Fig. 1 Zooplankton growth rates as a function of (A) food quantity with food of different quality, (B) food quality in the presence and absence of a second limiting nutrient, (C) food quantity at two different temperatures, and (D) LC-PUFA contents at two different temperatures. In (B) and (D), food quantity is non-limiting. Arrow in (A) denotes the food quality effect on growth rates, in (B) the effect of a co-limiting food quality component, in (C) and (D) the effect of water temperature. Note that in (C) the effect of water temperature on growth rate at low food concentration is opposite to the effect of water temperature on growth rate at high food concentrations.

Food quality

Besides food quantity, the growth of zooplankton can be limited by food quality. The shape of functional response curves and thus threshold food concentrations and ILLs are influenced by food quality. Typically, food quality effects become most pronounced at high food concentrations, causing strong differences in maximum growth rates (Fig. 1A). Poor food quality can be either due to dietary deficiencies impairing growth and/or reproduction, or due to harmful secondary metabolites potentially resulting in severe intoxication. Dietary deficiencies may result from imbalanced supply of elements, or certain biochemicals, which are required for growth and reproduction but cannot be synthesized *de novo* from low molecular precursors. Biochemicals considered to be essential can be found among the polyunsaturated fatty acids (PUFAs), sterols, amino acids, and vitamins. The actual requirements for a particular nutrient, however, may differ between animal taxa, species or even clones of the same species. In recent years, aquatic food quality research has increasingly focused on assessing the physiological and ecological consequences associated with dietary element, PUFA, sterol, and—more recently—amino acid deficiencies, as well as harmful secondary metabolites. In comparison, the role of e.g., vitamins in determining food quality has been poorly addressed.

Elements

All animals require a set of elements to cover their physiological demands, most notably carbon (C), nitrogen (N) and phosphorus (P). The stoichiometry of these elements, i.e., their quantitative relationships, and its significance for trophic interactions has been extensively studied in past decades (Sterner and Elser, 2002). Carbon is the most abundant element in organic matter; it typically represents 40–50% of the dry biomass of most organisms, and thus is used as a surrogate for food quantity. Zooplankton growth has been shown to be crucially affected by the availability of dietary N and P, more specifically by the C:N and the C:P ratio of their food. Compared to most other zooplankton taxa, *Daphnia* contain high amounts of P, which is most likely linked to their high growth rates, and thus are more susceptible to P limitation than taxa containing less P and achieving lower growth rates, such as *Bosmina* or calanoid copepods (Sterner and Elser, 2002). However, copepod nauplii may also have low C:P ratios (Villar-Argaiz and Sterner, 2002), which suggests that juvenile life stages even of calanoid copepods may be sensitive to stoichiometric constraints. The Growth Rate Hypothesis (GRH) proposes positive relationships between growth rate, body P and ribonucleic acid (RNA) content. More than 25% of the overall biomass P content is implemented in RNA, suggesting that protein biosynthesis is sensitive to dietary P supply and that P demands increase with growth rate. The GRH is a central component of the ecological stoichiometry concept and provides a mechanistic explanation of P-limited growth responses (Sterner and Elser, 2002). Zooplankton consumers also require other elements in their food to cover their physiological demands. Nitrogen is a central component of amino acids and dietary deficiencies in N may potentially impair zooplankton growth (Hessen, 1992). Other elements that serve as obligate constituents of macromolecules may similarly impair the performance of zooplankton consumers but our knowledge of elemental nutrient limitations other than those mediated by P and N is still scarce.

Fatty acids

As in other organisms, fatty acids play an important role in zooplankton physiology. They are indispensable components of cell membranes and as such involved in e.g., temperature acclimation (Hazel and Williams, 1990), and they serve as precursors for eicosanoids, which are important mediators in reproduction, the immune system, and ion transport physiology (Stanley, 2000). Animals are typically incapable of synthesizing long-chain PUFAs *de novo*, i.e., from low-molecular-weight precursors, and thus must acquire these essential nutrients from their diet. Five PUFAs are commonly considered to be physiologically important: the three ω-3 (n-3) PUFAs α-linolenic acid (ALA, 18:3n-3), eicosapentaenoic acid (EPA, 20:5n-3), and docosahexaenoic acid (DHA, 22:6n-3), and the two ω-6 (n-6) PUFAs linoleic acid (LIN, 18:2n-6) and arachidonic acid (ARA, 20:4n-6). The long-chain (>C18) PUFAs, EPA, DHA, and ARA, are conditionally essential because some animals can synthesize these long-chain PUFAs from their respective precursors ALA and LIN via elongation and desaturation or via retro-conversion from dietary PUFAs with longer carbon chains. However, the conversion rates at which these metabolic processes occur are typically low and often insufficient to meet physiological needs, i.e., dietary supply is still required to maximize growth and offspring production (Martin-Creuzburg et al., 2010; Taipale et al., 2011; Von Elert, 2002). Several PUFAs have been shown to support *Daphnia* growth. Which of these PUFAs actually becomes limiting under natural conditions may change with dietary PUFA availability. In general, however, EPA and ARA seem to be most effective in supporting growth and especially reproduction of *Daphnia* (Becker and Boersma, 2003; Ravet et al., 2003). Dietary DHA tends to be retro-converted to EPA in the metabolism of *Daphnia*, suggesting that the reported positive effects of DHA supplementation on *Daphnia* performance are in fact due to an increased availability of EPA (Martin-Creuzburg et al., 2010; Von Elert, 2002).

Sterols

Experimental evidence suggests that rotifer and crustacean zooplankton are incapable of synthesizing sterols *de novo* and thus require a dietary source of sterols to meet their physiological demands (von Elert et al., 2003; Wacker and Martin-Creuzburg, 2012). Sterols are indispensable structural components of all eukaryotic cell membranes. They modulate and refine membrane fluidity, permeability, and the functioning of various membrane proteins, serve as precursors for steroid hormones, such as the molt-inducing ecdysteroids in arthropods, and are required as signaling molecules during embryonic development (Martin-Creuzburg and von Elert, 2009). In contrast to plants and most algae, which contain a large variety of different sterols

(phytosterols), cholesterol is the predominant sterol in most animal tissues including crustaceans, but not in rotifers (Wacker and Martin-Creuzburg, 2012). Herbivorous crustaceans typically use dietary phytosterols to synthesize cholesterol. However, not all phytosterols found in algae are suitable as cholesterol precursors. Thus, in addition to low dietary sterol levels, the quality of dietary sterols may affect the performance of zooplankton (Martin-Creuzburg and von Elert, 2009).

Experimentally modifying the availability of dietary sterols revealed a strong impact of dietary sterols on various life history traits of *Daphnia*; somatic growth rates, offspring production, and the probability of survival were all significantly reduced with decreasing dietary sterol supply (Martin-Creuzburg et al., 2005b). Rapidly growing animals may have particularly high dietary sterol requirements because sterols are needed for the biosynthesis of new cell membranes and as precursors for the molt-inducing ecdysteroids, implying that an adequate dietary supply with sterols is particularly important for juvenile somatic growth (Martin-Creuzburg et al., 2009). However, sterols are presumably also important for ovarian maturation and egg production.

Amino acids

Amino acids are the structural units of proteins and peptides and dietary deficiencies in certain amino acids may thus interfere with protein biosynthesis. Nine amino acids are commonly considered essential: phenylalanine, valine, threonine, tryptophan, isoleucine, leucine, methionine, lysine, and histidine. Other amino acids, such as arginine, cysteine, and proline, are described as 'conditionally essential', as they are required only under certain circumstances or life stages. Reports on amino acid requirements of zooplankton are scarce. The amino acid content of animals tends to be regulated homeostatically, i.e., changes in the amino acid content of consumers are rather low despite considerable changes in the availability of dietary amino acids (Müller-Navarra, 2008). This might result in amino acid limitation if specific amino acids are underrepresented in zooplankton diet. Currently, there are hardly any studies providing experimental evidence for amino acid limitation of zooplankton growth. However, population growth of the rotifer *Brachionus calyciflorus* has been shown to be limited by leucine and isoleucine in laboratory supplementation experiments (Wacker and Martin-Creuzburg, 2012).

Harmful metabolites

Toxicity is another important food quality constraint that can severely impair zooplankton performance (Wilson et al., 2006). Many cyanobacteria are known to produce a variety of potentially harmful secondary metabolites such as microcystins, cylindrospermopsins, anatoxin-*a*, and various protease inhibitors. Also mixotrophic and heterotrophic flagellates of the genera *Ochromonas* and *Poterioochromonas* have been shown to produce various metabolites, i.e., chlorosulfolipids, that are toxic to zooplankton (Bedke and Vanderwal, 2011; Boenigk and Stadler, 2004). Microcystin-LR, the best studied of the various microcystins, has been shown to be toxic to zooplankton, most likely through inhibition of phosphatases (DeMott et al., 1991). However, detrimental effects of cyanobacteria on zooplankton performance could often not be linked to microcystin toxicity (Tillmanns et al., 2008; Wilson et al., 2006). Instead, other cyanobacterial peptides came into focus that have been shown to inhibit digestive proteases in zooplankton (Rohrlack et al., 2004; Von Elert et al., 2005). The diversity of potentially harmful metabolites found in cyanobacteria suggests that synergistic or additive effects among metabolites must be considered for improving our understanding of cyanobacteria-grazer interactions. It should be noted, however, that toxicity varies among species and even strains and that not all cyanobacteria are necessarily toxic to zooplankton.

Multiple nutritional constraints

Some food organisms may pose several challenges for their zooplankton consumers. For example, several cyanobacteria species may be inadequate food for zooplankton because of either filament or colony formation, production of harmful metabolites, and sterol and/or PUFA deficiency. Supplementation experiments with *Daphnia magna* feeding on different cyanobacteria species suggest that somatic growth rates are limited along a hierarchy of low ingestibility due to filaments, toxicity, sterol deficiency and PUFAs deficiency (Martin-Creuzburg et al., 2008).

Laboratory experiments revealed that zooplankton growth can be limited by multiple nutrients simultaneously. In respect to sterols and EPA (Sperfeld et al., 2012) as well as sterols and phosphorus (Lukas et al., 2011), somatic growth of *Daphnia* has been shown to be limited simultaneously by two diet components (Fig. 1B). Likewise, amino acids and sterols may co-limit rotifer population growth (Wacker and Martin-Creuzburg, 2012). Somatic growth rates of zooplankton in a multi-nutrient limitation setting can be described using the multiple limitation hypothesis (MLH, Gleeson and Tilman, 1992; Sperfeld et al., 2012), which considers interactions between co-limiting nutrients and predicts smooth transitions from a limitation by one nutrient to a limitation by another. Whereas co-limitation of somatic growth of *Daphnia* has been observed only for a certain range of resource concentrations, resulting in small effect sizes (Sperfeld et al., 2012), co-limitation of population growth of *Daphnia* may be more pronounced due to the differences in effect sizes of sterols and PUFAs on somatic growth and reproduction, respectively. While somatic growth seems to be primarily constrained by a low dietary sterol content, reproduction seems to be more affected by a low dietary LC- PUFA content (Martin-Creuzburg et al., 2010). As population growth requires both individual somatic growth and reproduction, there is a high possibility of co-limitation.

Temperature resource interactions

Zooplankton in lakes outside the tropics experience large seasonal changes in temperatures, which will strongly affect their metabolic rates and consequently their nutritional requirements in terms of food quantity and quality. As metabolic rates scale exponentially with temperature (Gillooly et al., 2001), nutritional demands increase with temperature, likely resulting in increasing ILLs with increasing temperatures (Giebelhausen and Lampert, 2001) and thus increasing food quantity effects with increasing temperatures (Fig. 1C)—as long as temperatures do not exceed the optimum temperature for growth. At low food concentrations, an increase of temperature might even have negative consequences for growth. Likewise, the effects of food quality also depend on ambient temperatures. The C:P ratio of food has been found to have a large effect on *Daphnia* growth at 25 °C, whereas there was hardly any effect at 10 °C (Persson et al., 2011). Also, sterol requirements increase with increasing temperature (Martin-Creuzburg et al., 2012; Sperfeld and Wacker, 2009). In contrast, PUFA requirements decrease with increasing temperature, i.e., temperature affects growth more strongly on a low PUFA diet (Fig. 1D) (Martin-Creuzburg et al., 2012; Sperfeld and Wacker, 2012), as more PUFAs are required to maintain membrane fluidity at low temperatures. Hence, temperature will influence both food quantity and quality constraints simultaneously possibly resulting in complex interactions that make it difficult to distinguish between temperature effects on quality versus quantity nutritional constraints. Such interactions must also be taken into account in experimental work. For example, studies analyzing temperature dependencies of growth in respect to food quantity or stoichiometric constraints might have incorrectly assumed that LC-PUFAs were not limiting in low-temperature treatments. Hence, LC-PUFAs might have acted as a hidden treatment in some experiments, which would result in an overestimation of the temperature dependency of growth in respect to e.g., food quantity or phosphorus supply.

Zooplankton nutrition in a food-web context

Freshwater zooplankton is a taxonomically and functionally diverse assemblage of organisms, consisting of unicellular protists, such as heterotrophic flagellates and ciliates, as well as metazoan grazers, most notably rotifers and crustaceans (see chapter on zooplankton diversity and variation between lakes). These taxa range in size from few micrometers (μm) for large flagellates to several centimeters for large crustaceans (Fig. 2). Zooplankton differ in the size range of food organisms they can exploit, resulting in group-specific predator-prey size ratios. These average predator:prey size ratios (in equivalent spherical diameters) range from 3:1 for flagellates towards 100:1 for cladocerans (Hansen et al., 1994), with yet extreme values. For instance, the predator:prey size ratio for raptorial crustacean consumers might be as low as 1:1 while it can reach 1000:1 for filter-feeders.

The food organisms of zooplankton change along the size gradient from prokaryotic cells, which dominate the food sources up to a size of 1 pg C, towards eukaryotic phytoplankton, which dominate from 1 pg C towards 4 ng C, and zooplankton from ~10 ng C onwards (Fig. 2). Within this range of zooplankton food sizes, there is a partial covariation between size and food quality. This covariation is caused by physical/physiological and taxonomical constraints. The surface-to-volume ratio increases with decreasing cell size, which is thought to result in higher nutrient affinities and consequently higher cellular elemental contents of small cells. While prokaryotes (bacteria and cyanobacteria) are potentially important providers of elements (phosphorus) for zooplankton, the majority of prokaryotic taxa lacks the biochemical machinery to build sterols and LC-PUFAs. Thus, while food

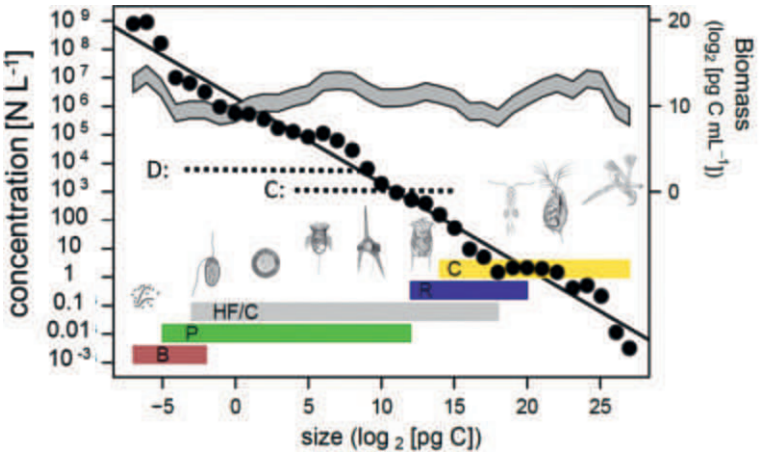

Fig. 2 Size spectrum of the pelagic community of Lake Constance. Shown is the overall biomass in each size range (grey polygon) and the concentration of organisms in each size range (black dots). Size ranges of organism groups are shown as horizontal bars (B: bacteria, P: phytoplankton, HF, C: heterotrophic flagellates and ciliates, R: rotifers, and C: crustaceans). The horizontal dotted lines indicate the size range of food items of a copepod (C) with a size of 0.5 μg carbon and a *Daphnia* (D) with a size of 4.2 μg carbon. Figure modified from Güde H and Straile D (2016) Bodensee—Ökologie und anthropogene Belastungen eines tiefen Voralpensees. *Limnologie Aktuell* **15**: 1–271.

cells below a size of 1 pg C may represent an important source of energy and enrich zooplankton diet with elements, a high percentage of small prokaryotic cells in the diet may dilute its LC-PUFA and sterol content. Within the whole size-range occupied by phytoplankton (Fig. 2), also zooplankton organisms, i.e., heterotrophic flagellates and ciliates, are present. For zooplankton feeding on prey sizes of 1 pg to 10 ng C, approximately 1–10% of available carbon is represented by heterotrophs. Small zooplankton taxa, especially heterotrophic flagellates and ciliates, feed on low quality bacteria, thereby converting low quality bacterial food into higher quality protozoan food that is then available to larger zooplankton. Such trophic upgrading of food particles by protozoans may be due to the repacking of otherwise poorly ingestible food particles to more easily accessible food particles, and/or biosynthesis of essential biochemical nutrients by the intermediary protozoan grazers. However, protozoan taxa might differ in their capacity to upgrade food for higher trophic levels. Heterotrophic flagellates, for instance, are capable of synthesizing sterols *de novo* (e.g., Bec et al., 2006), whereas ciliates might lack this capacity (e.g., Martin-Creuzburg et al., 2005a).

In contrast to mineral and biochemical content, there seems to be no toxicity gradient along the bacteria-phytoplankton size range. Toxic constituents are known from bacteria (Matz et al., 2004), cyanobacteria (Wilson et al., 2006), as well as mixotrophic and heterotrophic flagellates (Hiltunen et al., 2012).

Seasonal and lake trophy differences in zooplankton nutrition

Based on phytoplankton concentrations and composition, zooplankton nutritional constraints in terms of food quantity and quality are expected to vary seasonally (Sommer et al., 1986) and between lakes of different trophic status (Watson et al., 1997). A large amount of high quality food, i.e., diatoms and cryptophytes, is available to zooplankton during the spring bloom of phytoplankton in most lakes, suggesting that neither food quantity nor food quality constraints are relevant during this time of the year. Furthermore, low temperatures during spring suggest that growth rates are strongly temperature limited. In contrast to the spring bloom, the summer phytoplankton bloom is often dominated by inedible algae (Sommer et al., 1986), and the low concentration of edible algae suggests that zooplankton might be limited by food quantity. In addition, food quality is predicted to decrease during the season as the contribution of algae deficient in LC-PUFAs and/or suitable sterols, e.g., green algae or cyanobacteria, increases. The fraction of in-edible algae as well as the fraction of low to moderate food quality algae (cyanobacteria and chlorophytes) increases with increasing trophic status in summer phytoplankton (Watson et al., 1997), suggesting that the seasonal shift from edible to in-edible algae and from high to low quality food is getting larger with increasing trophic status.

Laboratory experiments provide threshold elemental or biochemical ratios (TER, TBR) for nutritional constraints of consumers, which can be related to seston elemental or biochemical ratios to infer nutritional constraints *in situ*. Most estimates for TER and especially for TBR have been established for *Daphnia* (but see Frost et al., 2006), which relates to the key role of *Daphnia* in freshwater food webs. However, as *Daphnia* is a non-selective consumer, TER and TBR estimates for *Daphnia* may be considered as upper bounds for TER and TBR for more selective consumers, because they might be able to select for higher-quality food. *Daphnia* are expected to be P limited when the P content of its food is <8.6 μg P mg C^{-1} (molar C:P ratio of >300; e.g., Urabe et al., 2018). In a compilation of 576 measurements from 285 lakes, roughly 20% of seston molar C:P ratios were found to exceed 300, suggesting P limitation of *Daphnia* (Sterner et al., 2008).

The proposed growth saturation thresholds for EPA depend on temperature (Sperfeld and Wacker, 2011). For example, an EPA content within a bootstrapped range of 0.7–2.0 μg mg C^{-1} was necessary to achieve 75% of the maximum somatic growth of *Daphnia* at 20 °C, whereas approximately twice (bootstrapped range: 1.6–4.9 μg mg C^{-1}) the EPA content was necessary to achieve 75% of maximum growth at 15 °C (Sperfeld and Wacker, 2011). These thresholds suggests that a moderate EPA limitation frequently occurs *in situ* (Sperfeld and Wacker, 2011).

It has been reported that sterol limitation is likely if prokaryotes contribute more than 40–50% to edible biomass (Martin-Creuzburg et al., 2011), which seems possible during cyanobacterial blooms in eutrophic lakes or in humic lakes in which, due to large amounts of allochthonous material, heterotrophic bacteria can account for a major fraction of suspended particulate organic carbon (Hessen, 1985). However, supplementation experiments revealed *Daphnia* ILLs in a range of 3.5–34.4 μg mg C^{-1} using 10 different phytosterols (Martin-Creuzburg et al., 2014), suggesting that the eukaryotic species composition also needs to be considered when assessing potential sterol limitations *in situ*.

While a comparison of seston concentrations with TER and TBR may point to potential nutritional constraints, there are three types of evidence for the actual occurrence of nutritional constraints of zooplankton *in situ*: (1) correlative studies comparing seston nutrient concentrations with zooplankton growth characteristics, (2) comparative studies, and (3) supplementation studies exploring potential nutrient limitations experimentally. Correlative studies suggested that zooplankton performance can be limited by food quantity as well as by several aspects of food quality. For example, clutch size of *Daphnia* has been shown to be tightly related to particulate organic carbon concentration in the edible size fraction (e.g., Lampert, 1978). Likewise, somatic growth rates of *Daphnia* that were reared on natural seston were found to be correlated with the concentration and/or content of EPA (Müller-Navarra et al., 2000), ALA (Wacker and von Elert, 2001), and sterols (De Lange and Arts, 1999). Correlative studies are limited in deepening our insights in the causal relationships, nor do they allow a straightforward estimation of the relative importance of food quantity versus food quality effects. The latter might be achieved via comparing zooplankton growth rates observed when feeding on seston ((g(seston)) with a) growth rates when feeding on a standard laboratory food alga, such as the green alga *Scenedesmus*, at a similar carbon concentration ((g(Scen)) and b) with growth rates when feeding at non-limiting concentrations ($g(Scen_{max})$) (Fig. 3). A food limitation index (FL-I = $g(Seston)/g(Scen_{max})$) can be calculated which is the product

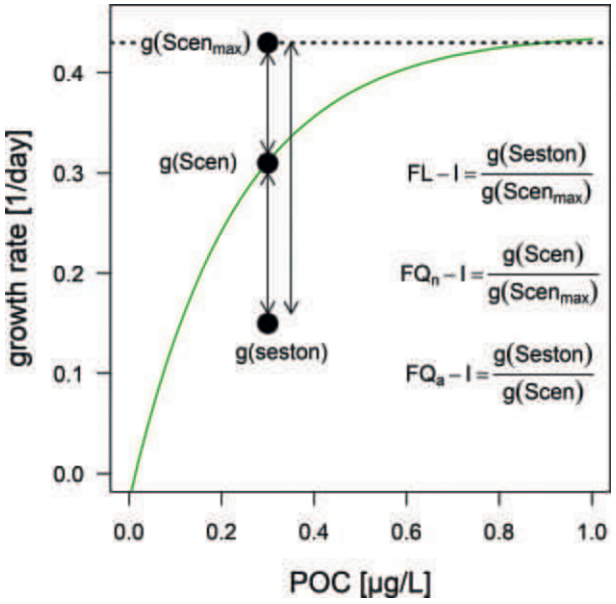

Fig. 3 Estimation of the strength of overall food limitation (FL-I), and of the effects of food quantity (FQ_n-I) and food quality (FQ_a-I) for zooplankton somatic growth on natural seston (g(seston)) relative to growth on standardized food (e.g., the green alga *Scenedesmus*, g(Scen), green line) at a similar concentration of particulate organic carbon (POC), and to maximum growth on standardized food ($g(Scen_{max})$). FL-I can be calculated as the product of FQ_a-I times FQ_n-I.

of a Food Quantity Limitation Index (FQ_n-I = g(Scen)/$g(Scen_{max})$) and a Food Quality Limitation Index (FQ_a-I = g(seston)/g(Scen)) (Fig. 3). Data for the calculation of such indices are scarce, but were reported during a seasonal course in mesotrophic Schöhsee (Müller-Navarra and Lampert, 1996), and at two different trophic conditions (mesotrophic and oligotrophic) in Lake Constance (Hartwich et al., 2012; Wacker and von Elert, 2001).

