic zone of standing waters (Wurzbacher et al., 2010, 2016) and their reproductive units display primary adaptations to an aquatic lifestyle in the form of uniflagellated motile zoospores (Wong et al., 1998).
3. *Aquatic ascomycetes and basidiomycetes* (**teleomorphic** stage; develops sexual reproductive units including ascospores characteristic for ascomycetes and basidiospores for basidiomycetes) are microscopic fungi that decompose submerged woody material that falls into aquatic habitats. Since the 1990s, several studies concerning freshwater ascomycetes have been performed increasing the number of described species from 370 (Shearer, 1993) to 622 species (Cai et al., 2014; Shearer et al., 2014). Currently, about 675 species related to freshwater ascomycetes have been characterized and comprise several taxonomic groups (i.e., dothideomycetes, sordariomycetes, and leotiomycetes) ubiquitously found in freshwater on submerged and exposed woody debris (Jones and Pang, 2012; Shearer et al., 2014). The majority of freshwater ascomycetes form microscopic ascomata (less than 0.5 mm) and contain structurally water-adapted ascospores characterized by several sheaths or wall ornamentations covered by a gel-like sticky material that supports spore dispersal and attachment (Digby and Goos, 1987).
4. *Yeasts* are unicellular fungi with spherical or oval-shaped cells, representing a diverse group belonging to ascomycetes and basidiomycetes (Shearer et al., 2007) that are found mainly in the pelagic zone of freshwater habitats (Wurzbacher et al., 2010) and the pelagic and estuarine habitats of marine systems. Our understanding of their ecology and functions in aquatic ecosystems is still limited (Wurzbacher et al., 2010). However, they may play a similar role as heterotrophic bacteria generally referred to as the main (micro)organisms taking up and re-mineralizing dissolved organic matter.
5. *Glomeromycota* represent another under-studied group of aquatic fungi with little information on their ecology, composition and role in aquatic ecosystems (Goh and Hyde, 1996). The majority of glomeromycetes is terrestrial, except for aquatic trichomycetes (Shearer et al., 2007), and form a polyphyletic group which grows parasitically or mutualistically (order Harpellales) together with aquatic arthropods (Hibbett et al., 2007; Jobard et al., 2010). In addition, Glomeromycota are comprised of ecologically beneficial mycorrhizal fungi forming symbionts with the roots of aquatic macrophytes. These mycorrhizal fungi are characterized by the formation of special structures (vascular and/or arbuscular structures) inside the plant roots providing the plant with nutrients, e.g., phosphorus in nutrient-limited aquatic ecosystems (Wurzbacher et al., 2011).
6. *Fungi-like organisms* (Oomycetes, Straminipila) are well-documented (Wong et al., 1998) and considered the most ubiquitous aquatic "fungal" group characterized by biflagellate heterokont (two unequal flagella) zoospores (Dick, 1989; Shearer et al., 2007). Although Straminipila (hyphochytriomycota, Oomycota, and labyrinthulomycota) share similar morphological and physiological traits with true fungi (chytridiomycota, rosellomycota, and aphelida), their ecological functions and trophic strategies appoint them as false fungi (Alexopoulos et al. 1996; Beakes et al. 2014; Karpov et al. 2014).

Although cultivation is often biased, e.g., by sample handling and the choice of media, more fungal isolates from aquatic ecosystems are required to better characterize their genetics, physiology, and ecological role (Grossart et al., 2019). Yet, it remains difficult to characterize and estimate total fungal diversity at any given sampling site, often due to the lack of experience and qualified staff and suitable identification manuals, especially in tropical regions. There is a great demand to provide new techniques and strategies to isolate and assess fungal diversity and enable realistic site estimates for conservation purposes (Cannon, 1997 and Hawksworth, 2001). The application of different isolation techniques to the same waterbody may yield entirely different fungal communities (Abdel-Raheem, 2004; Sridhar et al., 2010). Whereas direct observation techniques can be used for investigations of growth of **zoosporic fungi**, aquatic **hyphomycetes**, and **teleomorphic** fungi on different substrates (Müller-Haeckel and Marvanová, 1979; Sparrow, 1968), the baiting technique is commonly used for isolation of **zoosporic fungi** and aquatic **hyphomycetes** from water samples using specific baits such as boiled sesame and hemp seeds (for oomycetes, fungal-like organisms), phytoplankton, pollen grains, and snakeskin (for chytrids) and plant leaves (for aquatic **hyphomycetes**) (Shearer and Von Bodman, 1983;

Shearer, 1972; Sparrow, 1968). Furthermore, the moist chamber technique can be employed to isolate **teleomorphic** fungi using woody blocks (Shearer and Von Bodman, 1983; Shearer, 1972). Finally, yeasts can be obtained by dilution plating of water or sediment on specific media (Fell, 2001; Kumar et al., 2011). Although most aquatic fungi remain uncultivated, new methods, baits, and media may isolate the entire fungal community in aquatic systems.

The phylogenetic relationship of aquatic fungi, including Ascomycota, Basidiomycota, Chytridiomycota, Neocallimastigomycota, Kickxellomycotina, Blastocladiomycota, and fungi-like organisms is given in Fig. 1. Recently, a new and surprisingly large fungal diversity has been discovered in aquatic habitats using molecular tools. These so-called **dark matter fungi** are mainly related to the early branches of the fungal tree, i.e., Aphelida, Rozellomycota, and Chytridiomycota (Grossart et al., 2016). Thus, considerable efforts to discover and evaluate their ecology and ecophylogenetics are needed. For example, their role as parasites or saprotrophs still needs to be identified and quantified (e.g., Banos et al., 2020). Whereas parasites exploit their living host for nutrition, saprotrophs use an array of excreted (extracellular) enzymes to digest their dead nutritional substrate directly (e.g., dead organism or other nonliving organic matter).

Current conceptual models indicate a multitude of different processes by which aquatic fungi transform and incorporate **allochthonous** and **autochthonous organic matter** into organismic biomass and transfer it to higher trophic levels. Recently, three major processes have been identified to describe the different ecological roles of fungi in the aquatic realm (Grossart et al., 2019): (i) **mycoloop**, (ii) **mycoflux**, and (iii) **benthic shunt**.

The **mycoloop** has been well described (Kagami et al., 2007, 2014) and refers to parasitic fungi that render inedible phytoplankton available to zooplankton grazers by producing zoospores or by fragmentation of large phytoplankton cells. The **mycoflux** relates to the important role of fungal interactions in organic matter and organisms that result in aggregation or disintegration of sinking organic particles, including living organisms and dead cell debris (Grossart et al., 2019). Most consequences of the mycoflux are still unknown, but we propose that they significantly affect the efficiency of the aquatic carbon pump and hence carbon sequestration. The **benthic shunt** describes how fungal colonization of (mainly terrestrial) organic litter and the formation of fungal biomass allows for an efficient transfer of this organic matter to macrozoobenthos on the sediment (Attermeyer et al., 2013). Macrozoobenthos represents an excellent food source for higher trophic levels in the pelagic zone, such as fish, and thus increases the efficiency of trophic transfer throughout the aquatic benthic and pelagic food webs. These three concepts take the various lifestyles and interactions (e.g., parasitism and saprotrophy) of aquatic fungi into account and highlight their ecological and biogeochemical importance in freshwaters. In sections "Aquatic fungi-like organisms" and "Fungi-virus interactions: An emerging topic" we describe two prime examples for interactions with fungi-like and fungi interactions with organisms and virus which until now have received only a little attention.

Aquatic fungi-like organisms

The fungi-like organisms represent non-fungal organisms from a taxonomical point of view but are often considered as a fungal group (Shearer et al., 2007; Grossart et al., 2019) given that they show ecological traits and functions in water similar to true fungi (Wong et al., 1998; Khallil et al., 2020). Aquatic fungi-like organisms are frequently found in the orders of *Saprolegniales* and (to a much lesser extent) *Peronosporales* within the class of Oomycetes. *Saprolegniales* has nearly 15 genera known as water molds causing destructive endemics in aquatic animals. *Achlya, Aphanomyces,* and *Saprolegnia* are the most dangerous threats to fishes and crabs across the world. In addition, *Pythium* and *Phytophthora* represent common parasitic genera in freshwater ecosystems although not all members of *Peronosporales* occur in aquatic environments. It's worth mentioning that zoosporic fungi are another term for describing both aquatic fungi and fungi-like organisms with motile spores (Wong et al., 1998; Dick, 1989; Shearer et al., 2007). Obviously, the word became obsolete when oomycetes and fungi got separated taxonomically.

Within the phylum Oomycota, oomycetes consist of two main assemblages including basal and crown oomycetes. Basal oomycetes as early-diverging ones are usually obligate parasites in marine ecosystems. Crown oomycetes, however, are considered to mainly occur in freshwater ecosystems. This group of fungal-like parasites has six orders with *Saprolegniales* and *Peronosporales* (see "Diversity and ecology of aquatic fungi and fungi-like organisms" section) as the biggest and most recent taxa, both including aquatic genera (Beakes and Sekimoto, 2009). Saprolegniales, or water molds, are well-known, exclusively aquatic organisms in freshwater ecosystems belonging to the phylum Oomycota. They are phylogenetically and systematically separated from the kingdom fungi and placed within the kingdom Chromista (Thines and Kamoun, 2010). Their positive association with water-related ecosystems is mainly due to their life cycle consisting of motile zoospores. The littoral zone, which is rich in **allochthonous organic matter** from animal and plant debris, seems to be their main niche (Marano et al., 2016). Their parasitic lifestyle on various species of fishes, crayfishes, etc. causes not only billions of dollars of damages to fisheries but also seriously endangers native aquatic animals (Van West, 2006).

Aquatic Saprolegniales such as *Achlya*, *Aphanomyces*, and *Saprolegnia* species are considered among the most widespread and dangerous animal pathogens worldwide (Bruno et al., 2011). Consequently, the multiple aspects of Saprolegniales pathogenicity in terms of ecology, diversity, as well as taxonomy, have been studied for more than a century. Several species of *Saprolegnia* and, to a lesser extent, *Achlya,* are responsible for drastic annual economic losses in salmonids and massive amphibian and crustacean mortality events, called Saprolegniosis (Hussein and Hatai, 2002; Fregeneda-Grandes et al., 2007). Their destructive potential is intensified by predisposing factors such as increases in mean temperatures, extreme drought periods, and aquatic contamination.

The species *Aphanomyces astaci* represents a key example of the destructive potential of parasitic Saprolegniales. This species causes the crayfish plague, which has been studied in terms of physiological adaptations and host responses toward parasitism since

the early 1960s (Unestam, 1965; Makkonen et al., 2012). The involvement of *A. astaci* in crayfish plague points to its crucial ecological role in freshwaters. Crayfish species significantly affect aquatic food webs and biogeochemical cycling via control of macrophyte biomass and growth, species richness, benthic primary productivity, etc. (Matthews and Reynolds, 1992). *A. astaci* is considered a significant threat to European crayfish populations that were transmitted to mainly Europe and other continents through the commercial exchange of American crayfish species (which are resistant against *A. astaci*, but transmit it) in the 19th century (Schrimpf et al., 2013). Now, *A. astaci* is listed among the world's 100 worst invasive species owing to the extremely high susceptibility of Non-American crayfish species (Luque et al., 2014).

Aside from parasitism, the ecology of Saprolegniales has been largely ignored with studies often limited to seasonality, occurrence, and correlation to various environmental parameters. Saprolegniales may be as common as their fungal counterparts in aquatic ecosystems since they may also colonize different **allochthonous** animal and plant debris in addition to being parasitic. This notion raises the question of whether Saprolegniales are as enzymatically active as fungi, making them important for **allochthonous organic matter** degradation. Interestingly, it has been shown that several genera in Saprolegniales behave opportunistically, quickly benefitting from the availability of small organic molecules while being ineffective in the degradation of more complex polymers (Masigol et al., 2019, 2020). This inefficiency is unlike fungi that can degrade a plethora of organic molecules by producing laccases and peroxidases. However, studies dealing with enzymatic capacities of Saprolegniales are rare and additional work is much needed to test whether ligninolytic inefficacy in Saprolegniales is universal.

Fungi-virus interactions: An emerging topic

One of the least studied topics in fungal ecology in inland waters is their interactions with viruses. In fact, little is known about the diversity of viruses in aquatic ecosystems, their relationships with fungal hosts such as their possible role(s) in regulating aquatic fungal populations e.g., chytrids after a diatom bloom, modes of dispersal, seasonal dynamics, and geographic distributions (Kotta-Loizou, 2019; Prussin et al., 2020). Yet, studies of viruses that infect economically important fungi (e.g., crop and aquaculture pathogens), reveal that **mycoviruses** are widespread in all major fungal groups and that most of them evolved at a very early stage of their fungal host's evolution and cause little or no apparent symptoms in their hosts (Ghabrial, 1998; Liu et al., 2012; Roossinck, 2015).

Recently, the number of reported **mycoviruses** has increased dramatically due to the use of high-throughput sequencing of fungal genomes and transcriptomes, which also allow the detection of their viromes (Nerva et al., 2016; Neupane et al., 2018; Ponsero and Hurwitz, 2019; Zoll et al., 2018). There are currently 12 classified and seven unclassified families of **mycoviruses** (Peyambari et al., 2021). The majority of **mycoviruses** are double-stranded RNA (dsRNA) viruses, while single-stranded RNA or DNA viruses are less common (Castón et al., 2020; Jiang, 2020; Li et al., 2020). The fungal viruses with dsRNA genomes, in most cases, encode for only two proteins: a capsid protein and an RNA-dependent RNA polymerase. Some families of dsRNA fungal viruses like Totiviridae can infect protozoa, while members of Partitiviridae can also infect plants (Liu et al., 2010; Yokoi et al., 2007). The broad host range of dsRNA fungal viruses, including hosts from different eukaryotic kingdoms, hints at their ancient origin (Peyambari et al., 2021).

Mycoviruses can be transmitted intracellularly during cell division, sporogenesis, or cell-to-cell fusion, resulting in life cycles generally without an extracellular phase. Each virus strain has a narrow host range, although certain viral families may have a broader spectrum of hosts. Most **mycoviruses** are asymptomatic, but those that reduce pathogenicity in fungal hosts are of great biotechnological interest for developing natural fungicides (Ghabrial et al., 2015; Preisig et al., 2000; Yu et al., 2013).

The effects of **mycoviruses** on aquatic fungal communities remain unknown, such as the virus-induced mortality that can provoke large-scale alterations of the fungal community structure and the subsequent impact on carbon and nutrient cycling, modification of fungal metabolism (e.g., by gene disruption or the introduction of new genes), and alteration of fungal fitness, e.g., by virus-borne toxins (Roux, 2019; Suttle, 2005; Wilhelm and Matteson, 2008). The associations of viruses with fungi should be explored with a higher resolution given the high diversity existing in the fungal kingdom. Of particular interest are the associations with early divergent fungi belonging to groups such as Chytridiomycota and Rozellomycota, which, despite being abundant in aquatic environments, have been relatively little studied.

In summary, the vast majority of **mycoviruses** in freshwaters (both in natural and urban environments) and their ecological roles remain poorly understood. Freshwater **mycovirology**, although accepted as a conventional research area, is less developed compared to human, animal, or plant virology (Kotta-Loizou, 2019). Due to their potential key role for freshwater fungi, **mycoviruses** deserve considerably more attention from aquatic microbial ecologists.

Aquatic fungi in the Anthropocene

Fungi inhabit a broad range of habitats (Grossart et al., 2019). In the case of those that inhabit natural aquatic ecosystems, there has been a growing interest in studying their diversity and ecology (Bärlocher and Boddy, 2016; Krauss et al., 2011), but much less is known about fungi in the urban aquatic environments (such as houses, hospitals, recreational parks and wastewater treatment plants) that are steadily increasing worldwide. Urban aquatic environments provide a series of conditions that result in a very different composition of fungal species from that found in natural environments. In other words, the human-build environment favors the enrichment of some fungal species, whose effects on environmental and human health are yet unknown. On the other

Fig. 2 Overview of habitats (in red circles) for aquatic fungi within urban environments. Houses contain numerous habitats for aquatic fungi, particularly in the kitchen and bathroom (e.g., sinks, tap water, showers, toilets, washing machines, and dishwashers), which are extensible to more massive constructions such as apartment buildings, hospitals, shopping malls, and industries. Aquatic fungi are also found in open spaces such as fountains, ponds, and swimming pools, as well as in wastewater treatment plants.

hand, these enriched species may be of great biotechnological interest. Few studies have been conducted to understand the diversity of fungi in different human-made aquatic systems, the effects of pollutants and human waste on fungal community structure, and the abundance of opportunistic pathogens (Assress et al., 2019; Biedunkiewicz and Góralska, 2016; Newbound et al., 2010).

Human homes contain numerous habitats for aquatic fungi, particularly in kitchens and bathrooms (Fig. 2). For example, fungal populations are regularly found in sinks, drinking water pipes, showers, and toilets (Flores et al., 2011; Gashgari et al., 2013; Hamada and Abe, 2009; Zhou et al., 2017). Aquatic fungi frequently occur in household appliances such as washing machines and dishwashers, where they adapt to extreme conditions of high temperatures, drastic changes in pH, high salinity, presence of detergents, and high shear forces (Babič et al., 2016; Raghupathi et al., 2018; Zupančič et al., 2016). House conditions, and thus habitat for fungi, are extensible to more massive constructions such as apartment buildings, hospitals, shopping malls, and industries (Steinberg et al., 2015).

Aquatic fungal communities have also been identified in habitats that are in close contact with humans such as fountains, artificial lakes, and swimming pools of public parks and recreational areas (Brandi et al., 2007; Jankowski et al., 2017). Fungi are found in the municipal systems designed for collecting and transporting wastewaters, including street gutters and sewers (Hervé et al., 2017; Yuan et al., 2020). Wastewater treatment plants (WWTPs), the endpoint for most of the waters from cities, provide aquatic fungi with a habitat that is better characterized than most urban aquatic environments, possibly for their sanitary and biotechnological interest (Assress et al., 2019; Espinosa-Ortiz et al., 2016; Matsubayashi et al., 2017; Wei et al., 2018).

Studies to date indicate that the majority of urban aquatic environments are dominated by a relatively small number of fungal taxa, i.e., opportunistic yeasts (*Candida, Cryptococcus* and *Rhodotorula)*, black yeasts (*Aureobasidium* and *Exophiala*), filamentous fungi (*Fusarium, Aspergillus, Cladosporium, Trichoderma*, and *Acremonium*) and some members of Cryptomycota. Interestingly, a common feature among many of these genera is their ability to form biofilms (Babič et al., 2017; Raghupathi et al., 2018; Zupančič et al., 2016). Although fungal diversity in urban aquatic ecosystems is likely lower than in natural ecosystems (Newbound et al., 2010; Wei et al., 2018), we propose that studying the diversity and ecology of fungal communities in human-disturbed environments is deserving of greater importance since approximately half of the world's population lives in cities and people spend about 90% of their lifetime in indoor ecosystems (Adams et al., 2013; Bello et al., 2018; Flores et al., 2011; Humphries, 2012).

Fungal metabolism and anthropogenic pollutants

Generally, fungi are characterized by a broad spectrum of extracellular enzymes (Harms et al., 2011) that allow them to break down highly polymeric substances consisting of very large molecules or macromolecules, composed of many repeating subunits. This metabolic feature renders fungi ideal candidates to break down natural polymeric substrates (Rojas-Jimenez et al., 2017) and anthropogenic pollutants that contain a large variety of macromolecules. Thereby, the high resistance against anthropogenic pollutants makes them ideal bioindicators of anthropogenic stressors in the environment. Aquatic fungi are ubiquitous and promising candidates for polymeric organic matter decomposition and humification of plant litter, which provides energy for microbes in various aquatic habitats (Webster et al., 1999). Aquatic **hyphomycetes** are considered one of the most prevalent microbial communities associated with emergent plant materials and submerged terrestrial plant residues in aquatic ecosystems, comprising 63–100% of total microbial biomass (Gulis and Suberkropp, 2003). These fungi exhibit a high degradation potential for lignocellulosic compounds due to their constant activity in a wide range of climatic conditions (Graça and Ferreira, 1995) and production of a wide array of extracellular ligninolytic enzymes such as cellulases, xylanases, pectinase, laccases and peroxidases (Harms et al., 2011; Rojas-Jimenez et al., 2017).

This degradation potential enables fungal colonization and growth and results in subsequent plant litter mass loss, skeletonization, and maceration (Bärlocher, 1998). The formed fungal biomass provides a significant feedstock for other aquatic heterotrophic microbes and higher trophic levels, leading to accelerated mineralization and transformation of plant biomass into humic substances (e.g., humic acids, fulvic acids, and humin) (Bärlocher, 1985). Furthermore, the quantity and quality of additional labile materials, such as algal exudates, determine the dominance of fungal groups within aquatic ecosystems and, consequently, terrigenous C turnover (Fabian et al., 2017). Moreover, environmental conditions and the fungi's enzymatic repertoire ultimately affect the rate of litter decomposition in streams (Benstead and Huryn, 2011). This relationship remains little studied for lacustrine environments (Grossart et al., 2019). Other polymeric compounds such as pollen grains and non-plant material, e.g., chitin and keratin, are mainly decomposed by chytrids and non-fungal oomycetes via the production of specific exoenzymes (Wurzbacher et al., 2014), resulting in fungal biomass and spore formation serving as a food source for higher trophic levels such as invertebrates.

Fungal processing of pollutants

One of the most evident traces of human activity on the planet is increasing pollution, which negatively impacts the biosphere. Today, the discharge of toxic liquids from urban and industrial activities carrying a large amount and variety of pollutants has reached dangerous levels in both freshwater and marine ecosystems. There are at least six pathways by which humans pollute freshwater ecosystems: (a) sewage, (b) nutrients and terrigenous materials, (c) crude oil, (d) synthetic dyes, (e) heavy metals, and (f) plastics (Häder et al., 2020). Fungi, as one of the most important and conspicuous components of aquatic microbial communities, are detrimentally affected by these pollutants. For example, species diversity and richness, functions, and physiology of aquatic fungi can be severely impacted by the ever-increasing discharge of pollutants into freshwaters (Krauss et al., 2003; Lecerf and Chauvet, 2008; Zeng et al., 2012; Op De Beeck et al., 2015). Yet, some aquatic fungi have developed a high capacity to deal with numerous environmental pollutants and are being used as part of environmental remediation strategies.

Many traditional pollutants are degraded by aquatic fungi, including surfactants (Mallerman et al., 2019; Nakamiya et al., 2005), 2,4,6-Trinitrotoluene (TNT) (Hoehamer et al., 2006), pesticides (Purnomo et al., 2011; Rodríguez-Castillo et al., 2019; Ulčnik et al., 2013; Wang et al., 2015) and other toxic persistent organic chemicals (Aranda, 2016; Marco-Urrea et al., 2009; Sun et al., 2016; Xu et al., 2014). However, the number of fungi that have been studied for their degradation capabilities is relatively small. Therefore, the likelihood to find new species with the potential for bioremediation of aquatic pollutants is high.