In mesotrophic conditions (Schöhsee and mesotrophic Lake Constance), FL-I values approached one during spring and autumn, implying no food constraints during these periods (Fig. 4A). This supports correlative studies, suggesting that *Daphnia* growth during spring is mainly controlled by temperature (Straile et al., 2012) and not by nutritional constraints (Straile, 2015). Strongest food constraints were observed around May and June, i.e., during the clear-water phase and intermediate food constraints during summer. In oligotrophic Lake Constance, FL-I was lower especially during spring and the clear-water phase. However, in all three studies, food constraints were never strong enough to stop *Daphnia* growth. FQ_n-I reached higher values in Schöhsee compared to the two study years in Lake Constance, and varied between 0.6 and 0.8 during most parts of the summer (Fig. 4B). FQ_a-I varied considerably between the three studies during spring and early summer with values approaching or even exceeding one in mesotrophic conditions (i.e., seston quality approaches or exceeds the quality of *Scenedesmus*), and lowest values in oligotrophic Lake Constance (Fig. 4c). During summer, FQ_a-I varied between 0.6 and 0.8 in all lakes/conditions. The ratio FQ_a-I/FQ_n-I gives a measure of the relative importance of quantity versus quality constraints (Fig. 4D). Values above one indicate the predominance of quantity constraints, whereas values below one suggests predominantly quality constraints. The ratio was close to one in all three studies around July and August, suggesting co-limitation by food quantity and quality, and that quantity and quality constraints on juvenile growth were of similar magnitude during this time of the year (Fig. 4D). Dominance of quantity constraints during spring may result from true quantity constraints in oligotrophic lakes, but also from FQ_a-I values exceeding one.

The high seston quality in spring (FQ_a-I >1) is presumably a result of the algal taxonomic composition, i.e., the dominance of PUFA-rich diatoms and cryptophytes during the spring bloom, but also due to low *in situ* water temperatures during spring, resulting in higher PUFA production of algae (Piepho et al., 2012). Thus, FQ_a-I values exceeding one point to an important limitation of this approach, the ignorance of food x temperature interactions. *Daphnia* growth rates in the three studies were determined at 20 °C, which is close to *in situ* temperatures during summer, but not during spring and autumn. Consequently, the use of 20 °C, instead of lower *in situ* temperatures, as experimental temperatures might have caused underestimation of FQ_n-I (= overestimation of food quantity limitation) and overestimation of FQ_a-I (= underestimation of food quality limitation) during spring and autumn.

Finally, direct evidence of quantity and quality limitation can be achieved via supplementation studies (DeMott et al., 2001, 2004; Hartwich et al., 2012; Santer and Lampert, 1995). One of the few studies available, which did not work with *Daphnia*, showed that nauplii of cyclopoid copepods are unable to develop during summer on natural seston collected from Lake Schöhsee, but were able to do so upon supplementation with the green alga *Chlamydomonas reinhardtii* (Santer and Lampert, 1995). This study provides strong evidence that also selective feeders, such as copepods, experience nutritional constraints within sensitive life stages, but does not allow distinguishing between food quantity and quality constraints. This was achieved, at least partially, in *Daphnia* studies in hypereutrophic ($P > 50$ µg L^{-1}) Dutch lakes (DeMott et al., 2001), eutrophic (P ~ 25 µg L^{-1}) and oligotrophic lakes ($P < 10$ µg L^{-1}) in Michigan (DeMott et al., 2004), and in oligotrophic (P < 10 µg L^{-1}) Lake Constance (Hartwich et al., 2012). In the latter study,

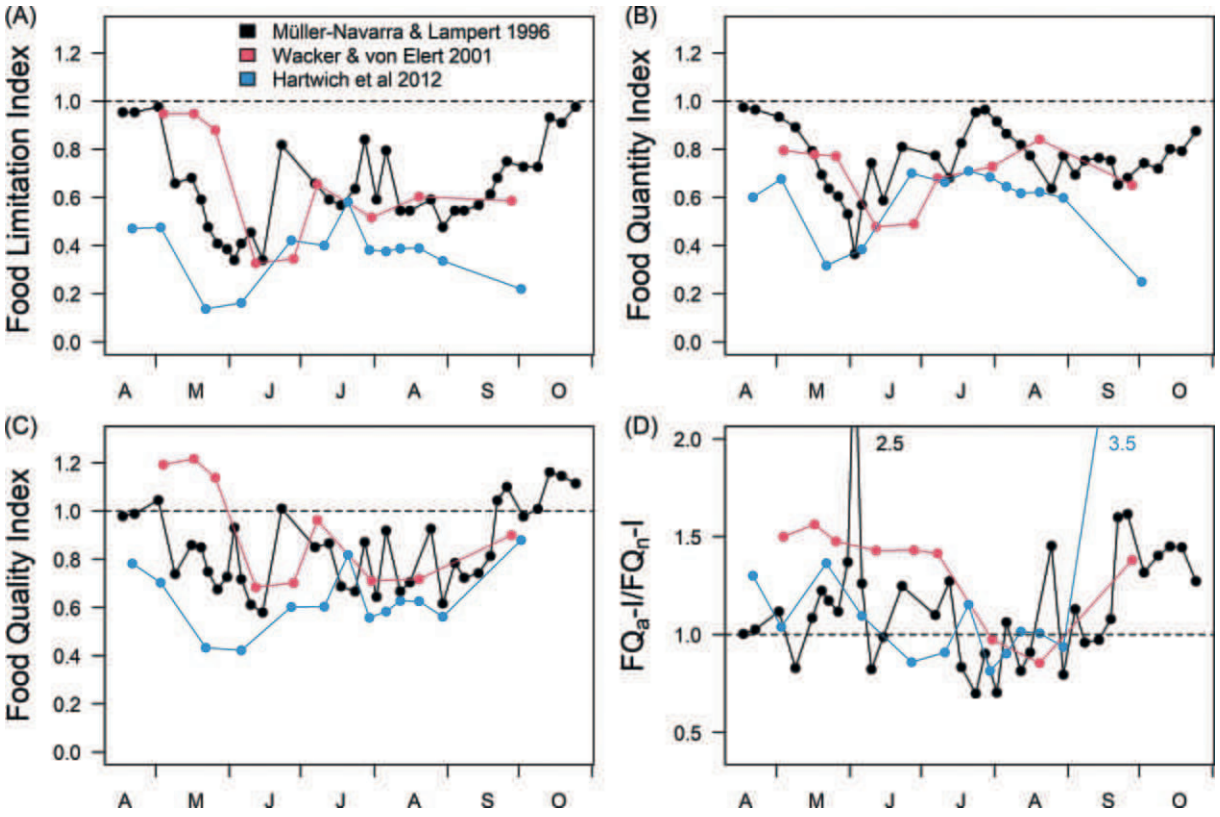

Fig. 4 Seasonal changes in the (A) food limitation index, (B) food quantity index, (C) food quality index, and the ratio of the two indices in three studies quantified using the somatic growth rate of juvenile *Daphnia* as shown in Fig. 3. Note that all indices are based on growth experiments conducted at 20 °C using the green algae *Scenedesmus* as reference food. Hence, all indices ignore the food X temperature interactions and underestimate the role of food quantity limitation, i.e., overestimate the food limitation Index, the food quality Index, and the ratio FQ_a-I/FQ_n-I, i.e., as food algae of higher quality compared to *Scenedesmus* do exist.

the cyanobacterium *Synechococcus* was used to test for food quantity limitation, in addition phosphate and LC-PUFAs were supplemented to natural seston to assess P and PUFA limitation, respectively (Fig. 5). The largest increase of *Daphnia* somatic growth rates was obtained by adding *Synechococcus* to the diet, suggesting food quantity constraints. As *Synechococcus* does not contain LC-PUFAs and sterols, but is rich in phosphorus, this increase indirectly suggests that LC-PUFAs and sterols were not limiting. However, it does not exclude the possibility of a co-limitation by food quantity and phosphorus. In most of the experiments documented in the literature (DeMott et al., 2001, 2004; Hartwich et al., 2012)—with the exception of experiments conducted in two out of the three Dutch lake—phosphate supplementation (Fig. 5B) stimulated growth less than *Synechococcus* supplementation suggesting that in one Dutch lakes, the Michigan lakes and in Lake Constance, food quantity constraints were more important. Likewise, growth rate increase via EPA and ARA supplementation in Lake Constance was small relative to *Synechococcus* supplementation (Fig. 5C and D).

The rather small increases of growth rates observed after phosphate and LC-PUFA supplementation (median increases all <10%) contrasts with a rather low FQ_a-I of 60–80% in comparative studies (Fig. 4); i.e., in order to balance such FQ_a-I values, growth rates should have increased 25–67% upon supplementation. One possible explanation would be that food quality constraints, as indicated by FQ_a-I values, are unlikely due to single dietary compounds, pointing towards co-limitations and interactive effect mediated by multiple food compounds. For example, algal P limitation enhances the digestion resistance of some green algae, thereby increasing food quantity limitation of *Daphnia* (DeMott and Van Donk, 2013). In addition, harmful algae might additionally have contributed to growth limitation of zooplankton (see above).

Zooplankton adaptive response to food constraints

Supplementation experiments testing the quality of *in situ* seston are usually performed using neonates of consumers produced under standardized conditions. Such an approach may overestimate nutritional constraints as only phenotypic responses to nutritional constraints taking place during the consumer growth period, but not maternal effects or rapid evolutionary responses of consumers are considered. Many studies have shown that zooplankton adapt physiologically and evolutionary to temporal and spatial changes in food quantity and quality. For example, *Daphnia* and rotifers cultured at low food concentrations will have lower

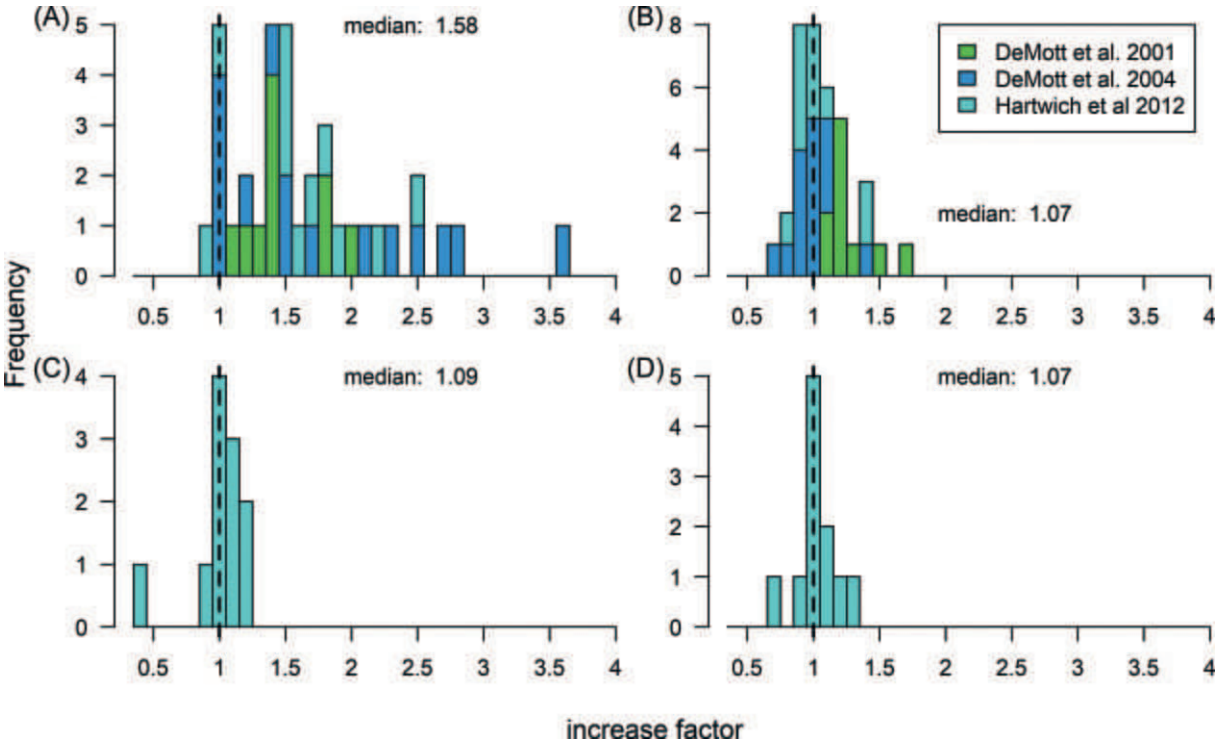

Fig. 5 Frequency of growth increases in supplementation experiments from three studies supplementing lake seston with (A) the cyanobacterium *Synechococcus*, (B) phosphate, (C) EPA and (D) ARA. One experiment from DeMott et al. (2004) was excluded, as close to zero growth on seston resulted in extremely high growth increases for *Synechococcus* and phosphate supplementation.

threshold food concentrations compared to *Daphnia* and rotifers of the same clone cultured at high food concentrations (Rothhaupt and Lampert, 1992). In *Daphnia*, such phenotypical adaptation is due to phenotypic plasticity, i.e., formation of larger filter areas and smaller mesh sizes of filters, which will allow them to filter a larger amount of water and smaller particles in a given amount of time (Lampert and Brendelberger, 1996). Likewise, phenotypic response to cyanobacteria can result in tolerance to cyanobacterial microcystins, e.g., via the regulation of transporter gene expression (Schwarzenberger et al., 2014). Microevolutionary adaptation of *Daphnia* to the presence of toxic cyanobacteria has been observed during two decades of lake eutrophication (Hairston et al., 1999), but also during one seasonal course of plankton succession (Schaffner et al., 2019). There is also clonal variability of *Daphnia* in respect to phosphorus (Weider et al., 2004) and PUFA limitation (Brzeziński and Von Elert, 2007), suggesting that *Daphnia* populations may also show microevolutionary responses to changes in seston C:P ratios or LC-PUFA contents. However, microevolutionary adaptation to lower food quality and quantity likely seems to involve costs when food is abundant and of higher quality, which prevents an evolutionary fixation of these traits. For example, lake oligotrophication resulted in a microevolutionary loss of *Daphnia* tolerance to cyanobacteria that had previously evolved over three decades of eutrophication (Isanta-Navarro et al., 2021).

Knowledge gaps and perspectives

1) Our understanding of nutrient limitations under controlled laboratory conditions has improved significantly in recent years. However, our understanding of zooplankton nutritional constraints *in situ* is still limited. We need more seston supplementation experiments in lakes of varying trophic state, degree of autochthonous production, and mixing depth to unravel the relative roles of food quality versus food quantity limitation, as well as the role of co-limitation of various food quality compounds. Such work may be accompanied by studies examining the nutritional phenotype (Frost et al., 2014), i.e., the molecular and biochemical status of experimental and sampled zooplankton in order to improve our ability to infer the strength and type of nutritional constraints *in situ*.
2) Our understanding of the role of temperature x food constraints interactions is still limited. Changes in both food quantity and quality requirements of zooplankton with temperature requires careful design of laboratory experiments to prevent hidden treatments. Likewise, field studies are needed which explicitly address the interaction between temperature and both food quantity and quality constraints on zooplankton.
3) Zooplankton will respond to nutritional constraints phenotypically, via maternal effects, and evolutionary. The relative role of these responses *in situ* for the mitigation of nutritional constraints is insufficiently understood.

4) Due to the central position of *Daphnia* in lake food webs and its suitability as a laboratory model organism, research on zooplankton nutritional constraints is primarily centered on *Daphnia*. More work on the nutritional constraints of other zooplankton taxa is urgently needed.
5) Finally, the availability of genomic information for aquatic consumers opens new avenues to explore the molecular basis of zooplankton responses to nutritional constraints and to link physiological responses to these constraints. Applying recently developed high-throughput" -omics" tools (transcriptomics, proteomics, metabolomics) to reveal molecular patterns of resource acquisition and exploitation at various environmental conditions may now rapidly advance our understanding of how zooplankton respond to nutritional constraints.

Predation on Zooplankton

Andrea Bertolo, Centre de recherche sur les interactions bassins versants - écosystèmes aquatiques (*RIVE*), Département de Sciences de l'Environnement, Université du Québec à Trois-Rivières, Trois-Rivières, QC, Canada

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie Elodie Perga and Damien Bouffard.

Glossary

Benthic Organisms living at the bottom of aquatic ecosystems.
Community In ecology is used to define an assemblage of interacting individuals belonging to different species at a given place or region.
Lentic Relative to freshwater systems lacking a directional current such lakes and ponds.
Meta-analysis Statistical approach allowing to make a global analysis of the outcome of different studies.
Phylogenetic Relative to the evolutionary relationships among living organisms.
Population In ecology is used to define an assemblage of individuals belonging to the same species at a given place or region.
Seston Pool of living (e.g. phytoplankton) and non-living particles (e.g. detritus) suspended in the open water.
Zoochory Dispersal mediated by animals.

Introduction

Freshwater zooplankton can be found in a wide array of habitats, ranging from temporary pools to permanent ponds and large lakes. Because of this variability and their relatively high dispersal potential, they are thus exposed to an extremely large range of environmental conditions including different levels of predation pressure from both vertebrates and invertebrates. Nearly all fishes have at least one early stage feeding on zooplankton and zooplanktivory is an essential step for most of them. In response to this strong selective pressure, zooplankton has evolved a large array of adaptations, ranging from changes in life-history traits to rapid anti-predator behavioral responses.

Predation has profound effects on zooplankton at many levels, from the individuals to the community. Examples of such effects include higher mortality of more conspicuous zooplankters, consequent changes in the size structure of both populations and communities, with potential effects on zooplankton diversity. These changes have the potential to affect both ecosystem functioning and the associated ecosystem services, because of the huge potential impact of zooplankton to graze phytoplankton. An increase in the predation pressure on large-bodied filter-feeding zooplankton could in fact translate into an increase of phytoplankton with negative consequences for the quality of the water (e.g. reduced transparency).

The aim of this chapter is to give an overview of the state-of-the-art of the studies about the mechanisms of predation itself, the effects of most widespread to less common predators feeding on zooplankton in inland waters and on the most important anti-predator adaptations found in the different zooplankton groups.

Planktivory

Feeding modes

Zooplanktivory has evolved in many orders of freshwater fishes (Lazzaro, 1987) as well as in many invertebrate taxa such as insect larvae (e.g. phantom midge and dragonfly), crustaceans (both carnivorous copepods and cladocerans), rotifers and even carnivorous plants (e.g. bladderwort). In both cases, zooplanktivory could be either facultative or obligate. In the case of invertebrates, besides the presence of some obligate predators (e.g. the rotifer *Asplanchna*), many cyclopoid copepods, for example, feed on algae and protozoa at the larval stage, but can predate on other zooplankters (including their own conspecifics) while still consuming large algae when adults. Whereas some specialized fishes such as paddlefish (*Polyodon spathula*) are obligate planktivores during their whole lifetime, many others are facultative because they can integrate zooplankton to their diet by switching, say, from zooplankton to benthic invertebrates depending on their relative availability. Ontogeny has another important impact on the ability of fish to capture prey since most species are gape-limited. Whereas zooplankton prey are relatively small for most adult fish, fish larvae might be constrained by gape-limitation to feed only on the smaller zooplankters. Thus, planktivorous fishes vary their selectivity and their potential effects on zooplankton during their ontogeny.

Most invertebrate zooplanktivores such as copepods and phantom midge larvae (*Chaoborus* spp. Diptera) are tactile predators which use mechanical stimuli produced by prey to locate and attack them. Tactile predators are grasping-feeders which capture and handle their prey with specialized appendages (Fig. 1D). As fish larvae, most are gape-limited and select relatively smaller

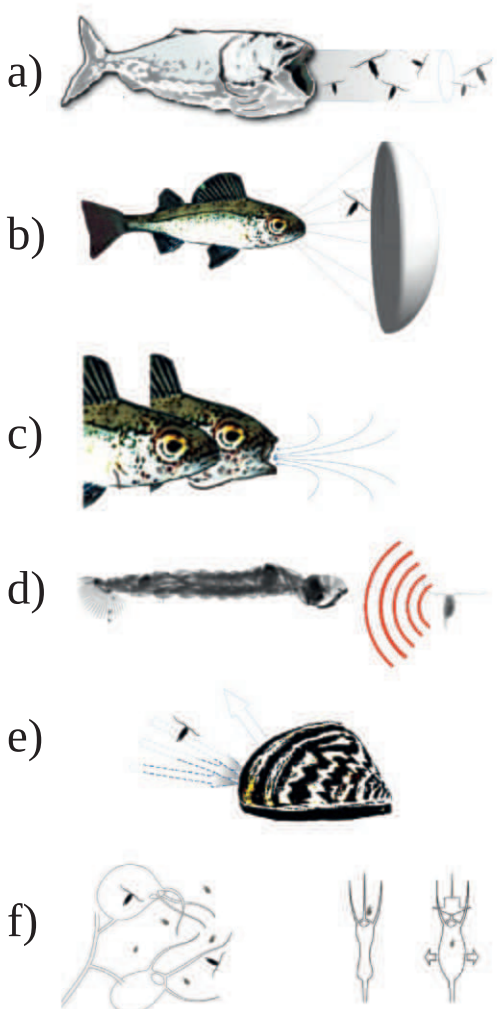

Fig. 1 Types of zooplanktivores. (A) Filter-feeder: the cylinder describe the "search volume"; (B) Particulate-feeder: the section of the sphere represent the visual field with the reaction distance (RD) represented by lines; (C) Particulate-feeder using its protrusible jaw to capture a prey; (D) Tactile predator: a phantom midge larvae reacting to the vibrations of a nearby zooplankton prey; (E) Current-feeder: a zebra mussel entraining in its current a small prey; (F) Trap-feeder: bladderwort. On the left are illustrated two bladders attached to the carnivorous plant, whereas on the right is shown a bladder before and after the prey's capture. (A) Based on a frame captured from a video online: Filter-Feeding Menhaden | Caught On Camera: https://www.youtube.com/watch?v=WhprcLcGGBs from: https://myfishingcapecod.com/filter-feeding/. zooplankton individuals compared to adult fish (Riessen, 2015). Benthic sessile organisms could also feed on zooplankton as shown by (i) current-feeders such as mollusk bivalves (e.g. zebra mussel) which can capture small zooplankters by entraining them with the continuous current generated by their ciliated gills (Fig. 1E) or by (ii) carnivorous aquatic plants (e.g. bladderwort) which use bladder-like traps activated by trigger hairs to capture and digest zooplankters and other small invertebrates (Fig. 1F).

Among planktivorous fishes, two different types of feeding are typically distinguished: particulate and filter feeding (Lazzaro, 1987; Fig. 1A and B). In the first case, fish predate on zooplankters by locating them visually and pursuing/attacking them individually. To increase their efficiency in particle capture, many teleost fish have evolved jaw protrusibility, which enhances their capacity of engulfing a relatively large volume of water in a very short lapse of time (Fig. 1C). Some filter-feeding fishes can use this mechanism to draw zooplankters into their oral cavity (pump filter-feeding), whereas others capture zooplankters by ram swimming with their mouth agape (tow-net filter-feeding) (Lazzaro, 1987) (Fig. 1A). In both cases, filter-feeders do not spot individual preys, but retain all the particles above a given size by using their gill rakers and other oral structures.