Aquatic fungi can use at least four mechanisms for processing and transforming a wide variety of pollutants in inland waters (Fig. 3). They are highly unspecific and can act independently or synergistically. The first mechanism involves the production of two main types of extracellular enzymes: peroxidases and phenoloxidases (Grinhut et al., 2011b; Majeau et al., 2010; Rodríguez-Rodríguez et al., 2019). The second consists of the production of low-molecular-weight redox mediators such as reactive oxygen species (e.g., singlet oxygen, peroxide and the hydroxyl radical) that also act extracellularly and with low specificity on the substrates (Grinhut et al., 2011a; Grossart and Rojas-Jimenez, 2016; Jensen et al., 2001). The third involves intracellular degradation by enzymes such as the cytochrome P450 complex (Haroune et al., 2017; Marco-Urrea et al., 2009). The fourth is related to the biosorption of compounds (Ulčnik et al., 2013; Xu et al., 2020) (Fig. 3).

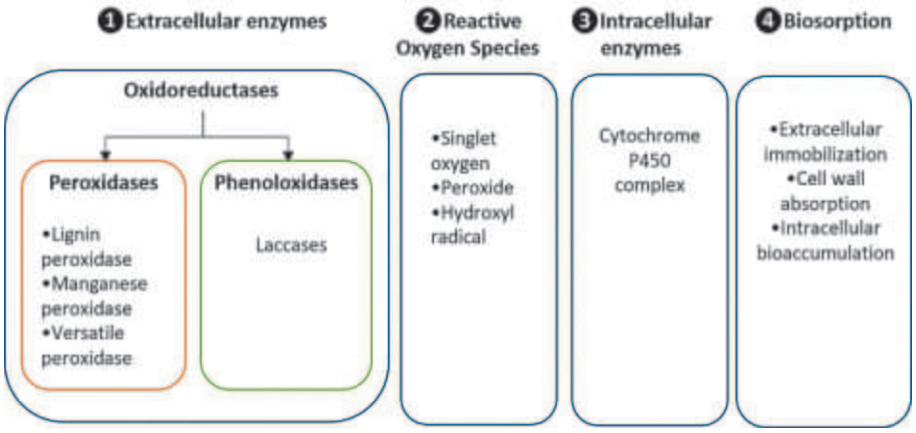

Fig. 3 Four mechanisms via which aquatic fungi process a wide variety of pollutants in inland waters. In general, these mechanisms are not specific for the type of molecules to degrade and can operate independently or synergistically. The first mechanism involves the production of two main types of extracellular enzymes: peroxidases and phenoloxidases. The second consists of the production of low-molecular-weight redox mediators such as reactive oxygen species that also act extracellularly and with low specificity on the substrates. The third involves intracellular degradation by enzymes such as the cytochrome P450 complex. The fourth is related to the biosorption (adsorption and absorption) of compounds.

Fungi possess enormous metabolic diversity, which makes them critical organisms for processing **pollutants** in aquatic systems (Grossart and Rojas-Jimenez, 2016; Harms et al., 2011; Krauss et al., 2011). Some of the most concerning are the so-called "**emerging pollutants**" that include synthetic or naturally occurring chemicals that are generally not controlled but could have adverse effects on human and ecosystem health (Llorca et al., 2016; Rodríguez-Rodríguez et al., 2019). Members of Basidiomycota and Ascomycota are capable of degrading pharmaceuticals, which are considered among the most diverse group of aquatic pollutants, including antibiotics, antidepressants, anti-cancer, antiepileptics, steroid hormones, and anti-inflammatory substances (Asif et al., 2017; Ferrando-Climent et al., 2015; Haroune et al., 2017; Kovalakova et al., 2020; Liu et al., 2016; Rusch et al., 2019; Silva et al., 2012). Moreover, aquatic fungi are capable of degrading various types of plastics (Ali et al., 2014; Deguchi et al., 1997; Jeyakumar et al., 2013; Krueger et al., 2015; da Luz et al., 2013; Wang et al., 2016) as well as accompanying contaminants such as plasticizing substances that can have endocrine-disrupting effects or carcinogenic effects on environmental and human health (Ahuactzin-Pérez et al., 2018; Ferrer-Parra et al., 2018; Loffredo et al., 2012; Skinner et al., 2009; Zhao et al., 2018).

In recent years, aquatic fungi have been studied and established as one of the most active groups of microorganisms for degrading synthetic dyes (Wesenberg et al., 2003). In fact, aquatic fungi degrade/adsorb dyes and intermediates such as aromatic compounds and mineralization of azo dyes (Papanikolaou et al., 2008). The high capacity of fungi, especially of white-rot basidiomycetes, to produce extracellular ligninolytic enzymes including laccase, manganese peroxidase, and lignin peroxidase (Gomi et al., 2011) renders them important for bioremediation measures.

In general, fungal dye decolorization is achieved in two ways: (a) biosorption and (b) biodegradation. In biosorption approaches, fungal biomass in wastewater is a byproduct of industrial fermentations. It contains amino, carboxyl, thiol, and phosphate groups in the cell wall, which can be applied for dye removal (Crini and Badot, 2008). In biodegradation approaches, fungi are used to degrade a wide variety of recalcitrant dyes via non-specific attachment of ligninolytic enzymes to the target substrate. Although results of biodegradation from lab-scale studies have been promising, their performance in the purification of various industrial effluents is little studied (Kaushik and Malik, 2009). The application of a broad spectrum of fungi resisting the toxicity of dyes allows for optimizing the overall biosorption and biodegradation ability at changing environmental conditions.

Increasing concentrations of heavy metals lead to deleterious impacts on fungal biodiversity, communities, and biological activities in aquatic ecosystems (Solé et al., 2008), including respiration, sporulation, and growth/biomass formation and fungal leaf-degradation rates (Krauss et al., 2001; Lecerf and Chauvet, 2008; Sridhar et al., 2000).

However, some aquatic fungi possess tolerance and resistant mechanisms for metal-induced toxicity through the production of extracellular and intracellular biomolecules (protein chelating agents, enzymes, slimes, and other metabolites) (Krauss et al., 2011). Furthermore, the structure of fungal cell walls possesses unique characteristics for heavy metal removal through adsorption mechanisms including; hydroxyl (OH), amino (NH), carbonyl (C═O), phosphate (P═O) groups in the fungal biomass, in addition to the porous nature with the high surface area cell wall (Braha et al., 2007, Hassan et al., 2018). Consequently, due to their high biosorption or bioaccumulation capabilities, aquatic fungi may play a critical role in the sequestration of heavy metal ions than bacteria (Massaccesi et al., 2002).

Case study: Fungal communities in the Plastisphere

The **Plastisphere** is a term used to describe the newly emerging habitat created by the massive introduction of microplastics to all environmental areas (Eckert et al., 2018). Microbiologists frequently study bacteria on plastics, but much less information exists for fungi (Amaral-Zettler et al., 2020). We suggest that fungi on plastic debris are an important emerging area of research (Fig. 4).

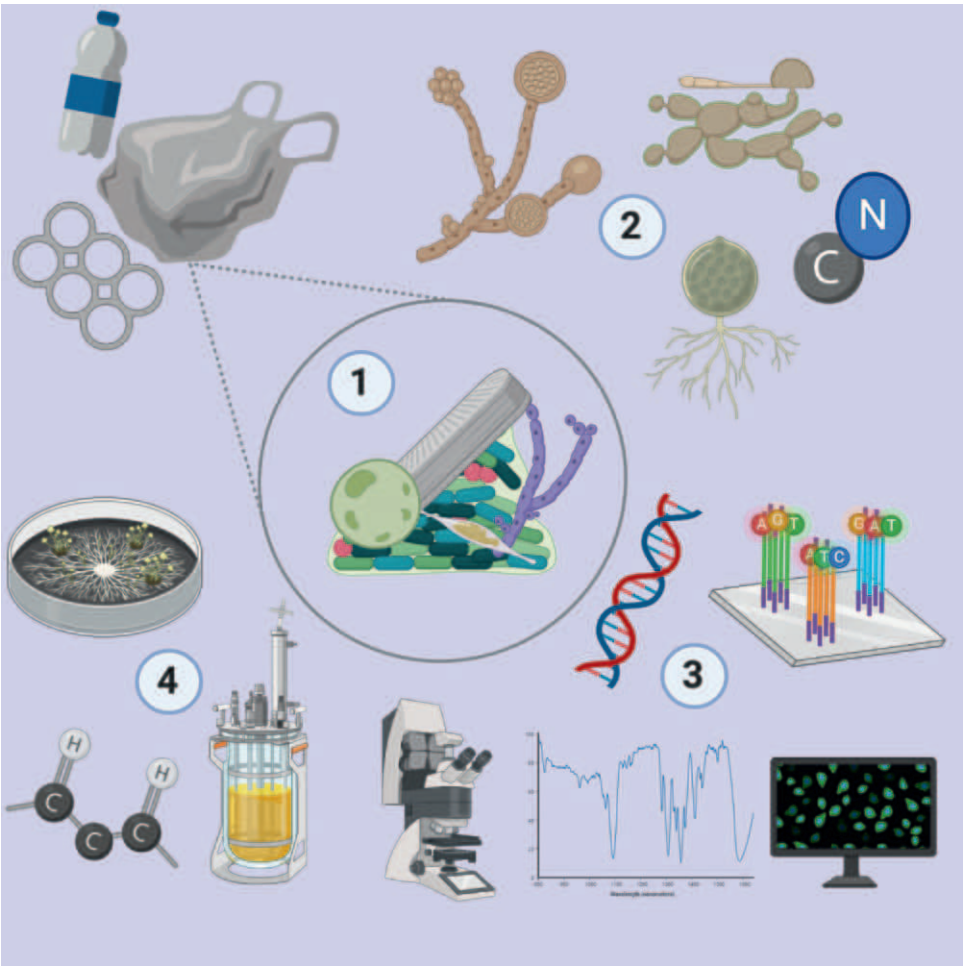

Fig. 4 There are many reasons and methods for studying fungi on plastic debris. (1) Plastic debris results in biofilm structures that include fungi, together with bacteria, green algae, diatoms, and other heterotrophs, termed the **Plastisphere**. (2) Fungi in the **Plastisphere** can include yeasts, filamentous, and parasitic fungi (e.g., some Chytridia). These groups contribute significantly to freshwater carbon and nitrogen cycling. (3) DNA-based sequencing technologies are well suited to decipher the fungal diversity within these biofilms. Other methods that combine fluorochrome-tagged genetic probes and spectral imaging techniques can help to observe and study different species of fungi within the biofilm structure and thus to determine their ecological role. (4) Isolation of fungi from the **Plastisphere** can lead to the discovery of new metabolic pathways of plastic polymer degradation.

Fungi are paramount to carbon and nitrogen degradation and transfer within aquatic food webs (Soares et al., 2017) and it has been shown that plastics have an impact on the heterotrophic activities of fungi (Arias-Andres et al., 2018). Furthermore, fungal parasites can control algae and cyanobacteria (Frenken et al., 2017), which are also present in plastic biofilms. Thus, it is important to know the implications of plastics on various ecological interactions and biogeochemical cycles.

In particular, fungi are well known for their xenobiotic degrading capacity, and more testing is needed to quantify fungal degradation of different plastic polymers (Brunner et al., 2018). Fungal metabarcoding and metagenomics will allow for great advances in the exploration of fungal biodiversity and functionality (Matsuoka et al., 2019) in the **Plastisphere**. Given the 3D structure of biofilms on plastic debris and the importance of interactions between fungi, algae, and bacteria, tools allowing for spatial and taxonomic analyzes should be included. For this purpose, methods that combine both high taxonomic and spatial resolution must be considered and adapted to studying fungi in the **Plastisphere** (Arias-Andres, 2020; Schlundt et al., 2019).

Fungi as bioindicators of ecosystem's health: A conceptual proposal

Structural bioindicators describe the composition or biodiversity of a given organismic group whereas functional bioindicators assess a specific function (e.g., the degradation of lignocellulose) or an ecosystem service (e.g., carbon or nitrogen cycling). Complex ecological indicators address the interconnection between structure and function through the food web (Parmar et al., 2016). Aquatic fungi are relevant bioindicators of freshwater ecosystem's health because of their role in the degradation of **allochthonous organic matter** (e.g., leaves falling from a nearby tree into a stream) in aquatic food webs (Baudy et al., 2019).

Fungal enzymatic tools for degrading lignocellulose (the main component of plant matter) are very well known (see "Fungal metabolism and anthropogenic pollutants" section) and explain their role from a biological point of view (Krauss et al., 2011; Rossi et al., 2017). For freshwater fungi, the most studied functional indicators are leaf litter degradation rate, biomass (ergosterol found in fungal cell membranes), and the capacity to produce spores for reproduction or sporulation (Bruder et al., 2016; Gomes et al., 2018; Krauss et al., 2011; Soares et al., 2017). Meanwhile, the most common group described in the literature are different spore (or conidia)-producing fungi, commonly referred to as "**Ingoldian**" or aquatic **hyphomycetes** (see above; Bärlocher, 2016; Baudy et al., 2019; Chauvet et al., 2016). The OMICS era is identifying more potential indicator groups (Ceci et al., 2019; Kettner et al., 2017).

Ecological indicators often involve changes in fungal community composition which, e.g., indicate high invertebrate feeding pressure (Baudy et al., 2019; Canhoto et al., 2017; Mora-Gómez et al., 2016). Consequently, specific fungal communities are well suited to serving as bioindicators of anthropogenic stressors and environmental change in aquatic systems. Differences among types of aquatic ecosystems (e.g., streams vs. wetlands), habitats (e.g., pelagic zone vs. sediment), and multiple stressors, however, need to be taken into account since they may affect the role of fungi as environmental indicators (Graça et al., 2016; Gulis et al., 2019; Ortiz-Vera et al., 2018; Röhl et al., 2017).

Two major and relevant anthropogenic stressors in aquatic systems, i.e., pollution and eutrophication due to nutrient input (N and P) (Reid et al., 2019) can be well detected by changes in fungal communities. Accordingly, the fungal community response to pollution and eutrophication is relatively well documented. Overall, eutrophication selects for specific tolerant groups (Bai et al., 2018; Samson et al., 2020), increases the abundance and diversity of fungal taxa, and lowers fungal sporulation rates and biomass (Pereira et al., 2016; Pietryczuk et al., 2018).

In contrast to eutrophication, the usage of fungal indicators to detect other factors is much less studied. For example, higher flow velocity increases fungal diversity (Fiuza et al., 2019) in running waters. In low-flow areas downstream of dams, there is a lower fungal richness and biomass production (Colas et al., 2016), probably due to sedimentation and lower concentrations of dissolved oxygen (Bruder et al., 2016). Salt concentration is well known to affect fungal community composition (Gonçalves et al., 2019). Thus increasing salinization due to climate change (Pesce et al., 2016) and run-off from salted roads in winter can be deduced from specific changes in fungal communities in parallel to a significant reduction in fungal sporulation and biomass (Canhoto et al., 2017; Gonçalves et al., 2019). So far, metal and chemical pollution effects on aquatic fungal communities are least analyzed (Barros et al., 2020; Pimentão et al., 2020), but indicate a high bioindication potential. Most of this information stems from rivers and streams, and the role of fungal bioindicators for anthropogenic stress in standing waters has been less explored.

Emergent metal pollution selects for specific species of tolerant fungi and affects fungal leaf litter degradation (Duarte et al., 2019), protein expression, and enzymatic activities (Barros et al., 2020). For synthetic chemicals, the scarcity of fungal models for ecological risk assessment of fungicides is noteworthy (Ittner et al., 2018; Ortiz-Cañavate et al., 2019). Other emergent contaminants have been evaluated for their effect on fungal communities and include antibiotics (Bundschuh et al., 2009), nanomaterials (Du et al., 2020), and microplastics (Kettner et al., 2017). In these cases, enzymatic activities have been identified as potential fungal bioindicators for chemical stress, in particular those related to lignin degradation (Rossi et al., 2017).

Conclusions and perspectives

In this article, we have highlighted the immense diversity and metabolic versatility of fungi and fungi-like organisms in natural and human-made aquatic ecosystems (Fig. 5).

Aquatic fungi are key organisms for organic matter cycling and the transformation and detoxification of anthropogenic pollutants, including synthetic dyes, aromatic hydrocarbons, and other polymeric and potentially toxic substances. Urbanization leads to increased inland water pollution affecting environmental and human health. We highlight the role of aquatic fungi in breaking down natural polymers such as cellulose, lignin, and chitin as well as more complex substances of anthropogenic origin such as antibiotics, anti-depressants, dyes, surfactants, hormones, and plasticizers, known as **emerging pollutants**. Thus, we demonstrate how aquatic fungi play an important ecological role in the cycling of nutrients and carbon and in mitigating the increasing effects of humans on the environment. However, there are still large knowledge gaps in the field of inland water **mycology**. It will be of paramount importance to further study the effects of **emerging pollutants** on the structure of aquatic fungal communities and their interactions with other organisms such as bacteria, viruses, and other eukaryotes. Finally, we need to better understand pollutant-fungi relationships, including those on microplastics, given the abundance, low degradability, and wide distribution of anthropogenic pollutants on the planet.

New technologies will continue to expand our knowledge and appreciation for aquatic fungi in natural and urban ecosystems. For example, the combination of molecular and advanced microscopy tools and new physiological and cultivation approaches will result in better characterization of fungal metabolic processes. This biotechnological research could also lead to discovering new pathways for the degradation of pollutants such as plastic polymers. Further, a deeper understanding of the ecological role of fungi and fungi-like organisms is required to identify new fungal bioindicators of anthropogenic stress. Filling these knowledge gaps is key to tackle the many challenges facing future environmental and human health due to urban development and anthropogenic pollution, including biodiversity loss and alteration of aquatic ecosystem functions.

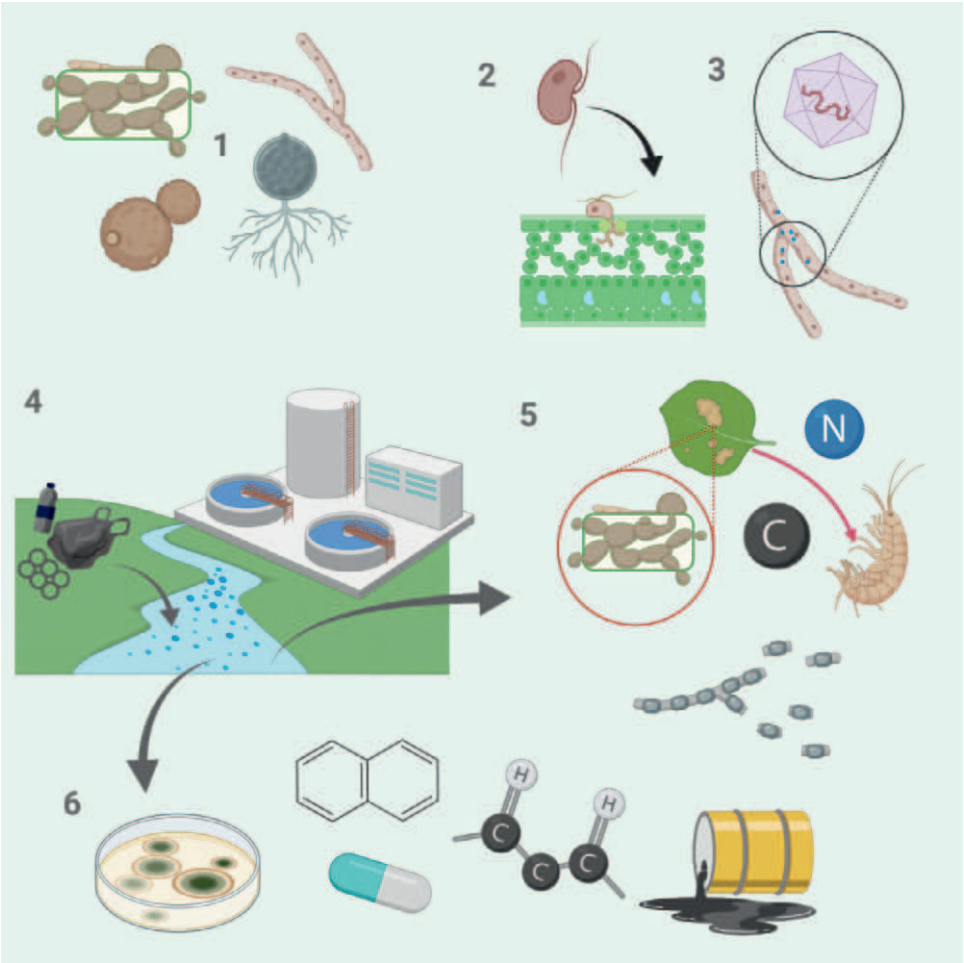

Fig. 5 We provide a summary of important and unexplored aspects of aquatic fungi in the **Anthropocene**. (1) Fungi in freshwaters display multiple lifestyles, e.g., saprophytic and parasitic, spore, and hyphae-forming species. All of them respond in an as yet largely unknown manner to anthropogenic stressors. Thus, further research is needed to better understand the fungal ecology and effects of inland water pollution in an urbanized world. For example, (2) fungi-like organisms such as aquatic oomycetes (some of which are prevalent plant and fish pathogens); (3) fungi-virus infections in aquatic systems; (4) increasing anthropogenic pollution via the release of nutrients, industrial chemicals, and urban waste into aquatic ecosystems effects; (5) fungal transfer of carbon and nitrogen from allochthonous organic matter to the aquatic food web, whereby sporulation (reproduction) rates act as common bioindicators of ecosystem health. Finally, (6) new fungal pathways for the biodegradation of emergent contaminants such as pharmaceuticals, persistent organic pollutants, and petroleum-based plastic polymers should be explored in new fungal isolates obtained from urban water ecosystems.

Knowledge gaps about fungi in the face of urbanization

- Anthropogenic effects of combined environmental factors and hydrologic conditions on fungal growth and organic matter transformation
- Changes in functional diversity of aquatic fungi in the presence of anthropogenic stressors such as eutrophication, warming, salinization, and emerging pollutants
- Loss of fungal diversity following habitat modification due to urbanization as a part of the global freshwater biodiversity crisis
- The ecological role of fungi-like organisms such as oomycetes in agricultural landscapes
- Fungi-virus interactions and their ecological consequences at increasing anthropogenic stress
- Specific fungal degradation processes of polymeric organic matter in urban environments
- Anthropogenic impact on biodiversity, ecology, and function of mycorrhizal fungi and endophytes in urban aquatic habitats
- Specific fungal degradation mechanisms of synthetic dyes and other anthropogenic pollutants
- Role of the emerging anthropogenic pollutant (micro)plastics as fungal habitat and substrate
- Role of fungi as bioindicators of anthropogenic stress and degradation of ecosystem state

Environmental DNA Advancing Our Understanding and Conservation of Inland Waters

Mathew Seymour, School of Biological Sciences, The University of Hong Kong, Hong Kong S.A.R., China

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Kendra Cheruvelil.

Glossary

Amplicon PCR amplified DNA fragment contained between two primer regions.
Barcode A specific region within a gene that is used to genetically identify individual species or other taxonomic levels.
Control samples field or lab comparison that matches the eDNA sampling type (e.g., sterilized water when aquatic eDNA is collected) and serves to assess false positives in downstream analyzes due to sampling contamination. Laboratory controls are used to assess contamination during lab analysis due to contaminated equipment.
Environmental DNA (eDNA) DNA isolated from an environmental sample (e.g., soil or water) that does not target a species or community of interest.
False negative When a species/taxon is not identified from a sample even though it is present.
False positive When a species/taxon is incorrectly assigned to a sequence due to contamination of the sample or incorrect assignment methodology.
Metabarcoding High throughput sequencing of PCR-generated sequence libraries, which allows for multiple unique sequences to be read from a single sample.
Polymerase chain reaction (PCR) A molecular technique used to replicate small (usually specific) segments of DNA.
Primer A short single-stranded nucleic acid (~20–50 base pairs) utilized in the initiation of DNA synthesis during PCR (e.g., extension stage of PCR). Primer specificity refers to how stringent the primer is binding to target DNA sequences.
Quantitative PCR (qPCR) A molecular technique that monitors the amount of amplification during a PCR via fluorescence.

Environmental DNA (eDNA)

Environmental DNA (eDNA) is a new technique and field of study with far reaching implications for environmental and biodiversity assessment within the fields of ecology, evolutionary biology, agriculture, disease control and beyond. Environmental DNA is defined as DNA extracted from an environmental sample that does not target a particular organism or set of organisms

(Bohmann et al., 2014; Seymour, 2019). The sources of eDNA are expected to be predominantly free-floating DNA that has recently left its species of origin through natural body secretion (e.g., shedding, molting, feces, urine, gametes), or as fragments released from decaying bodies (Jo et al., 2019; Moushomi et al., 2019). A major breakthrough in the utilization of eDNA was the discovery that once eDNA has been isolated from a sample it can be used to identify the species of origin using molecular methods (Ficetola et al., 2008). Since eDNA can be sampled from practically any environment imaginable, including water, soil, air, ice; the general concepts and methods regarding eDNA-based research can be broadly applied.

It is important to clarify that the definition of what constitutes an eDNA sample is debatable among researchers. In very broad terms, eDNA is often used to describe any DNA captured from environmental sampling, including bacteria and single cell eukaryotes or homogenization of bulk samples (e.g., insects from a trap blended together). However, it is important from a methodological standpoint to be aware of the environmental source and intended target because methods that work to identify bulk samples or bacteria communities are not always optimal for identifying non-target eukaryotes from water or sediment samples. To avoid confusion, this chapter will restrict the definition of environmental sampling to non-bulk sampling (e.g., water and sediment) and eDNA to eukaryote-derived DNA from environmental samples. Overall, this chapter provides a concise summary of eDNA concepts and applications in freshwater ecosystems, outlines the use of eDNA-based biodiversity assessment and the standard approach in using eDNA to sample freshwater environments, and offers insights into current pursuits using eDNA.

Biodiversity assessment in freshwater environments encompasses a diverse set of methodologies depending on the community or species of interest, sampling environment and the level of taxonomic identification required for a given study. Often methods are very specific to a set of species or environmental conditions, which can limit the ability, or effectiveness, of using the method across different sampling sites or time points. For example, sampling macroinvertebrates from streams is often conducted with kick-net sampling, which is only fully feasible if the depth of the rivers are shallow enough to traverse, to sample the middle of the river and both edges, and the substrate is suitable for adequately disturbing the riverbed. If the substrate is too coarse (e.g., boulders or bedrock) or fine (mud or silt), the method will often miss individuals within the environment. Additionally, seasonal conditions may alter a sampling site's physical characteristics (e.g., flooding, freezing or drought), thereby preventing subsequent or regular sampling.

In contrast, sampling for eDNA is more standardized for the type of environmental sample, be it water, soil or air, and can be consistently sampled regardless of the ecosystem type, season, or taxa of interest. The reliability of eDNA to detect communities has repeatedly been shown to be on par or better than traditional sampling methods (Valentini et al., 2016; Sales et al., 2020; Seymour et al., 2020). In addition, the standardized molecular and bioinformatics approaches used to process and analyze eDNA data are often faster and cheaper to routinely conduct compared to traditional taxonomic identification methods (Davy et al., 2015) and avoid the potential bias induced by using multiple or inexperienced taxonomic identifiers (Deiner et al., 2017). However, there are still several limitations, ongoing developments and potential pitfalls associated with the use of eDNA. For example, it is important that the environment is sampled in a structured manner, such as depth profile sampling within a lake or a sampling transect along the distance of a river, to account for eDNA movement within the environment (e.g., distribution/transport) (Li et al., 2019). This chapter serves as an overview to the understanding and practice of eDNA-based research in freshwater environments, particularly for new and interested researchers. It is not intended as a definitive statement on the subject, as the field is rapidly changing and many views and discussions are ongoing regarding the topic, some of which are highlighted below.

Freshwater environments

This section describes three important aspects of the use of eDNA in freshwater environments: The background and utilization of eDNA, how eDNA accumulates in freshwater environments and the processes that remove eDNA from the environment. Fig. 1 illustrates the factors that influence eDNA detection in natural environments.

Background of eDNA research and utilization in freshwaters

The methodological background for eDNA originated in the late 1970s and early 1980s with the establishment of the polymerase chain reaction (PCR) and DNA sequencing (Thomsen and Willerslev, 2015). PCR allows for the replication of targeted genetic sequences, which is important for eDNA since the concentration of target DNA in environmental samples is generally too low to be detected using visual or sequencing methods, unless PCR is first used. The development of quantitative PCR (qPCR) in the 1980s, which allows for real-time observation of a PCR reaction via fluorescence, provided a more accurate means to detect single species from eDNA samples. qPCR is still widely used today for population-level assessments and has well-established reporting guidelines and practices, referred to as the Minimum Information for Publication of Quantitative Real-Time PCR Experiments MIQE guidelines (Bustin et al., 2009).

Community-based assessments from eDNA, which are reliant on the development of DNA sequencing, have taken longer to develop methods and guidelines. Modern DNA sequencing allows us to determine the nucleotide order of a genetic sequence without the use of a reference genetic sequence. The development of DNA sequencing led to the development of DNA barcoding in the early 2000s (Hebert et al., 2003). DNA barcoding is a method of using a specific genetic sequence, often a specific gene or region within a gene, to identify species. Several DNA barcode reference libraries have been created, with the intent to catalog barcode sequences of all life on the planet, and are essential for eDNA studies that use high throughput sequence methods because we use these reference databases to link sequences detected in environmental samples to actual species identifications.

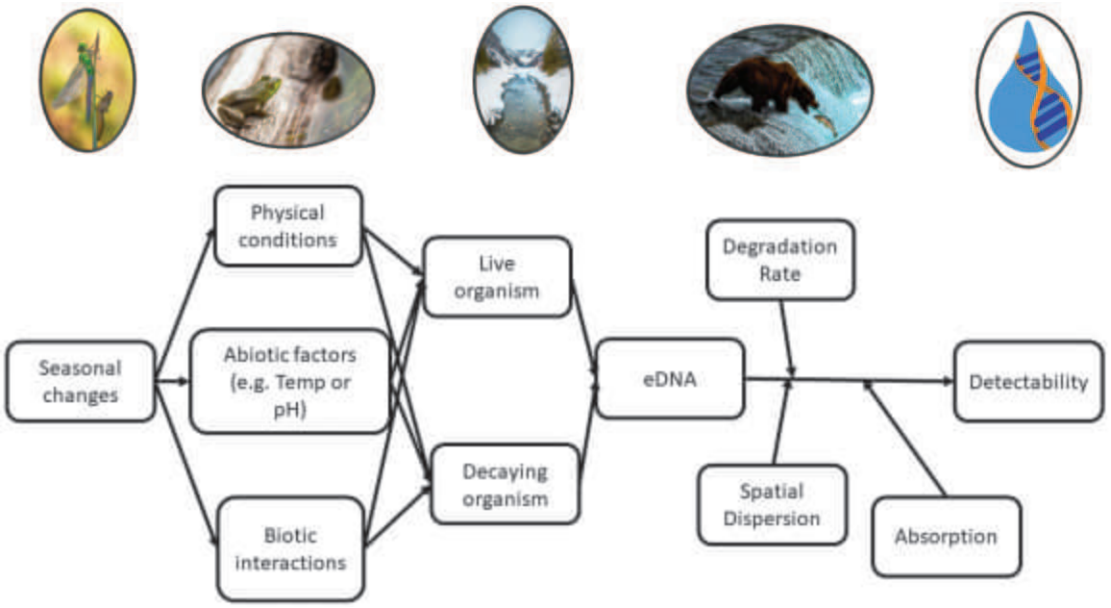

Fig. 1 Diagram showing the ecology of eDNA and how environmental, physical and biotic factors can influence eDNA detection. As eDNA is released into the environment, the tissues, cells and cell particles that are needed for sampling and detection are readily broken down, or absorbed, over time, meaning the detection of eDNA is time dependent. Many factors influence the detection of eDNA, such as seasonal changes to species activities or life stages, which will affect eDNA production, or differences in environmental conditions, such as chemical composition, which can affect degradation of eDNA. Environmental DNA may also readily traverse through waterways, meaning the detection of eDNA may not represent the specific location of the sample. Substrates may also bind eDNA particles making them undetectable, unless the substrate itself is sampled.

Using molecular methods to detect bacterial and fungal communities from environmental samples predates eDNA research, including using soil and water samples to detect microbial strains (Ogram et al., 1987; Fisher and Triplett, 1999) and permafrost to assess ancient fungal and pollen diversity (Eske and Alan, 2005). It is important to distinguish these earlier microbial and fungal studies from eDNA here, as eDNA entails detecting species and communities from genetic material that is not part of the target organism(s). Additionally, the concentration of targeted genetic material in eDNA is much smaller, compared to the high concentration of bacterial or fungal DNA found in environmental samples that require different methodologies (e.g., primer selection to avoid sequencing non-targeted species). The closely related field of ancient DNA (aDNA) uses a combination of museum and environmental samples (ice or deep sediment cores) to assess ancient communities and populations (Hofreiter et al., 2001). Apart from similarity in molecular methodological approaches, aDNA research has greatly influenced eDNA clean room and sample processing protocols, which are essential for ensuring data generated from eDNA samples is viable.

Interest in using eDNA for monitoring programs received a lot of attention, but was initially slow to take hold, as the method was largely untested. The first studies showing the application of eDNA, specifically multi-cellular eukaryotes, used water samples to detect American bullfrogs (*Lithobates catesbeianus*) in French ponds (Ficetola et al., 2008). The establishment of the silver carp (*Cyprinus carpio*) eDNA monitoring program in the United States is perhaps one of the most important eDNA applications to occur, as it established an important baseline for using eDNA as an established biomonitoring tool (Jerde et al., 2013). Additionally, the UK monitoring of the current great crested newt (*Triturus cristatus*), an important conservation species in Europe, was one of the first programs specifically designed to utilize eDNA detection (Biggs et al., 2015). With these and other subsequent successes, there is an ever-growing list of single species (i.e., population-based) eDNA programs across several countries and organization. Community-based eDNA assessments that rely on reference databases are less common but have been increasing since about 2014. Seminal works for key taxonomic groups include fish (Valentini et al., 2016; Hänfling et al., 2016), macroinvertebrates (Bista et al., 2017), and diatoms (Vasselon et al., 2017) and provide proof of concept matching eDNA biodiversity to traditional sampling methodologies. Presently many government bodies are planning to or have established community-based eDNA biodiversity assessment protocols for a wide range of species and biomonitoring communities.

An understanding of how eDNA is generated and remains in the environment is essential for utilizing eDNA-derived population and community information (Barnes and Turner, 2016). There are two important processes that affect eDNA in freshwaters: accumulation (or production) and removal (via transport and degradation). Environmental DNA is constantly being produced and subsequently degraded through biological and physical processes. The amount of eDNA present in the environment at any time varies depending on the abundance of the individuals and the intraspecific rate at which each species sheds or releases eDNA, either through bodily functions or via decomposition (Jo et al., 2017; Moushomi et al., 2019). While some species routinely shed eDNA via skin cell loss or excrement, other species may be poor shedders due to limited or timed molting or slow-decaying exoskeleton and can be difficult to detect at low population abundances, such as the American signal crayfish (*Pacifastacus leniusculus*)

(Dunn et al., 2017), and some invasive aquatic plants (Kuehne et al., 2020). Additionally, eDNA accumulation is likely to be affected by seasonal activity of individual species. For example, spawning times for fish can result in large volumes of gametes released into the environment, which may dominate other species eDNA detection and not be directly related to population sizes. Likewise, algal blooms can dominate samples and affect detection of other species such as diatoms and other primary producers. The timing of macroinvertebrate larval emergence may also affect the lateral transfer of biomass in lakes and streams, whereby pupae move from the benthos to the water surface, thereby affecting detection at different time points if not accounted for in the sampling design.

Once eDNA is produced, it can be transported away, particularly in rivers, or degraded. Degradation times differ depending on the environmental conditions; eDNA detection in lentic environments (e.g. lakes and ponds) can be up to 2 months, whereas in sediments it can be for several years (Barnes and Turner, 2016). Lotic eDNA will readily travel downstream once produced and can be detected several kilometers downstream in highly channelized settings (Deiner and Altermatt, 2014; Seymour et al., 2018), though downstream detection is much shorter in natural settings due to effects of dilution from river confluences and absorption from clay based substrates (Shogren et al., 2017). The rapid degradation of eDNA in water environments is thought to be due to hydrolysis as well as microbial activity (Barnes and Turner, 2016; Jo et al., 2019; Moushomi et al., 2019), although the exact processes are still unclear. Environmental DNA can last for several years in freshwater soil environments once it settles into the anoxic zone, as DNA can maintain its structure more easily under low oxygen conditions. Abiotic factors can also increase the degradation rate of eDNA in the environment (Strickler et al., 2015; Seymour et al., 2018) including low pH, high temperature, and potentially high UV exposure, although natural levels of UV are not expected to have significant effects on eDNA degradation rates (Andruszkiewicz et al., 2017; Mächler et al., 2018). The short term detectability of eDNA in water samples makes freshwater eDNA a measure of recent species presence, as opposed to long-term historical measurements from sampling sediments (Deiner et al., 2017). As such, water eDNA sampling is preferred for studies looking to assess the current community and populations inhabiting a site. However, sediment sampling may be more appropriate for assessing species that predominantly live within the sediment as their eDNA may not be visible or obtainable via water eDNA.

Using eDNA for biomonitoring and conservation

Freshwater biomonitoring generally focuses on routine monitoring of three main groups that are linked to environmental status: fish, macroinvertebrates, and diatoms. Detection and monitoring of these three groups can be labor and time intensive, which has led to increased interest in using developing eDNA-based biomonitoring methods and applications. Traditionally the monitoring of these groups differs substantially, with different research groups generally specializing on one group or another. Similarly, the adaption of eDNA for monitoring these groups, while more similar than the differences in traditional methods, has differed in their utilization and methods employed.

Fish biomonitoring

Fish biodiversity is, by far, the most studied within the eDNA research sphere, due to the economic importance of fisheries and relatively low diversity of fish communities compared to macroinvertebrates or diatoms, making validation of studies relatively easy. In addition, there is general widespread consensus that eDNA-based fish biomonitoring outperforms traditional sampling methodology, with the majority of studies occuringwithin lentic environments (Jerde et al., 2013; Valentini et al., 2016; Hänfling et al., 2016). From a conservation standpoint, eDNA sampling is advantageous over other methods because it is non-invasive, and no animals are harmed, compared to the several traditional sampling methods, such as electro-fishing, gill-netting, fin clipping that harm or kill fish. Combined with other non-invasive monitoring methods, such as hydro-acoustic monitoring, eDNA sampling offers a rapid and routine means to monitor fish population dynamics across the globe (Berger et al., 2020). A limitation of eDNA-based fish biodiversity assessment is the need to ensure that the sampling location (e.g., a lake) is either well-mixed or that the sampling has sufficient spatial coverage for the size and depth of the habitat of interest (Li et al., 2019).

Freshwater macroinvertebrate biomonitoring

Macroinvertebrates are a group of major interest for biomonitoring, particularly in river ecosystems where they are an important component of environmental assessment (Seymour et al., 2016) and indicators of functional change (Heino et al., 2004). Several recent studies have shown stark differences in data from eDNA methods and traditional macroinvertebrate sampling; however, the general biodiversity assessment patterns (e.g., assessment scores, inter-community variation) are often found to be similar (Macher et al., 2016). A major advantage of eDNA sampling over traditional macroinvertebrate sampling is the ability to sample water from any type of freshwater environment, including lakes, as well as both deep and fast-flowing rivers. Conversely, traditional kick-netting used for macroinvertebrate sampling is largely restricted to rivers that are traversable by foot and where the substrate is gravel or small-stoned. Macroinvertebrate communities can be assessed rapidly, compared to traditional taxonomic identification, by extracting and sequencing DNA from a kick-net sample (i.e., bulk sampling), though this should not be directly compared with eDNA sampling given the targeted approach of the bulk sampling method. It is suggested that the bulk sampling approach produces more reliable detection compared to sampling of aquatic eDNA, although community dynamics are equally well observed

(Macher et al., 2018). Moreover, collection of aquatic eDNA that utilizes a spatially structured sampling design results in a more representative biodiversity being sampled compared to benthic kick net samples, including increased detection of biomonitoring species that are traditionally difficult to assess, including Chironomidae (Seymour et al., 2021).

Diatom biomonitoring

Diatom communities are highly sensitive to changes in abiotic conditions, are routinely used for biomonitoring purposes in both lotic and lentic environments, and are generally the most sensitive to environmental change compared to fish and macroinvertebrates (Pandey et al., 2017). The importance of diatoms for biomonitoring are highlighted by their use in the European Union's Water Framework Directive (WFD) (Valentin et al., 2019), with similar efforts ongoing in Canada (Maitland et al., 2020). However, diatom identification is notoriously difficult compared to fish or even macroinvertebrates, which prompted a faster adaptation of molecular methods for diatom biomonitoring purposes compared to other biomonitoring groups. Single species assays are possible for some species; however, community spatial and temporal dynamics have received the most interest, particularly for biomonitoring purposes (Tapolczai et al., 2019). While some studies have used surface water for collection of diatom eDNA (Seymour et al., 2020), this might not be optimal over standard field sampling approaches that directly sample diatom by scrapping stones collected from river beds (e.g., bulk sampling) (Vasselon et al., 2017).

Detection of rare species and conservation efforts

There is an ever-increasing list of eDNA conservation efforts under development for several freshwater species (Mauvisseau et al., 2019; Belle et al., 2019). Perhaps the oldest example of an established eDNA monitoring program is the endangered great crested newt (*T. cristatus*) monitoring program in the United Kingdom (Biggs et al., 2015). Great crested newts require a network of ponds to form their home ranges, which can make it difficult to identify which ponds harbor newts at any given time. Given the endangered status of the great crested newt, land use changes that might affect great crested newt habitat require extensive habitat surveying. Given the high cost and difficulty in determining great crested newt presence using traditional methods (e.g., aquatic funnel traps, netting, torchlight, and egg counts), an eDNA-based monitoring program was established by Natural England (a UK environmental agency) to provide a more rapid and efficient monitoring protocol (Rees et al., 2014). Other notable conservation studies, for which eDNA detection is of interest, include Eastern hellbenders (*Cryptobranchus alleganiensis*) (Santas et al., 2013), freshwater pearl mussel (*Margaritifera margaritifera*) (Stoeckle et al., 2016), European eel (*Anguilla anguilla*) (Weldon et al., 2020), and wetland amphibian and fish communities (Kačergytė et al., 2021).

Detection of invasive species

Invasive species pose a threat to endemic biodiversity, as their establishment can lead to dislocation or extirpation of local, often rare, species. Early detection is crucial to effectively manage invasive species eradication and to prevent establishment (Mehta et al., 2007; Sepulveda et al., 2020). If invasive species become established, they are often very difficult to eradicate and can have negative effects on local biodiversity, threaten endemic species and incur huge economic cost (Sepulveda et al., 2020). The high sensitivity of eDNA-based assays can offer successful early detection of invasive species, even preceding early stages of invasions (Sepulveda et al., 2020). The standards and methods of invasive species eDNA development and implementation are very similar and are closely linked to those used in conservation biology. Some examples of invasive species that are routinely surveyed for using eDNA include the bluegill sunfish (*Lepomis macrochirus*) (Takahara et al., 2013), the New Zealand mudsnail (*Potamopyrgus antipodarum*) (Goldberg et al., 2013), and the red swamp crayfish (*Procambarus clarkii*) (Tréguier et al., 2014).

Detection and tracking of disease

An emerging aspect of eDNA research is the use of environmental samples to monitor and track the spread of disease vectors, including recent interest in using water samples to survey human coronavirus in waste water (Farkas et al., 2018; Randazzo et al., 2020). Additionally, eDNA is currently being used to assess the spread of polycystic kidney disease (PKD) (Carraro et al., 2018), an economically important disease in salmonids, and to help develop better spatial models for human pathogens such as cholera (Vezzulli et al., 2017) and schistosomiasis (Sengupta et al., 2019).

eDNA methodological workflow: From sampling to data

Sampling the environment and extracting eDNA

Detection of eDNA is done by sampling the environment of interest, particularly the material that the species or community of interest regularly interacts with. Sampling itself can be conducted by taking a sample of the environment such as using a digging device to sample the soil (e.g., shovel, sediment corer) or using a bottle to take a water sample. However, one must be aware that it is very easy to contaminate eDNA samples, with other eDNA sources being transferred by the sampling person or from unclean or reused sampling equipment. For example, if a person sampling for fish eDNA in a lake was fishing in a neighboring lake the day

prior, they could contaminate the samples they are taking as particles acquired the day before could be transferred from their person to the sampling container. It is therefore important to develop stringent sampling protocols for cleaning of persons and equipment and using disposable or single-use sampling equipment (e.g., gloves and sampling containers). The use of field controls/blanks to help identify any potential false positives that may arise from contamination are also strongly advocated. Field controls are previously prepared samples that resemble the field samples, such as a sampling bottle of autoclaved water, that should be brought into the field and processed in the same manner as the field samples. The results from the field controls can then be crosschecked with the field samples later to assess any potential sources of contamination.