Whereas these structures were formerly thought to function as dead-end sieves (like a kitchen food strainer; Fig. 2A), it has been shown that the main water flow runs parallel, rather than perpendicular, to the filter surface, and that only small flows of water pass through the sieve openings (Sanderson et al., 2016; Fig. 2B). More recently it has been shown that the presence of closely-spaced small ribs in the fish oral cavity generate small turbulences at their backward-facing step which entrap particles and direct them toward the gut while reducing clogging to a minimum (Sanderson et al., 2016; Fig. 2B). Such mechanism, named "vertical cross-step filtration" has been demonstrated to hold for ram filter-feeding fishes such as paddlefish and is expected to work also for other filter-feeding organisms (Sanderson et al., 2016).

Whereas paddlefish represent a typical case of tow-net filter-feeding, its mode of detecting preys is peculiar compared to more common planktivores. This species uses in fact electrolocation to track zooplankton swarms when adult and individual zooplankters when juvenile. These latter use a particular mechanism of electrolocation named stochastic resonance, which could be seen as a form of enhancement of the signal-to-noise ratio when spotting a weak electrical signal emitted by an individual prey over a background of electrical white noise (as the one produced by a zooplankton swarm; Freund et al., 2002).

Several differences exist between particulate and filter feeding, including the geometry of the "search volume" of water within which the fish capture its prey. Whereas for filter-feeders such volume is the product of the distance traveled while ram-swimming agape by gape area, for particulate feeders this latter parameter is replaced by the fish visual field (Fig. 1A and B), which is function of the distance at which the fish detects its prey (the "reaction distance", RD; Eggers, 1977). Given that different factors such as predator species, prey size and light levels can affect RD (O'Brien, 1979), the efficiency of particulate-feeders has the potential to vary more with varying environmental conditions than that of filter-feeders, whose "searched volume" is mostly dependent on their anatomy and swimming speed. Whereas in both cases there is a certain degree of prey selectivity, visually-oriented particulate feeders are typically more selective, by eliminating efficiently more conspicuous individuals such as larger or more pigmented ones, together with those bearing eggs (Lazzaro, 1987; but see Gliwicz, 2002 for a more complete discussion).

Switching between the two feeding modes have been observed for certain fish species, either to adapt to ontogenetic changes or to cope with varying environmental conditions. The efficiency of zooplanktivores is in fact a function, among other things, of their feeding mode and of prey abundance. For example, the food intake of a typical filter-feeder is supposed to increase proportionally with zooplankton abundance for a given prey size (a so-called Type I functional response; Fig. 3). In contrast, particulate feeders are

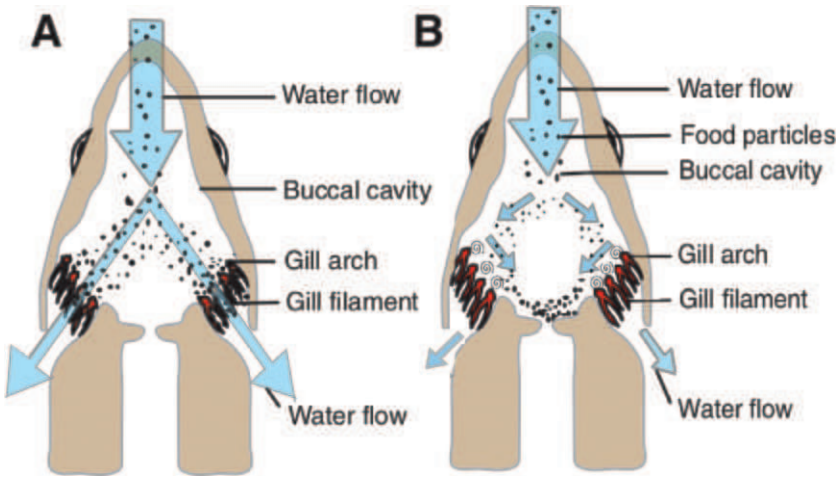

Fig. 2 Models of particle retention by filer-feeding fishes. (A) Dead-end sieve filtration. Particles are sorted by the filter formed by the branchial structures and then are directed toward the esophagus, with the mainstream flow running perpendicular to the filtering surface; (B) Vertical cross-step filtration. When the mainstream flow, which runs parallel to filtering surface, encounters backward-facing steps formed by gill structures it creates vortices which lead the water to pass between the gills, thus allowing particles to be retained without clogging the gills. Modified from Fig 1 in: Paig-Tran, E. M., Bizzarro, J. J., Strother, J. A., and Summers, A. P. (2011). Bottles as models: predicting the effects of varying swimming speed and morphology on size selectivity and filtering efficiency in fishes. *Journal of Experimental Biology* 214(10): 1643–1654.

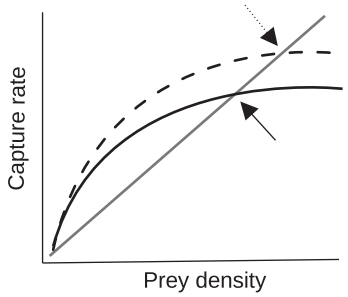

Fig. 3 Linear (type I; grey line) vs. asymptotic (type II; continuous black line) functional responses of predators to varying abundances of prey. Filter-feeding and particulate feeding conform, respectively, to types I and II functional responses. The black arrow indicates the point at which a switching is expected from particulate- (more efficient at low prey density) to filter-feeding (more efficient at high prey density) when prey density increases. By enhancing RD, increased light levels (and/or temperature) can push the switching point to the right (dotted arrow) by changing the shape of the type II functional response (dashed line).

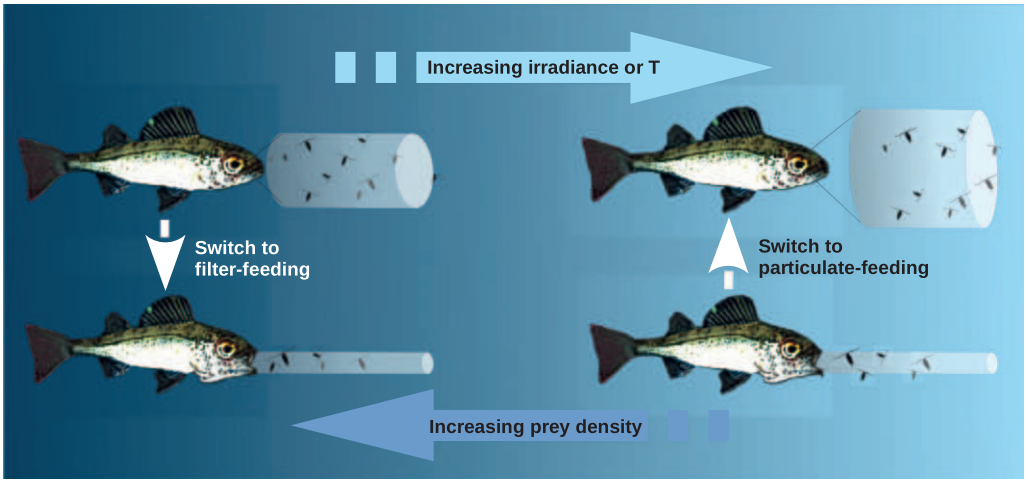

Fig. 4 Expected responses to light, temperature (T) and prey density of both particulate (above) and filter-feeders (below). In this simplified view, particulate feeders "scan" a conical portion of the water mass in front of them, characterized by a radius equal to the so-called "reaction distance" (RD), which increases with both irradiance and temperature. By moving forward, the fish detect and eventually capture individual zooplankters with directed fast pursuits aimed at the prey within an ideal cylinder of radius RD and of length S (the distance moved by the fish); As they move forward agape, filter feeders "scan" a cylindrical portion (the "search volume") of the water in front of them, with the radius of the cylinder determined by the gape width. The white arrows indicate the direction of the switch when either prey abundance or light levels/temperature change. Modified from Fig 2 in Stautland IT (2019). *Modelling the Switch between Bite-Feeding and Filter-Feeding in Planktivorous Fishes*. Master's Thesis. The University of Bergen.

more efficient than filter-feeders at relatively low prey densities, but become limited by prey handling time when prey abundance became too high, with their efficiency reaching a plateau (a so-called Type II functional response; Fig. 3). This could have important consequences not only on the issue of competition between particulate- vs filter-feeder species with varying prey abundance, but could also determine a switch between feeding modes in those species capable of a flexible feeding behavior (Fig. 4).

Effects of environmental factors on predation efficiency

Besides levels of visible light and prey abundance, other factors could affect predation efficiency on zooplankton. Ultraviolet radiation (UVR) has a potential role to play in this sense in clear-water systems, where it could improve the efficiency of those visual predators able to see in these wavelengths (Leech et al., 2009). By affecting light levels, turbidity is also expected to reduce the efficiency of visual predators. Despite in some cases the effects of visually-oriented zooplanktivorous fish have been shown to be similarly strong in clear vs turbid waters, a recent meta-analysis clearly showed that turbidity has clear negative effects on particulate-feeding fish in the majority of cases (Ortega et al., 2020). Surprisingly, the same study showed that filter-feeding fish were also negatively affected by turbidity, showing the potential weight that this driver can have on predator-prey interactions. All these results suggest together that the actual widespread human-driven increase in turbidity might have critical effects on predator-prey dynamics in lakes across large scales.

Temperature has also potential important consequences on predator-prey interactions since it can affect both encounter rates of zooplankters with predators (both vertebrate and invertebrate) and RD in particulate-feeders because of increased visual acuity.

Whereas in both cases an increase in temperature might cause an increase in predation risk for zooplankton, a recent experimental study has shown that warming can increase predation risk for zooplankton exposed to visual predator fish more due to increased RD than due to increased encounter rates (Gliwicz et al., 2018).

By increasing the structural complexity of the habitat and thus reducing fish attack rate, submerged aquatic vegetation (SAV) is also known to reduce predation risk for zooplankton. Therefore, SAV beds are key in maintaining both higher biomass and diversity of zooplankton in lakes. However, since SAV also offers shelter to large numbers of benthic invertebrate predators such as dragonfly larvae, these habitats are in some cases riskier than the open area and the relative risk of these two habitats should be considered when assessing predation risk for zooplankton.

Finally, the role of zooplankton behavioral traits should also be considered when predicting the outcome of predation since very large differences exists between taxa in their ability to flee predators and/or avoid encounter with them. Copepod nauplii, for example, are able to jump away very fast when a predator is approaching (speeds up to 130 body lengths sec-1) whereas slow-moving waterfleas (*Daphnia*) are easy targets. It has been shown that taking into account such traits can help explaining the outcome of predation on zooplankton by fish with different selectivity in freshwater ecosystems (Vincent et al., 2020).

The consequences of predation

From the individual to the community level

In ecology there has been a long-lasting debate about the relative roles of bottom-up (i.e. resource-driven) vs. top-down (i.e. predation driven) forces in determining both the success of individuals and the shape of the communities in which they are embedded. It is currently acknowledged that the interplay of predation and competition for resources can have profound effects on zooplankton, from the individual to both the population and community level (Gliwicz, 2002). Whereas their roles differ on prey populations, in both cases body size has been shown to be a key trait in determining their impact on zooplankton. This trait determines in fact both zooplankton vulnerability (larger individuals are more exposed to fish predators, while smaller ones are more exposed to invertebrate ones) and their efficiency as competitors (in most cases, larger zooplankters outcompete smaller ones because they better tolerate starvation).

Seminal work made in the 1960s revealed these huge effects that fish predation could have on zooplankton community structure in natural systems (Hrbáčkek et al., 1961). Selective predation by fish is in fact able to eliminate larger individuals/taxa, thus entirely re-shaping the zooplankton community (Fig. 5). In general, predation is considered to be responsible of zooplankton mortality at a higher degree compared to starvation, disease and parasitism whereas competition is expected to drive mostly the reproductive output and the efficiency of energy transfer from the base of the food web (Gliwicz, 2002). In a nutshell, whereas competition is expected to drive the rates at which processes take place, such as growth, birth, and food assimilation, predation is expected to control state variables such as abundance, body size and biomass, thus having a more visible impact on more easily measurable

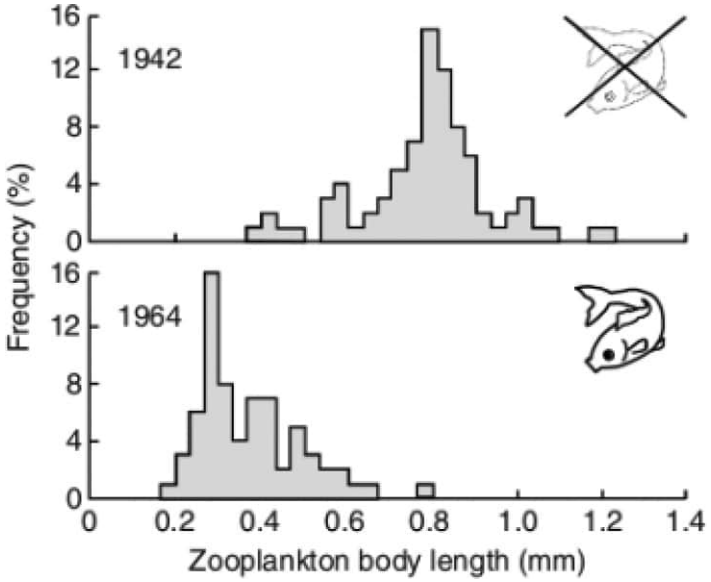

Fig. 5 Origin of the 'size–efficiency hypothesis': Large-bodied species, superior in competition for resources, dominate the zooplankton community in a lake in New England sampled in 1942 (top), but are absent in 1964 due to their inferiority in evading predation by a visually oriented planktivorous fish (bottom). The change in size distribution of the zooplankton occurred between 1942 and 1964, following the establishment of a landlocked population of *Alosa pseudoharengus* in the lake. Adapted from Fig. 4 in Brooks JL and Dodson SI (1965) Predation, body size and composition of plankton. *Science* 150: 28–35, with permission from the American Association for the Advancement of Science.

traits of the community (Gliwicz, 2002). The effects of competition can be seen among zooplankton taxa when predators are absent and food is limiting, where the lower food thresholds of larger zooplankters favor their dominance over smaller ones by increasing their birth rate relatively to the latter (Gliwicz, 2002). In the presence of predators, the effects of competition are not expressed at the level of population abundance since this latter is controlled by predation. It has been shown for example that a given level of predation usually leads to relatively stable abundances in zooplankton prey independently of food limitation (Gliwicz, 2002). The relationship between RD and prey size can help explain the fact that this effect seems to be size-specific. An individual fish can in fact perceive the abundance of a large zooplankton species as equal to that of a smaller, but more abundant one, simply because the RD for these latter is smaller, leading to an underestimation of their abundance relatively to the former (Fig. 6). Given that the mortality imposed by visual predators is proportional to the relative abundance of preys perceived by their retina, predation by a given size class of fish (of a given species) is expected to lead to species-specific prey abundances due to differences in their body size (Gliwicz, 2002).

In addition to body size, any other trait increasing conspicuousness of zooplankters are counter-selected in the presence of visual predators. Both pigmentation and the presence of eggs, for example, increase the vulnerability to visually-oriented predators. The presence of epibiotic organisms such as ciliates or euglenoids attached on zooplankton can also alter their conspicuousness exposing heavily burdened individuals to stronger fish predation. In general, transparency seems to have evolved in zooplankton to maintain a low conspicuousness to visual predators despite the varying degrees of contrast and lighting levels in the open water. Evasiveness also contribute to determine the issue of predation, with adult copepods and nauplii being less exposed to fish predation than slow-moving cladocerans such as large *Daphnia* (Vincent et al., 2020).

Both mesocosms and whole-lake experimental studies have confirmed the role of predation in shaping both taxonomic composition and size distribution of zooplankton communities. Thus, selective predation by fish tends to eliminate first the large bodied cladocerans such as large *Daphnia*, whereas smaller zooplankters (e.g. rotifers) suffer proportionally less mortality. The consequent release of competition allows these latter to increase in abundance and dominate the community in the presence of predators (Gliwicz, 2002). The combined result of size-selective predation and competition on zooplankton communities is known as the *size-efficiency hypothesis* (Brooks and Dodson, 1965; Fig. 5). The presence of invertebrate predators of zooplankton (themselves prey of fish) within the zooplankton community is expected to reinforce this pattern by exerting a selective predation pressure on small zooplankton when planktivorous fish are absent. However, some studies have challenged this view by revealing that in some cases invertebrate predators such as phantom midge larvae, carnivorous cladocerans such as spiny flea (*Bythotrephes longimanus*) and *Leptodora kindtii* can have unexpected strong impact on zooplankton, similar or even stronger than the one exerted by zooplanktivorous fishes (e.g. Walsh et al., 2017). The presence of such strong predators within the zooplankton community itself is thus key to understand the balance between vertebrate and invertebrate predators. Instead of taking into account only the presence/absence of fish, a more realistic view integrating gradients of fish predation pressure might give a more precise idea of the role of invertebrate predators in shaping zooplankton communities. This is shown for example in boreal lakes, where predation on zooplankton could result from unspecialized zooplanktivores fishes or from very efficient invertebrate predators such as large (>1 cm) predacious phantom midge larvae in fishless lakes. In many boreal lakes of Eastern North America, for example, the only planktivory from fish is due to the generalist brook charr (*Salvelinus fontinalis*), which exerts a relatively weak predation pressure on zooplankton, while it efficiently controls large-bodied phantom-midge larvae (e.g. Drouin et al., 2009). Within this context, predation pressure on zooplankton is larger in the absence, rather than in the presence of fish, as predicted by the classic paradigm, resulting in an increase in zooplankton body size distribution from fishless to fish lakes (Fig. 7).

Resilience to predation of zooplankton communities

Short-term variations in predation pressure are commonplace in freshwater systems due for example to the seasonal synchronization of fish hatching in temperate lakes. Whereas an increase in predation pressure can have rapid effects on zooplankton communities, the reverse might take more time. Despite short generation times and plasticity in anti-predator defenses can allow

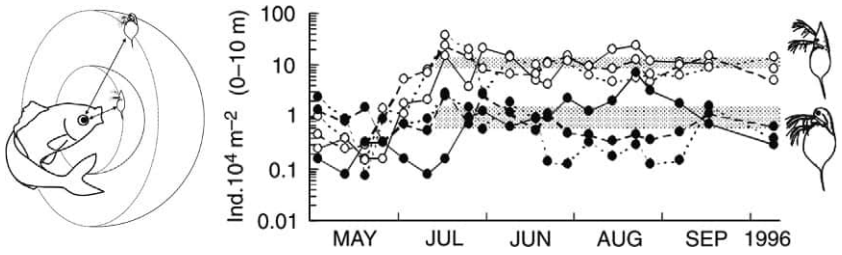

Fig. 6 Diagrammatic representation of the differences in reaction distance (RD) for two *Daphnia* species differing in body sizes (left panel) and the temporal evolution of their population densities in a lake with a visual planktivorous fish (right panel). Despite the fact that the smaller prey species has a larger population abundance (right panel), the smaller reaction distance of this species relatively to the larger one (left panel) leads to the perception of similar abundances by their common predator. This latter thus exert a stronger pression on the largest species despite its lower abundance, thus stabilizing the population abundance of the two species at different population densities. From (Left) Fig 9 and (Right) Fig 8 in Gliwicz MZ (2002) On the different nature of top-down and bottom-up effects in pelagic food webs. *Freshwater Biology* 47(12): 2296–2312.

zooplankton to cope with transient regimes of predation, it has been showed that planktivorous fish, even if present only for a short period of time, can have long-lasting effects on zooplankton communities (Ersoy et al., 2019). Several studies had in fact showed that, when re-colonization is limited because of depletion of the resting stage (e.g. eggs) bank in the lake sediments, the recovery from the effects of predation might take several years. The consequences of resting stages depletion might be particularly important for copepods since these crustaceans reproduce only sexually and have to find a mate to rebuild a population, which could be limiting at very low population densities. In contrast, cladocerans, which are able to go through either sexual or asexual reproduction, can re-build a population faster by reproducing clonally. Because of the high dispersal potential of their flying adult stages, key invertebrate predators such as phantom midge larvae can overcome these limitations and easily recolonize lakes and ponds after fish removal without being dependent on recruitment from resting stages banks.

Positive effects of predation on zooplankton populations

Whereas fish can impose a severe mortality on zooplankton populations, they can have at the same time both direct and indirect positive effects on them. In addition to induce an earlier reproduction in many zooplankton species (see below), which could compensate for the toll imposed by predation, the overall reduction of zooplankton grazing on phytoplanktonic algae translates into a reduced competition and overall greater availability of resources for herbivorous zooplankton itself. Therefore, by releasing competition for the resources, predation can lead to higher growth and fecundity rates and thus increase the zooplankton reproduction potential. Moreover, many zooplankton species have eggs with thickened shells (e.g. ephippia in cladocerans) whom have been demonstrated to be resistant to digestion in the fish gut. Since females bearing dark pigmented ephippia are more conspicuous, they suffer heavier predation from visually-oriented fishes which could also mean that they are potentially dispersed more easily by these latter across the watershed. Unfortunately, invasive species also benefit from this adaptive mechanism (a form of zoochory) as have been demonstrated for the spiny water flea (*Bythotrephes cederstroemi*), an invasive predator cladoceran introduced recently in North America (Taylor Jarnagin et al., 2000). Since these invertebrate predators can have themselves profound impacts on the zooplankton communities, the net effects of this predation-mediated dispersal on the zooplankton community are difficult to predict.

Food-web and ecosystem level

Cascading effects on primary producers

Since the 1960s the idea that consumers can control the biomass of primary producers has sparked interest for the role of predation in the functioning of the ecosystems (Hairston et al., 1960; Brooks and Dodson, 1965). The "green world hypothesis" (Hairston et al., 1960), for example, suggested that the biomass of plants in our planet is high because herbivores are controlled by predation (a so-called *"trophic cascade"*). Applied to lakes, the basic idea is that (i) planktivores can trigger an increase of phytoplankton by

reducing the biomass of filter-feeding zooplankton such as large *Daphnia*, and (ii) piscivorous predators can reverse this pattern by reducing the abundance of planktivorous fish. Based on these simple ideas, the biomanipulation concept became thus popular in the 1980s, when numerous attempts have been made to control the effects of eutrophication by the manipulation of the biomass of planktivorous fish. At the end of the 1990s it has been demonstrated that these effects are effective in the medium term (<10 years) but that in the long term they have to be accompanied by a reduction of nutrient sources to be maintained (Hansson et al., 1998).

This area of research attracted since then a large interest, stimulating theoretical work together with experimental approaches at both the mesocosm and the whole lake level. Whereas the simplest form of the trophic cascade hypothesis is based on a linear food chain rather than a more realistic food web and does not take into account the full realism of aquatic communities and lake ecosystems, many studies gave support to its overall predictions, suggesting that in many cases the trophic cascade concept is a heuristics which can help explain natural patterns in many lake food webs despite it fails to take account some key biotic interactions.

Effects on the biogeochemical cycles

Predation could also affect element cycling (e.g. C, N and P) via its impact on zooplankton grazers. The increase in phytoplankton primary production following an increase in predation on zooplankton has for example the potential to affect the carbon cycle. Whereas many oligo-mesotrophic boreal lakes tend to be net sources of carbon to the atmosphere since they receive relatively large amounts of carbon of terrestrial origin, an increase in pelagic primary production can shift the balance between autotrophy and heterotrophy and cause them to be net sinks of carbon of atmospheric origin (Schindler et al., 1997). This effect might be seen as somewhat counterbalancing the negative effects of planktivores on water quality due to a trophic-cascade from grazers to phytoplankton.