Processing of the samples as soon as possible after collection is important to avoid further eDNA degradation. Water samples should be filtered for eDNA as soon as possible and the filters kept dry, preserved with lysis or fixing agents or frozen to avoid DNA degradation. Likewise, soil or sediment, once sampled, should be kept in cool and dark conditions for transport, either for laboratory analyzes or to freezers for longer-term storage. Environmental DNA extraction is generally done following modified DNA extraction protocols (Spens et al., 2017; Tsuji et al., 2019). Extraction of eDNA can be performed with modifications of commercial kits or using "home-brewed" methods (Spens et al., 2017; Lear et al., 2018). It is important to note that eDNA will be extracted at low concentrations, compared to extractions from bulk or tissue samples, in many cases resulting in only trace amounts of relevant DNA, with much larger concentrations of non-target DNA from other taxa, such as bacteria or single-cell eukaryotes. Additionally, inhibitors of downstream PCR reactions (for qPCR or metabarcoding) might be retained during extraction from environmental samples, such as humic compounds from soil (Matheson et al., 2010). Therefore, it is important to check for sample inhibition and consider using an inhibition cleanup step post-DNA extraction.

Generating data from eDNA samples

Once eDNA is isolated from the environmental sample, the DNA fragments need to be associated with the species or group of species (i.e., community) of interest. Currently, two molecular approaches are generally used to identify the eDNA fragments (Fig. 2): quantitative PCR (qPCR), also called real-time PCR, and metabarcoding. qPCR allows for a species-specific detection method using species-specific primers. Metabarcoding is a high throughput sequencing (HTS) method that allows multi-parallel sequencing within a single sample, allowing for community-based (e.g., multiple species) assessments from a single eDNA sample. The qPCR workflow is currently more standardized, cheaper and faster compared to metabarcoding, making it the preferred method for monitoring of rare species, detection of invasive species, or disease monitoring (Wood et al., 2019). Metabarcoding applications are newer, generate more data and allow for community level assessments, although single species can also be extracted from metabarcoding results (Deiner et al., 2017).

Using qPCR (single species)

qPCR methods can be used for several different applications, ranging from control laboratory experiments to species-specific detection in complex natural environments (Goldberg et al., 2015; Thalinger et al., 2021). The qPCR method can detect low levels of DNA in a sample, making it suitable for eDNA-based research. Droplet digital PCR (ddPCR) may also be used, which uses similar molecular chemistry as qPCR with increased sensitivity to detecting low concentrations (Doi et al., 2015). Currently, however, ddPCR machines are more costly to set up and implement, leaving qPCR still at the forefront for those looking to do standardized single species detection (Doi et al., 2015).

A full breakdown of the steps to create and validate PCR primers for reliable use in biomonitoring has recently been outlined by MacDonald and Sarre (2017). Briefly, special consideration needs to be taken to ensure the primers are species-specific so that false positives are not mistakenly identified during the data processing. Steps for creating qPCR primers should include *in silico* assessment for primer specificity, using software such as NCBI's primer blast (Ye et al., 2012), as well as laboratory test of the primers against target and non-target organisms. Depending on the intended application of the primers, either laboratory only use (controlled experiments) or for government biomonitoring programs, the test of the primers can be quite extensive in order to ensure that the primers are species-specific and avoid false positives. To ensure comparison of results across multiple samples and to quantify the copy numbers for each sample, a set of size standards needs to be included into each set of reaction runs. These size standards should contain known quantities of the target sequence that is being amplified during the qPCR run. Size standards can be created using DNA cloning (e.g., plasmids) or purchased as synthetic sequences from a company. The range of size standards to include into each run should capture the full range of values that is to be amplified from the samples. Particularly for eDNA studies, it is important to assess the limits of detection (LOD), which is the primer's ability to detect target sequences at low concentrations (Klymus et al., 2020). It is important to also be aware that some environmental samples may incorporate PCR inhibition, which can be assessed by spiking samples with known quantities of the cloned or synthesized size standard.

While there are many things that need to be considered to quality check and verify qPCR data, the whole process is relatively quick once the primers and protocols are established. The final data is readily accessible after each qPCR run and usable for analyzes immediately, whereas the data generated via high throughput sequencing will generally take several days to reach a similar usage point.

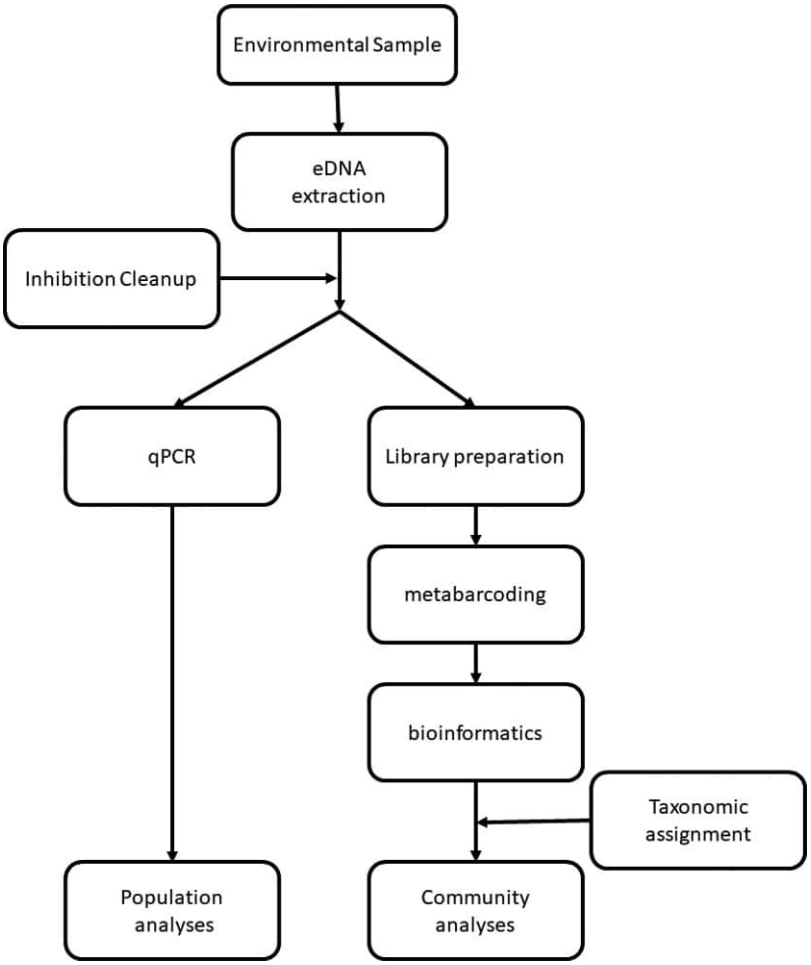

Fig. 2 Simplified workflow for single and multiple species detection using eDNA sampling. eDNA is extracted from environmental samples (e.g., water or soil). Depending on the quality of the extraction, it may be important to perform an inhibition cleanup prior to any PCR based method, although this is not always necessary. The general process for single species via qPCR follows standard qPCR procedures to generate population level data. The steps involved in multi-species eDNA assessment via metabarcoding includes preparing the genetic libraries from the extracted samples, performing the metabarcoding on a high throughput platform, using bioinformatics to quality check and process the sequence output and linking sequence information to taxonomy using a reference database.

Using metabarcoding (multi-species)

Metabarcoding entails using high throughput sequencing (HTS) to determine the sequence information from a pool of genetic material, which can then be linked to a DNA barcode database, hence the name metabarcoding (Deiner et al., 2017). The taxonomic diversity that can be detected from a metabarcoding analyzes is dependent on the specificity of the primers used and the reference database that is used to link genetic sequences to morphological taxonomy. No metabarcoding primer is perfect for all studies, with many different primers designed to capture different taxonomic groups (Cordier et al., 2019; Seymour et al., 2020). Some primers that work well with bulk sampling (e.g., insects blended together) will not work as well with eDNA samples because the primers will also sequence undesirable species, often protists or bacteria, that are more common (i.e., have more DNA available for sequencing) in the sample. With the increased interest in using eDNA, however, new primers are being developed that take into account the type of environmental sample and the desired taxonomic diversity (Leese et al., 2021). Generally, it is advised that primers perform better when they are specifically developed for each project, since they will be tailored to the regional diversity and environmental condition. However, the effort in designing study specific primers can be costly and time-consuming and several metabarcoding primer sets currently exist for a wide range of species that have been used across different studies, which may be suitable for a given project (Deiner et al., 2017).

After sequencing, the next steps require bioinformatics pipelines to perform quality checks, removing low quality reads, merging paired-sequence ends and checking for chimeras. The sequence reads are then grouped into clusters called operational taxonomic units (OTUs) or amplicon sequence variants (ASVs), depending on the pipeline and clustering algorithms being used (Porter and Hajibabaei, 2018; Tsuji et al., 2020). Once sequencing clusters (e.g., OTUs or ASVs) are created they can be analyzed directly, which is commonly done for bacterial or fungal diversity, or they can be linked to taxonomic identifiers using relevant reference databases (Hebert et al., 2003).

DNA sequencing reference databases contain the DNA barcode sequences for different species. Most publicly available libraries are incomplete, given the extensive number of species that require sequencing, with efforts ongoing to fill in the gaps (McGee et al., 2019). Three such databases are most commonly used. First, and the most iconic reference database, is the Barcode of Life Data System (BOLD), which curates species barcode sequences of the COI gene. Second is the substantial SILVA database for the small and large ribosomal subunits along with several smaller reference databases for other genes, including 12S (Mitofish), cytochrome *b* and rbcL (Weigand et al., 2019). Third, the NCBI database has the most diversity across available gene regions but these data are not as stringently curated compared to other reference databases. Despite this, the NCBI is highly accessible, compared to other databases, and is routinely utilized for generating personal reference sequence libraries for different gene regions (Hänfling et al., 2016; Fernández et al., 2018).

Once the data is formatted as either purely genetic cluster data or taxonomically linked community tables, it can be used similarly to other ecological analyzes. The read counts, which are the number of matching sequences recorded during the sequencing, will be available for each genetic cluster or taxonomic group. Read count numbers may provide some insight into the abundances of each group, however they are also generated due to variation in PCR efficiency. As such, caution should be made when using read counts in analyzes, as they do not represent abundances specifically, but will also vary artificially due to PCR chemistry. The most conservative approach is to convert the read count data to presence/absence, which is similar to how many traditional ecological analyzes proceed. There are alternative methods to convert read count data to semi-quantitative formats, such as relative read counts prior to additional analyzes; however, biases arising from the molecular methods may still persist (Lamb et al., 2019).

Future directions using eDNA

Environmental DNA is a tool as well as a field of study, which makes for an exciting and diverse set of future applications and research. Within the context of inland waters research, there are three key directions for eDNA research: network based analyzes, functional diversity assessment and use of alternative molecular methods. The description of these topics below is by no means exhaustive and the emerging foci are likely to change rapidly in the coming years.

Network analyzes

Ecological networks are a way to assess interactions among taxa across deep diversity pools, and have been linked to several aspects of metacommunity dynamics that are directly relatable to biomonitoring principles (Araújo et al., 2011). The scale of eDNA-derived data, particularly from metabarcoding, allows for the application of robust standardized analyzes to conduct network analyzes. Much research has been done to incorporate network-based approaches to link sample sites, either through time or space, which enables the assessment of environmental variables on network properties and the underlying biotic interactions, a key aspect for effective biomonitoring (Bohan et al., 2017; Seymour et al., 2020). In contrast to current biomonitoring assessments, eDNA-derived data has the potential to include a much wider range of taxa and indicator groups, which are currently excluded or simplified due to limitations of traditional taxonomic identification. Network-based eDNA assessment may further add to existing biomonitoring efforts by allowing for a finer-scale assessment, such as exploring differences in community dynamics among neighboring sites or evaluating moderate changes in environmental conditions (Cordier et al., 2017).

Although there is a need to ensure continuity between traditional and eDNA-based assessment methods, there should also be a forward-thinking approach that does not restrict eDNA research to simply confirming traditional expectations. Not only can eDNA data be used to assess environmental filtering on individual indicator taxa, allowing for comparable biometric data to traditional sampling, it can also be used to determine interactive qualities that are also linked to the stability and ecological complexity of habitats (Cadotte and Tucker, 2017). Additionally, the advancement of machine learning algorithms (Cordier et al., 2017) and newer abiotic monitoring systems, such as advanced mass spectrometry (Collins et al., 2021), combined with eDNA, potentially allows for a much deeper exploration of environmental samples for linking environmental effects to changes in natural populations and communities.

Functional diversity

Functional diversity has recently received increased focus in ecology, although it has long been recognized as an important factor in understanding the complete structure of an ecosystem (Young and Collier, 2009). More often biodiversity is quantified using species richness, which is the number of unique taxonomic units per site or sample. Richness is often positively correlated with heterogeneous environments, which is often attributed to higher levels of functional diversity (Cardinale et al., 2011; Donohue et al., 2013). Functional diversity directly quantifies the functionally disparate taxa within a community, and is becoming increasingly recognized as an important component of effective and more direct measure for linking community response to environmental change (Young and Collier, 2009). By measuring functional diversity, we get a better understanding of the characteristics within a community and can then relate these to environmental variation or to assess changes over time.

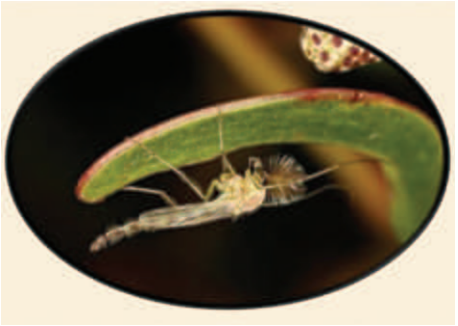
Environmental DNA research can further our understanding of functional diversity. For example, we can incorporate existing functional diversity of known species, such as feeding groups for macroinvertebrates (Moog, 2017), into eDNA data analyzes (Seymour et al., 2021). Attempts are also being made to detect variation in functional genes via transcriptomics directly from environmental samples (Taberlet et al., 2018).

Alternative molecular methods

A major interest in current eDNA research is to design methods that allow for estimation of abundances from high throughput sequencing (HTS). However, abundance estimates from HTS that use PCR (e.g., metabarcoding) are currently not reliable due to PCR amplifying sequences at different rates. Efforts are being made to incorporate PCR-free sequencing technologies with eDNA samples, such as shotgun sequencing (Ji et al., 2020), LAMP (Lee, 2017) and CRISPR (Williams et al., 2019). There are limitations to such applications at present, including incomplete reference databases, incompatibilities of some species to specific methods, the need for additional primer development, and the inability of methods to detect lower eDNA concentrations.

Another area of interest is to better understand the health of organisms sampled via eDNA. Currently, there is a lack of knowledge regarding the condition of the species when sampling eDNA, as the source of eDNA could originate from healthy, sick or dead organisms. The condition of the organism is important as different conditions may require different management strategies. As such, there is an increased interest in using eRNA, which refers to environmental RNA. The potential of eRNA may allow for aquatic health assessment via insights into organism functionality (Veilleux et al., 2021).

Case studies



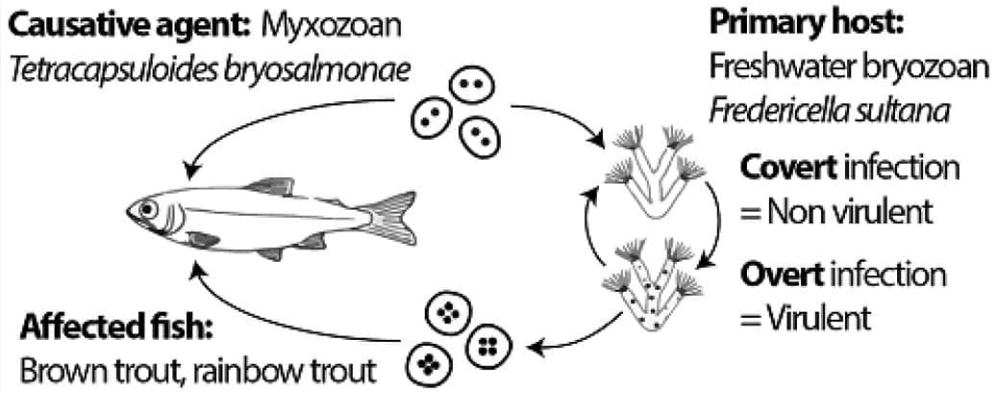
Bista et al. (2017) was one of the first to assess temporal dynamics of community diversity using eDNA, showing that eDNA can reliably depict temporal dynamics of Chironomidae communities. Chironomidae, informally known as non-biting midges, are a highly diverse family of flies with over 10,000 species globally. The larvae of Chironomidae are aquatic and form an important component of the benthic community of freshwater ecosystems, particularly in lentic or slow moving lotic systems. Chironomidae larvae predominately feed on algae, or small organisms, while serving as important food sources for fish, amphibians and larger predatory insects. Adult Chironomidae emerge, often en masse, from the surface of lakes or ponds by floating to the surface of the water as pupae and shedding their pupal skin (i.e., exuvia) as they transform into adults. As adults, Chironomidae serve as important food sources for bats and bird species, with some having evolved nesting strategies to coincide with annual cycles of Chironomidae adult emergences. Chironomidae are noted as important indicator species, meaning the presence or absence of key species is indicative of pollution.

However, traditional identification of Chironomidae species is notoriously difficult due to their small size and morphological similarity between species, which requires a high level of expertise to identify individuals to species level. Furthermore, sampling Chironomidae in lakes is mostly conducted by skimming exuvia from the lake surfaces during adult emergences, as sampling the lake bottom for larvae requires additional equipment and effort, and sampling from the edges of the lake will miss most species. Such traditional sampling limits observations to emergence times and does not capture the benthic community, which is essential for regular assessment. By using eDNA and monthly exuvia sampling of lake water Bista et al. (2017) compared emergence and biodiversity patterns of Chironomidae communities. Environmental DNA revealed much about the status of emerging species during their larval development times that had not been detected using traditional sampling through the winter months. Overall, these findings helped establish eDNA as a means to capture temporal trends in community biodiversity. Future efforts could look to compare surface and sediment eDNA to determine the overlap in community composition and dynamics.

Hänfling et al. (2016) presented a robust assessment of fish stocks in three large lakes in the United Kingdom and was one of the first studies to show that rank abundance comparisons across temporal eDNA sampling points was an effective means of assessing fish populations. Fisheries management is important for environmental assessment, societal enjoyment and economic stability. It is therefore important for agencies to accurately assess fish populations to apply appropriate management strategies. Fisheries managers use a wide range of assessment methods, which are often destructive or harmful to the fish, prompting many organizations to invest in non-invasive sampling methods.

Hänfling et al. (2016) looked to verify if eDNA metabarcoding was a viable means for routine monitoring of fish populations. The lakes used in the study have a long history of fisheries assessment, so their biodiversity and environmental condition linked to fisheries populations is well known. As such, results from eDNA assessments could be directly compared to current gill netting data as well as historical population structures. Hänfling et al. (2016) utilized a self-made reference database (freely available via their publication) that incorporated all fish species expected to live in or near the lake. Using a replicate transect sampling design, they compared the site occupancy of each fish species identified using two gene markers (12S and CytB). They showed that rank abundance of sequence reads reflected the rank abundance of species within the three lakes, suggesting read counts reflected differences in fish abundances. Additionally, they showed spatial preference for eDNA signal, whereby shore vs. off shore sampling affected the detection of different species (Hänfling et al., 2016). Overall, the key finding was that eDNA assessment of fisheries outperformed the traditional assessments methods, thereby providing a proof-of-concept for a non-invasive means of environmental assessment.

This study is an excellent example of a well designed and implemented eDNA research effort and has been followed by several other studies that have highlighted the importance of fisheries eDNA (Jerde et al., 2019; Miya et al., 2020). Additional work will look to improve on the ability to calculate abundances of different fish species from eDNA by incorporating biomass information directly from individual samples, such as proposed recently by Yates et al. (2020).



Lifecycle of Myxozoan Tetracapsuloides bryosalmonae

Carraro et al. (2018) is one of the first studies to apply river network based approaches to understand the spatial dynamics of eDNA in a river network. The study takes into account the transport time and spatial dynamics induced by flow to observe and model the biological distribution of the bryozoan *Fredericella sultana* and its parasite *Tetracapsuloides bryosalmonae*.

Tetracapsuloides bryosalmonae is of general interest to researchers and managers as it is the agent that causes proliferative kidney disease in salmonid fish. The life cycle of *T. bryosalmonae* involves seasonal cycles whereby the *T. bryosalmonae* persist in their primary host *F. sultana* throughout the year. During the summer, the *F. sultana* releases spores of *T. bryosalmonae* into the water, which infects fish through their gills. *Tetracapsuloides bryosalmonae* will grow and multiply inside the fish and during the autumn will leave the fish via being excreted with their urine to then infect other *F. sultana*. Effectively monitoring the timing and outbreaks of *T. bryosalmonae* life stages can therefore be essential for minimizing loss of fish to PKD.

Carraro et al. (2018) model highlights the importance of understanding the distribution of the target species and the hydrodynamics for effectively using eDNA for biomonitoring. Additional efforts to merge real time environmental data to project expected changes in species distribution will help managers gage what level of distribution is expected in combination with routine monitoring of key sampling sites along a given river stretch.

Concluding remarks

Environmental DNA is a rapidly growing field that is becoming more widely used. It has already made major inroads into freshwater science across academic, government and private sectors. Regardless of whether traditional or eDNA-based sampling is used, it is important to be aware of the use and application of eDNA, as many agencies and employers are rapidly looking to adapt eDNA methods where applicable. Environmental DNA research can also be seen as an opportunity for emerging scientists. The field is very new, which allows for new researchers to rapidly develop and implement novel ideas and studies. Combined with other emerging and developing research fields, eDNA based research offers a valuable doorway into modernized biomonitoring of ecosystems, environmental assessment, conservation biology, and many other potential avenues for understanding and discovering previously unobservable aspects of our natural world.

Glossary

Acoustic telemetry The transmission in water of ultrasonic energy or sound signals at frequencies generally in the range of 20–500 kH; requires use of a transmitter and hydrophone.
Archival logger A device that records and stores information (e.g., on depth use) until it is retrieved for downloading; a form of biologging.
Biologging Information is recorded and stored in an animal-borne device (archival logger) and information is downloaded when and if the logger is retrieved or in some devices stored until later transmission.
Biotelemetry The process of conveying information from one location to another, typically in a wireless manner; signal emanating from a device carried by the animal (transmitter) sends the information to a receiver.
Electronic tags A term that broadly captures the range of biotelemetry and biologging devices that can be attached to or implanted in aquatic animals.
Passive integrated transponder (PIT) Transponders are tags that send information upon interrogation only; tag consists of an integrated circuit chip and coil antenna which, when energized by a low-radio frequency (125–400 kHz) reader coil, transmits a unique identity code.
Radio telemetry Reception of data at a location remote from the source of the data, using radio-frequency electromagnetic radiation as the means of transmission; requires use of transmitter, antenna and receiver.
Receiver A device that collects (receives) information emitted from a transmitter, typically as either radio waves or acoustic waves.
Sensor An electronic component that can be incorporated into electronic tags to record various forms of environmental and biological information such as temperature, pressure (depth), acceleration, and electrocardiograms.
Telemetry array Deployment of automated telemetry systems to continuously track telemetry tags over long periods; variety of configurations that can be used for automated 2- or 3-dimensional positioning or simply presence/absence.
Tracking The process of locating tagged animals using either manual tracking approaches (e.g., by foot, boat, airplane) or use of a fixed telemetry array.
Transmitter An electronic device usually implanted or externally attached to a fish or other aquatic animal that transmits information to a receiver.

Introduction

Inland waters around the globe are home to diverse communities of fish and wildlife. Yet, life in freshwater is often cryptic as a result of turbidity, entrained air, algal blooms, emergent macrophytes, depth, and ice cover (Hussey et al., 2015). As such, even the most basic natural history is unknown and ecological data are lacking for many freshwater species. Fundamental questions such as (i) When do they breed?, (ii) What are their critical habitats?, and (iii) What are their environmental tolerances? remain largely unanswered for many species.

The advent of electronic tagging and tracking tools (i.e., biotelemetry and biologging devices; see Glossary for definitions) has enabled biologists to begin to unravel these mysteries of life in freshwaters (Cooke et al., 2013). Researchers use these tools to position individuals and recreate a path or network of movements for analysis. Calculating the time and distance between individual positions can contribute to improved understanding of the where, when, why, and how animals move, revealing information about an individual or a population, and how they interact with their ecosystem (Cooke et al., 2016a). The knowledge obtained from an animal's location in the environment, the timing of changes in their location, and the factors that might have driven those changes, can contribute to improved understanding of not only the life history of that species, but also to their conservation and/or management.

Animals move on a scale of centimeters to kilometers, and across microseconds to years, depending on various internal and external factors. For example, light levels and temperature may dictate the position of an organism in the water column, with fine-scale shifts in depth based on the time of day (Stangel and Semlitsch, 1987; Mehner et al., 2007; Mehner and Kasprzak, 2011), but also have been known to cue longer annual spawning/reproductive migrations (Jonsson, 1991). Aspects of the natural history of an animal can also be explored using telemetry, including any site fidelity, or homing behavior they may exhibit, the size of their home range and how this may change throughout the year and their lifespan (Minns, 1995; Tucker, 2010). Telemetry with biologging technology could also further our understanding of the resources an animal is selecting (e.g., depth, altitude, temperature, dissolved oxygen), and the bioenergetics of an individual, i.e., how they use their energy, and the various abiotic and biotic factors that can influence this energy expenditure (Cooke et al., 2016b).

Understanding animal movements, and how they may be affected by anthropogenic factors, can assist in management and conservation of fish and wildlife. Unfortunately, inland aquatic ecosystems suffer from issues concerning habitat/ecological fragmentation and connectivity (Grill et al., 2015; Reid et al., 2019). Telemetry can be used to determine the efficacy of passageways at dams, for example, at restoring the up and downstream connectivity (Castro-Santos et al., 1996; Aarestrup et al., 2003). Locally extirpated species can be captively bred and reintroduced. Tracking these individuals can allow for a better understanding of the success and ramifications of these reintroductions, helping inform conservation efforts (Peters et al., 2009; Wang et al., 2011; Brooks et al., 2019a). Knowing the location of an animal can provide information about the resources that the animal is selecting for (chemical, physical, biological), which can be beneficial when planning and monitoring habitat restoration efforts (Brooks et al., 2017). Fish and wildlife are often managed within a particular geographical area, i.e., a waterbody, a watershed, or a jurisdictional boundary; however animals rarely stick to these boundaries (Hussey et al., 2017; Brooks et al., 2019b). More broadly, temperature is a major driving force for any ectotherm and understanding how an animal may respond to changes in temperature, and the spatial scale of that response, will help better predict changes in animal distributions with our changing climate.

The tools

The tools used to track animals that live in inland waters can be divided into two categories; **(1)** *biotelemetry*, whereby the tag transmits a signal to a receiver that decodes and logs the information and (2) *biologging*, whereby the tag stores information generated from the tagged individual for later retrieval and downloading (see Table 1). Biotelemetry tags can be tracked manually (e.g., by boat, foot, aircraft, snowmobile) or by deploying automated receiving stations that log detections from tagged animals. Because biologging tags do not transmit data, they must be retrieved, either from the animal or the environment if the tag is shed, to download data.

Although revealing basic information on animal space use is a primary reason to tag animals, it is also possible to use both types of tags to incorporate various sensors that measure environmental conditions (e.g., water temperature, depth, light levels, pH), animal status (e.g., heart rate, acceleration), or even record images or ambient noise. Within these two broad categories of devices, there are many different technologies and configurations that allow scientists to answer questions about inland water organisms. However, every tool has its limitations (e.g., radio telemetry does not work in deep water, acoustic tags cannot be tracked on land, biologgers have to be retrieved and small animals cannot carry a large tag burden) and it is important that those limitations are understood prior to embarking on a study. In general, the objectives of the study, the characteristics of the system, and the biology of the focal animal dictate which tools make sense for a given study.

To track animals, they first must be tagged. Although the details of tagging vary widely among taxa, the most common approaches involve either external tagging (e.g., a backpack on a waterbird, glued to the carapace of a turtle or crayfish) or internal tagging (e.g., surgical implantation in fish and mammals). Protocols have been developed to ensure that researchers use techniques that minimize negative impacts on welfare of tagged animals (Withey et al., 2001). Investigators can refer to taxon-specific guidelines regarding the mass of devices that can be carried by animals before the tags cause undue energetic or postural burden.

Table 1 Overview of electronic tag types and their relevance to the study of animals in inland waters. See Cooke et al. (2013) for additional details on electronic tagging tools relevant to freshwater organisms.

Electronic tag type	*Ideal environments for deployment*	*Typical organisms studied*	*Common applications*
PIT tags	Shallow streams and rivers (<1 m deep); In and around fish passage facilities	Small invertebrates (e.g., dragonflies) amphibians (e.g., frogs) and fish; tags lack batteries so can be quite small	Space use of organisms in small systems; timing of migration; fishway efficiency studies; survival studies of small animals
Radio telemetry	Shallow rivers and lakes (<10 m deep)	Large invertebrates (e.g., crayfish), turtles and fish; Can be used to track aquatic animals that spend some time on land	Space use of organisms; timing of migration; winter biology studies including under ice; survival studies; energetics
Acoustic telemetry	Large rivers and lakes; Works best in >2 m of water but no maximum depth limit	Large invertebrates and fish; only works when animals are in water so best for animals that spend all their time in water	Space use of organisms; timing of migration; winter biology studies including under ice; survival studies; energetics
Biologgers	Can be used in any environment but must be retrieved to download data	Tends to be used on larger animals like turtles, fish and aquatic birds, but recent decreases in tag size are increasing options	Activity patterns; timing of migration; winter biology studies including under ice; animal-environment relationships; energetics

Tag size is determined largely by battery size, which is often the largest physical component of tags (except passive integrated transponder [PIT] tags, which do not have a battery as they are powered from external energy sources). Through time, tag size has decreased to the point where some battery-powered tags weigh less than 0.3 g and are the size of a grain of rice although their longevity may be on the order of days. Larger tags with larger batteries enable the tracking of animals across seasons and years. For the data to be representative of untagged conspecifics, it is essential to ensure that the tagging process and the burden of the tag do not alter the behavior, condition, or survival of tagged animals. However, trade-offs with device size relative to the size of the animal and study objectives are common.

Next, we provide an overview of the most common tools used in inland water systems for tracking freshwater animals. We direct readers to Cooke et al. (2013) and Lennox et al. (2017a) for more comprehensive reviews of technology. We exclude satellite tags from this discussion because they have rarely been applied to freshwater systems and have technical issues related to transmitting signals through water. In fact most satellite tags are limited to use with very large animals, and because their spatial resolution tends to be insufficient for understanding space use in freshwater systems (e.g., Kough et al., 2018). We also exclude technology that can solely be used on land (e.g., for tracking waterbirds or insects during flight) such as those that rely on harmonic radar (see Mascanzoni and Wallin, 1986).

Biotelemetry: Passive integrated transponder telemetry

Passive integrated transponder tags, or PIT tags as they are more commonly known, is a collective term for small electronic tags (Fig. 1) fitted to an animal that transmit data (a unique code) wirelessly via radio waves using radio-frequency identification (RFID). The tags comprise an encapsulation material, typically glass or food-safe plastic, which encases a coil antenna and integrated circuit that when energized transmits a unique code to a reader. The tags contain no battery and hence are in a passive state until energized. Read range of PIT tags is typically centimeters to meters, influenced by the technology used (full duplex (FDX) or half duplex (HDX)), tag size, environmental variables including temperature and habitat type, as well as specifics relating to antenna construction. As a result of their simple circuitry and absence of a battery, PIT tags are small, long-lasting, and relatively cheap, which provide for a number of inherent advantages when used in animal tracking studies including large sample sizes, longevity, and an ability to tag small animals weighing as little as a few grams. The application of PIT tags in aquatic animal studies has been reviewed for fish (Lucas and Baras, 2000) and more generally for aquatic animals (Cooke et al., 2013) and this information is synthesized below.

Once fitted to the study animal, the use of PIT tags can be grouped into three broad applications that vary in their level of future disturbance to the focal individual from: (1) mark-recapture that requires additional capture and handling, (2) manual re-location of the tagged individual in a field or mesocosm environment using a portable scanner, and (3) remote data logging using fixed stations. The use of mark-recapture methods enables estimation of population size and quantification of vital population statistics including mortality, survival, growth and movement (Gibbons and Andrews, 2004). The application of PIT tags to mark-recapture methods is not exclusive, with numerous external visual marks or tags, or natural (e.g., genetics, elemental ratios in the ear bones of fish) and chemical tags also readily applied. The advantage of PIT tags in mark-recapture methods is the use of a hand scanner to read a tag that enables digital data collection and retention of the tag over an external mark or tag.

Manual relocation of PIT tagged animals is undertaken with a portable scanner/datalogger and antenna combination and is well suited to small wadable streams and other restricted habitats. Recordings of unique tags are taken by passing an antenna over likely locations with minimal disturbance and no additional handling of the study animal. This method is suitable for determination of small-scale movements of aquatic animals and fine-scale habitat use, including tracking through ice (Linnansaari et al., 2007) or in

Fig. 1 A small (12 mm) PIT tag is implanted in a small-bodied fish. Photo credit = Steven Cooke.

complex habitats (Bubb et al., 2002). Novel applications include assessment of colonial waterbird predation on juvenile salmon through the field collection of PIT tags previously fitted to the salmon and subsequently located at breeding colonies (Collis et al., 2001).

Remote data logging using fixed stations is where PIT technology excels. When tagged animals undertake movements through restricted locations, enabling installation of an antenna that act as a "gate" or "door," the timing of movements can be determined. The technique, used extensively to monitor migrating fish movements through fishways, was pioneered by Castro-Santos et al. (1996) and is now applied globally to assess fishway efficiency (Cooke and Hinch, 2013).

Biotelemetry: Radio telemetry

Radio tagging has a long history of contributing novel insights to the ecology of fish, mammals, birds, turtles, and insects. Radio signals propagate through air and freshwater and are therefore widely used for tracking terrestrial, semi-aquatic, and aquatic animals. Radio tags are designed to transmit a wave of a defined frequency at an appropriate pulse interval, which is heard within a certain range by a compatible receiver (Fig. 2).

Tags can be configured with a coded signal indicating a unique individual on a given frequency. Coded signals allow a tracker to scan on a single frequency and find multiple fish without toggling through a prohibitive number of channels. When a large number of tags are deployed, coded signals can limit the channels an investigator needs to scan through, reducing the chances of missing a detection. Data logging receivers can be placed at strategic points in study systems and attached to a power source to toggle through radio frequencies and log the time and date of detection or carried by an investigator with a manual Yagi-type antenna to find an animal and record the coordinates of location. For linear systems such as rivers or corridors in between lakes, movement can be measured as the animal transits past the receiver in a series of one dimensional points; this has been applied successfully to the river migration study of various fish species, particularly salmonids (e.g., Thorstad et al., 2003; Thiem et al., 2013). Often, this requires paired receivers or directional antennas (e.g., upstream and downstream) to establish the direction of movement. In open two-dimensional systems such as lakes, multiple positions may be required to calculate a coordinate based on triangulation

Fig. 2 Manual tracking of radio tagged animals using a hand-held radio receiver and antenna. Photo credit = Eva Thorstad.

(Fish and Savitz, 1983). The frequency and spatial resolution of positioning will drastically influence the value of the data recovered from the study system and the ability to interpret the behavior of the tagged individual.

Designing radio telemetry studies can be challenging and has a variety of pitfalls. Radio telemetry can be challenged by interference from other local radio equipment. Detection efficiency will also vary as a function of environmental conditions such as water salinity and conductivity; water chemistry should therefore be considered when determining the suitability of radio telemetry for a project. Habitat features may also attenuate or block signals. Animals may also find hiding spots that generate false negatives in data. Occasionally, tags can disappear from a system and ruling out various pitfalls can help isolate a most probable explanation. Radio equipment, and the frequencies selected for the project, should be piloted at the study site to ensure optimal performance (e.g., Sullivan et al., 2019).

Tags can be attached in many ways (Thorstad et al., 2003), including externally through the musculature (e.g., fish), glued to fur (e.g., river otters) or carapace (e.g., turtles), harnessed or collared (e.g., beavers or mink), or internally implanted under anesthesia (e.g., fish; Fig. 3). Capture, handling, and tagging can all affect animal behavior and undermine the study if not rigorously studied. Predation, mortality, or straying of animals from the study system can introduce errors that are challenging to interpret and mitigating potential pitfalls is therefore important to improve interpretability of findings emanating from the study.

Radio telemetry is most frequently used for positioning animals, but additional sensors have been integrated to extend the information provided by the transmitters. Mortality sensors are sometimes integrated into radio tags to provide better resolution about the fate of tagged animals. Depth and temperature sensors have been developed, which can provide a third dimension to telemetry data. Lucas et al. (1993) tested the utility of heart rate loggers integrated in radio tags, although these sensors have not been developed much further in radio tags.

Biotelemetry: Acoustic telemetry

Similar to radio telemetry, acoustic telemetry involves the use of receivers to detect the position and movements of tagged animals, either with mobile tracking by people equipped with a receiver or using stationary, strategically positioned receivers (i.e., passive tracking; Fig. 4). However, rather than using radio wave transmissions, acoustic telemetry uses pulses of sound to transmit ultrasonic "barcodes" from tags that can then be deciphered by acoustic receivers. Acoustic telemetry uses short, fast, pulses of ultrasonic sound (low frequency) as signals (this technology is sometimes referred to as "ultrasonic telemetry"; Ogura and Ishida, 1995). Because sound travels much better through water than it does through air, acoustic telemetry is confined to the underwater world. It has become the most widely used technology for tracking fine and broad scale movements of animals in underwater environments, especially in marine environments and deeper freshwaters, where other tracking technologies like radio and PIT telemetry do not function well.

The largest acoustic transmitters that are routinely used are about twice the size of an AA battery, best suited for large animals like sturgeon, walleye, or snapping turtles. The largest tags can be programmed for 10+ years of battery life and have a strong signal that is easily detected by receivers. The smallest acoustic tags are about the size of a green pea, suitable for small species like gobies (Christoffersen et al., 2019) or juvenile salmon, which are routinely tagged on their outmigration from rivers (Deng et al., 2015). Acoustic tags are often surgically implanted into anesthetized animals and the smallest tags can now be injected (Deng et al., 2015). Acoustic tags are sometimes externally attached, either through the musculature (Raby et al., 2015) or in the case of turtles or some invertebrates, fastened to the carapace (Micheli-Campbell et al., 2013).

Once a tagged animal is released, it can be tracked using acoustic receivers positioned underwater. Typically, receivers are anchored to the bottom (seafloor, lake bed, etc.) and suspended in the water column by rope, with a float attached to the top of the receiver. Receivers can also be attached to existing structures (e.g., weirs, buoys), or cabled to an anchor point on shore. Acoustic

receivers typically need to be retrieved for download and battery replacement every 6–12 months, but sometimes shorter or longer deployments occur depending on study design and receiver type. Receivers can, in many environments and with common tag types, detect tagged animals from 500 to 1000 m away or more. However, while ultrasonic signals can travel several kilometers through water, they can be impeded by ambient noise (ice, ships, other organisms, waves, etc.) and physical obstructions (bubbles, submerged vegetation), and they can "bounce" off of artificial or natural structures in ways that obscure the signal. Thus, how well tags are detected by each receiver is among the biggest technical challenges to consider by researchers using acoustic telemetry (Brownscombe et al., 2019). If a study is using an array of receivers that vary widely in their ability to detect tagged fish because of local physical conditions that affect acoustic signals, that variance can bias the apparent habitat use and behavior of animals (Kessel et al., 2014). In turn, researchers using acoustic telemetry sometimes put special emphasis on assessing the performance of their receivers (Klinard et al., 2019) and incorporate variation in their performance into how they interpret animal movement tracks (Brownscombe et al., 2020).

Biologgers

Biologgers are sensors that are attached to or implanted inside of animals to collect information about their environment (e.g., spatial position, temperature), and/or the animal's physiology (e.g., heart rate), or behavior (e.g., running, swimming, feeding), and store the information in memory on the device (Rutz and Hays, 2009). This storage facilitates continuous and high-frequency collection of the information derived from a diversity of sensors (e.g., acceleration, heart rate, magnetometer, temperature, dissolved oxygen, water speed, global position at up to hundreds of samples per second). These capabilities have enabled biologgers to be applied to diverse questions about a wide range of species inhabiting inland waters. For example, loggers containing varied combinations of acceleration, heart rate, temperature, and water depth sensors have been used to track the behavior and survival of fishes and turtles after exposure to stressors such as fisheries interactions (Algera et al., 2017; Gutowsky et al., 2017; Prystay et al., 2017; Lennox et al., 2018), as well as the metabolic costs of fish spawning behaviors (Clark et al., 2010; Prystay et al., 2019). Tri-axial accelerometers, which measure acceleration as a proxy for movement in three directions, can be used to remotely measure very fine scale behaviors, such as air breathing at the water surface by arapaima (Arapaima cf. arapaima; Lennox et al., 2018). One particularly exciting application of biologgers is in remotely estimating animal bioenergetics (Cooke et al., 2016b), which requires calibration between oxygen consumption and sensor output (e.g., heart rate or acceleration) with laboratory equipment (Clark et al., 2010) prior to deployment on wild animals.

Although biologgers enable continuous measurement at great resolution, the need to recover the device back from the tagged animal limits applications in inland waters to situations that allow for retrieval, which are often short-term studies within a constrained area. In semi-aquatic animals such as diving birds, biologgers including GPS, acceleration, and depth sensors are commonly used to assess movement patterns, foraging behaviors, and locations (Ropert-Coudert et al., 2009). In a more extensive study on fish, Raby et al. (2018) used temperature loggers to track thermal experience of walleye (*Sander vitreus*) over multiple years to understand how temperature influences movement patterns in Lake Erie, North America, with device retrieval facilitated primarily by large scale fisheries. To overcome challenges with device retrieval, biologger tag packages with timed pop-off devices can enable retrieval, although these packages are large and constrained in application to relatively large animals due to issues with tag burden (Broell et al., 2016).

The continuous, fine scale information that biologgers provide on animal behavior, physiology, and proximal environmental conditions makes them an important tool for understanding how environmental conditions impact individuals, which is used to scale to populations and entire inland water ecosystems. Continuing advancements in device sensor capacity, miniaturization, and retrieval mechanisms (Boyd et al., 2004; Block, 2005; Rutz and Hays, 2009), as well as integrating of other environmental measures and telemetry technology will be essential to understanding and mitigating the impacts of rapid environmental changes on biodiversity, ecosystem integrity and services provide by inland waters (Cooke, 2008; Cooke et al., 2012; Bograd et al., 2010).

Case studies

A networked approach to fish tracking across the great lakes

A comprehensive understanding of the ecology and biology of exploited freshwater fish is imperative to maintain population sustainability. The Laurentian Great Lakes ecosystem is large and geographically and limnologically complex, consisting of interconnected waterways, shallow, heavily vegetated and deep pelagic regions (Fig. 5). That complexity makes it difficult for fishery researchers to develop a comprehensive understanding of the movement patterns of Great Lakes fish, particularly those species exhibiting large-scale migratory behaviors such as lake sturgeon (*Acipenser fulvescens*), lake whitefish (*Coregonus clupeaformis*) and walleye (*S. vitreus*) (Scott and Crossman, 1973).

In 2010, the Great Lakes Acoustic Telemetry Observation System (GLATOS) network was established to provide fishery managers and decision makers with fish behavior information using acoustic telemetry technology not feasible with traditional fishery assessment gears (Krueger et al., 2018; Fig. 5). The GLATOS network relies on researchers working collaboratively throughout the basin to monitor fish movements at spatial-scales that otherwise would be cost-prohibitive or impractical if attempted individually. Individual researchers tag fish with acoustic transmitters internally and externally and deploy acoustic receivers to address project-specific objectives. Individual receiver detection data are shared with participating GLATOS researchers via a web-based data portal which serves as a basin-wide data repository. Although the receiver detection data are shared across the network, researchers only have access to transmitter detections associated with their projects (i.e., as investigator, co-investigator or

collaborator). By participating in this manner, researchers monitor the movements of their tagged fish across the Great Lakes basin rather than being limited to the geographic extent of where they maintain receivers. Researchers have used the GLATOS network to understand population dynamics (survival and mortality), movement rates, habitat use, spawning ecology, and post-stocking survival of native and invasive fish populations across the basin. This information has been used by fishery managers to inform sustainable management of exploited fish, native species restoration, and invasive species control efforts (e.g., Binder et al., 2018; Raby et al., 2018; Kessel et al., 2018; Klinard et al., 2020).

Tracking Atlantic salmon across life-stages

The Atlantic salmon (*Salmo salar*) has a long history of being important for Indigenous peoples, recreational and commercial fisheries, and local cultures, and has been studied for more than 100 years. The Atlantic salmon has a diverse array of life-histories, most forms being anadromous with spawning and juvenile phases in fresh water and feeding migrations to the ocean. Even for this well-studied species, the development of telemetry has opened new research opportunities and provided new behavior knowledge during nearly all life stages that has continued to surprise us and helped solve management issues.

The typical upstream migration pattern by Atlantic salmon adults in rivers without large migration barriers consists of distinct migration, search and holding phases. As juveniles, they live within restricted areas, but can perform surprisingly extensive movements (Økland et al., 2004). However, less was known about the marine phase of this species until acoustic telemetry methods improved. Studies of the outward coastal migration showed a surface-oriented and relatively fast migration (e.g., Dempson et al., 2011; Barry et al., 2020). Recent studies of the ocean migration using archival and satellite tags have shown that Atlantic salmon use larger areas of the North Atlantic Ocean than previously known (Chittenden et al., 2013; Strøm et al., 2017, 2018).