Another potential intriguing effect of predation on zooplankton might be mediated by the relative ability of different zooplankton taxa in retaining and recycling different nutrients. Freshwater zooplankton is in fact known to have the potential to modify the stoichiometry of the seston because their needs in terms of C, N and P differ among species. *Daphnia* and Copepods have a very distinct stoichiometric composition, with the former being more P-enriched than the latter (lower C:P and N:P ratios; Fig. 8A). Given that the seston in lakes is typically enriched in both C and N relatively to P, this food source is imbalanced relative to the *Daphnia* nutritional demands (Fig. 8A), suggesting a potential P-limitation for this key zooplankter relative to copepods. Therefore, in *Daphnia*-dominated systems, not only phytoplankton is under a stronger top-down control than in copepod-dominated systems, but there is also a potential consumer-driven P-limitation due to a reduced recycling of P relative to N by *Daphnia*. Therefore, the tendency of *Daphnia* to sequester relatively high amounts of P to maintain its homeostasis could contribute to maintain low phytoplankton biomass via nutrient limitation. In lakes, phytoplankton growth has been showed to shift from P- to N-limited when the zooplankton community shifts from *Daphnia* to copepod dominance (Sterner and Elser, 2002). It has been showed (Sommer and Sommer, 2006) that such stoichiometric effect of predators is less likely to occur in marine systems because the difference in N:P ratio between seston and grazers does not suggest nutrient imbalance (Fig. 8B). Since body size is another factor potentially affecting nutrient recycling, fish predation can have an additional potential effect on this ecosystem property by shaping the size structure of the zooplankton community. Since smaller organisms have relatively higher metabolic rates per unit biomass than larger ones, the elimination of larger zooplankters by selective predation should increase the potential of the zooplankton community to recycle nutrients.

Predation can also affect the transport of nutrients by zooplankton organisms moving across habitats (e.g. taxa performing vertical migrations) and across ecosystems (e.g. planktonic larvae of emergent aquatic insects). By reducing the numbers of planktonic phantom midge larvae, for example, fish predation has the potential to reduce the cross-ecosystem export of essential fatty acids from aquatic to terrestrial systems (Martin-Creuzburg et al., 2017). It is in fact known that preys of aquatic origin may

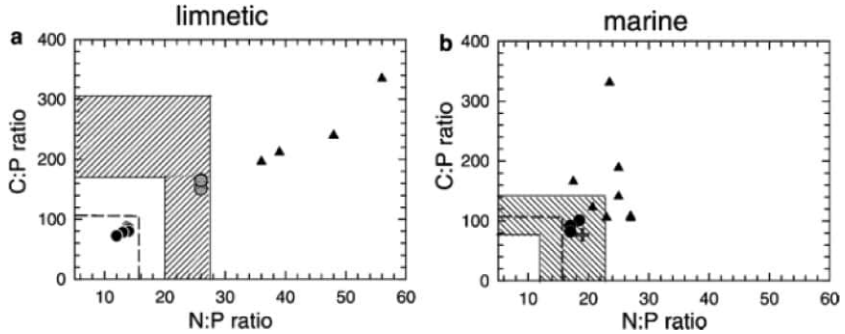

Fig. 8 Stoichiometry of zooplankton and seston in freshwater (A) and marine (including brackish water) systems (B). Hatched area: range of mean values for seston stoichiometry; broken line areas represent mean values for zooplankton and seston, respectively. Broken line represents the Redfield ratio (C:N: $P = 106:16:1$), which is the average elemental ratio consistently found in many phytoplankton species and is often assumed as a reference; Zooplankton symbols: (A) black circles *Daphnia* spp., grey circles *Bosmina* spp., triangles copepods. (B) Circles *Evadne* spp., triangles copepods, cross *Oikopleura dioica*. have superior food quality for terrestrial consumers given their high content in good quality poly-unsaturated fatty acids (PUFA). Moreover, predation, by forcing some zooplanktonic organisms to move between the hypolimnion to the epilimnion (see below), could increase their potential to transfer nutrients and contaminants from one habitat to the other, as it has been demonstrated for methylmercury transported from the bottom to the top of the water column by migrating *L. kindii* (Hall et al., 2020).

Anti-predator defenses

Constitutive vs inducible defenses

In response to the strong selective force represented by predation, zooplankton have evolved a large array of anti-predator defenses, either constitutive (i.e. fixed over ecological times) or inducible (i.e. plastic). Within the former category we could cite the fact that (i) some species evolved long spines or gelatinous sheaths reducing their vulnerability to predators without increasing their conspicuousness (e.g. the spiny flea and *Holopedium* spp.;), (ii) most zooplankters have evolved body transparency, (iii) the life cycles of some taxa include a period of suspended development which allows them to avoid the pelagic habitat (e.g. the diapause allows some copepods to stay buried in the sediments during long periods) or (iv) the strong swimming abilities of some zooplankters allowing them to flee when a predator is attacking (e.g. copepod nauplii). Besides these relatively fixed traits (some of them might eventually be modulated in response to varying predation risk), other anti-predator defenses are expressed only in the presence of a cue from a predator. Among freshwater zooplankton species we have the most striking examples of inducible defenses such as changes in morphology, pigmentation, life-history traits and behavior (e.g. Kruppert et al., 2017; Ekvall et al., 2020). This phenotypic plasticity likely reflects the need for these organisms to rapidly respond to the potentially varying predation risk found in freshwater ecosystems.

Induced anti-predator morphological defenses have been largely studied in freshwater zooplankton boosted by the demonstration that cyclomorphosis (i.e. a seasonal variation in body shape), a widespread phenomenon known in limnology since the 19th century, was not due to seasonal variations in abiotic variables as previously thought, but to a varying predation pressure on certain zooplankters such as some rotifers (e.g. *Keratella* and *Brachionus*) and *Daphnia* spp. (Diel et al., 2020).

Not only it has been demonstrated that these morphological changes are adaptive in a context of a varying predation pressure, but also that they are mediated in most cases by chemical cues ("*kairomones*") released by the predators. For example, chemical cues released by phantom midge larvae have been shown to induce variations in both body shape and carapace stiffness in *Daphnia* (Kruppert et al., 2017). By interfering with predator efficiency in capturing and handling prey, respectively, these changes have the potential to reduce *Daphnia* vulnerability to its predator. Some *Daphnia* species can reduce the predation by tactile predators such as tadpole shrimps (*Triops cancriformis*) by inducing a "crown of thorns" (Petrusek et al., 2009) whereas others develop a "neckteeth" in response to phantom midge larvae (Kruppert et al., 2017). Among the inducible defenses observed in *Daphnia*, there is also the first case mentioned that the bilateral symmetry by *D. barbata* in the presence of tadpole shrimps is abandoned. The so-obtained twisted carapace is thought in fact to interfere with the feeding apparatus of this benthic predator and reduces its efficiency in handling prey (Herzog et al., 2016). More common examples include the formation of spines or "helmets" to reduce capture rate by gape-limited predators (Lass and Spaak, 2003).

A phenomenon similar to what was found in *Daphnia* has been observed with *Holopedium glacialis* (*H. gibberum*) whose gelatinous sheath embedding its carapace (ca. 2–3 times larger its body length) can significantly increase in size when exposed to phantom midge larvae (Stenson, 1987). Given the transparency of the gelatinous sheath, this strategy reduces predation from gape-limited tactile predators while not increasing conspicuousness to visual predators. This example in interesting since the gelatinous sheath could have also a role in reducing prey palatability by diluting prey nutritional quality due to the high water content of the sheath, thus probably reducing its attractiveness to predators. Besides this, there are only few examples of reduced palatability or use of distasteful/toxic substances in freshwater zooplankton.

One of the most studied case of behavioral anti-predator defense in freshwater zooplankton is the diel vertical migration (DVM) which is considered one of the most massive migration phenomena on earth. When performing DVM, individuals spend the night feeding in surface waters and descent to deeper (and colder) waters at dawn to avoid predation and/or UVR risk in well lit-waters (Diel et al., 2020). The opposite pattern is also known in some taxa (inverse DVM) and it is probably due to invertebrate predators such as phantom midge larvae performing DVM in the presence of fish (Diel et al., 2020). State-of-the-art labelling techniques based on fluorescent nanoparticles have recently allowed to follow experimentally the behavioral response of individual zooplankters to kairomones from different predators in the laboratory. This innovative approach showed that *Daphnia* spp. can adjust both their swimming speed and their vertical position in the water column depending if the predation risk was due to a fish (cyprinid) of from an invertebrate (dragonfly larvae) (Ekvall et al., 2020).

Costs of induced defenses

Whereas the reversibility of induced defenses in the absence of predators is usually used as a demonstration of the presence of a cost of predator-induced phenotypic plasticity, direct estimation of such costs is not always straightforward to obtain. The costs associated to non-consumptive effects of predators via changes in prey behavior (e.g. DVM) can be understood as the consequences on fitness associated with the use of sub-optimal habitats. For example, the lower temperature found in the refuge from predator relative to the feeding habitat could cause a reduction in growth and reproductive rates, with potential large consequences in terms

of population abundance, as shown from both laboratory and time-series studies on natural systems. Another potential cost associated with the use of sub-optimal habitats is an increased disease risk, as it has been shown for *Daphnia* because of an increased risk of encountering parasites such as fungi when migrating to bottom layers (Decaestecker et al., 2002). Other trade-offs concerning anti-predator defenses deserves attention, such as those cases involving multiple predators. Whereas in some cases prey may experience a net benefit in terms of mortality if different predators interfere with each other, it is possible that adopting a given induced defense for a given predator would increase its predation risk relative to other predators. This has been suggested for zooplankton performing DVM in the presence of both vertebrate and invertebrate predators (Fiksen et al., 2005). Given that many anti-predator induced defenses are often specific to one or few predators, it cannot be excluded that the overall predation rate from multiple predators could be higher than could be predicted by summing the predation rates estimated for each predator separately.

Demonstrating the cost of other types of defenses (e.g. morphological) has been proven more challenging since the direct cost associated to forming and maintaining a given morphological defense might be only a minor part of the total cost a prey has to assume. In some cases, changes in life-history traits are necessary for the defense to be effective, thus changing the total cost for the prey.

Freshwater vs marine zooplankton

Whereas freshwater and marine zooplankton share many features, some of their specificities are helpful to understand their differences in terms of response to predators. One of the differences between freshwater and marine zooplankton concerns the relative broader phylogenetic spectrum of organisms found in marine systems relative to inland waters. Moreover, marine zooplankton is composed of both taxa spending their entire life cycle in the pelagic realm (the so-called "holoplankton"; e.g. ctenophorans) and, to a large extent, to taxa such as mollusks and sponges spending only their larval phase as planktonic organisms (the so-called "meroplankton") but their juvenile/adult phase as benthic organisms. In freshwaters, only some organisms such as the larvae of trematodes (miracidia and cercariae) and of some mollusk bivalves (e.g. zebra mussel veligers) are considered as equivalent to marine meroplankton.

Whereas freshwater systems lack many of the predaceous taxa that consume zooplankton in marine systems, such chaetognats and jellyfish (whereas insects, well represented in freshwater systems, virtually are lacking in the marine ones), the relative proximity of the pelagic realm to the littoral zone (due to relatively small size of most inland systems) implies an increased likelihood for zooplankton to be predated by carnivorous benthic organisms such as dragonfly larvae, backswimmers and even carnivorous plants.

Plasticity in anti-predator defenses is apparently less present in the marine realm, where zooplankton communities are exposed to less variable predator regimes. Marine zooplankton is known to adopt non-plastic morphological (spines), nutritional (gelatinous bodies or sheaths) and behavioral (DVM) adaptations to predation. The fact that meroplankton is relatively more abundant in marine relative to freshwater zooplankton probably explains partly this difference. The diversity of freshwater zooplankton is in contrast due nearly entirely to holoplankton, within which phenotypic plasticity in response to predation had probably more occasions to evolve.

The presence of highly efficient and plastic grazers such as *Daphnia* itself (and cladocerans in general, relatively rare in the marine realm) is another peculiarity of the freshwater lentic ecosystems, which could explain why the impact of herbivory on phytoplanktonic algae is particularly strong in freshwaters relative to the marine systems, whose holoplankton is dominated by calanoids copepods.

Conclusion/synthesis

The results of a vast body of research had illustrated many aspects of how predation can shape zooplankton populations and communities. Understanding the differences between types of predators is not only relevant to those interested in natural history, but has deep consequences to forecast for example the impact of a given predator on a natural freshwater system and its water quality. Moreover, studying the strategies adopted by freshwater zooplankton to cope with the pervasive effects of predation allows not only to refine our predictions about the impact of this key biotic factor, but also offer a glimpse on the extraordinary complexity of the evolutionary solutions adopted by zooplankton to reduce the toll of predation.

Knowledge gaps/*future needs*

- Better understanding of the interactions between predation and other environmental factors (e.g. UV radiation risk).
- Direct and indirect costs associated to inducible defenses.
- Better taxonomic resolution of functional traits relevant to predation other than body size.

Nomenclature

a	Relative cost of producing new individuals to replace those lost through mortality
$\mathbf{B}$	Total population biomass
$\mathbf{B_j}$	Biomass of new individuals that recruit to the population at age j
$\mathbf{E}$	Mean activation energy of cellular respiration
$\mathbf{g}$	Instantaneous rate of biomass increase, includes both somatic growth of existing age groups and recruitment of new individuals to the youngest age group
$\mathbf{i_0}$	Normalization constant
$\mathbf{k}$	Boltzmann constant
$\mathbf{K}$	Population carrying capacity
L_{act}	Population rate of energy expended on interactions with the environment
$\mathbf{L^a_{act}}$	Population rate of energy expended on attacking prey
$\mathbf{L^s_{act}}$	Population rate of energy expended on searching for prey
$\mathbf{L_{inf}}$	Asymptotic length
$\mathbf{L_m}$	Population rate of energy expended on basal maintenance costs
$\mathbf{L_R}$	Population rate of energy loss to propagule (eggs/sperm) release
$\mathbf{L_z}$	Population rate of energy loss to mortality
$\mathbf{M_{ind}}$	Individual metabolic rate
$\mathbf{M_{pop}}$	Average routine metabolic rate of individuals in a population that is at its carrying capacity.
$\bar{N}_i$	Average abundance of a cohort over its $[i+1]^{th}$ year of life.
$\mathbf{P}$	Tissue production
P_{cc}	Production of a population at its carrying capacity.
P_F	Population rate of energy acquired from foraging
$\mathbf{P^{max}_{\varepsilon}}$	Maximum rate of energy acquisition
P_{ε}	The rate of energy flow from the environment through a population
ρ_F	Proportion of energy available in forage that is acquired by population members

☆*Change History:* January 2022. BJ Shuter updated every section in this chapter. Figs. 2,5, and 7 have been updated.

ρ_R	The degree to which the energy of propagules released to the environment is augmented, over early life, to generate the energy of older individuals recruiting to a population.
R	Population rate of energy acquired from addition of newly recruited individuals
r	Proportion of adult body weight that is released as propagules at each breeding period.
s	Relative cost of synthesizing somatic tissue
t	Time
T	Environmental temperature (°K)
W_i	Weight of an individual
$\bar{W}$	Mean weight of individuals in a population that is at its carrying capacity.
$\mathbf{W_{ind}}$	Individual somatic weight
$\mathbf{W_{inf}}$	Asymptotic weight
z	Instantaneous mortality rate; rate of biomass loss through mortality.

General introduction

Freshwater fisheries are essential economic, cultural and subsistence resources in many countries around the world, with freshwater fish harvests supplying enough food protein for an estimated 158 million people globally (McIntyre et al., 2016; Funge-Smith and Bennett, 2019). It has long been recognized (e.g., Leach et al., 1987) that sustainable harvests are determined by the capacity of natural populations to produce new biomass—their rates of biomass production. Historically, fisheries conservation was achieved mainly through focused efforts on fisheries regulation. More recently, the negative effects of anthropogenic stresses (i.e., climate change, habitat degradation, pollution, invasive species) on the fundamental processes supporting the viability of fish at both the individual and population level have been recognized, leading to an expansion of conservation efforts to include protection of both the quantity and quality of fish habitat (Sass et al., 2017).

Fishes are dynamic in time and space. They are influenced by a range of species-specific abiotic and biotic factors and require a minimum amount of usable habitat to be viable, resulting in both population abundance and production varying directly with the quantity and quality of available habitat (Fig. 1). Countries like Canada have recognized legislatively that the productivity of fish populations and communities are inextricably linked to habitat availability and have implemented policy requirements and

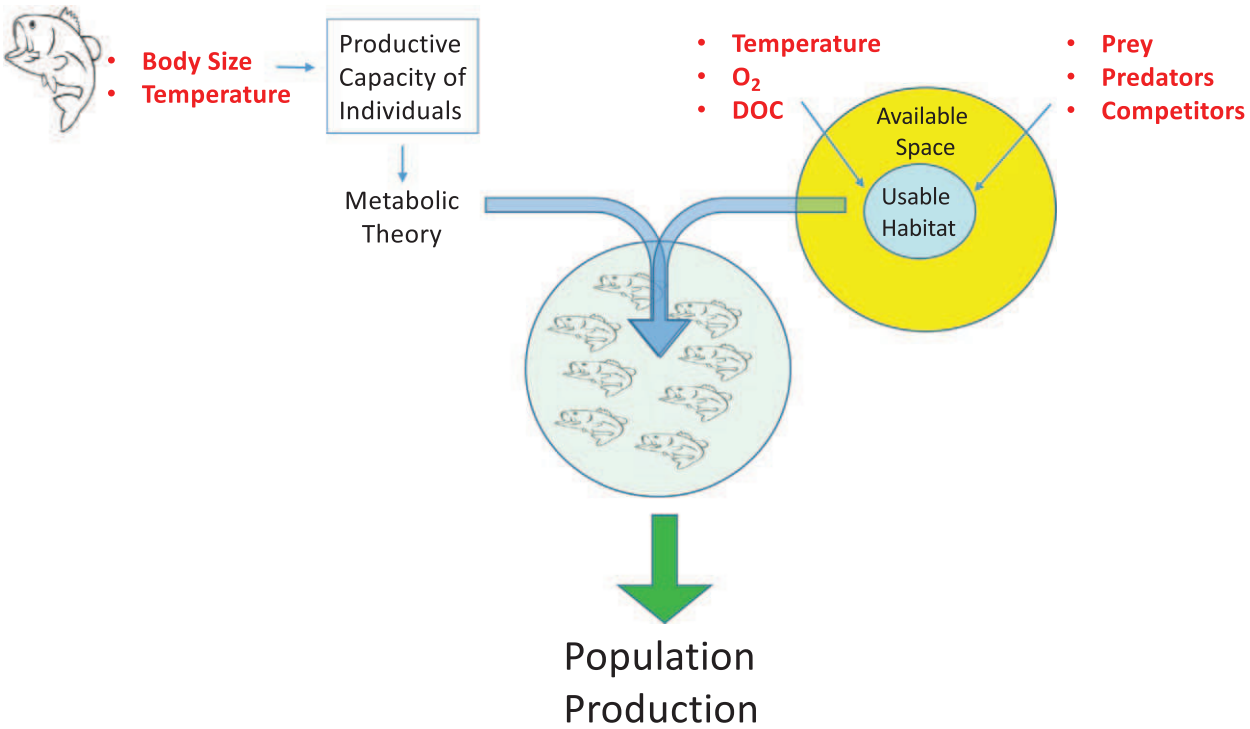

Fig. 1 Body size and temperature preference are the dominant traits that determine the capacity of an individual from a particular species to synthesize new biomass from its environment. The physical space available (e.g., lake size, river width/length) sets an upper limit on realized production. The degree to which realized production reaches that upper limit is determined jointly by the fraction of the available space that is usable as habitat by the target species, and the "quality" of that habitat space. This, in turn, is determined by: (i) the abiotic characteristics of the available space that define the fraction of that space that is usable = the relative amount of space that supports tolerable temperatures and water chemistry for the target species; (ii) the degree to which abiotic conditions in the usable space match species-specific optimal performance traits = the quality of the usable habitat (iii) the relative abundance of prey, competitors and predators that inhabit the usable habitat.

scientific approaches that focus on sustaining production through habitat conservation using regional productivity benchmarks (DFO, 2016). However, the effectiveness of this approach hinges on developing a sound understanding of the environmental and ecological forces that shape the productivity of freshwater fish populations in their natural environments. Currently our understanding of these forces is limited, due mainly to the time and cost of the field studies required to quantify how production varies among wild populations of limnetic and riverine fish.

Production at the population level is defined as the amount of tissue elaborated in the population over a time period (Δt), regardless of whether that tissue survives to the end of that period (Waters, 1977). Production is expressed as biomass elaborated per unit space per unit time (e.g., kg ha^{-1} year^{-1}). It is determined by the three separate processes that add or subtract new biomass to that segment of the population (i.e., typically older juveniles to the oldest adults) that can be accurately tracked with existing technologies. Those processes are (i) tissue growth, which causes the weight of existing population members to increase from W_t to $W_{t+\Delta t}$; (ii) reproduction, which causes new individuals to recruit to the population as members of the youngest observable group; and (iii) mortality, which causes the number of older population members to decrease. We illustrate the fundamental way in which these separate processes interact to generate production as follows. Assume that: (i) the overall increase in population biomass, associated with both tissue synthesis and reproduction, can be approximated by a single value (g) representing the instantaneous fractional rate of biomass increase; and that (ii) the loss in population biomass associated with mortality can be approximated by a single value (z) representing the instantaneous fractional rate of biomass decrease. Therefore, the instantaneous rate of change in biomass (dB/dt) can be expressed as:

$$\mathrm{dB/dt} = (\mathrm{g} - \mathrm{z}) * \mathrm{B} \tag{1}$$

and the production generated over the interval Δt equals (see Gillespie and Benke, 1979 for a demonstration):

$$P_{\Delta t} = [B_{t+\Delta t} - B_t][\mathrm{g}/(\mathrm{g} - \mathrm{z})] \tag{2}$$

where B_t is the initial biomass density (kg ha^{-1}) at time t.

For a population at its carrying capacity (i.e., B is constant and therefore $\frac{dB}{dt} = 0$), growth (including both tissue synthesis and recruitment) and mortality rates must be equal and therefore, $g^*B = z^*B$, from Eq. (1). While Eq. (2) is undefined for $g = z$, Gillespie and Benke (1979) demonstrated that, P_{cc}, the production of a population at its carrying capacity, can be computed as

$$P_{cc} = g * B = z * B \qquad \text{when } (\mathrm{g} - \mathrm{z}) \to 0 \tag{3}$$

In nature, g and z are dynamic and sensitive to changes in both environmental conditions and population biomass. However, Eq. (3) should hold, provided B, g and z vary randomly around relatively constant mean values.

Ideally, production estimates are based on extended time series of comprehensive demographic information (i.e., abundance, biomass, growth and mortality; Dolbeth et al., 2012; Rypel et al., 2015) and hence are logistically demanding. However, the high value of population production estimates compensates for their cost since: (i) they provide direct measures of the degree to which individual populations extract energy from their supporting ecosystems (Downing et al., 1990; Downing and Plante, 1993); (ii) they provide indirect measures of sustainable harvest at the population level (e.g., Leach et al., 1987); and (iii) they provide the empirical basis for advancing our understanding of the forces that drive variation in production in the natural world (Downing and Plante, 1993). This last role is of value since it is fundamental to the development of new and better models for predicting the responses of production both to environmental changes, and to the management actions designed to mitigate those changes. In this chapter, we begin by first reviewing the standard methods used to estimate production in the field. We then go on to (i) review the fundamental bioenergetic processes that support production at the population level, (ii) summarize current knowledge regarding the sensitivity of those processes to changes in both abiotic and ecological conditions, (iii) identify recent methodological advances that promise to increase the precision and accuracy of production estimates, and (iv) suggest promising directions for increasing our knowledge of how production is determined in the wild.