Atlantic salmon populations have declined and are largely impacted by human activities. Telemetry is widely used to document the human impacts and identify management solutions, for instance related to migration barriers, power stations, fishways, aquaculture, hatchery-rearing and climate change (e.g., Hagelin et al., 2016; Moe et al., 2016; Frechette et al., 2018; Persson et al., 2019; Larinier et al., 2020; Silva et al., 2020). Telemetry has also been used to document high survival, but behavioral irregularities, after catch and release angling (Lennox et al., 2017b).

Tracking freshwater crayfish across habitats

The behavior and habitat use of freshwater crayfish has been studied through the application of both passive integrated transponder (PIT) tags and radio telemetry. Crayfish shed their exoskeleton (molt) as they grow, and the small size of PIT tags has enabled internal implantation that allows for molting to occur without tag loss (Bubb et al., 2002; Westhoff and Sievert, 2013). Larger species of crayfish can carry a heavier tag burden; therefore, radio tags have been glued externally to the carapace of numerous species for short-term movement studies.

The world's two largest freshwater crayfish species, the Tasmanian giant freshwater crayfish (*Astacopsis gouldi*) and Murray River crayfish (*Euastacus armatus*; Fig. 6), occur in Australia and can reach maximum weights of 6 and 3 kg, respectively. Manual re-location of radio-tagged individuals enabled researchers to determine movement distances over days and weeks to understand how the animals utilize their environment. Ryan et al. (2008) found that Murray crayfish continually occupied pool habitats, had overlapping home-ranges with other tagged crayfish species, and had no discernible movement pattern between day and night. Tracking the Tasmanian giant freshwater crayfish, Webb and Richardson (2004) found that despite occupying a comparatively

Fig. 6 Murray River crayfish (*Euastacus armatus*) with a radio tag attached to the carapace. Photo credit = Brendan Ebner.

smaller stream that was only 13 m wide and 2 m deep, crayfish walked up to 700 m in a single night, ranged up to 2.2 km over a period of months, and often returned to the same refuge location.

These and other crayfish species are increasingly being recognized as under threat from human disturbance. For example, Reynolds and Souty-Grosset (2011) identified that 151 of the 650 global species of freshwater crayfish species are threatened. Use of electronic tagging and tracking to understand crayfish behavior, preferred habitats, and the limits on dispersal and subsequent recolonization assists natural resource managers to prioritize recovery efforts. Numerous tools including biologgers, acoustic tags, and remote data logging using radio-telemetry (see Thiem et al., 2010) may provide novel insights in future applications of telemetry on this unique group of animals.

Tracking freshwater turtles across seasons

Turtle researchers primarily use radio telemetry to document movement patterns and habitat use, including overwintering habitats (e.g., Brown and Brooks, 1994; Litzgus et al., 1999; Markle and Chow-Fraser, 2017). At northern latitudes, freshwater turtles can spend nearly half of the year hibernating under water making the location and characterization of overwintering sites extremely relevant to the biology and conservation of turtles. Here, we illustrate how the identification of hibernation sites using radio telemetry has been critical for understanding key aspects of the ecology and conservation of a Canadian population of northern map turtles (*Graptemys geographica*).

Between 2004 and 2007, 51 turtles were fitted with radio-transmitters (Fig. 7) and tracked to quantify habitat use (Bulté et al., 2008) and movement patterns (Carrière et al., 2009). Turtles were also tracked in the winter while hibernating under several centimeters of lake ice. Winter tracking led to two large communal hibernation sites that played a major role in the design of subsequent studies of the populations. The two hibernation sites became the focal point of a long-term mark-recapture study from which fundamental demographic data were derived (Bulté and Blouin-Demers, 2009). Those data were then used to quantitatively assess the impact of mortality from powerboats on the study population (Bulté et al., 2010). The hibernation sites also served as a platform to test new techniques to study wildlife in the field. Map turtles mate at their communal hibernation sites. Taking advantage of these aggregations, Bulté et al. (2018) demonstrated the potential of underwater videography and 3D printed decoys to study the behavior of freshwater turtles in the wild. Moreover, the spatial data obtained from radio-telemetry was used to demonstrate that environmental DNA (eDNA) surveys can accurately pinpoint turtle hibernation sites (Feng et al., 2020).

Radio telemetry remains a cost-effective tool to locate hibernating turtles, and it can now be combined with a wide range of biologging devices such as small pressure sensors and accelerometers. Turtles are well suited for such deployment because most species are large enough to accept long duration devices, they have a hard surface on which they can easily be mounted, and they are generally placid and can be handled and fitted with devices with minimal risk to them and the researchers. The combination of radio telemetry and biologging will undoubtedly continue to yield novel insights on the hibernation ecology of turtles.

Challenges in platypus tracking

The platypus (*Ornithorhynchus anatinus*) is an extraordinary animal, with a unique composite of traits; it is an egg-laying monotreme mammal that is armed with venomous spurs and electric and tactile sensors at the tip of its duck-like bill to find macroinvertebrate prey species (Grant and Fanning, 2007; Bino et al., 2019). Platypuses are endemic to river systems along Australia's eastern mainland, Tasmania, and two islands, encompassing a wide range of environments, from tropical to alpine. Understanding

Fig. 8 Platypus (*Ornithorhynchus anatinus*) implanted with a radio transmitter. The antenna is visible trailing the animal. Photo credit = Gilad Bino.

movement behavior of platypuses has been accomplished through repeated captures (Bino et al., 2015), radio telemetry (Serena et al., 2001), PIT tags (Macgregor et al., 2014), externally attached acoustic transmitters (Griffiths et al., 2013; Hawke et al., 2021a), and, most recently, implanted acoustic transmitters that offer longer tracking periods (Bino et al., 2018; Hawke et al., 2021b; Fig. 8). Accumulated knowledge from tracking movements by platypuses portray an animal with varying foraging and dispersal habits, occupying linear habitats between 0.5 and 15 km, but able to move over 40 km at times, which vary between breeding and non-breeding periods (Bino et al., 2019).

Tagging has been a challenge for platypuses. Unlike many other species, it is impractical to use collars or harnesses to hold telemetry devices on the platypus. There is a high risk of strangulation or drowning while platypuses forage among submerged roots and branches or when digging their burrows between tree roots (Grant and Fanning, 2007). Gluing tracking devices to the body is limited by short attachment periods given fur growth (Griffiths and Weeks, 2015; Hawke et al., 2021a). PIT tags offer lifetime tracking but have short detection distances (<1 m), limiting application to narrow streams (Macgregor et al., 2014). Therefore, there is still much to learn relating to understanding the species' habitat and foraging requirements, dispersal, and intraspecific interactions, warranting continued research that capitalizes on improvements in tracking technologies, particularly given increasing concerns over the species' deteriorating conservation status.

Knowledge gaps

Tracking data are broadly useful for inland waters animal management, species-at-risk monitoring, and invasive species control; yet, the potential of electronic tagging and tracking is still growing and there are a variety of important knowledge gaps to pursue.

- Tracking animals in inland waters largely relies on tags being detected by compatible receivers, and can contribute to biased estimates (e.g., Mourier et al., 2017). Therefore, detection efficiency of receivers is a pressing area for further research. Detection efficiency of receivers (especially acoustic ones) depends on environmental conditions (e.g., temperature, conductivity, noise, interference, macrophytes (Klinard et al., 2019; Weinz, 2020), and the configuration of receivers (Kraus et al., 2018).
- The effects of capture, handling, and carrying a tag on animal biology remains an active area of research and can drastically affect the results of tracking inland animals. Telemetry is often used to estimate vital rates such as natural and fishing mortality or estimating population sizes via mark-recapture, for which an accurate estimate of the tag effect is crucial (Crossin et al., 2017). Meta-analyzes of tag effects will be useful to provide guidance for well-known species but tag effects studies specific to the study system are always useful prior to embarking on a study.
- Analysis of tracking data can be laborious as it generates vast quantities of data. Determining how to best analyze and visualize data can be challenging (see Fig. 9 for examples).
- Positioning software (e.g., Baktoft et al., 2017) for triangulating positions and reconstructing paths are increasingly popular and extensions of these tools will drastically enhance the potential for information gain from aquatic telemetry systems.
- Tracking technology is still limited primarily to larger individuals, with smaller tags being limited in battery life. Continuing advancements in battery and sensor technology will enable greater understanding of a wide range of freshwater taxa over longer time periods. A recent study of immature dragonflies (from emergence to early flight) involved tagging and tracking using devices that weighed a mere ~16.5 mg (LeNaour et al., 2019) sets the new standard for tracking freshwater organisms (in this case during their life in riparia).

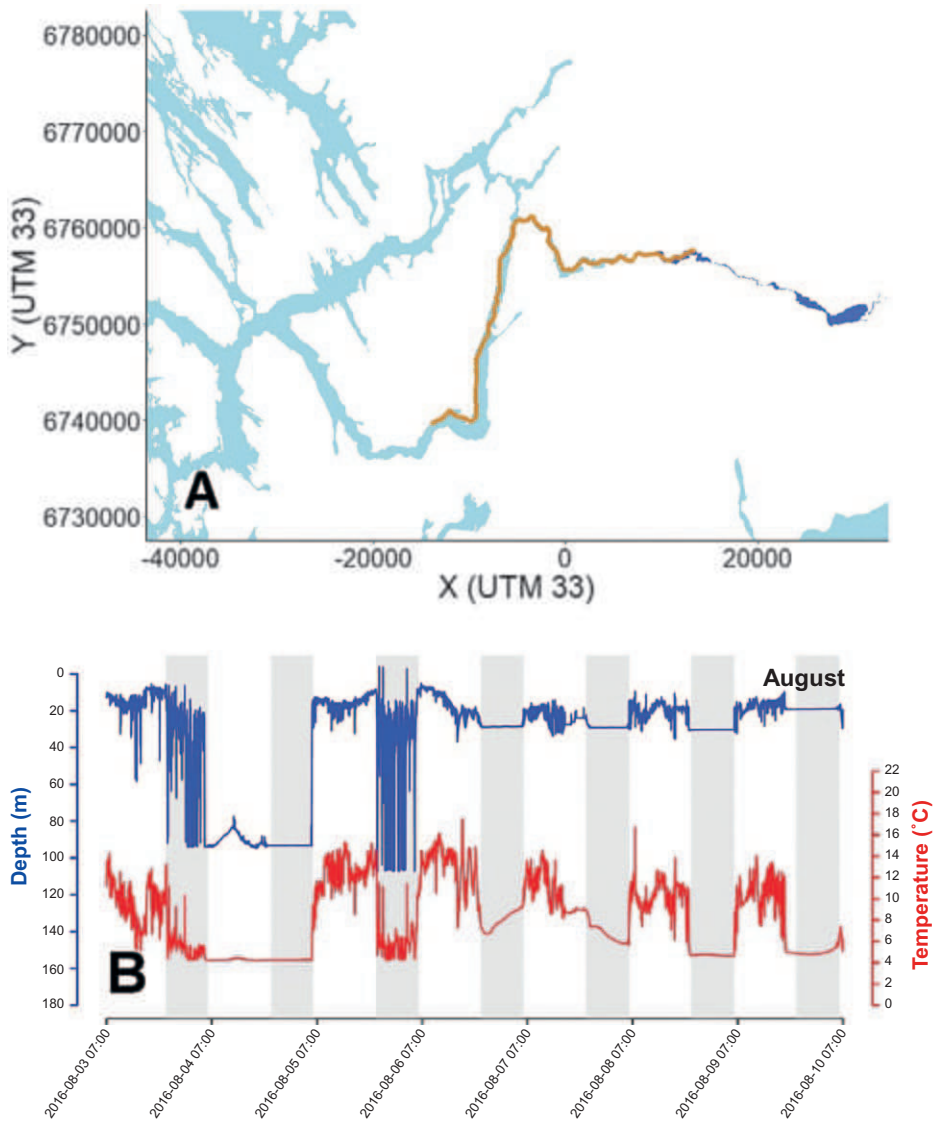

Fig. 9 Visualized samples of fish tracking data across the landscape (A) and in terms of depth and temperature (B) for two different animals. A: Spring outmigration (orange line) of a 52 cm long sea trout tagged in the Vosso River system in 2020 (Norway). The acoustic transmitter implanted in the trout was detected by multiple receivers during the river exit and fjord entry as it traveled eastward through the Osterfjord system in western Norway, which is a ring-shaped fjord around the island of Osterøy. The trout will continue to be followed as it moves through the summer and hopefully returns to the river to spawn again in the future. The detection data provide details of the timing and extent of movements between the freshwater and marine environments to better understand habitat requirements and exposure to anthropogenic stressors in multiple environments. (B) One week in the life of a 61 cm long lake trout in Lake Ontario (Canada/United States) in terms of depth (blue, left axis) and temperature (red, right axis) based on an externally attached data logger (see Raby et al., 2017 for detailed methods). Each x-axis tick is a 24 h period; shaded vertical bars represent nighttime (sunset to sunrise).

Conclusion

Freshwater organisms and ecosystems are in crisis. As such, there is an urgent need to develop strategies to protect and restore freshwater biodiversity (Tickner et al., 2020). Knowledge of habitat use, movement corridors, environmental tolerances, and survival rates are fundamental to developing science-based management and recovery plans (Cooke et al., 2016a). There are also many fascinating scientific mysteries that remain to be solved about freshwater species interactions, reproductive behavior, species-area relationships, and other fundamental aspects of life in inland waters. Electronic tagging and tracking tools are making freshwaters less opaque and providing a window into the underwater world (Hussey et al., 2015). These tools are not a panacea and are best used in concert with other assessment and research tools and techniques including habitat mapping, population assessment by mark-recapture, and individual sampling. In fact, electronic tagging and tracking has rapidly progressed from a niche area of research to one that is now embraced by hundreds of researchers and that is generating new knowledge to inform management of inland water biological resources.

Fatty Acid—Markers as Foodweb Tracers in Inland Waters

Olesia N Makhutova[a,b], Nadezhda N Sushchik[a,b], and Michail I Gladyshev[a,b], [a]Institute of Biophysics of Federal Research Centre, Krasnoyarsk Science Centre of Siberian Branch of Russian Academy of Sciences, Krasnoyarsk, Russia; [b]Siberian Federal University, Krasnoyarsk, Russia

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Kendra Cheruvelil.

Glossary

Acetylenic FAs Fatty acids containing triple bonds.
Alkaliphiles Organisms that thrive in alkaline environments.
Allochthonous organic matter An organic matter that comes from outside the aquatic systems (e.g., leaf litter).
Autochthonous organic matter An organic matter that has been produced in the aquatic systems (e.g., algae).
Benthic organisms Freshwater or marine bacteria, algae or small animals living on, at or in the bottom.
Coenzyme A A coenzyme of acylation (the process of adding an acyl group to molecules). It has an important role in the synthesis and oxidation of fatty acids.
Conditionally essential nutrients compounds that can be synthesized by species in amounts sufficient to meet their physiological requirements in the absence of stress, disease, and other adverse factors.
Eicosanoids (prostaglandins, leukotrienes and thromboxanes) Signaling molecules, products of oxidation of arachidonic or eicosapentaenoic fatty acids.
Essential nutrients Compounds that cannot be synthesized by the species.
Fatty acid desaturases Enzymes that catalyze removing two hydrogen atoms from carbon atoms placed next to each other (C—C) in a fatty acid creating a double bond (C=C).
Fatty acid A carboxylic acid, containing a long aliphatic chain (>4 carbon atoms).
Halophile An organism that thrives in high salt concentrations.
Isotopic signature or isotopic fingerprint A ratio of isotopes of elements (C, N, H, etc.) in samples studied.
Long-chain PUFAs (LC-PUFAs) Polyunsaturated fatty acids with 20 and more carbon atoms.
Non-methylene-interrupted fatty acids Fatty acids that have two or more double bonds that are separated from each other by two or more methylene groups (—CH_2—).
Opportunism The ability of species to adapt to changing environments and thrive in them, e.g., by adapting feeding behavior.
Pelagic organisms Free-swimming or floating organisms in the water column.
Planktonic organisms freshwater or marine bacteria, algae or small animals floating in the water and unable to swim well enough to move against currents.
Stable isotopes Nonradioactive nuclides of one chemical element that contain different numbers of neutrons (e.g., carbon can contain 6 protons and 6 or 7 neutrons—stable isotopes ^{12}C and ^{13}C, respectively).
Sympagic organisms Aquatic organisms associated with ice. Ice algae and specific zooplankton communities inhabit such environments.
Sympatric species Two or more related species existing in the same geographic area.
Triacylglycerols Organic molecules containing three fatty acids esterified to a glycerol molecule.
Trophic fractionation A change in the isotope values of consumers relative to their food due to different rates of enzymatic reactions (during assimilation, synthesis and excretion of substances) involving the lighter and the heavier isotopes.

Introduction

Ecosystem functioning is based on fluxes of matter and energy in foodwebs. There are a number of methods for untangling foodwebs in aquatic ecosystems. In recent decades, fatty acids (FAs) have been widely used as foodweb tracers in aquatic ecosystems. Based on FAs, feeding spectra of many consumers have been specified. FA-marker analyses also contribute to differentiating between allochthonous and autochthonous (see glossary) organic matter inputs to foodwebs of inland water ecosystems. In this chapter, we describe FAs and their use as foodweb markers in aquatic ecosystems, describe and compare the FA-marker analysis with other methods for studying diets of aquatic animals, and describe the identifying characteristics of FAs in the main taxonomic groups of organisms inhabiting freshwater ecosystems (bacteria; algae and other photosynthetic eukaryotes; non-photosynthetic eukaryotes).

What are fatty acids and how can they be used to study foodwebs?

Fatty acids (FAs) are biomolecules consisting of straight or branched carbon chains. One end of the molecule is a methyl group (—CH_3) and the opposite end is a carboxyl group (—COOH). Additionally, FAs can be saturated or unsaturated. In saturated FAs, carbon atoms are linked by single covalent bonds. In unsaturated FAs, some carbon atoms are linked by double bonds or, sometimes, by triple bonds. Depending on the number of double bonds, unsaturated FAs are divided into monounsaturated (MUFAs) ones, which contain one double (triple) bond, and polyunsaturated (PUFAs) ones, which contain two or more double (triple) bonds. Usually, the structure of a FA is represented by the following formulas: e.g., 18:2n-6 or 18:2ω6, where 18 is the number of carbon atoms, 2 is the number of double bonds, n-6 or ω6 is the position of the first double bond from the methyl end of the molecule, and the second double bond is separated by two carbon atoms (or one methylene group, —CH_2—) from the first double bond (the 9th carbon atom here). Sometimes, FAs contain conjugated or non-methylene interrupted double bonds. Among branched FAs, the most common are iso and *anteiso*. The structures of typical FAs are shown in Fig. 1.

Fatty acids have many important functions within organisms, including structural, signaling, energy storage, etc. All cell membranes consist of a lipid bilayer, the molecules of which are mainly composed of the polar group and two FAs. Physical properties (e.g., fluidity) of cell membranes and their permeability mainly depend on the structure of FAs (chain length and number of double bonds). Some FAs, namely, arachidonic (ARA, 20:4n-6) and eicosapentaenoic (EPA, 20:5n-3) acids, play an additional role as precursors for eicosanoids (prostaglandins, leukotrienes and thromboxanes; see glossary) and other lipid mediators. Among FAs, EPA and docosahexaenoic acid (DHA, 22:6n-3) attract special attention of scientists, since they play an important role in many physiological processes in animals, including humans. For example, these PUFAs are necessary for the normal development of the cardiovascular and nervous systems. Many dietary FAs, such as some MUFAs (16:1n-7, 18:1n-9, 20:1n-9, etc.) and some PUFAs (16:2n-4, 16:3n-4, 16:3n-3, 18:2n-6, 18:3n-3, etc.), are often stored as part of triacylglycerols (TAGs) (see glossary). TAGs are usually used by animals as energy sources.

Bacteria, algae and plants synthesize a broader range of FAs de novo, when compared to animals. This is because animals have limited abilities to elongate and desaturate FAs. Animals, though, convert some dietary FAs to longer and more unsaturated ones. For instance, benthic mollusks synthesize non-methylene interrupted FAs with two or three double bonds from MUFAs, which is considered as an adaptation to their specific habitats or deficiencies in the physiologically important EPA and DHA in their diet. Mosquitoes produce 14:2n-6 and 14:3n-3, which very rarely occur in other organisms. Some fish species synthesize EPA and DHA when their diet lacks these PUFAs. Bacteria, algae, plants, and some animals synthesize specific FAs, which are transferred through foodwebs and accumulated in lipids (especially in TAGs) of animals of the higher trophic levels; they can be used as FA-markers of these organisms. By analyzing FA compositions of animals and finding FA-markers, scientists are able to identify their diets.

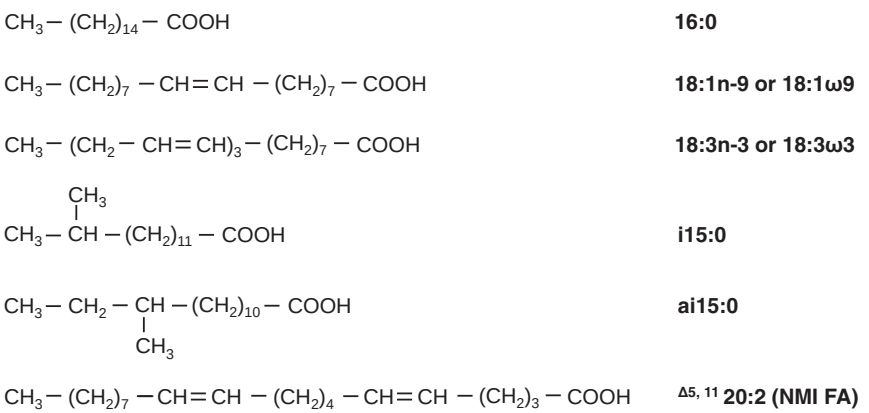

Fig. 1 The structures of typical fatty acids.

Comparing the use of FAs to other methods for studying foodwebs

There is no one ideal method for examining the diets of aquatic animals. All methods have limitations (Table 1). However, it is possible to choose the best method for your specific goal (Nielsen et al., 2018). Below, we briefly describe seven methods used in field studies and compare their advantages and disadvantages when investigating the diets of aquatic organisms of different trophic levels. The methods are: (a) visual gut content analysis, (b) controlled diet experiments, (c) DNA identification of prey items (hereafter the DNA-method), (d) stable isotope analysis, (e) FA-marker analysis, and (f and g) compound specific stable isotope analysis of fatty acids (FA-CSIA) and amino acids (AA-CSIA).