Estimating production

Traditional methods

Production is typically estimated first within a given size-class or age-cohort. These results are then aggregated across classes or cohorts to give an overall estimate of production for the population or community of interest. A variety of estimation methods exist and the choice of method is largely dictated by the data available to calculate the estimate. In the simple situation where age-specific growth and survival rates are constant over time, the following elaboration (patterned after Benke and Huryn, 2017, assuming a time unit of 1 year) of Eq. (1) captures the basic information alluded to, or directly used, in all of these methods:

$$P = B_j + \sum_{i=j}^{i=n} \overline{N_i} * \Delta W_i \tag{4}$$

where:

- P is the production of new biomass generated by the entire population over 1 year,
- $\{j,n\}$ is the range of ages for which both abundance ($\overline{N}_i$ = the average abundance of a cohort over its $[i + 1]^{th}$ year of life) and size at age (W_i and $\Delta W_i = [W_{i+1} - W_i]$) are known, and
- B_j is the biomass of new individuals that recruit to the population when they reach age j.

If $j = 0$, then this equation provides an unbiased estimate of production for the entire population. If $j > 0$, then B_j represents the accumulated tissue growth of individuals surviving from age 0 to age j; this equals the annual production of those age groups only in the unrealistic situation where all individuals survive from age 0 to age j. In the real world, where significant mortality occurs in early life, B_j underestimates the production of early age groups and thus P is underestimated. If B_j is omitted from the result, then P is an unbiased estimate of production over the age range $[j, n]$: the range of ages that can be effectively monitored. If the growth and mortality rates for a population are relatively constant over time, data from a point-in-time sample can be used in Eq. (4) to estimate the value of P that is typical for that population. If growth and mortality rates vary widely from year to year, consecutive annual samples are required to provide the year-specific estimates for $\bar{N}_i$ and ΔW_i that are needed to generate annual values for P over the time interval of interest. When applying any of the methods listed in Table 1, sampling programs need to be designed to minimize the biases in estimates of both $\bar{N}_i$and ΔW_i that typically arise from such factors as size/age selectivity of sampling gear, variation in sampling efficiency across habitat types, life cycle complexity (e.g., migration or developmental changes in habitat), and, consequently, the completeness of sampling coverage of the population or community of interest.

While production estimation methods follow the basic concepts outlined above, accepted methods in the literature for calculating production estimates vary based on the data available. The Instantaneous Growth Rate (IGR) method (see Table 1) remains the most widely accepted and popular method for production calculations due to its greater precision. However, the price for this precision is the high data demand of the method (Hayes et al., 2007). While the size-frequency method is based on length-classes and does not require aging data, it too requires at least two consecutive sampling periods to calculate a single estimate. Older and less frequently used methods include the Allen curve and Summation (Removal and Increment) methods. The Allen curve is a graphical extension of the IGR method and is based on cohort-specific growth-survivorship curves. However, it is rarely implemented now because it lacks a variance estimator. Summation methods are based on estimates of the gain or loss of tissue by a population over time: removal summation focuses on estimating the loss rate of individuals, while increment summation focuses on estimating the tissue growth of individuals. Variance estimators for the removal summation method are also unavailable (Hayes et al., 2007). There are numerous worked examples for each of these methods in the literature, and a selection for each is listed in Table 1.

Recent refinements

Five of the seven methods listed in Table 1 require characterization of the life-time growth patterns of typical population members. Growth is a sensitive component of production estimates that offers insight into the state of a population. However, growth

Table 1 Overview of fish production calculation methods, examples, and data requirements.

calculations within production estimation methods are often a significant source of error. Error introduced through growth calculations can arise from the under-sampling of age groups that is common in fisheries surveys: when few (e.g., <5) individuals are captured, weight data for age-cohorts or size-classes will be quite inaccurate. By replacing estimated weights for under-sampled age classes with predicted weights from growth curves fitted to individual cohorts, error will be reduced and the overall precision of production estimates will be increased.

Additional refinements include a simplified IGR method from Embke et al. (2019) that allows for the calculation of production estimates without consecutive annual measurements, while incorporating biomass lost to harvest. However, this method relies on simplifying assumptions that should be recognized (i.e., subsamples of ages and lengths determine relative age-class densities; age-specific mean weights are determined from ecosystem specific age-length keys). This method offers the opportunity to explore conservative "snap-shot" estimates of production based on limited data, particularly from harvested populations.

The bioenergetics of fish production

Seminal empirical work has shown that freshwater fish production is correlated with total phosphorus, primary production (Downing et al., 1990), standing biomass and mean body-mass of fishes, annual mean air temperature, latitude, and species richness (Downing and Plante, 1993). Since these associations are largely consistent with expectations generated from the Metabolic Theory of Ecology (MTE: Brown et al., 2004; Savage et al., 2004), we will use the MTE explicitly in our account of how individual-level bioenergetic processes support population-level production in wild freshwater fish populations (Fig. 1).

General principles: The Metabolic Theory of Ecology

The Metabolic Theory of Ecology (MTE) contends that the primary factors that shape the energy metabolism of individuals (i.e., body size and temperature) also shape the rates of energy gain and loss that determine the flow of energy through a population in the wild. This focus of the MTE makes it particularly relevant to the study of production since it is the flow of energy through a population that must underlie the rates of biomass gain and loss (g and z in Eq. 1) and therefore also determine population production. This is seen most clearly through the relationship that defines production for a population at its carrying capacity. From Eq. (3), at carrying capacity, production equals g^*B. Given that the synthesis of new biomass requires the input of new energy, changes in mass-specific production rates (i.e., changes in g) must reflect changes in energy flow. Hence, understanding the forces that drive changes in energy flow will lead directly to a deeper understanding of the forces that drive changes in production. What follows is a brief summary of the MTE, focusing on its relevance to understanding the forces that drive production in the wild.

For most ectotherms, basal metabolic rate (M_{ind}, the flow of energy required to sustain life in an individual) is given by:

$$M_{ind} = i_0 W_{ind}^{3/4} e^{-E/kT} \tag{5}$$

where M_{ind} is individual metabolic rate, W_{ind} is the somatic weight of the individual, T is the environmental temperature (°Kelvin) the individual is experiencing, i_0 is a constant that is specific to each species, E is the mean activation energy of cellular respiration (0.60–0.70 eV) and k is the Boltzmann constant ($8.62\ 10^{-5}$ eV/K; Brown et al., 2004; Gillooly et al., 2001). The routine and maximum metabolic rates typically seen in the wild roughly follow simple multiples of this basic equation (Peters, 1983).

Now that we have a bioenergetic description of individual metabolism (Eq. 5), we show how it can be used to describe the flow of energy through an entire population. Following Savage et al. (2004), the flow of energy through a population that is maintaining itself at its carrying capacity within its supporting habitat can be derived as follows:

(i) replace individual somatic weight (W_{ind}) in Eq. (5) by the average weight of individuals ($\overline{W}$) when the population is at its carrying capacity (K),

(ii) energy flow ($P\varepsilon$) through the population under an environmental temperature (T) is then given by:

$$P\varepsilon = (1 + s + a) * M_{pop}(\overline{W}, T) * K(\overline{W}, T) \tag{6}$$

where $M_{pop}(\overline{W}, T)$ is the basal metabolic rate of individuals in the population, s and a augment basal metabolism to account for costs associated with generating new somatic and reproductive tissue, respectively, at the rates required to maintain the population at its carrying capacity, and $K(\overline{W}, T)$ is the numerical abundance at carrying capacity.

(iii) the bracketed first term in Eq. (6) explicitly identifies the processes that underlie the growth term (g) in Eq. (3): tissue maintenance (1), somatic growth (s) and reproduction (a). It also clarifies how body size and environmental temperature (through $M_{pop}(\overline{W}, T)$ as defined by Eq. 5) act together with abundance to determine overall energy flow and consequently production.

Now, if we replace population abundance $[K(\bar{W}, T)]$ in Eq. (6) with its biomass equivalent $[K(\overline{W}, T)^*\overline{W}/\overline{W}]$ and expand M_{pop} with the temperature and weight effects from Eq. (5), then Eq. (6) becomes:

$$P_\varepsilon = (1 + s + a) * \left[K(\overline{W}, T) * \overline{W}\right]\left[i_0 * e^{-\frac{E}{kT}} * \overline{W}^{3/4}/\overline{W}\right] \tag{7}$$

and this simplifies to:

$$P_{\varepsilon} = (1 + s + a) * [population\ biomass]\left[i_0 * e^{\frac{E}{kT}} * \overline{W}^{-1/4}\right] \tag{8}$$

where i_0 is the normalization constant from Eq. (5). Note that, since $\overline{W}/\overline{W}$ is equal to 1, multiplying Eq. (6) by $\overline{W}/\overline{W}$ to get Eq. (7) does not alter the validity of either equation. Given that production (P) must be supported by energy flow (P_{ε}), it is reasonable to expect that production will also follow Eq. (8). This expectation is supported by the fact that there is a qualitative and quantitative match between Eq. (8) and the empirical analysis of production presented by Downing and Plante (1993). These authors showed that the statistical links between population production and standing biomass, temperature and mean body-mass are consistent with the form of Eq. (8) and that the fitted exponent for body weight (−0.17) in their analysis is similar to the expected value of −0.25.

Another important production metric is the production to biomass ratio (P/B). The P/B ratio is an expression of population growth that is linked to the productive capacity of a population's habitat (Randall and Minns, 2000) and has been used in a variety of contexts to estimate production when data intensive methods cannot be applied (e.g., Sprules and Stockwell, 1995; Shuter and Ing, 1997; Randall and Minns, 2000). By simply dividing both sides of Eq. (8) by population biomass, we arrive at:

$$\frac{P\varepsilon}{[population\ biomass]} = (1 + s + a) * \left[i_0 * e^{\frac{E}{kT}} * \overline{W}^{-1/4}\right] \tag{9}$$

which highlights the role of both temperature and somatic weight in determining the P/B ratio.

Support for the MTE rests on general summaries of empirical data on the performance of various plants and animals in the wild. Data on marine and freshwater fish populations have also played a supporting role in these analyzes, indicating that it is a relevant framework for considering the production of fishes. The following section provides a more detailed demonstration of the degree to which current knowledge of fish bioenergetics matches expectations from the MTE.

MTE and freshwater fish—Examining the role of body size and temperature in detail

The acquisition and allocation of energy towards biomass production occurs simultaneously with energy losses to maintenance and activity (L_m and L_a respectively), individual mortalities (L_z) and propagule release (eggs and sperm; L_R). Assuming that P is roughly proportional to P_{ε}, this implies that:

$$P \propto\ P\varepsilon = [\rho_F * (\text{available forage}) + \rho_R * \mathrm{L_R} - (L_m + L_{act}) - L_z - L_R] \tag{10a}$$

which simplifies to:

$$P \propto [\mathrm{P_F} + R - (\mathrm{L_m} + \mathrm{L_{act}}) - \mathrm{L_z} - \mathrm{L_R}] \tag{10b}$$

where $\boldsymbol{\rho}_F$ is the proportion of available forage energy that is acquired by population members (i.e., foraging efficiency), $\mathrm{P_F}$ represents total energy acquired by the population from foraging, $\boldsymbol{\rho}_R$ is the degree to which energy released to the environment as propagules accumulates during offspring development to return to the monitored segment of the population as newly recruited individuals, and R is the product of $\boldsymbol{\rho}_R$ and $\mathrm{L_R}$ (Fig. 2). Notably, the degree of energy allocated towards propagule production is a positive reflection of the size and health of the individual and this, in turn, will contribute directly to the degree to which energy released as propagules returns to the population as newly recruited individuals ($\boldsymbol{\rho}_R$; e.g., Venturelli et al., 2009, 2010).

From the MTE, we would expect these processes of energy acquisition and recruitment to vary predictably with body size and temperature, following the allometric Arrhenius weight-temperature functional form defined in Eq. (5), with individual somatic

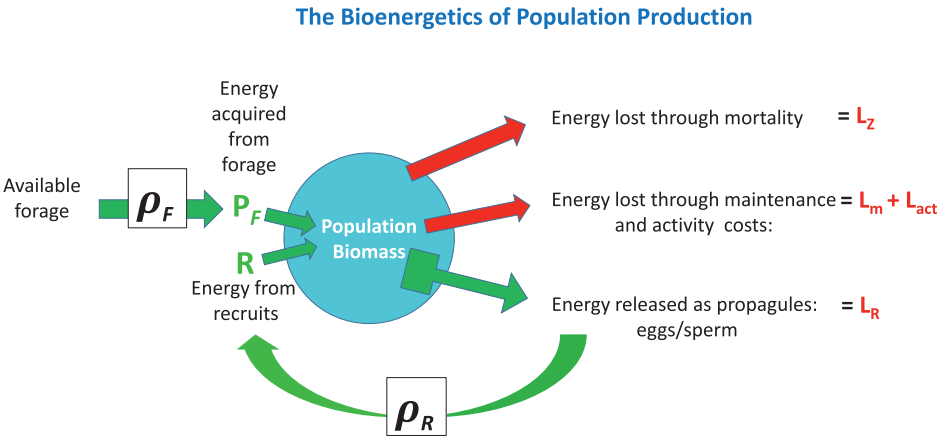

Fig. 2 Over any time period, realized production by the older individuals in a population derives from several different flows of energy through those individuals: For a population in equilibrium with its environment [dB/dt = 0], the following relationships should hold: (i) the production of new biomass (somatic tissue + reproductive tissue) is determined by the net gain in energy from foraging ($= \mathrm{P}_{\boldsymbol{F}} - (\mathrm{L_m} + \mathrm{L_{act}})$) where $\mathrm{P}_{\boldsymbol{F}}$ depends on the amount of prey available in the environment and the foraging efficiency ($\boldsymbol{\rho}_F$) of a typical individual. (ii) the increase in biomass from new individuals recruiting to the population is determined jointly by the biomass released as propagules ($\mathrm{L_R}$) and the degree to which that biomass is augmented over early life ($\boldsymbol{\rho}_R$) by the combined effects of individual growth and mortality. (iii) the total gain in biomass from growth and recruitment = losses from metabolic costs, propagule release and mortality.

weight replaced by the population mean somatic weight (Eqs. 6–8, following Savage et al., 2004) and the proviso that T does not exceed the tolerance range of the species in question. Thus, maintenance losses can be described as:

$$L_m = i_{\mathrm{m}}\, \overline{W}^{\beta m} \tag{11a}$$

the maximum rate of energy acquisition, P_{ε}^{max}, as

$$P_{\varepsilon}^{\ max} = i_{\varepsilon max}\, \overline{W}^{\beta_{\varepsilon max}} \tag{11b}$$

losses to mortality as:

$$L_z = i_z\, \overline{W}^{\beta z} \tag{11c}$$

and losses to propagules as:

$$\mathrm{L_R} = \mathrm{r} * \overline{W} \tag{11d}$$

where:

$$\beta_m \approx \beta_{\varepsilon max} \approx 3/4 \tag{11e}$$

$$\beta_z \approx -1/4 \tag{11f}$$

and $[i_m,\ i_{\varepsilon max}]$ exhibit the temperature dependence evident in Eq. (5), i_z increases with temperature and r is a species-specific constant. For individuals, there is good empirical support for Eqs. (11a), (11b), (11d) (Fig. 3A and B) regarding maintenance losses and energy acquisition: (i) estimates of bioenergetic performance parameters for 58 fish species described in the fish bioenergetics model FB4 (Deslauriers et al., 2017) are consistent with the allometric form; (ii) typical values for β_m and $\beta_{\varepsilon max}$ are close to the expected value of ¾ (Eq. 11e); and (iii) over species-specific thermal tolerance ranges (Savage et al., 2004), the effect of temperature on i_m and $i_{\varepsilon max}$ is consistent with the Arrhenius relationship (Fig. 4A and B; Deslauriers et al., 2017).

For populations, there is also good empirical support for Eq. (11c) regarding losses to mortality (McCoy and Gillooly, 2008; Fig. 3C): the allometric form is followed, the exponent has a value close to the expected value of −1/4 (Eq. 11f), and i_z shows the expected increase (vertical offset) with increasing environmental temperature. In Eq. (11d), energy lost to reproductive activity ($r * \bar{W}$) is assumed to be proportional to somatic weight. This is consistent with the typical metric used in field studies for this quantity (i.e., GSI = gonad weight/body weight). For fish generally, values of r for mature females can range from 0.2 to 0.6 (Lester et al., 2004b).

The variable L_{act} (Fig. 2) measures the energetic cost to the individual of interacting with its environment and is often dominated by foraging costs. These separate into the cost of search (L^s_{act}) and the cost of attack (L^a_{act}). There is strong theoretical (Weihs, 1977; Ware, 1978) and empirical (Videler and Nolet, 1990; Ryan et al., 2015) support for asserting that search velocity in the wild will match the velocity that maximizes distance traveled per unit swimming cost. Travel at this velocity varies with (body length)$^{0.45}$ with a metabolic cost, at the level of the individual, that is roughly proportional to basal metabolism. It then follows that the overall activity cost needed to provide a population with a fixed daily ration of prey biomass will vary with the overall attack cost (L^a_{act} = [# attacks]*[cost/attack]). This will increase with the number of prey required to meet that ration and, all else being equal, that number and the overall attack cost will decrease as prey size increases. This effect of prey size on foraging cost has been observed in many natural populations (Paloheimo and Dickie, 1966; Kerr and Ryder, 1977; Sherwood et al., 2002a; Giacomini et al., 2013).

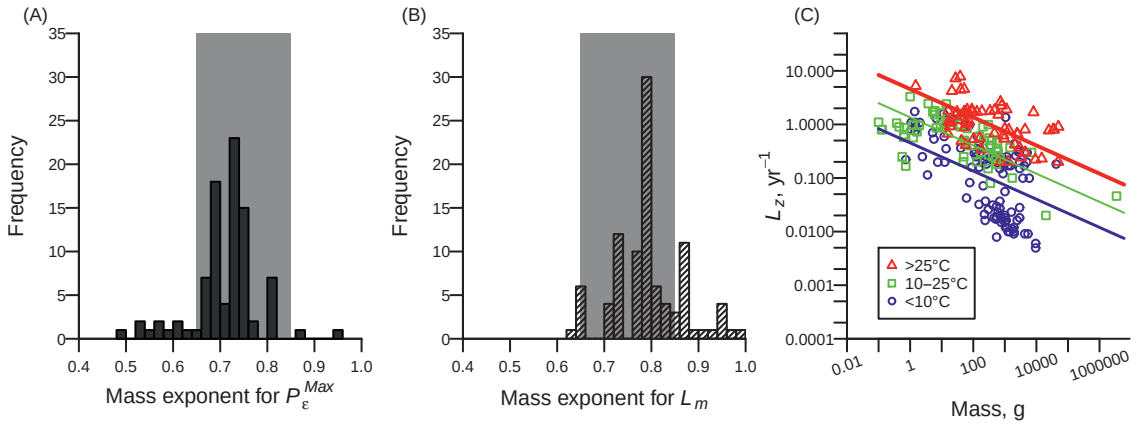

Fig. 3 Relationships of fish consumption (Panel A), metabolism (Panel B) and mortality (Panel C) with body mass. Histograms of fish mass exponents for consumption (Panel A, as g food per day) and metabolism (Panel B, as g O_2 consumption or energetic units per day) both approximate 0.75. The median values for consumption and metabolism are 0.73 and 0.79, respectively and the shaded region highlights density of observations between 0.65 and 0.85. Instantaneous mortality (Panel C) scales negatively with body mass among fishes occupying cold, cool and warmwater habitats: the common slope across habitats approximates −0.25 (estimated slope = −0.263; note log scales on axes). Panels A and B: Data FROM Deslauriers D, Chipps SR, Breck JE, Rice JA, and Madenjian CP (2017) Fish bioenergetics 4.0: An R-based modeling application. *Fisheries* 42:586–596; Panel C: Data from McCoy MW and Gillooly JF (2008) Predicting natural mortality rates of plants and animals. *Ecology Letters* 11:710–716.

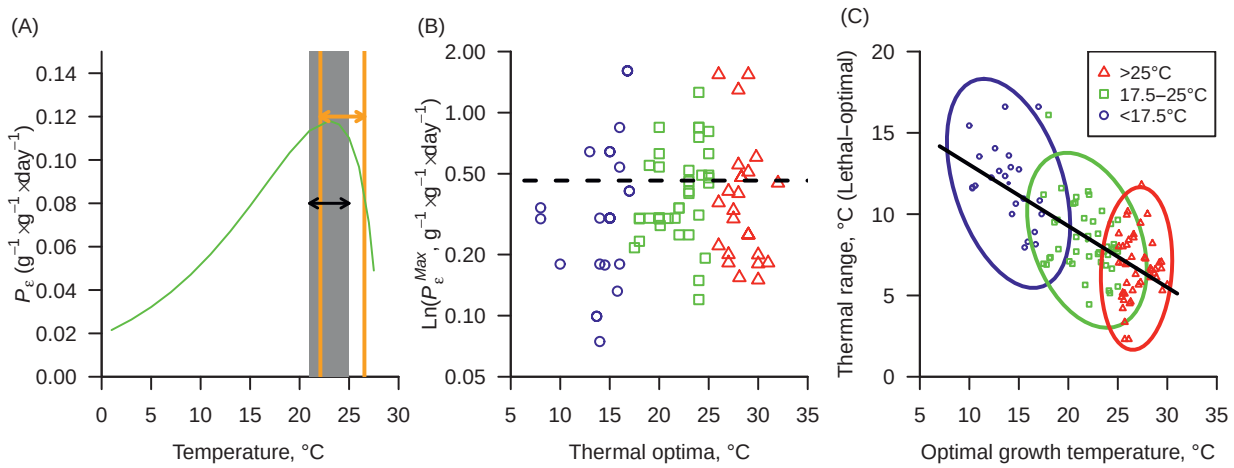

Fig. 4 Influence of thermal range on individual performance in fishes. Panel A: In fishes, both consumption and basal metabolism increase with temperature to a peak value and then decline rapidly, with death occurring at a critical maximum temperature. The green curve shows the thermal response of consumption for Walleye (*Sander vitreus*) when prey are abundant. The temperature range supporting optimal performance is characterized by the fundamental thermal niche (after Magnuson JJ, Crowder LB, and Medvick PA (1975) Temperature as an ecological resource. *American Zoologist* 19: 331–343, in gray) of 4 °C around the optimum temperature. The overall shape of the basal metabolism vs temperature curve is similar to that in Panel A but shifted to the right by 2C. For temperatures below the optimum, the pattern of increasing rates with increasing temperature approximates the Arrhenius temperature relationship in the MTE. This holds for both consumption and basal metabolism. Panel B shows that the peak consumption observed at the species-specific optimum temperature does not vary systematically across thermal guilds. Each point refers to a particular species; points are colored by thermal guild, where guild membership is set by optimum growth temperature (OGT, from Hasnain, SS, Escobar MD and Shuter BJ (2018) Estimating thermal response metrics for north American freshwater fish using Bayesian phylogenetic regression. *Canadian Journal of Fisheries and Aquatic Sciences* 75:1878–1885): cold-blue OGT < 17.5; cool-green OGT falls between 17.5 and 25.0; warm-red OGT > 25. The mean peak consumption rate across all guilds $= 0.46$ g^{-1} g^{-1} day^{-1}. Panel C shows that thermal range (the difference between the optimal growth and lethal temperature, shown in orange in Panel A) narrows significantly from cold to cool to warmwater fishes. Data in panels A and B from Deslauriers D, Chipps SR, Breck JE, Rice JA and Madenjian CP (2017) Fish bioenergetics 4.0: An R-based modeling application. *Fisheries* 42:586–596; panel C data from Hasnain, SS, Escobar MD and Shuter BJ (2018) Estimating thermal response metrics for north American freshwater fish using Bayesian phylogenetic regression. *Canadian Journal of Fisheries and Aquatic Sciences* 75:1878–1885.

For a particular species, individual metabolic rates are relatively insensitive to temperature over a specific thermal range (Fig. 4A) where performance is optimal in regards to activity, feeding, growth, and reproduction (Fry et al., 1947; Pörtner, 2002; McMeans et al., 2020). This optimal range has been dubbed *the fundamental thermal niche* (Magnuson et al., 1979). The diversity of temperature constraints that have shaped ecological performance of freshwater fish has produced wide diversity in realized thermal niches, with species-specific optimal performance temperatures ranging from 5 °C to 30 °C (Hasnain et al., 2018). The center of the fundamental thermal niche has been used to group freshwater fish species into three discrete thermal guilds (McMeans et al., 2020): cold-water—optimal temperatures <17 °C; cool-water—optimal temperatures ranging from 17 °C to 25 °C; and, warm-water—optimal temperatures >25 °C (Fig. 4B and C). Although the peak feeding rate at the optimal temperature is similar across guilds (Fig. 4B), the width of the thermal niche declines progressively as the optimal performance temperature increases (Fig. 4C). Within a thermal guild, feeding rate (Fig. 4A) and basal metabolic rate respond in a similar way to temperature differences: for temperatures below the thermal niche, both rates approximate the Arrhenius temperature relationship; for temperatures above the thermal niche, both rates decline rapidly following rapid declines in enzymatic efficiency (Fry et al., 1947; McMeans et al., 2020; Pörtner, 2002).

The impetus for an individual to seek its optimal operating temperature shapes its habitat use and consequently its realized growth and mortality risk (e.g., Cruz-Font et al., 2019). This, in turn, shapes its productive capacity and, thus, the productive capacity of the population to which it belongs. Empirical data suggests that functioning at temperatures exceeding the preferred range can lead to energetic inefficiencies (e.g., metabolic costs increase faster than ingestion rates) that reduce population productive capacity (Gorman et al., 2016). However, at temperatures within and below the preferred range, temperature differences can promote variation in production in at least three ways:

(I) By promoting changes in the overall abundance of new forage through changes in factors like primary production (e.g., Cross et al., 2015; Junker et al., 2020) and growing season length (Shuter and Ing, 1997; Gorman et al., 2016).
(II) By promoting higher feeding rates on existing forage supplies: for freshwater fish, temperatures below optimal have similar exponential effects on both maximum consumption rates and metabolic costs (Deslauriers et al., 2017; Fig. 4A), therefore, temperature increases at the lower end of the tolerance range can promote higher net energy gain by promoting higher feeding rates on existing forage resources.
(III) By promoting changes in the availability of existing forage supplies: for example, temperature change (e.g., seasonal warming or cooling in boreal lakes) can extend/limit the opportunities for a particular consumer to forage in some habitats by driving ambient habitat temperature into/out of the consumer's tolerance zone (Guzzo et al., 2017).

When forced to forage in habitats outside of their optimal thermal niche, reduced foraging efficiencies (Fig. 4A) and additional energetic costs reduce the net energy available for production of new tissue. Ultimately, this can impact fitness through impaired survivorship and/or reproductive success (Quince et al., 2008; Guzzo et al., 2017; Cruz-Font et al., 2019).

The role of habitat

Ecosystem size ultimately dictates the habitat available to support fish production. Additional characteristics such as light (Lester et al., 2004a), oxygen (Plumb and Blanchfield, 2009), and temperature (Guzzo and Blanchfield, 2017) determine the amount of habitat that is actually useable by that population (Fig. 1). These characteristics can then be further modulated by nutrients, such as dissolved organic carbon (DOC; Ask et al., 2009). Thermal habitat constraints on fishes have been thoroughly discussed in Section "MTE and freshwater fish—Examining the role of body size and temperature in detail", thus, our attention below turns specifically to the constraints set by space, oxygen and nutrients.

The role of habitat: Spatial limits

Production is often quantified on a per unit habitat basis (e.g., Downing and Plante, 1993; kg ha^{-1} year^{-1}) with the implicit assumption that this value is independent of lake or river size. However, physical boundaries (e.g., lake shoreline, riverbanks) clearly limit fish population function in most freshwater ecosystems. In rivers compared to lakes, home ranges are smaller for a given fish size (Minns, 1995), while P/B ratios are larger (Randall et al., 1995). This is likely due to the greater role of throughput (i.e., more allochthonous than autochthonous inputs) in rivers. Similarly, since the fraction of littoral zone surface area typically decreases with lake size, allochthonous nutrient inputs and littoral benthic production often make a greater contribution to overall production in small lakes than in large lakes. This is important as ecosystem size can limit food chain length, and consequently top predator size, in both terrestrial and aquatic systems (Schoener, 1987). These effects are particularly evident among top predators living in lake ecosystems (Vander Zanden et al., 1999; Post et al., 2000, 2002). Simple energetic arguments and empirical findings (outlined below) support the contention that these effects will influence fish population production.

Given that:

- Metabolic demand increases with body size (Eq. 5), and
- Hydrodynamic constraints ensure that the metabolic cost of areal search is proportional to basal metabolism ($L^s_{act} \sim L_m$; Ware, 1978; Videler and Nolet, 1990).

It follows that:

- Foraging space, which is approximated by home range size, should increase with body size;
- Large piscivores will be absent from very small ecosystems;
- The adult size of piscivores will tend to be larger in the longer food chains that are common in larger systems; larger systems tend to support longer food chains because foraging spaces are larger, food web diversity is higher and forage species tend to be larger (e.g., Sherwood et al., 2002a; McGarvey et al., 2016).

Fig. 5 illustrates this congruence between individual capabilities (e.g., areal search rate), metabolic need (e.g., home range size), increased foraging opportunities (e.g., presence/absence of pelagic forage fish) in larger systems and population traits (e.g., mean adult size). Data used to generate the black and blue lines are from the Lake Trout (*Salvelinus namaycush*) life history data base documented in Lester et al. (2021). Here "Body Length" is typical adult body size, estimated as the mean of length at maturity and maximum length.

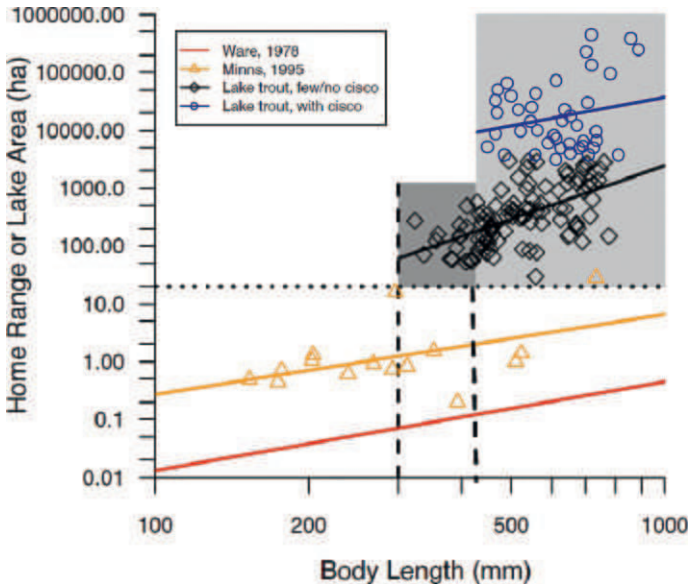

Fig. 5 Similarities across spatial scales of how body size influences the use of space by fish: (i) The lowest (red) line: the relationship (Ware, 1978) linking fish body size to prey search rate (ha time^{-1}), (ii) the orange line: the relationship (Minns, 1995) linking home range size to fish body size (ha) in lakes, (iii) The black line: the relationship linking lake size (ha) to adult body size for populations of Lake Trout (*Salvelinus namaycush*) where pelagic piscivory is negligible, (iv) The highest (blue) line: the relationship linking lake size (ha) to adult body size for populations of Lake Trout (*S. namaycush*) where pelagic piscivory is dominant.

All four relationships exhibit very similar slopes. Lakes below the horizontal dotted line are too small to support a top predator like Lake Trout (*S. namaycush*). The range of small body sizes marked by the two vertical dashed lines are only found in small lakes where pelagic piscivory is absent (dark gray rectangle).

In aquatic systems (freshwater and marine—Sprules and Barth, 2016) both numerical and biomass abundance (per unit habitat) decline as body size and trophic position increase (Andersen, 2019). Therefore, changes in prey size will affect the net benefit to predators through changes in both prey abundance and predator foraging efficiency. Eqs. (6), (8) and (9) can be used as guides to generate predictions of how these diverse effects will impact predator production *per individual* (Eq. 6) and predator production *per unit predator biomass* (Eqs. 8 and 9). They also identify the central role that overall population abundance (numerical and biomass) plays in determining total population production and consequently production *per unit habitat*. Eq. (10a) explicitly identifies the primary roles that available forage (i.e., forage *per unit habitat*) and predator foraging efficiency play in determining production *per unit habitat*.

Population biomass production (per unit habitat) should vary inversely with adult size (Eq. 8; Downing and Plante, 1993) and hence be higher in smaller ecosystems. Lester et al. (2021) quantified this effect for North American Lake Trout (*S. namaycush*) populations, showing that the equilibrium rate of biomass production (including growth and recruitment) among adults in unexploited populations was an allometric function of adult size ($\sim W_{inf}^{-1.63}$)—a result consistent with the theoretical work of Andersen and Beyer (2006). Here, and in other studies, the measure of adult size is the weight or length (W_{inf}, L_{inf} respectively) typical of the largest adults in the population. For two well studied Lake Trout populations (Lake 373: 27 ha, $L_{inf} = 425$ mm; Lake Opeongo: 5800 ha, $L_{inf} = 603$ mm; Cruz-Font et al., 2019), this implies that biomass production per hectare for Lake 373 is approximately five times the production for Lake Opeongo. This drop in production is roughly consistent with the drop in trophic efficiency (e.g., Andersen, 2019 p. 36) expected, given that Opeongo Lake Trout are feeding on pelagic fish, one trophic level higher than Lake 373 Lake Trout, which feed on zooplankton (Vander Zanden et al., 1999).

The role of habitat: Oxygen limitation

The physiological performance of ectotherms depends strongly on aerobic metabolic rate, which varies with both oxygen concentration and temperature. At high temperatures or during times of intense activity, oxygen supply can exceed demand, and the metabolic rate approaches a limit (Fry et al., 1947; Pörtner, 2002; Rubalcaba et al., 2020). The difference between basal metabolism and this metabolic limit represents the aerobic scope (i.e., the energy available) for fitness-enhancing activities such as movement, feeding, digestion, growth, and reproduction. From Eq. (5), we expect metabolic oxygen demand to increase with higher temperatures within the liveable thermal boundaries of fishes, and this expectation has strong empirical support (e.g., Rubalcaba et al., 2020). In the aquatic environment, oxygen and temperature act together to define the oxythermal habitat space that supports optimal performance by individuals of a particular species (Fig. 1). The size and positioning of this space within the larger habitat will vary with climate/latitude, with implications for behavior patterns, activity costs and, ultimately, population productivity. Behavioral telemetry studies have found that Lake Trout (*S. namaycush)* reduced their use of littoral regions due to shorter spring and longer summer seasons (Guzzo et al., 2017). This was accompanied by (i) loss of optimal oxythermal habitat; (ii) reduced access to littoral prey resources; leading to (iii) reduced individual growth rates and body condition. These findings are particularly important within the context of climate change, where warmer, longer summer seasons can lead to significant decreases in oxythermal habitat for cold-water fish and increases for warm-water fish (Guzzo and Blanchfield, 2017).

The role of habitat: Nutrient limitation

Nutrient limitation of ecosystem productivity is an important theme of freshwater ecology and this limitation is implicit in the population abundance terms in Eqs. (6)–(9): increased nutrient inputs are expected to increase production at lower trophic levels, promoting increased population abundance, and consequently higher production at higher trophic levels. Many studies have identified phosphorus as a correlate (Downing et al., 1990) and a driver (Mills, 1985; Rennie et al., 2019; Hecky and DePinto, 2020) of both fish biomass and production. This is nicely demonstrated in several whole lake experimental lake studies (Schindler 1990, Bristow et al., 2008) that involved nutrient additions and increases in total phosphorus concentration in small oligotrophic lakes. In one experiment, the production of the resident top predator (*Coregonus clupeaformis*), rose and fell with the initiation and cessation of nutrient additions (Mills 1985). These changes in production were the combined result of parallel increases in abundance, recruitment, and somatic growth (Mills 1985). In another experiment (Rennie et al., 2019), the abundance of both small forage fish (i.e., minnows) and the resident top predator (*S. namaycush*), rose and fell with the initiation and cessation of nutrient additions. The increases in top predator abundance were accompanied by parallel increases in somatic growth and maturation size and a parallel decrease in age at maturation.

Beyond the direct effects of nutrient levels on ecosystem productivity, other components of water chemistry (e.g., pH—Mills et al., 2002a,b; Schindler 1990) can indirectly modulate fish production through bottom-up effects on nutrient and habitat availability. For example, DOC attenuates light and thus can alter vertical temperature profiles (Pilla et al., 2018), primary productivity (Ask et al., 2009) and oxythermal habitat availability (Knoll et al., 2018). Increases in DOC can be accompanied by decreases in fish abundance (Seekell et al., 2018), growth (Benoît et al., 2016), and biomass production (van Dorst et al., 2019). Such effects are of immediate concern since DOC concentrations are increasing in aquatic ecosystems due to climate change and altered precipitation cycles (Solomon et al., 2015).

The role of community: Prey and competitors

Like production (as outlined earlier in Sections "General principles: The Metabolic Theory of Ecology" and "MTE and freshwater fish—Examining the role of body size and temperature in detail"), the life history of a population emerges from the bioenergetic processes that determine the amount of energy allocated to fitness-enhancing traits such as somatic growth and reproduction (Lester et al., 2004b; Shuter et al., 2016). As discussed in Section "MTE and freshwater fish—Examining the role of body size and temperature in detail", these bioenergetic processes are strongly dependent on prey availability and quality (Giacomini et al., 2013). Prey quality, and particularly prey size relative to predator size, (the predator/prey size ratio; Andersen and Beyer, 2006; Brose et al., 2006) can be just as important as prey availability in determining the energy budget of individual fish and populations (Fig. 6A). The net energetic benefit associated with acquiring a unit biomass of food typically increases as prey become bigger (e.g., Kerr, 1971; Shuter et al., 2016)—even if the biomass density of small prey is high, many individual prey captures are needed to meet the energy needs that arise with increasing predator size (Cruz-Font et al., 2019). The high attack costs that result can create a bioenergetic bottleneck where the value of reaching larger adult size (i.e., increased fecundity with larger size; Giacomini et al., 2013; Cruz-Font et al., 2019) is offset by the energetic cost of reaching and maintaining that size (Sherwood et al., 2002a,b). Life history theory dictates that this trade off will shape both the size-at-maturity and post-maturation growth pattern of the predator (Jensen, 1996; Charnov and Gillooly, 2004; Lester et al., 2004b): when larger prey are available, fitness is maximized by an increase in adult size and a reduction in reproductive allocation (Fig. 7A). These differences feed back, through their effects on adult size and somatic growth, to exert a strong influence on population production (Eq. 8).

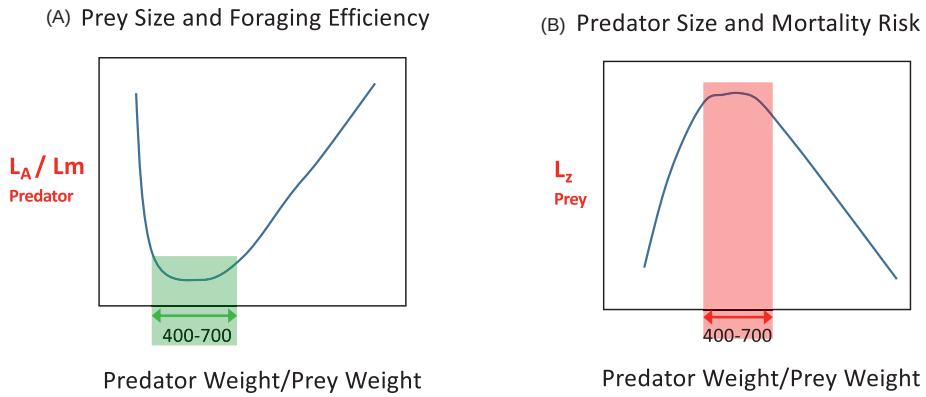

Fig. 6 Forces affecting the balance of energy flow (gains vs losses) through a population when the overall supply of prey resources is fixed. (A) Relative prey size determines foraging costs for predators: very large prey are very costly (if not impossible) to capture; as prey become smaller, the cost per capture declines but the gain per capture also declines—acquisition of a fixed amount of biomass is accompanied by increasing activity costs; the net result of this tradeoff is that relative feeding costs reach a minimum (and feeding efficiency reaches a maximum) when the predator/prey weight ratio lies in the range [400,700]— Andersen, 2019. (B) Relative predator size determines mortality on prey. The relationship between predator benefit and prey size evident in panel A has a parallel effect on prey mortality risk. For the prey, mortality risk rises and falls with increasing predator size. Since predator feeding efficiency on very large and very small prey is low then, all else being equal, the mortality risk for prey should be correspondingly low, with highest risk associated with predators that are 400–700 times larger (by body weight) than prey.

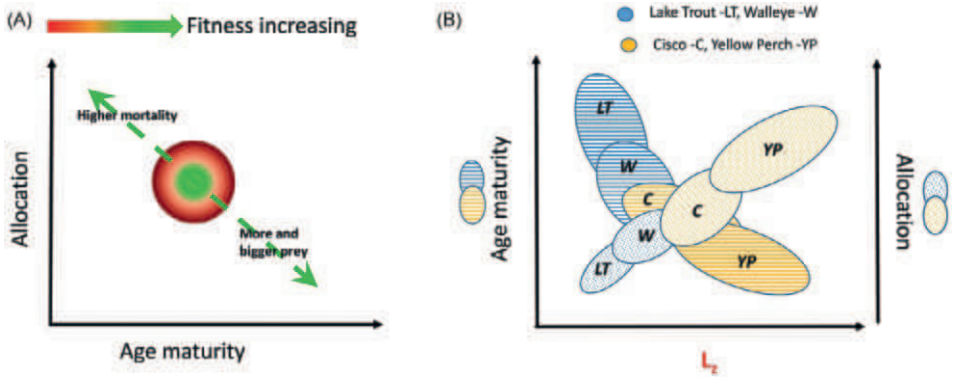

Fig. 7 Prey availability and predation risk act together to determine the timing/extent of reproductive allocation and hence the lifetime growth pattern of a typical individual. Panel A: the theoretical relationships linking optimal life history traits (allocation of energy to reproduction and age at maturity) to both variation in prey size and mortality. Panel B: the observed relationships (after Fig. 3 in Shuter et al. (2005) linking life history traits to trophic position and mortality (L_z) for a sample of fish populations from freshwater lakes (number of populations: 14 Lake Trout *(Salvelinus namaycush)*, 17 Walleye *(Sander vitreus)*, 10 Cisco *(Coregonus artedi)*, 15 Yellow Perch *(Perca flavescens)*).

Competition for prey can also drive population production, with production decreasing as species richness increases (Downing and Plante, 1993). In particular, invasions of non-native species can alter fish production in potentially unpredictable ways. When introduced, Northern Pike (*Esox lucius*) often negatively impact native species (DeBates et al., 2003; Haught and von Hippel, 2011)—in some cases eliminating prey species, leaving pike monoculture lakes (Regmi, 2012; Nicholson et al., 2015). In lakes without an offshore prey fish population, the invasion of non-native Smallmouth Bass (*Micropterus dolomieu*) can negatively impact Lake Trout (*S. namaycush*) dramatically by reducing their access to larger nearshore prey (minnows), forcing an increased reliance on offshore zooplankton (Vander Zanden et al., 1999) leading to slower growth rates and reduced production. From an ecosystem perspective, it is currently unclear as to whether the production of invasive fishes can ultimately offset the loss of native fish production in invaded ecosystems such as these.

The role of community: Predator pressure

Trade-offs between predation mortality and growth are common in fishes, since mortality losses are driven by the relative size of predator and prey (Fig. 6B). Growth can provide an escape from predation, with prey fish (or, in cannibalistic species, juvenile life stages) growing rapidly and maturing earlier to exceed predator gape (Day et al., 2002; Biro et al., 2005; Urban, 2007). Ironically, the increased foraging required to achieve rapid early growth rates often leads to increased exposure to predation. However, this comes with the benefit of reaching an invulnerable size faster (Urban, 2007). Alternatively, if refuges (spatial or temporal) are available, fish may modify their behavior to avoid predation, but this may force a decrease in foraging opportunities (e.g., Peacor, 2003). Linked changes in both overall activity and foraging can generate wide variation in growth trajectories (Abrams and Rowe, 1996). In Yellow Perch (*Perca flavescens*), maximum size, size at maturity, growth rate and growth efficiency all increased with increased predation risk, despite negative correlations with consumption and activity (Rennie et al., 2010). These results suggest that increased use of refuges in these populations permitted increased growth when risk of predation was high.

This trade-off between mortality and growth impacts life history decisions in ways that are similar to the trade-off between prey size and growth (Fig. 7A). The value of reaching larger sizes through allocating most available energy to somatic growth is offset by the increases in mortality that accompany higher foraging rates. Life history theory dictates that individuals will reach a point where the benefits of growth will be outweighed by the risk of mortality and all surplus energy should be allocated to reproduction (Jensen, 1996; Charnov and Gillooly, 2004). This will lead to earlier maturity and reduced post-maturation somatic growth under high mortality, with consequences for production through changes in both adult size and somatic growth. This set of joint differences in mortality, growth and maturity schedules is typical of the differences observed between forage fish and top predators (Fig. 7B).

Future directions and conclusions

It should be clear now that bioenergetic theory provides a unified paradigm for developing explicit hypotheses regarding the forces driving variation in production in wild populations of freshwater fish. However, the empirical work needed to explicitly test these ideas has lagged behind theory development. In the 2017 summary of currently available data provided by Rypel and David (2017), less than 30% of production estimates were based on direct estimates of production and over 60% of these were published prior to 2000. This highlights the need for new direct empirical estimates of fish production to refine our understanding of how drivers like habitat limitation, temperature/climate change, and prey size/foraging efficiency shape production in the wild. In addition to new empirical studies, a wider application of methodological refinements and further development of logistically simpler predictive models of fish production are needed, both to extend our understanding of production and to develop more effective, evidence-based strategies for conserving fish productivity.

Addressing costs of reproduction in production estimates

In most fish species, energy assigned to biomass synthesis shifts significantly at sexual maturity from somatic tissue to the predominate production of energy dense reproductive products (i.e., propagules; Gunderson and Dygert, 1988; Henderson et al., 2000). This shift in energy allocation leads to significant changes in the growth curve of individuals and populations: (i) prior to maturation, body weight increases steadily as biomass production accumulates; (ii) after maturation, body weight increases prior to spawning but then declines suddenly at spawning with the expulsion of propagules (Fig. 8A). Failure to account for these changes in weight and energy allocation to reproduction can generate age-specific bias in production estimates (Fig. 8B and C, Box Fig. 1).