(a) *Visual gut content analysis*: When ingested items are not yet digested and well preserved, this method can provide information on ingested items such as species composition, their size, and the proportion of each item in gut content. When studying the diets of small organisms such as protozoa, rotifers, crustaceans, insect larvae, and worms, visual analysis identifies most of the gut contents as detritus, (i.e., unidentifiable particles). When studying fish diets, visual analysis of gut contents identifies organisms of higher trophic levels, like copepods and amphipods, as food items, but small or too soft organisms, like flatworms, remain unidentified. Fish guts sometimes contain sand, stones, and other inedible materials, as well as accidentally ingested animals (e.g., rodents), which do not make up a significant proportion of the fish's diet. One more important limitation of all methods based on gut content (visual gut content analysis and DNA-method) is the impossibility of estimating which items are assimilated. For example, some algae are not digested by fish during gut passage and are excreted alive, which is known as "viable gut passage". Thus, the algae will be mistakenly attributed to the animal diet. Despite the widespread use of visual analysis for examining animals' diets, this method has significant disadvantages compared to FA-marker analysis (Table 1).

(b) *Controlled diet experiments*: Controlled diet experiments were popular for studying animals' diets last century. The diversity of food items in natural ecosystems and environmental conditions cannot be fully reproduced in the experiments. Thus, it is hardly possible to extrapolate the results obtained in the laboratory to natural ecosystems. The use of flow cultivators removed certain limitations of closed tanks such as wall fouling, food sedimentation, food transformation in time, etc. However, viable gut passage of some algae (e.g., Cyanobacteria) was discovered using this particular method.

Table 1 Disadvantages and advantages of the most popular methods for studying trophic interactions in aquatic ecosystems.

Method	*Disadvantages*	*Advantages*
Visual gut content analysis (gut, stomach or fecal content)	1. Low taxonomic resolution (unidentified compounds) 2. Short term (no more than 48 h) 3. Taxonomic knowledge of potential prey items 4. Viable gut passage of ingested items	1. Identification of new or rare items 2. Identification of prey size and proportion
Controlled diet experiments	1. Limited result extrapolation to natural ecosystems 2. Inability to recreate natural conditions	1. Determination of the size of ingested particles
DNA identification of prey items (the DNA-method)	1. Short term (hours) 2. Libraries are not complete 3. DNA degradation during digestion 4. Unquantifiable 5. Environmental contamination 6. Viable gut passage of ingested items	1. High taxonomic resolution 2. Identification of new or rare items
Stable isotope analysis ($\delta^{13}C$, $\delta^{34}S$, $\delta^{2}H$, and $\delta^{15}N$, ‰)	1. Time determination (unclear time span and time-lag) 2. Low accuracy (the estimation of trophic discrimination factors is necessary) 3. Knowledge of isotope values of all items in the trophic chains 4. Diet resolution (3–5 items)	1. Determining of trophic position 2. Long time span 3. Identification of the assimilated items 4. Separation between allochthonous and autochthonous food sources
Fatty acid analysis	1. Time determination (unclear time span and time-lag) 2. Medium taxonomic resolution (no species identification) 3. Blind spot (not all food items have FA markers) 4. FA modification by consumers	1. Long time span 2. High accuracy 3. Identification of the assimilated items
Compound specific stable isotope analysis—fatty acids	1. Time determination (unclear time span and time-lag) 2. Measurement of isotope values of expected diets 3. Medium taxonomic resolution (no species identification) 4. Trophic fractionation (unknown for most organisms; possibly TF is not the constant) 5. A lot of controversial results	1. Identification of the assimilated items
Compound specific stable isotope analysis—amino acids	1. Time determination (unclear time span and time-lag) 2. Measurement of isotope values of expected diets 3. Medium taxonomic resolution (no species identification) 4. Different integration times of different amino acids	1. Identification of the assimilated items

(c) *DNA-method*: The most modern method for examining diets of aquatic organisms is the DNA-method. Unfortunately, many samples are needed to get comprehensive information on the diet of the organisms and this method provides information only about ingested, not assimilated, food. Different diet components (bacteria, animals, plants) require different modifications of the DNA-method, which makes the method more complicated and expensive than others (Table 1). The development of this method, including the replenishment of libraries with genetic data of new species, and quantitative assessments will be able to remove many of the disadvantages of this method in the future.

(d) *Stable isotope analysis*: The basis for using isotope analysis to study the trophic structure of aquatic ecosystems is the differences in the isotopic values of carbon ($\delta^{13}C$) between terrestrial and aquatic organisms (allochthonous and autochthonous food sources) and nitrogen ($\delta^{15}N$) between organisms of different trophic levels. Additionally, isotopes of other elements, such as sulfur and deuterium are less frequently used for untangling foodwebs in aquatic ecosystems. The differences in $\delta^{13}C$ between terrestrial and aquatic organisms are caused by substantial differences in $\delta^{13}C$ of atmospheric CO_2 (the source of carbon for terrestrial primary producers) and dissolved organic carbon (the source of carbon for aquatic primary producers). The differences in $\delta^{15}N$ between organisms of different trophic levels are caused by transformation of substances containing nitrogen that are consumed (e.g., amino acids) during metabolism. However, this method is limited by the impacts of food quality and quantity and the environment on the isotope values in consumers as well as the time-lag before the $\delta^{15}N$ or $\delta^{13}C$ of consumers' tissues have equilibrated the subsequent changes in consumers' diet (Table 1).

(e) *FA-marker analysis*: This method is based on using FAs as tracers of the organic matter transported through trophic chains. Many organisms, such as bacteria, algae, and some invertebrates synthesize specific FAs characteristic only of them. These specific FAs or FA combinations can be found mainly in groups of organisms that have genetic kinship. Tracking the transfer of specific FAs in foodwebs can be used to investigate trophic relationships in aquatic ecosystems (e.g., Desvilettes et al., 1997; Galloway et al., 2015). This method determines the groups of bacteria and algae that are part of even small organisms' diets, reveals the assimilation of bacterial, algal and animal organic matter by consumers, and indicates the primary carbon source for consumers. Many invertebrates and vertebrates that had been previously considered detritivores were found to exhibit food selectivity using FA-marker analysis.

(f and g) *FA-CSIA & AA-CSIA*: These methods are the combination of FA-markers/AA-markers and stable isotopes. Sometimes, food sources do not differ by FA-markers—i.e., the group of algae is the same, but these algae use different carbon sources (pelagic and subglacial/sympagic diatoms; see glossary). In this situation, by comparing the isotope values of carbon of the FA-marker in the consumer and in the algae from the pelagic zone and subglacial algae, it is possible to identify which algae the consumer prefers. Additionally, this method can be useful for investigating autochthonous and allochthonous utilization by organisms, which makes a significant contribution to understanding the carbon cycle in the biosphere. AA-CSIA is a more complicated, but similar method, to FA-CSIA. The AA-CSIA method includes not only carbon isotopes but nitrogen isotopes as well. However, there are limitations associated with revealing essential (see glossary), conditionally essential (see glossary), and non-essential amino acids for various animals. When using FA-CSIA & AA-CSIA methods, it is necessary to take into account the trophic fractionation that occurs in the consumers. Finding coefficients of trophic fractionation is not an easy task, which complicates the use of these methods (Table 1).

Although some authors propose integrating several methods to more accurately determine the diets of aquatic organisms, that approach may be laborious and expensive. Having studied the disadvantages and advantages of different methods (Table 1), we believe that the FA-marker method is generally sufficient, but sometimes we use additional methods to refine the results obtained. To correctly use FAs to determine the animal diets, knowledge of FA-markers of potential food items is necessary. Next, we will discuss the FA-markers of various groups of organisms.

The identifying characteristics of bacterial FAs

The diversity of the FA composition of bacteria was discovered in the middle of the 20th century. FAs began to be used for taxonomic identification of bacteria from phyla down to genus level as early as the 1970s. In fact, bacteria contain odd and branched saturated FAs (*iso* and *anteiso*), monounsaturated FAs, cyclopropane FAs, and FAs with OH-groups. FA composition of bacteria depends on their taxonomic position and environmental conditions.

Fatty acid synthesis (FAS) de novo in all organisms is carried out by cyclically repeating a series of reactions. Two types of fatty acid synthesis are distinguished: FAS I and FAS II (White et al., 2005). The first type of FA synthesis occurs mainly in non-photosynthetic eukaryotes, and the second type in most prokaryotes and photosynthetic eukaryotes.

Some bacteria are able to synthesize PUFAs, including long-chain ones (e.g., Metz et al., 2001; Bell and Tocher, 2009; Monroig et al., 2013). However, the PUFA synthesis in bacteria has a fundamentally different mechanism compared to animals and plants. Bacteria use anaerobic polyketide pathway. Different bacteria have different sets of enzymes for the synthesis of unsaturated fatty acids. As a result, different groups of bacteria have FAs inherent only to their specific group. FA-markers of the main groups of bacteria that are widespread in aquatic ecosystems have also been identified (Table 2). The generally recognized and widely used FA-markers of bacterial organic matter in water bodies are i13:0, ai13:0, 13:0, i15:0, ai15:0, 15:0, i17:0, ai17:0, 17:0, i17:1n-7, 18:1n-7 (Table 2).

Table 2 Fatty acid—markers of groups of bacteria inhabiting aquatic ecosystems.

Taxon/group	*FA—markers*	
Gram-positive bacteria	i15:0, ai15:0, 15:0, ai17:0, i17:1, ai17:1, 16:1n-9, 16:1n-5	Shaw (1974), Komagata and Suzuki (1987) and Wang et al. (2014)
Gram-negative bacteria	Cyclopropyl-FAs (cyc19:0, cyc17:0), 2- and 3- OH-FAs (3OH-14:0) C16 and C18 MUFAs, especially trans18:1n-7	Shaw (1974), Komagata and Suzuki (1987) and Grogan and Cronan (1997)
Sulfate reducing bacteria	Methylhexadecanoic acids (10Me16:0), i17:0, i15:1n-7, i17:1n-7, cyc17:0, 17:0, cyc19:0, i19:1n-7, 16:1n-7, 18:1n-7	Vainshtein et al. (1992) and Colaco et al. (2007)
Desulfobacter	10Me16:0	Mancuso et al. (1990)
Desulfovibrio	i15:1n-7, i17:1n-7, i19:1n-7	Colaco et al. (2007)
Methanotrophic bacteria	cis16:1n-8, trans16:1n-5, cis16:1n-6, cis18:1n-8 and cis18:1n-7	Bowman et al. (1993) and Le Bodelier et al. (2009)
Gammaproteobacteria	C16 MUFAs	Le Bodelier et al. (2009)
Alphaproteobacteria	C18 MUFAs	Le Bodelier et al. (2009)
Methylocystis	cis18:2n-7,12 and cis18:2n-6,12	Le Bodelier et al. (2009)
Acidophilic-thermophilic bacteria	Omega-cyclohexyl undecanoic, omega- cyclohexyl tridecanoic acids	Oshima and Ariga (1975) and Komagata and Suzuki (1987)
Alicyclobacillus (Gram-positive bacteria)	Omega-cyclohexyl FAs	Simbahan et al. (2004)
Iron-reducing actinobacteria	i16:0, ai17:0, i18:0	Itoh et al. (2011)
Mycobacterium, Corynebacterium, Rhodococcus and Nocardia	Mycolic FAs (C22-C60)	Erwin (1973) and Schweizer and Hofmann (2004)

The identifying characteristics of algal and other photosynthetic eukaryotic FAs

Photosynthetic eukaryotes are able to synthesize a wide variety of FAs. Unsaturated FAs are of the greatest interest as valuable markers. In algae and other photosynthetic eukaryotes, the introduction of double bonds into saturated FAs occurs after the incorporation of FAs into lipids in chloroplasts (prokaryotic pathway) or in the endoplasmic reticulum (eukaryotic pathway). In the eukaryotic pathway, C18 PUFAs are synthesized, while in the prokaryotic pathway, C16 PUFAs are synthesized. The introduction of double bonds into FAs in most algae occurs via the prokaryotic pathway, while in many higher plants, it occurs via the eukaryotic pathway. This means that algae contain more C16 PUFAs, while higher plants contain more C18 PUFAs. The photosynthetic eukaryotes discussed in this chapter are shown in Figs. 2 and 3.

Various taxa of photosynthetic organisms are distinguished by their sets of enzymes, resulting in the synthesis of different fatty acids. Among the FA profiles of photosynthetic eukaryotes and prokaryotes, individual FAs or sets of FAs have been identified that

Table 3 Fatty acid—markers of photosynthetic eukaryotes and prokaryotes inhabiting inland waters.

Taxa/group	*FA—markers*	
Prokaryotes		
Cyanobacteria	18:2n-6, 18:3n-3, 18:3n-6	Ahlgren et al. (1992), Desvilettes et al. (1997) and Gugger et al. (2002)
Eukaryotes		
Chlorophyta	16:1n-9, 18:2n-6, 18:3n-3, C16 PUFAs of n-3 and n-6 (e.g., 16:2n-6, 16:3n-3, 16:4n-3)	Ahlgren et al. (1992), Napolitano (1999), Petkov and Garcia (2007) and Kelly and Scheibling (2012)
Euglenophyceae	18:2n-6, 18:3n-3, 20:5n-3, 22:6n-3	Taipale et al. (2013)
Dinoflagellata	18:5n-3 > 18:3n-3, 18:5n-3, 20:5n-3, 22:6n-3	Napolitano (1999), Bergé and Barnathan (2005) and Kelly and Scheibling (2012)
Bacillariophyta	16:1n-7/16:0 > 1, 14:0, C16 PUFAs of n-7, n-4 and n-1 (16:2n-7, 16:2n-4, 16:3n-4, 16:4n-1), 20:5n-3	Dijkman and Kromkamp (2006) and Kelly and Scheibling (2012)
Chrysophyceae	14:0, 16:1n-7, 18:1n-7, 18:4n-3, 20:5n-3, 22:5n-6, 22:6n-3	Ahlgren et al. (1992), Desvilettes et al. (1997) and Taipale et al. (2013)
Cryptophyta	18:3n-3 + 18:4n-3; 20:5n-3 + 22:6n-3	Desvilettes et al. (1997) and Guevara et al. (2011)
Angiospermae	18:2n-6, 18:3n-3, 20:0, 22:0, 24:0, 26:0	Shorland (1963) and Kelly and Scheibling (2012)
Bryophyta	Acetylenic FAs (6a,9,12–18:3, 8a,11,14–20:3)	Kalachova et al. (2011)

are specific only for a particular taxon. Currently, these FAs are widely used to study trophic interactions in aquatic ecosystems. FA-markers of the most common freshwater algal taxa and some higher plants are listed in Table 3.

Freshwater inland waters are mainly dominated by three taxa of photosynthetic organisms—blue-green and green algae and diatoms. Other taxa dominate for a short time or in a small number of ecosystems.

Blue-green algae (Cyanobacteria) are photosynthetic prokaryotes. Unlike most non-photosynthetic bacteria, they are able to synthesize PUFAs with 18 carbon atoms. FAs with a chain length of more than 18 carbon atoms have not been detected in cyanobacteria (Table 3).

Green algae (Chlorophyta) synthesize FAs of the n-3 and n-6 families, mainly with 16 and 18 carbon atoms. In most species, 18:3n-3, 18:2n-6, and 16:4n-3 dominate the PUFAs (Table 3). It is not usual for the majority of green algae species to synthesize FAs with chain lengths above 18 carbon atoms. In species of Prasinophyceae, FAs uncommon for green algae were found, namely, 18:4n-3, 20:5n-3 and 22:6n-3, while species of Trebouxiophyceae and Chlorophyceae had FA composition common for green algae. However, some authors have noted the presence of a significant amount of long-chain PUFAs (LC-PUFAs) (see glossary) in Chlorophyceae and other taxa. In general, findings of the FAs unusual for certain taxon may be associated with the erroneous identification of species; contamination of the samples of microalgae by other algae, e.g., the presence of diatoms attached to the surface of algae or plants (Fig. 4); or erroneous identification of FAs during chromatography using only retention times.

Diatoms (Bacillariophyta) synthesize a lot of specific FAs, such as C16 PUFAs of the n-7, n-4 and n-1 families (Table 3). Additionally, the high level of 14:0 and 20:5n-3 in many diatom species led to the use of these FAs as diatom markers. Most species of diatoms contain traces of C18 PUFAs. Like other taxa, some species of Bacillariophyta show specific FA profiles. Differences in FA levels in species of diatoms and in other algae may be explained by species specificity and different environmental conditions.

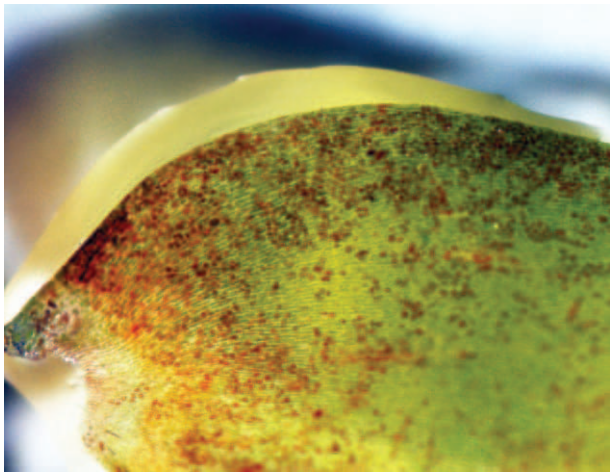

Fig. 4 Diatoms attached to the surface of the aquatic moss (Fontinalis antipyretica). Courtesy: Olesia Makhutova.

The presence of Cryptophyta in aquatic animals' diet is well recognized by a high level of 18:4n-3 in the consumers. The level of 18:4n-3 in Cryptophyta can reach approximately 10–20% of total FAs. Additionally, 18:3n-3, 20:5n-3, and 22:6n-3 dominate in cryptophytes, while the levels of other C20 and C22 PUFAs are very low in general. One more feature of cryptophytes is a high n-3/n-6 ratio (~20/1).

Dinoflagellates are typical representatives of marine phytoplankton, but they are also found in freshwater ecosystems. The presence of dinoflagellates in aquatic animals' diet is usually identified by significant levels of 18:5n-3 and 22:6n-3 (Table 3). However, some species demonstrate specific FAs. Phospholipids of two species of *Gymnodinium* contained unusual LC-PUFAs, namely 28:7n-6 and 28:8n-3, the level of which reached 2.2% of total FAs (Bergé and Barnathan, 2005).

It is difficult to determine the presence of other algal taxa, such as Euglenophyceae and Chrysophyceae, in diets of aquatic animals according to FA-markers. The proportion of these algae in animals' diet is usually low and these taxa do not contain specific FAs that would be found only in them (Table 3). Angiospermae or flowering plants are an important food source for consumers in littoral trophic chains. Similar to green algae, the main PUFAs of flowering plants are 18:2n-6 and 18:3n-3, which are mandatory compounds of photosynthetic membranes of eukaryotes. In addition to 18:2n-6 and 18:3n-3, aquatic plants contain long-chain saturated FAs with an even number of carbon atoms, namely, 20:0, 22:0, 24:0, 26:0, which are compounds of cuticle waxes. These FAs are widely used as markers of flowering plants and allochthonous organic matter in foodwebs of aquatic ecosystems.

Bryophyta is one more taxon that can be found in freshwater ecosystems especially in streams. *Fontinalis antipyretica*, the representative of Bryophyta, contains highly specific FAs, namely acetylenic FAs (see glossary), which were successfully used as tracers in trophic chains in the Yenisei River (Kalachova et al., 2011).

Case study: Selective feeding of filter-feeding crustaceans (Feniova et al., 2018)

The FA-markers of photosynthetic eukaryotes were successfully used in studies of the diets of invertebrates, including very small animals such as water fleas (*Daphnia*). *Daphnia* are filter-feeding planktonic animals, consuming all food particles of suitable size, and therefore are regarded as keystone species in freshwater planktonic ecosystems. However, a mesocosm experiment revealed that two sympatric species (see glossary), *Daphnia magna* and *Daphnia pulicaria*, had different feeding spectra. *D. magna* selectively consumed diatoms or flagellates and some allochthonous organic matter, while *D. pulicaria* selectively consumed bacteria and green algae (Fig. 5). This surprising result was verified in further experiments. Initially, *D. magna* and *D. pulicaria* were reared in laboratory cultures and fed green algae. According to the FA analyses, these two species did not differ in their FA composition, and markers of green algae adequately indicated their diet (Fig. 6). However, when placed in mesocosms with natural algal communities, *D. magna* switched primarily to diatoms and terrestrial organic matter, and *D. pulicaria* switched to bacteria (Fig. 6). This series of experiments strongly confirmed the relevance of FA-marker analysis for revealing the feeding spectra of small aquatic animals.

Using FAs to study non-photosynthetic eukaryotes

Non-photosynthetic eukaryotes have some specificity in their FA profiles. The non-photosynthetic eukaryotes discussed in this chapter are shown in Figs. 7 and 8. The synthesis of saturated FAs, mostly 16:0 and 18:0, in animals is located in cell cytosol and is linked with the acyl carrier protein (ACP). The subsequent elongation and desaturation are located in mitochondria and

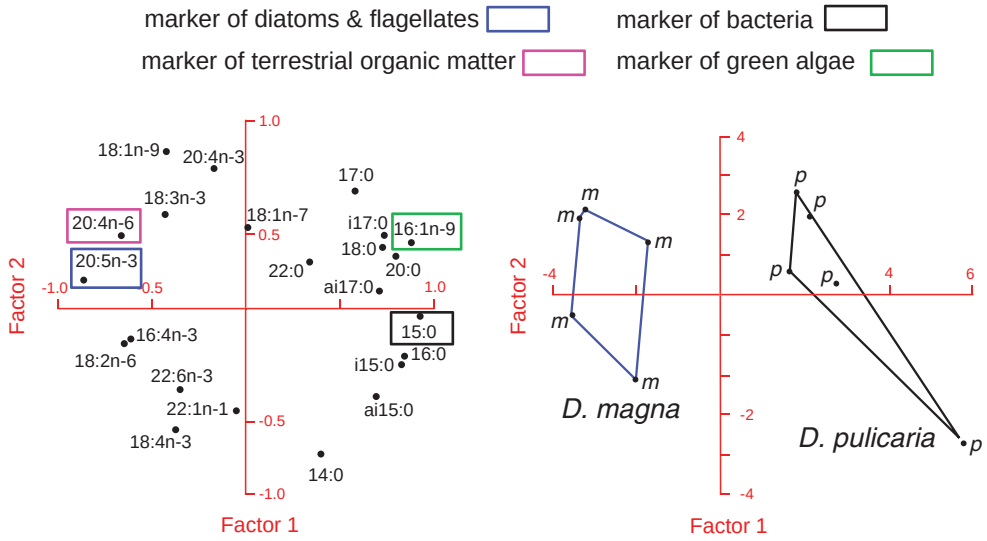

Fig. 5 Principal component analysis of FA levels in *Daphnia* from mesocosms. Fig. 6 Principal component analysis of FA levels in *Daphnia* from laboratory cultures (circled with green line) and from mesocosms (transition from laboratory cultures to mesocosms is designated with arrows). Colors for highlighted FA markers (15:0 and i17:0—FA-markers of bacteria; 16:2n-6 and 18:3n-3—FA-markers of green algae; 20:5n-3—FA-marker of diatoms and flagellates; 20:4n-6—FA-marker of terrestrial organic matter) are explained in Fig. 2. From Feniova I, Dawidowicz P, Ejsmont-Karabin J, Gladyshev M, Kalinowska K, Karpowicz M, Kostrzewska-Szlakowska I, Majsak N, Petrosyan V, Razlutskij V, Rzepecki M, Sushchik N and Dzialowski AR (2018) Effects of zebra mussels on cladoceran communities under eutrophic conditions. *Hydrobiologia* **822**: 37–54, with changes.

endoplasmic reticulum, respectively (Chan and Vogel, 2010). Non-photosynthetic eukaryotes contain enzymes, namely, acyl-CoA-desaturases, which incorporate double bonds into FAs bound with coenzyme A (see glossary). Animals have Δ9 desaturase and can effectively synthesize 18:1n-9. The majority of animals, excluding some ciliates, insects, and some other invertebrates, do not contain Δ12 and Δ15 (ω3) desaturases, which are necessary for synthesis of 18:2n-6 and 18:3n-3 from 18:1n-9 (Castro et al., 2016). Mammals and many other animals are not able to convert FAs of the n-3 family to n-6 and vice versa. Therefore, 18:2n-6 and 18:3n-3 are essential FAs for the majority of animals. Dietary 18:2n-6 and 18:3n-3 can be used as precursors for LC-PUFA synthesis, including physiologically important 20:4n-6, 20:5n-3 and 22:6n-3 (e.g., Tocher, 2015).