Biphasic growth models capture these energy shifts particularly well and have been widely accepted since they were first proposed (Charnov et al., 2001; Lester et al., 2004b), with empirical work demonstrating their efficacy in providing accurate descriptions of lifetime growth (Shuter et al., 2005; Quince et al., 2008). These models explicitly recognize the landmark change in energy allocation that occurs with sexual maturity (Fig. 8A) through depicting (i) pre-maturation length growth as a linear function of age and (ii) growth at, and post-maturation, as an abrupt switch to an asymptotic form that is consistent with the von Bertalanffy equation. These models are then able to quantify traits that are critical in determining individual fitness (i.e., age at first reproduction, reproductive investment; Charnov et al., 2001, Shuter et al., 2005). This provides the opportunity to test hypotheses regarding how age-at-maturity and reproductive allocation (and hence lifetime growth pattern) should change with changes in mortality rate, prey availability (Fig. 7) and other environmental and ecological factors. Lastly, biphasic model fits can provide an

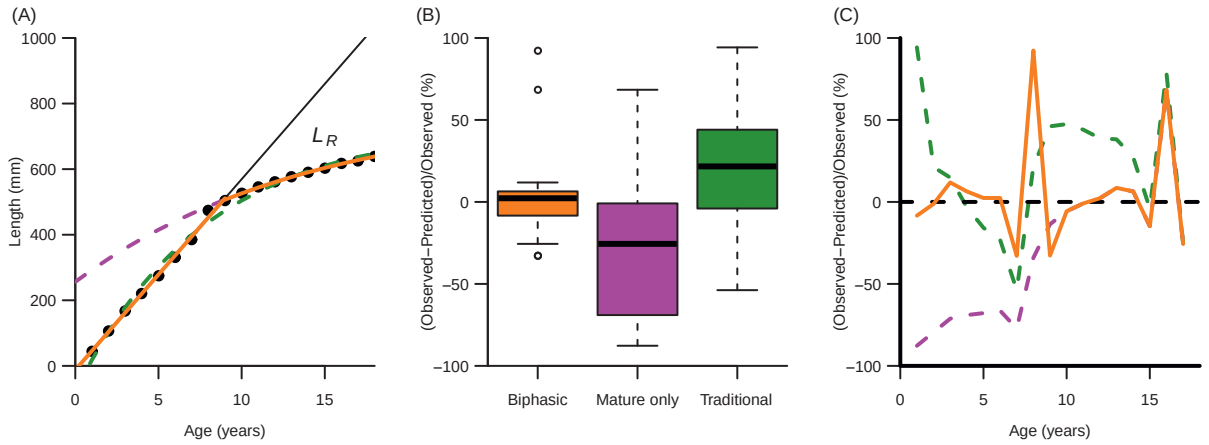

Fig. 8 Growth in fishes is often approximately linear when immature, but slows following maturity once allocation to reproduction (L_R) is initiated (Panel A, size at age of Lake Opeongo lake trout). The deviation from the initial linear pattern increases progressively with higher allocation of energy to reproduction. This growth pattern can be characterized by a von Bertalanffy growth function (Green dashed line), but more recently bi-phasic models of growth (orange) that explicitly recognize linear immature growth are more common. Absence of information on immature fish (common in commercial fisheries; shown in purple) can lead to overestimation of immature fish size if the growth curve for older ages is extrapolated to younger ages. When these growth curves are used to measure instantaneous growth (as they are in common production estimation methods), the bi-phasic model more accurately describes observed growth on average (Panel B). Growth curves fit to only mature fish are variable relative to observed growth (Panel B) and tend to greatly overestimate immature growth (Panels B and C). The traditional von Bertalanffy fit to all age classes is also variable and tends to underestimate instantaneous growth (Panel B), especially at the smallest age classes and immediately post-maturation (Panel C). (A) Data from Shuter BJ, Giacomini HC, de Kerckhove D and Vascotto K (2016) Fish life history dynamics: Shifts in prey size structure evoke shifts in predator maturation traits. *Canadian Journal of Fisheries and Aquatic Sciences* 73:693–708.

indirect estimate of reproductive energy allocation Shuter et al. (2005) that can be used to scope the magnitude of potential bias in empirical studies that do not cleanly allow for its cyclic gain and loss over a typical growing season. For example, the biphasic fit to the data in Fig. 8A generates an estimate of annual reproductive investment by females that is equivalent to ~23% of body weight.

This highlights the importance of ensuring that the production that is allocated to reproductive tissue is accounted for in production calculations, as well as the production allocated to somatic tissue. This requires:

- Accounting for the greater energy density of reproductive tissue (particularly eggs—see summaries in Gunderson and Dygert, 1988; Shuter et al., 2005) over somatic tissue;
- Scheduling field sampling to allow for the fact that seasonal patterns of reproductive allocation can exhibit accelerated allocation just prior to spawning and that most reproductive tissue is expelled when spawning ceases.

Failure to recognize these issues can lead to significant underestimates of population production—as illustrated in Box 1.

Refining the P/B ratio approach

The P/B ratio method for estimating production is founded on statistical regression models that summarize patterns in observed population production data. It is simple to apply, requiring only estimates of biomass and mean fish size for a given population, community, or ecosystem. Further development of this method along the following lines is needed both to confirm its reliability and broaden its applicability to a wider range of ecological contexts:

- Challenge the basic P/B model with new empirical data on how the relationship between production and biomass is affected by cofactors such as climate, food web diversity, habitat type (e.g., lake vs. river), and habitat size and complexity (e.g., Minns, 1995; Randall et al., 1995);
- Include size composition data in a weighted mean P/B and compare resultant production estimates with those derived from more data-intensive methods (such as the IGR method—Table 1);
- Use estimates of (dW/dt)/W from individual growth models (e.g., biphasic models) to derive species or stock-specific P/B ratios and compare with those derived directly from empirical data;
- Evaluate whether key life history parameters (e.g., growth coefficients), along with phylogenetic and environmental variables, can be used to derive species- and site-specific P/B values (see Thorson, 2020).

Currently, there is limited appreciation of how basin-wide production is shaped by scale and habitat factors (Oberdorff et al., 2011); recent work with Alaskan Pacific Salmon (*Oncorhynchus tshawytscha*) populations (Brennan et al., 2019) suggests that the integration of biocomplexity across large spatiotemporal scales can act to stabilize production basin-wide. Development of a more diverse and precise set of P/B models may provide the tools needed to design logistically feasible studies of variation in production across entire watersheds. The new knowledge of basin-wide patterns in production, obtained from such studies, could provide the empirical foundation needed for developing more effective, evidence-based strategies for assessing fisheries and conserving productivity at broader spatial scales (e.g., Rypel and David, 2017; Jarvis et al., 2020).

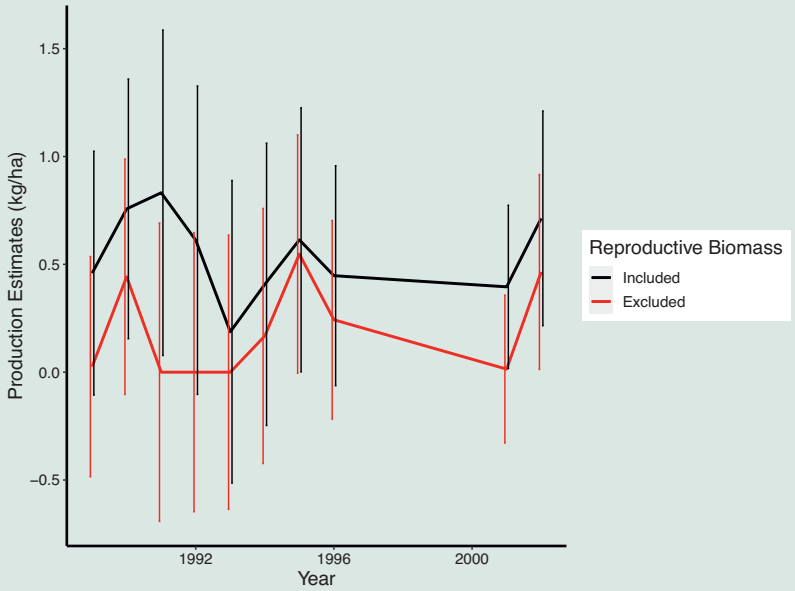
Box 1 Consequences of missing reproductive biomass in production estimates.

Access to prey resources and habitat suitability can exert a strong influence on the age or size at which an individual begins to allocate acquired energy to reproduction (Shuter et al., 2016). This key life-history trait is important to the overall productivity of a population since it dictates both adult maximum size and life-time fecundity. Current production estimation methods do not explicitly account for the energy or biomass lost through propagules (eggs/sperm) during spawning. By not accounting for loss of reproductive tissue, such estimates may underestimate the overall productivity of a population. This is of particular concern if field sampling occurs at times that do not coincide with spawning events, when investment in gametes is highest prior to release.

We aimed to assess the extent to which sampling of non-spawning individuals could underestimate overall production by failing to account for the production of reproductive tissue. Using long-term Lake Trout size-at-age data from Lake 375 in the IISD-Experimental Lakes Area (ELA), we calculated production estimates using the IGR method from 1989 to 2002 under population scenarios reflecting different sex ratios (50:50 and 80:20 females:males; the latter represents an extreme case of potential biomass allocation to gametes). Reproductive investment scenarios were set by the GSI (gonad weight expressed as a percentage of body weight: 15% for females, 5% for males) values observed for Lake Trout in Lake Opeongo in Algonquin Park, Ontario (Pazzia et al., 2002).

Since ELA Lake Trout data were collected in the fall during spawning, we felt justified in assuming: (i) our observed weight-at-age values included the full weight of tissue allocated to reproduction, and therefore (ii) these data provided the ideal dataset for evaluating potential bias as outlined below. A weighted average for population gonadal investment was calculated using female and male GSI values (0.1 and 0.13 for 50:50 and 80:20 females:males populations, respectively). These values were then multiplied against the weight of all aged individuals greater than 6 years of age, under the assumption that fall spawning Lake Trout *(Salvelinus namaycush)* spawn for the first time at the end of their 6th growing season. These amounts were then subtracted from the age class specific mean weight of all mature individuals, simulating spawning losses in the population. This allowed us to determine the degree to which we would underestimate production if our sampling occurred outside of the spawning period. Production estimates that excluded reproductive tissue were up to 50% lower than estimates based on the full observed weight of individual fish at spawning (Box Fig. 1; $t_{18} = -3.7628$, $P < .001$), with little difference between the 50:50 and 80:20 scenarios.

We demonstrate that underestimates of production may be substantial when reproductive biomass is not captured through appropriately timed sampling. This highlights the need to carefully consider the timing of field surveys such that reproductive energy allocation can be included when developing field sampling protocols designed to estimate production, or components of production.



Box Fig. 1 Comparison of annual production estimates that include reproductive biomass versus estimates that exclude reproductive biomass. Estimates are based on Lake *(S. namaycush)* Trout from lake 375 at the IISD-Experimental Lakes Area. A female:male sex ratio of 50:50 was assumed and reproductive biomass was estimated using sex specific mean values for the ratio of gonad weight to body weight (the GSI). Error bars represent estimate variance.

Conclusions

Our summary of current knowledge suggests that the primary drivers of production in freshwater fish populations can be divided in two distinct categories:

1. Forces that drive food availability:
   (i) Production at lower trophic levels sets the level of available food;
   (ii) The presence of competitors reduces available food through sharing;
   (iii) The presence of predators limits access to available food by imposing additional mortality risk.
2. Forces that shape life history and hence determine adult size:
   (i) Temperature, as a modulator of growth rates through its effects on both foraging efficiency and basal metabolic costs;
   (ii) Ecosystem size;
   (iii) Relative prey size, through its effects on foraging efficiency;
   (iv) Predation-induced mortality.

The fundamental link between environmental temperatures and foraging as it relates to production is worth stressing here. The empirical findings and theory discussed earlier demonstrate that bottom-up influences—which control prey resource availability—appear to be critical drivers of fish production. This is consistent with other theoretical work suggesting that prey resources may often be the primary factor driving animal production, overriding direct effects arising from temperature and/or metabolic limitations (Cross et al., 2015; Junker et al., 2020).

On this basis, we offer the following testable hypotheses to guide future research:

1. Given that prey body size is a main determinant of predator body size, an increase in prey body size in the absence of changes in prey trophic level and abundance should lead to an increase in both predator foraging efficiency and predator size, with the following consequences for production: *increases* in both predator production per unit habitat area and predator production per individual (as per Eqs. 10a and 6); a parallel *decrease* in predator production per unit biomass, as per Eq. (8). The fact that the predicted direction of change depends very much on the units used to measure production highlights the importance of clearly defining those units.
2. As habitat size increases, top predators tend to occupy higher trophic levels. This is accompanied by the following changes in the dominant prey species: *increases* in both trophic level and individual size; *decreases* in both numerical and biomass abundance (Sprules and Barth, 2016, see chapter on the Biomass Size Spectrum, Andersen, 2019). The consequences for predator production will be diverse: at the population level, production per unit habitat will decrease (assuming increased foraging efficiency cannot compensate for the overall reduction in prey abundance), production per unit biomass will also decline (as per Eq. 8) but production per individual will increase (as per Eq. 6).
3. P/B ratios can be used as logistically simpler surrogates of detailed fish population production estimates, particularly for population and community production estimation on larger regional scales such as watersheds and lake regions.
4. Oxythermal habitat loss as a consequence of climate change will decrease production in stenothermic predators.
5. As DOC increases, light limitation increases, reducing the overall productive capacity of freshwater ecosystems, with negative consequences for fish production.

Fish production has long been recognized as the ideal metric for understanding the state of fish populations since it is the outcome of a major pathway of energy flow (Waters, 1977). Establishing the mechanisms that drive fish production within freshwater ecosystems through exploring the hypotheses we have laid out above will advance current knowledge in useful ways by: (i) answering fundamental questions around freshwater ecosystem function, and (ii) promoting the development of the practical management tools needed to mitigate future stresses on these systems from climate change, human development, invasive species, and exploitation.

Knowledge gaps

- New and defendable empirical estimates of production from a diversity of freshwater systems
- A better accounting for reproduction costs in production and MTE approaches
- How the relationship between production and biomass is affected by cofactors such as climate, food web diversity, habitat type (e.g., lake vs. river), and habitat size and complexity
- Refine the upscaling of individual growth models to population levels
- Accounting for phylogenetic diversity in production models

Glossary

Food web A description of the feeding relationships among organisms in an ecosystem.
Trophospecies A group of species that use the same resources and/or occupy the same trophic level (sometimes referred to as a "trophic guild").
Omnivory A feeding preference wherein an organism feeds on multiple prey or trophic levels.
Benthic energy pathway Resources originating from the bottom substrates of a lake.
Pelagic energy pathway Resources originating from the open-water area of a lake.
Bottom-up control The case in which nutrients regulate the biomass and community of primary producers, with effects that propagate to higher trophic levels to structure the ecosystem.
Top-down control The case in which predators regulate the abundance and/or size structure of their prey, with subsequent effects on the abundance and/or size structure of lower trophic levels to structure the ecosystem.
Trophic cascade The propagation of predation-driven, indirect changes in the abundance and/or community composition of trophic levels in a food chain, sometimes driven by the addition or removal of a top predator.
Biomanipulation Deliberate modification of an ecosystem by adding or removing species, usually predators.
Microbial loop Food web pathway in which dissolved organic matter is returned to the classical metazoan food web via food web linkages involving bacteria, protists, and crustaceans.
Biomagnification The process of the accumulation of contaminants in consumers at successively higher trophic levels.
Benthification A shift in energy production from the pelagic to benthic habitat.

Introduction

The study of food webs is the study of feeding or trophic relationships among species in an ecosystem. Interest in studying food webs stems from the fact that no species exists on its own. Rather, each species is embedded in a network of predator-prey interactions. These predator-prey interactions are of interest themselves and food web studies often provide a description of the feeding relationships among species within an ecosystem. Yet it has become clear that food webs have far-reaching consequences for ecosystems. Food web interactions greatly affect the abundance and dynamics of species. Food webs also have implications for ecosystem-level processes such as nutrient cycling and energy flux. Thus the study of food webs bridges population, community, and ecosystem ecology. At a foundational level, food webs provide a powerful framework for evaluating a collection of organisms as an ecological system.

It is critical to recognize that food web studies can encompass an exceptionally broad range of approaches and types of studies. Here, we identify three major approaches to studying food web study. A *connectance* (also known as topological or structural) food web is the binary (presence/absence) of predator-prey links among species in a community (Fig. 1A; Martinez, 1993, Dunne et al., 2002). *Energetic* food webs aim to represent the pathways and flows of energy through the food web, where links are weighted according to their energetic importance (Fig. 1B). Finally, *dynamic* (also known as functional) food webs focus on the factors that structure the abundance of different organisms and trophic levels, with emphasis on how the effect of predation cascades throughout food webs (Fig. 1C).

Food webs in nature are exceptionally complex. Studies of food webs inevitably involve simplifying this vast complexity into something more manageable. Examples include lumping similar species into 'trophospecies' (e.g., trophic guild), simplifying the ecosystem into discrete trophic levels or steps in a food chain, and ignoring taxa and habitats that are not considered important.

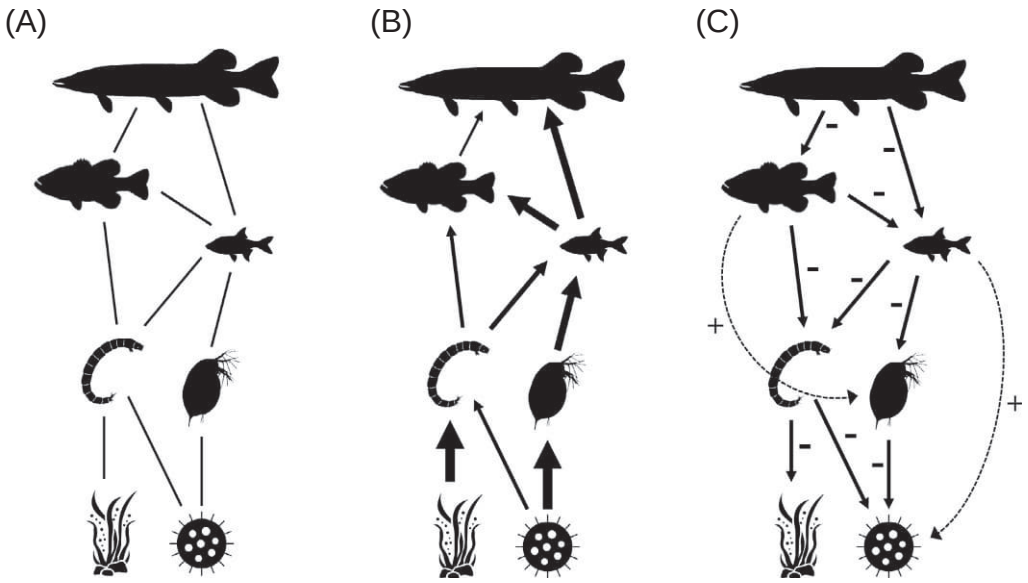

Fig. 1 Conceptual illustration of three approaches to the study of food webs: (A) connectance webs represent predator-prey links in an ecosystem, (B) energetic webs include information about the energetic importance (fluxes and flows) of food web links, (C) dynamic webs represent the linkages important for regulating abundance, including indirect and direct effects. In panel B, the size of the arrow indicates the magnitude of energy flow between trophic levels. In panel C, dashed arrows represent indirect interactions. Sign (– or +) represents the effect of the interaction.

Given the complexity of food webs, it is important to think carefully about what information is being described in a food web diagram or study.

The goal of this chapter is to provide a broad overview of lake food webs and highlight current areas of research interest. Lakes occupy a small portion (<2%) of the earth's surface, but are a vital source of freshwater to humanity, and provide a diversity of exceptionally valuable ecosystem services (Wilson and Carpenter, 1999). Studies have demonstrated that shifting food webs can have important implications for lakes and the ecosystem services they provide (Walsh et al., 2016). Moreover, several foundational advances in ecology emerged from studying lake food webs, including Lindeman's tropho-dynamic concept (Lindeman, 1942) and the concept of trophic cascades (Carpenter et al., 1985). One reason that the study of lake food webs has made broad contributions may be that lakes have well-defined boundaries, making them amenable to ecosystem study. While early ecologists viewed lakes as self-contained microcosms, researchers now recognize that there are strong inter-connections between lakes and their surrounding watersheds.

We divide this chapter into four sections. The first briefly addresses *connectance food webs*. While we do not expand broadly on this perspective, we offer multiple references for further reading. The second section focuses on food web studies taken from an energetic approach (*energetic food webs*). These studies tend to be 'bottom-up' in nature and emphasize how resources or energy at the base of the food web are transferred to higher trophic levels, as well as identifying the resources and energy pathways supporting higher trophic levels. The third focuses on *dynamic food webs*. These studies emphasize the effects of predators on their prey, and the interaction between 'bottom-up' and 'top-down' controls in structuring lake food webs. The fourth and final section highlights *integrative and applied perspectives* on food web studies including areas of emerging research interest in the study of lake food webs.

Connectance food webs

Connectance food web studies examine broad-scale patterns across collections of empirical food webs. These food webs are based on information about the presence/absence of trophic linkages. Connectance food webs are essentially network diagrams (Martinez, 1993; Dunne et al., 2002). Broad patterns can be examined - for example the number of observed trophic links can be related to the number of species, leading to a measure of food web connectance (Cohen and Briand, 1984; Paine, 1988). Connectance studies have also evaluated the relationship between the number of links in a food web and how many predators and prey occur (Cohen and Briand, 1984). Although connectance food webs can provide information about a system, many have critiqued this approach based on the arbitrary and poor quality of the data, as it fails to go beyond simple presence/absence of food web linkages (Paine, 1988).

Energetic food webs

Food chain concept—While natural food webs are characterized by vast complexity, many food web studies simplify matters by grouping functionally similar organisms. When considered in energetic terms, organisms are often combined into trophic levels – groups of species that are thought of as comprising a single step in ecosystem energy transfer. Photosynthetic organisms are considered primary producers (Λ1) and are the foundation of the food web. They are consumed by herbivores or primary consumers (Λ2), which are in turn consumed by secondary consumers (Λ3), and in many cases, tertiary consumers (Λ4). At each step, energy is lost, ultimately limiting the number of trophic levels in the food chain (Fig. 2). This fundamental concept of energy flow through successive trophic levels and concurrent energetic loss at each trophic level was presented by Elton (1927) and later Lindeman (1942) in his study of Cedar Bog Lake, Minnesota. While the transfer of energy from one discrete trophic level to the next is undoubtedly an oversimplified depiction of real food webs, the food chain concept has proven to be an exceptionally useful heuristic for conceptualizing energy flow in ecosystems.