The main ways non-photosynthetic eukaryotes synthesize FAs are shown in Fig. 9. This figure highlights the diversity of the enzymes that non-photosynthetic eukaryotes can contain and the FAs that they are able to synthesize. Some enzymes are more universal than others and catalyze several reactions. Despite the presence of enzymes that catalyze the synthesis of 20:5n-3, 22:6n-3, and 20:4n-6 in animals, the rate of their synthesis is not high enough to maintain physiological processes in their bodies. Hence, these LC-PUFAs are partially essential for animals.

Fungi do not exhibit a high variability in FA composition. In fact, there are very few data on FA profiles of aquatic fungi, limiting characterization of this group as a whole. Some Hyphomycetales found in bottom sediments (Fig. 7), namely *Alatospora acuminata*,

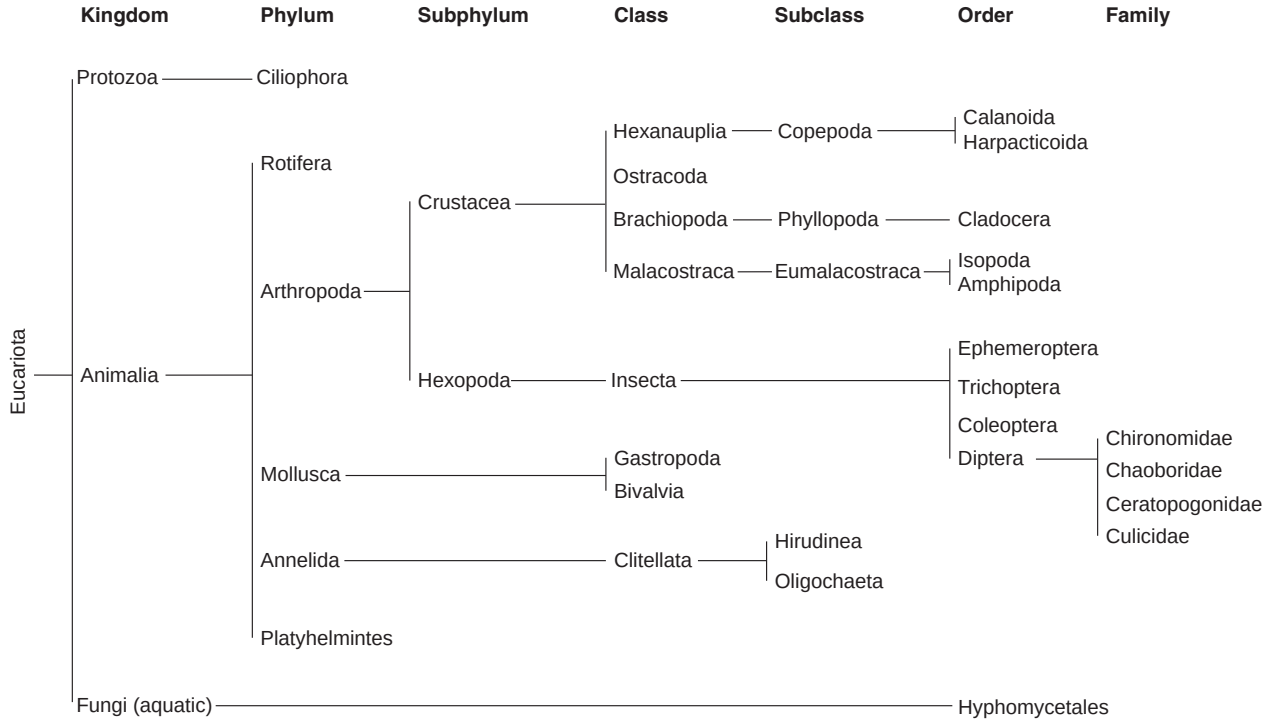

Fig. 7 A phylogenetic tree of the non-photosynthetic eukaryotes.

Heliscus lugdunensis, and *Tricladium chaetocladium*, synthesize C18 PUFAs of the n-3 and n-6 families (Arce Funck et al., 2015). Fungi may be an important source of essential PUFAs for invertebrates consuming detritus, which is usually poor in any PUFAs.

The FA composition of Ciliates (Ciliophora) and Rotifera (Fig. 7) has been poorly studied. The studied species do not contain specific FA-markers, with rare exceptions. In general, ciliates mainly contain 18:1n-9, 18:2n-6, 18:3n-6, and some other n-6 PUFAs, namely 20:2n-6, 20:4n-6, 20:3n-6, and 22:5n-6 (Desvilettes et al., 1997). Rotifera usually are rich in 16:0, 18:0, 18:1n-9, and n-3 and n-6 PUFAs.

Crustacea, namely Cladocera and Copepoda (Fig. 7), are the most dominant taxa of plankton in inland waters. They contain significant levels of 16:0, 16:1n-7, 18:1n-9, 18:2n-6, 18:3n-3, and 20:5n-3. In contrast to Cladocera, Copepoda contain high levels of C22 PUFAs, especially 22:6n-3. Specific FAs have been found in some species of Crustacea. For example *Limnocalanus macrurus* (Calanoida, Fig. 7) contains significant levels of unusual LC-PUFAs such as 24:4n-3, 24:5n-3, 24:6n-3, 26:4n-3, and 26:5n-3 (Hiltunen et al., 2014). Marine representatives of Copepoda, namely, Calanoida, store waxes esterified by 20:1n-11, 20:1n-9, 22:1n-11, 22:1n-9 (up to 10–15% of total FAs) (Scott et al., 2002). These MUFAs and LC-PUFAs are widely used as markers of marine copepods in trophic chains, including trophic chains of freshwater rivers and lakes containing semi-migratory fish. For example, a significant level of these MUFAs in semi-migratory fish reflects migration of fish from freshwaters to the sea.

FAs of some other crustaceans have also been identified. Although freshwater Isopoda (Fig. 7) are poorly studied, the benthic Ostracoda and Amphipoda (Fig. 7) are rich in both physiologically important n-3 LC-PUFAs—20:5n-3 and 22:6n-3. High levels of 22:6n-3 in freshwater and marine amphipods are associated with their carnivorous feeding habits. However, it seems that the high level of 22:6n-3 in amphipods indicates predation on animals rich in this PUFA. A 6-month experiment showed that *Gammarus lacustris* (a widespread representative of Amphipoda) individuals that consumed green algae and *Daphnia* (Cladocera that are deficient in 22:6n-3) had an absence of 22:6n-3 in their bodies. By contrast, when *G. lacustris* consumed copepods rich in 22:6n-3, its level increased to 8%. Amphipods also contain a significant level of 18:1n-9 and a high 18:1n-9/18:1n-7 ratio. Although some authors associate this with carnivory of amphipods, a high level of 18:1n-9 has been found in detritivorous gammarids (Legeżyńska et al., 2014). Thus, the use of 18:1n-9 as a marker of carnivory is questionable.

Mollusca (Fig. 7) synthesize specific FAs—non-methylene-interrupted (NMI FAs) (see glossary), which are widely used as their markers (Zhukova, 2019). Presumably, NMI FAs play structural and antioxidant (protection) roles in cell membranes. The ways of NMI FAs synthesis are shown in Fig. 9. In addition to NMI FAs, mollusks are rich in 20:1n-13, the rare isomer of 20:1. Bivalvia and Gastropoda differ in FA profiles. In contrast to Bivalvia, Gastropoda usually contain significant levels of n-6 LC-PUFAs, namely 20:4n-6 and 22:4n-6. The presence of specific FA-markers in Mollusca makes it possible to accurately discern the diets of fish and birds based on these invertebrates.

Fig. 8 The representatives of the non-photosynthetic eukaryotes (the aquatic invertebrates). Courtesy: Olesia Makhutova.

Case study: Adapt your diet or go extinct: Selective feeding of mollusks (Makhutova et al., 2013)

FA-marker analyses revealed differences in the feeding spectra of mollusks inhabiting the same aquatic ecosystem. Three mollusk species, *Dreissena polymorpha*, *Dreissena bugensis*, and *Unio tumidus*, were studied in the Kanevskoe Reservoir of the Dnieper River (Ukraine). *Dreissena* species, which settled on *Unio* shells and therefore were located in a higher layer than the fouled *Unio*,

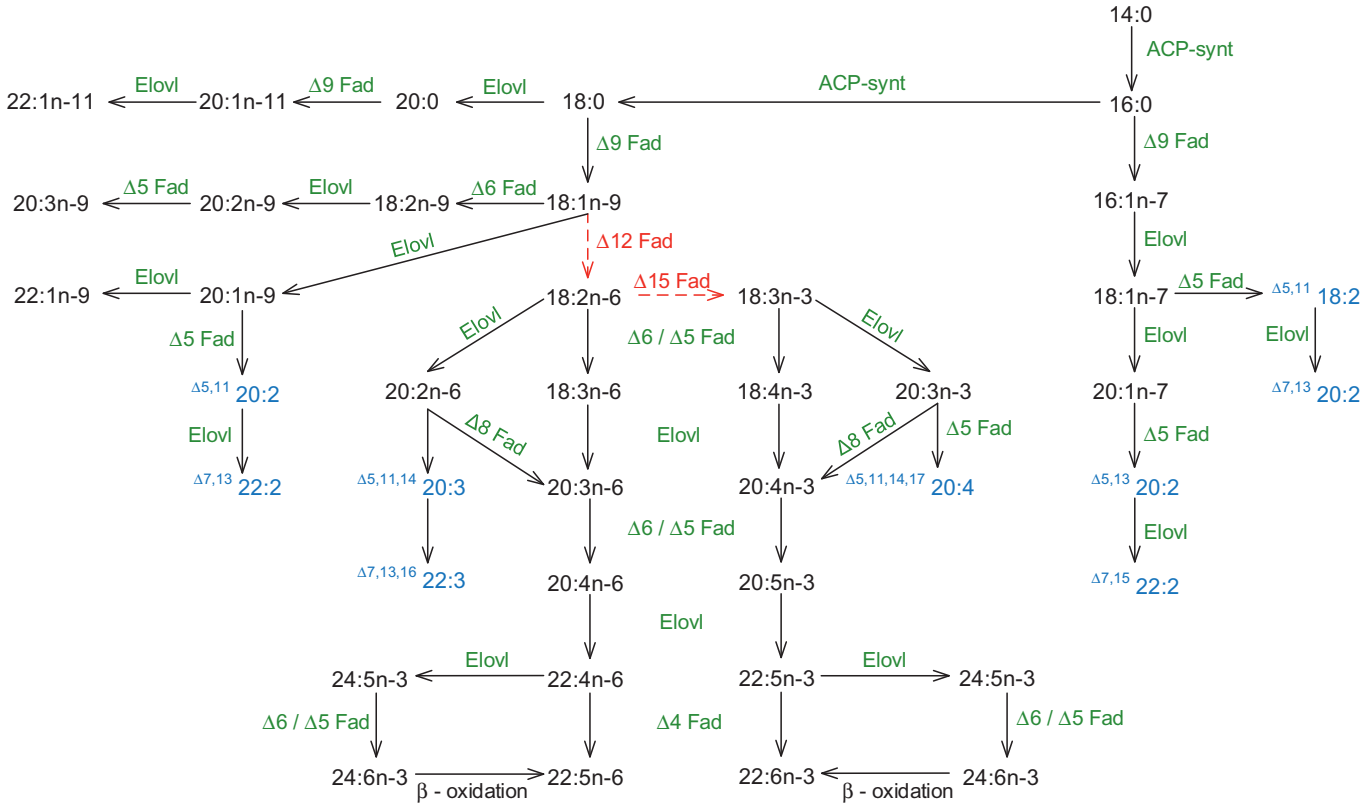

Fig. 9 The common ways of FA synthesis in non-photosynthetic eukaryotes. The enzymes, which are found in animals, are marked in green. The exceptions, which are very rare in non-photosynthetic eukaryotes, are marked in red, NMI FA are marked in blue.

preferably consumed more valuable food—planktonic algae and bacteria, while *Unio* mostly fed on detritus and benthic algae, which were of a lower food quality. The different feeding spectra of the mollusks and adaptations of *Unio* to benthic food might be the basis for the successful coexistence of the mollusks for a long time and prevent extinction of *Unio* due to *Dreissena*, as is the case in most waterbodies.

Insecta (Fig. 7) have diverse FA profiles. This diversity is explained by selective consumption of food (especially algae and bacteria) and synthesis of specific FAs. Larvae of nonbiting midges (Chironomidae, Fig. 7) usually contain FA-markers of diatoms, green algae, cyanobacteria, and other bacteria. For example, chironomids from Lake Biwa had high levels of 16:1n-8, 16:1n-6, and 16:1n-5—markers of methanotrophic bacteria (Kiyashko et al., 2004). Mayfly larvae (Ephemeroptera, Fig. 7) contain high levels of FA-markers of diatoms, whereas caddisfly larvae (Trichoptera, Fig. 7) FA-markers are dominated by green algae and diatoms.

Some species of Insecta synthesize specific FAs. For example, Mosquito larvae (Culicidae, Fig. 7) contain 14:2n-6 and 14:3n-3, which can be used as their markers (Sushchik et al., 2013). Caddisfly (*Apatania fimbriata*) larvae contain a number of short-chain PUFAs (12:2, 12:3, 14:2, 14:3) that they excrete with secretory fluid to scare away predators (Wagner et al., 1990). Among LC-PUFAs, only 20:5n-3 dominates in Insecta. LC-PUFAs with 22 and more carbon atoms are usually absent in Insecta or their level is negligible. There are some exceptions, however. In addition to 20:5n-3, glassworm larvae (Chaoboridae, Fig. 7) have a rather high level of 22:6n-3. When we studied the FA composition of various invertebrates inhabiting a fishless lake, we had been surprised to find rather high level of 22:6n-3 in water beetles *Dytiscus lapponicus* (Coleoptera, Fig. 7) because all previously studied predatory freshwater insect larvae like dragonflies and stoneflies only contained trace amounts of this FA (Makhutova et al., 2016). Then, we observed the beetles consuming gammarids that were rich in that FA and realized that gammarids were the sources of 22:6n-3 in beetles. Thus, some carnivorous insects may contain 22:6n-3 if their prey contain this FA.

In addition to the invertebrate taxa listed above, Annelida (especially Oligochaeta and Hirudinea) and Platyhelminthes (Fig. 7) are widespread in freshwater ecosystems. Oligochaeta contain a variety of FAs, including PUFAs. The level of 20:5n-3 can reach 22% of total FAs, while the level of 22:6n-3 is usually low. Another distinguishing quality of the FA composition of oligochaetes is a relatively high content of 20:1n-9, which can reach 10% in some species. The data on FA composition of Hirudinea and Platyhelminthes are scant. 20:2n-6 is considered a marker of freshwater Hirudinea because the level of this FA is rather high (~5%) only in this taxon. Some freshwater species of the family Planariidae (Platyhelminthes) contain a very high level of 22:5n-3 (~9%), which is unusual for invertebrates. Thus, 22:5n-3 is suggested as a marker of freshwater planarian.

Case study: Selective feeding of insect larvae inhabiting saline rivers (Zinchenko et al., 2014)

FA-marker analysis indicated that selective feeding could be a characteristic of benthic invertebrates that are commonly categorized as 'omnivores' or 'detritivores.' For instance, the larvae of three species of Chironomidae (*Cricotopus salinophilus*, *Chironomus salinarius,* and *Chironomus aprilinus*) found in two saline rivers within the basin of hypersaline Lake Elton) selectively consumed bacteria, diatoms, and some other microalgae from bottom sediments, but avoided consuming organic debris at a high degree of decomposition. Similarly, *Palpomyia schmidti* larvae (Ceratopogonidae, Fig. 7) inhabiting the same saline rivers selectively consumed diatoms and other algae, but avoided bacteria and decomposed dead organic matter.

Case study: Using photosynthetic and non-photosynthetic FA-markers to understand tadpoles' diets

FA-markers of all described aquatic organisms, namely, bacteria, algae, and invertebrates, are successfully used for studying diets of aquatic vertebrates. For example, the study of tadpoles' diet required the knowledge of FA-markers of various organisms. Whiles et al. (2010) found that although tadpoles in Illinois ponds (United States) obtained substantial amounts of food from heterotrophic sources, they displayed a high degree of opportunism (see glossary) in their feeding. The same species inhabiting different ponds had different diets. For example, *Lithobates clamitans* consumed detritus and plankton invertebrates in one pond; detritus and algae attached to submerged surfaces in another pond; detritus, plankton algae and aquatic insect larvae in a third pond. Two other tadpoles, *Rana arvalis* and *Pelobates fuscus*, cohabiting oxbows of the Khoper River (Russia), had differences in feeding spectra: *R. arvalis* primarily consumed bacterial food, while the diet of *P. fuscus* was based on cyanobacteria, green algae, diatoms, and higher plants.

Conclusion: Using FA-markers across taxa to understand foodwebs

There is no one ideal method for determining the diets of aquatic animals. However, scientists have discovered FA-markers for many taxa that are used in studies of trophic interactions in aquatic ecosystems (Fig. 10). FA-marker analysis has facilitated amazing discoveries such as selective feeding of filter-feeders, the diet variability of detritivores, and adaptations of feeding behavior to the changing environment. FA compositions of aquatic organisms are extremely diverse, providing many opportunities for further studies.

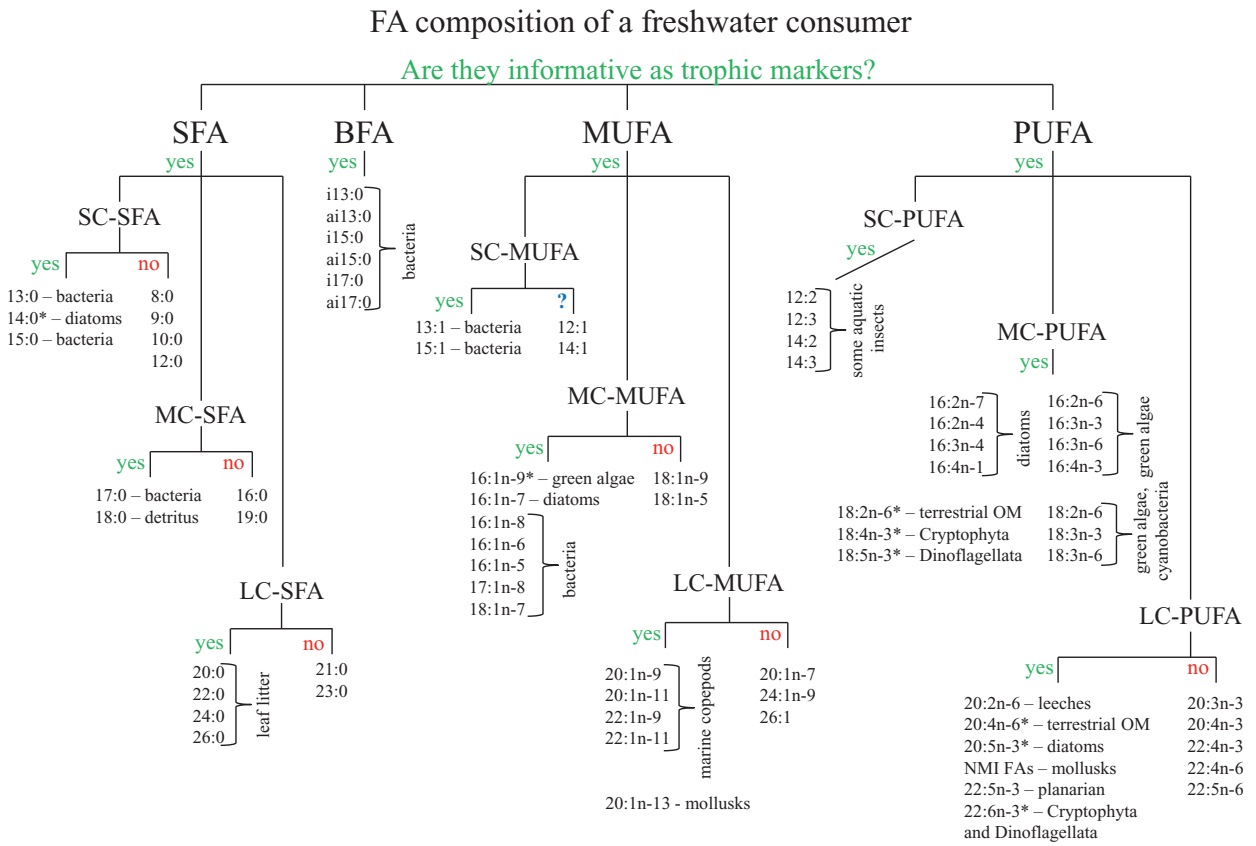

Fig. 10 The common FA-markers and non-marker FAs in a typical freshwater consumer. *: FAs that can be used as markers only if other FA-markers are also found. *SFA*, saturated FAs; *BFA*, branched FAs; *MUFA*, monounsaturated FAs; *PUFA*, polyunsaturated FAs; *SC*, short-chain; *MC*, medium-chain; *LC*, long-chain; *OM*, organic matter. The absence of the position of double bonds in some FA indicates their variability.

Future research

- Find FA-markers of other animal taxa,
- test recently proposed FA-markers,
- reveal the effect of changes in temperature, salinity, and other environmental factors on FA composition of aquatic organisms,
- develop a quantitative approach for estimating diets of aquatic animals using FA-markers.

INDEX

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization, and it is arranged in set-out style, with a maximum of four levels of heading. Location references refer to the volume number, in bold, followed by the page number. Page numbers suffixed by *f*, *b* and *t* refers to figures, boxes and tables terms respectively. *vs*. indicates a comparison.