Embracing complexity – the food web concept—Observational studies of feeding relationships generally reveal that the food chain concept with its simple trophic levels is a gross oversimplification of nature. Many species are 'omnivorous,' feeding on multiple

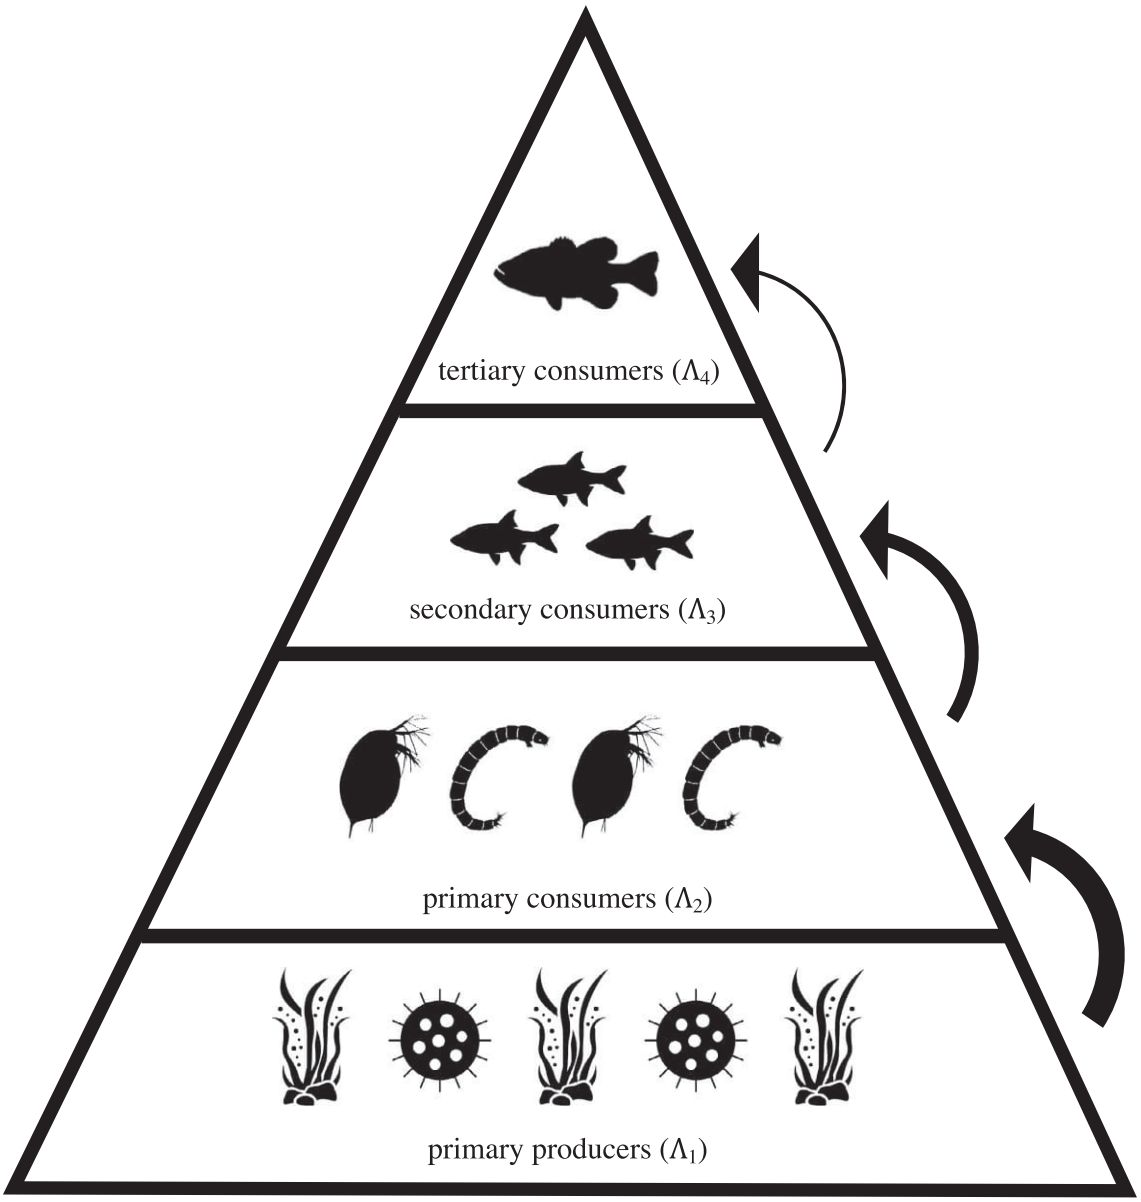

Fig. 2 Trophic pyramid showing energy flow across four trophic levels (Λ1, Λ2, Λ3, Λ4). Pyramid highlights the decrease in production at successive trophic levels. Arrow width indicates the magnitude of energy flow.

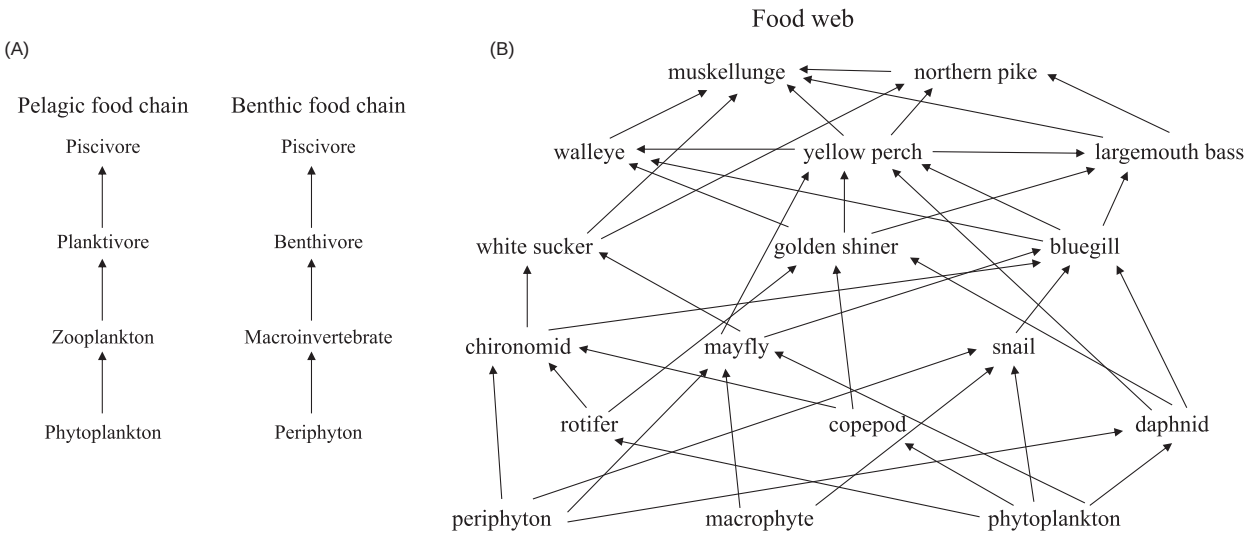

Fig. 3 Two idealized, linear food chains from pelagic and benthic habitats (panel A), as well as a simplified reticulate food web of a north temperate lake (panel B). Adapted from Rudstam LG, Allen Y, Johnson BM, Luecke C, Post JR, and Vanni MJ (1992) Food web structure of Lake Mendota. In: *Food Web Management*, pp. 233–242. New York, NY: Springer.

prey or trophic levels. Diets can vary among individuals of a trophic level, and shift during the ontogeny of a species, adding further complexity. Food web diagrams, sometimes comprised of numerous food chains (Fig. 3A), can be used to represent these more reticulate and complex food web relationships (Fig. 3B). But even these still tend to be an oversimplification of actual feeding relationships. The concept of trophic position incorporates some of this complexity. Though conceptually analogous to trophic level, trophic position is non-integer in nature and reflects the weighted average of the various feeding pathways supporting a consumer. Trophic position can be estimated from diet data. In recent decades trophic position has been estimated using stable nitrogen isotope ratios sampled from organismal tissues. Stable nitrogen isotope ratios become enriched between prey and predator tissues, thus providing a measure of consumer trophic position (Cabana and Rasmussen, 1996; Fry, 2006).

What basal energy sources support lake food webs?—Lake food web studies in the past decades have focused on identifying the trophic basis of support for higher consumers. These studies have revealed new insights into energy flow pathways in lakes. One important area of research has examined the energy (carbon) sources supporting higher trophic level production. Studies examining organisms' diets and stable carbon isotopes have found benthic (bottom) algae-based production pathways to be especially important in supporting higher consumers such as fish (Vander Zanden and Vadeboncoeur, 2002). This was surprising, as benthic production and trophic pathways have traditionally received little attention in limnology. An important implication is that fish play a central role in coupling benthic and pelagic production pathways in lakes.

Studies have also reported an important role of terrestrial-derived carbon in supporting higher trophic levels in lakes (Pace et al., 2004). This is especially the case in small lakes with high levels of terrestrially-derived dissolved organic carbon (DOC). This work reveals the potentially important role of heterotrophic bacterial food web pathways in supporting the production of metazoan consumers. Heterotrophic bacteria are known for their role in decomposition of organic matter. More recent work reveals that microbial food chains involving flagellates, protozoans, and rotifers funnel bacterial production (albeit with varying efficiency) back into classical metazoan food webs, ultimately supporting higher consumers such as fish. The presence of terrestrially-derived DOC plays a critical role. It reduces light penetration, and thus limits lake primary production. It also fuels heterotrophic bacterial production, and the microbial food web pathways described above (Karlsson et al., 2009).

Cross-habitat linkages—It has long been recognized that the structure and function of lakes is strongly influenced by their surrounding landscape. Due to their low-lying position in the landscape, organic matter and nutrient runoff from the land readily make their way into waterways and ultimately into lakes. Expanding agricultural and urban land use have dramatically accelerated nutrient inputs. Land use is the dominant driver of lake and coastal eutrophication (i.e., nutrient enrichment of a waterbody), a global problem that has led to the degradation of lakes worldwide.

More recently, studies have identified the importance of lake-to-land linkages wherein lake-derived productivity fuels or influences adjacent terrestrial ecosystems (Gratton et al., 2008). Lakes support the early life stages of many invertebrates, which then emerge and continue their lives in terrestrial environments. Emergent insects transport nutrients from lake-to-land, sometimes resulting in a significant flux of nutrients and prey to terrestrial systems. Riparian predators rely on emergent aquatic insects as a food source. The export of aquatic production to terrestrial ecosystems is common and can alter the functioning of terrestrial food webs through a nutrient fertilization effect, and by providing prey subsidies to terrestrial consumers.

Dynamic food webs

Drivers of food web structure—What ultimately controls the abundance of organisms at different trophic levels in an ecosystem? This is a central question of dynamic food web studies. Energy flow in ecosystems is unidirectional, moving from lower to higher trophic levels. So it is perhaps obvious that lower trophic levels influence higher trophic levels as a result of this direct energetic reliance. But predators also influence their prey, and the implications can be far-reaching. Dynamic food web studies attempt to understand the controls that structure organismal abundance across different trophic levels. Two predominant paradigms arose: bottom-up and top-down, leading to a debate over the relative importance of these controls. For decades, scientists emphasized the importance of bottom-up factors. In lakes, this was supported by that fact that there is a strong relationship between nutrient loading or nutrient concentration and algal biomass (Schindler, 1974). More recently, the structuring role of consumers, or top-down controls have been investigated in lake food web studies. Today it is well recognized that both bottom-up (nutrients) and top-down (consumers) forces interact to structure lake food webs, and that complex interactions yield a much richer range of dynamics than would be the case with simple linear food chains (Zaret and Paine, 1973; Carpenter et al., 1987; Knight et al., 2005; Koel et al., 2019).

Trophic cascade concept—The influential role of predators in structuring prey communities in lakes has been known for many decades. In response to variability in phytoplankton biomass that could not be explained by nutrients, it was proposed that changes in top predators could propagate to lower trophic levels through what is now known as a trophic cascade (Carpenter et al., 1985). Through whole-lake manipulations, it was established that while potential phytoplankton biomass is set by nutrients, realized biomass is influenced by the reciprocal effects of predators on prey transmitted through the food web. In these experiments, the removal of top predators (piscivores) resulted in the increased abundance of zooplanktivores, decreased grazer abundance, and higher algal biomass (Fig. 4).

Behaviorally mediated effects—Many studies emphasize the effects of direct, lethal predation in creating cascades in lake food webs, but predators also greatly influence prey behavior, which indirectly alters community interactions. In the presence of predators, prey may reduce activity or change their use of habitat, thereby altering prey diets and interactions in food webs. For example, the presence of piscivorous largemouth bass (*Micropterus salmoides*) altered the habitat use of juvenile sunfish (*Lepomis* spp.), leading to behaviorally-mediated cascading effects on benthic macroinvertebrates (Werner et al., 1983). Without largemouth bass, juvenile sunfish prefer the pelagic zone, but in the presence of largemouth bass, sunfish change habitat to the vegetated littoral zone where

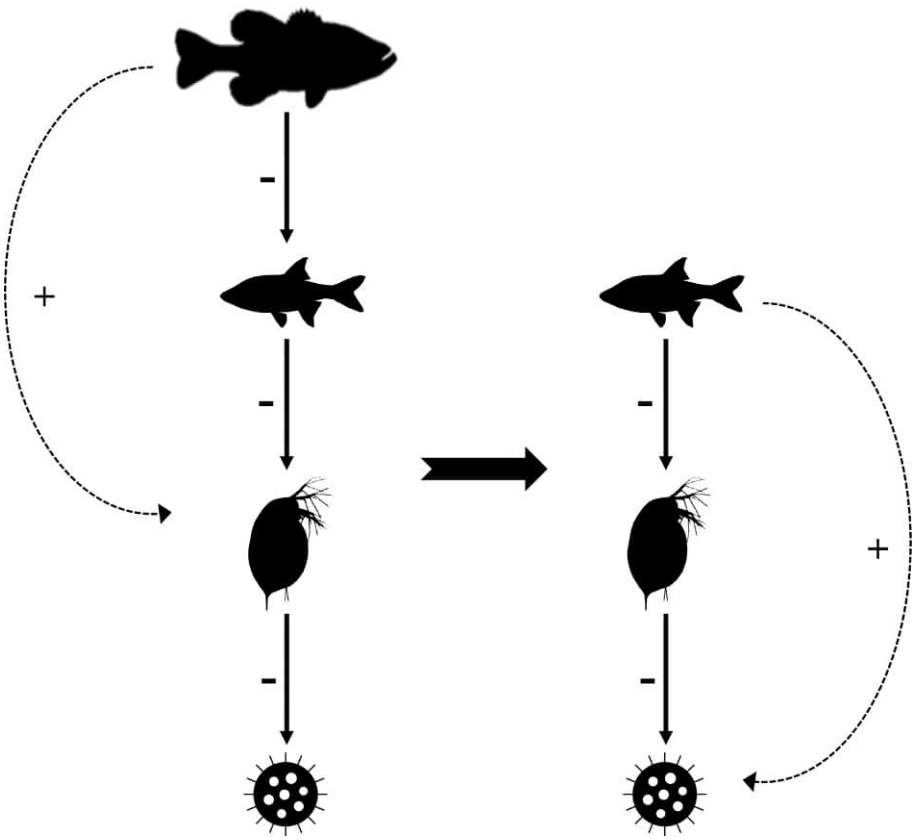

Fig. 4 A simplified dynamic pelagic food web consisting of four trophic levels. Solid arrows indicate direct interactions. Dashed arrows represent indirect interactions. Sign (– or +) represents the effect of the interaction. The horizontal arrow indicates an ecosystem shift wherein the top piscivore predator is removed.

they increase feeding on benthic macroinvertebrates, leading to reduced macroinvertebrate densities. It is clear that predators can have significant indirect effects on lake food webs by causing behavioral shifts in intermediate consumers.

The importance of indirect food web interactions is now well documented in a variety of contexts. This includes responses to the introduction of invasive species, situations involving cross-habitat linkages, and dynamics that play out over long time scales. In addition to providing a useful framework for assessing the role of top-down and bottom-up factors in structuring food webs, the trophic cascade concept also informs efforts to improve water quality in lakes (Hansson et al., 1998). Food web manipulations ('biomanipulations') such as stocking piscivores or removing coarse fish, are commonly employed to improve lake water quality, particularly where further nutrient reductions are not possible.

Structuring role of macrophytes—Macrophytes (i.e., aquatic plants) are an important group of primary producers in lakes that can play a role in regulating food webs. Beyond serving as a food source for certain lower level consumers, they also play an important structuring role in food webs. Macrophytes provide habitat for many species, serve as a predation refuge for invertebrates and fish, and greatly influence animal communities in a variety of ways (e.g., spawning, feeding habitat). By shaping predator-prey interactions, their effects can propagate through food webs. In this way macrophytes play a central role in the coupling of pelagic and littoral zones (Jeppesen et al., 1998).

Alternative stable states—Ecosystems exposed to changing environmental conditions, such as climate change or nutrient loading, may respond in different ways. Some systems change gradually, while others may abruptly shift between alternative states over a range of environmental conditions. An ecosystem exhibits 'alternative stable states' when the system response is not continuous given gradual changes in an environmental variable but instead shifts abruptly between two alternative equilibria (Scheffer et al., 1993). This theory was established from the study of shallow lakes in response to varying nutrient loading. Researchers observed that lakes displayed two equilibria: a clear state dominated by aquatic vegetation and a turbid state characterized by high phytoplankton biomass. Characteristic of alternative stable states, the lakes remained in their respective regime and a change in nutrient loading was insufficient to reverse states. Instead, considerable effort or a severe perturbation, such as intensive removal of zooplanktivorous fishes (biomanipulation) was needed to "push" the system back to the alternative state.

Food web stability—A topic of long-time interest to food web ecologists centers on how food web structure and complexity influences ecosystem stability. Stability can have different meanings, but often refers to susceptibility to runaway variation in species' abundances. Historically it was argued that complex food webs were buffered against strong dynamics and thus likely to be more stable. But theoretical analyses by May (1972) found that complexity tended to destabilize food webs. The most recent work reveals that if most food web linkages are weak, complexity tends to confer stability to food webs (McCann et al., 1998). Weak links serve to reduce fluctuations between consumers and producers, thereby maintaining populations further away from collapse. Studies of natural lake communities reveal that food webs are largely composed of weak interactions and few strong interactions. Today, food web stability and interaction strength in lakes continues to be a topic of great interest.

Integrative and applied perspectives

Lake food webs are characterized by complex biotic interactions. Food web interactions in lakes can also be influenced by external physical, chemical, and biological drivers. While the primary paradigms for how organisms interact and regulate one another are well established, the study of lake food webs is interdisciplinary and draws upon multiple realms of knowledge. As a result, there are many other approaches used to further our understanding of lake ecosystems that ultimately inform the use and management of lakes. Here we highlight several integrative and applied perspectives that demonstrate the cross-disciplinary approaches taken in the study of lake food webs.

Incorporation of microbial components—Historically studies of lake food webs largely overlooked microbial components of the ecosystem. But even with traditional food web approaches, many observed that the energy produced by phytoplankton was not enough to explain the productivity of higher trophic levels, prompting recognition of the importance of the 'microbial loop'. Heterotrophic bacteria are well known for their role in the decomposition of organic matter in lakes. There is a more recent recognition that bacteria form the basis of a pelagic microbial food web involving organisms such as heterotrophic flagellates, ciliates, and rotifers that ultimately links to the traditional metazoan food web (crustacean zooplankton, fish). The degree to which this microbial loop is an energetic 'link' or 'sink' in lakes is highly context dependent. Incorporation of the microbial loop provided new insights into energy flow in lakes.

Stoichiometric approach – "you are what you eat"—Everything in ecosystems is made up of chemical elements, such as carbon (C), nitrogen (N), and phosphorus (P). The study of the ratios among these chemical elements is called stoichiometry, which has become particularly influential in aquatic ecology with the field of ecological stoichiometry. Ecological stoichiometry considers the relative contribution of nutrients (e.g., C, N, P) as structuring agents of food webs (Sterner and Elser, 2002). This approach stems from the finding that a consumer's chemical composition reflects the chemical composition of its food, or in other words, "you are what you eat." Although ecological stoichiometry is applicable to any element, most studies focus on C, N, and P as they are the dominant components of organisms and often growth limiting (especially N and P). In aquatic systems, the ratio between C, N, and P (C: N: P) in the water is used to assess which of these nutrients is limiting for primary producers and thus higher trophic levels. In this view, relative nutrient concentrations provide the fuel for potential ecosystem productivity and animals represent large pools of nutrients that interact to structure lake communities (Sterner and Elser, 2002).

In addition to storing nutrients in their bodies that may be made available as they die and decompose, animals also have important indirect effects on lake stoichiometry. Higher level consumers, such as fishes, excrete and translocate nutrients within ecosystems, providing a substantial portion of phytoplankton nutrient demand (Vanni, 2002). For example, when zooplanktivorous fish become abundant they reduce grazing pressure by zooplankton (top-down effect), but they also promote phytoplankton growth by increasing available phosphorus through excretion (indirect bottom-up effect). Through direct and indirect impacts on ecosystems, consumers act as sources and sinks of nutrients and can impact lake community interactions.

Contaminants—The study of food webs has also made contributions to our understanding of contaminants in lakes. For contaminants such as methyl mercury, Polychlorinated biphenyls (PCBs), and dichloro-diphenyl-trichloroethane (DDT) that are transferred up food chains from prey to predator, the trophic position of a consumer is a strong determinant of contaminant levels (Cabana and Rasmussen, 1994). For these toxins, higher contaminant concentrations are found in progressively higher trophic levels, accumulating as they move up the food chain in a process known as 'biomagnification.' Food chain biomagnification can have noteworthy impacts, especially when highly contaminated prey are eaten by fish-eating birds and mammals, and toxins are passed on to adjacent ecosystems (Blais et al., 2007). Recent work has also identified concern over neonicotinoid insecticides. These chemicals are widely used in agriculture and have toxic impacts on planktonic and benthic invertebrates. The decimation of the food base due to neonicotinoids has led to fishery declines and is an emerging area of research (Yamamuro et al., 2019).

Biomanipulations with unintended consequences—Natural resource managers have often intentionally introduced species to achieve management objectives. Such efforts have involved the introduction of predatory fish to elicit a trophic cascade to increase water clarity (Hansson et al., 1998). Others have aimed at supplementing the forage base. These species introductions can have unintended consequences that ripple throughout the food web. One example involves the opossum shrimp (*Mysis relicta*), a predatory zooplankter that has been introduced into lakes of western North America and elsewhere to augment the food base for salmonids. Opossum shrimp introductions have led to sharp declines in large zooplankton species (e.g., *Daphnia*) and a shift to smaller zooplankton taxa, often leading to fishery declines. Specifically, in Lake Tahoe (CA-NV, USA), opossum shrimp were introduced in the 1960s, which led to significant declines in large zooplankton, reduced water clarity, and declines in Kokanee salmon. In Flathead Lake (MT, USA) the effect of introduced *Mysis* was similar in that zooplankton declined. In addition, this introduction bolstered populations of the non-native piscivore, Lake Trout. This increased predation on Kokanee salmon, thereby leading to their collapse. Further, these shifts redirected ecosystem energy flow, limiting resources available to nearby ecosystems and causing declines in terrestrial top predators (e.g., bald eagles; Ellis et al., 2011).

Fish species are commonly introduced to lakes to satisfy fishery management objectives but can have unexpected food web consequences. In some instances, the introduction of non-native species can have effects that cascade through the food web and adjacent ecosystems. For example, following the stocking of non-native lake trout (*Salvelinus namaycush*) in Yellowstone Lake (WY, USA), highly valuable endemic Yellowstone cutthroat trout (*Oncorhynchus clarkii bouvieri*) declined significantly (Koel et al., 2019). But it is not only non-native species that cause concern. Stocking of native fishes has also resulted in unintentional effects. In many lakes in North America and Europe, fishes of recreational interest are stocked annually. This practice can homogenize fish faunas, reduce genetic variation, and alter community composition as a result of higher predator populations than may occur naturally (Eby et al., 2006). In summary, intentional efforts to manipulate biotic composition in lakes often has unexpected effects that can ripple through multiple trophic levels and even into adjacent ecosystems (Koel et al., 2019).

Invasive species impacts on food webs—The introduction of non-native species can have profound effects on lake food webs. The Laurentian Great Lakes, with >180 introduced non-native species, have experienced so many food web disruptions that it can be difficult to interpret. One exception has been the invasion of Dreissenid mussels (*Dreissena* sp.). In 1988, Dreissenid mussels were discovered and quickly spread throughout much of the Great Lakes. Dreissenids are effective filter feeders and excrete organic material to the benthic substrate they inhabit. Given the rapid expansion and population growth of Dreissenid mussels in the Great Lakes, water clarity increased. This resulted in widespread 'benthification' wherein energy production shifted from pelagic to benthic regions, leading to an ecosystem-wide shunt from pelagic to benthic food web pathways (Mayer et al., 2013). The invasion of Dreissenid mussels greatly modified physical habitat with far-reaching effects on lake food webs.

Climate change impacts on food webs—As climate changes, food webs may experience strong perturbations resulting in unexpected consequences if interacting species respond differently to shifting environmental conditions. In Lake Washington (WA, USA), it was shown that increasingly warmer springs over the past 40 years have led to the uncoupled timing of phytoplankton and zooplankton blooms (Winder and Schindler, 2004). The spring diatom bloom no longer synchronized with the keystone herbivore (*Daphnia*) hatching period due to climate warming, resulting in long-term declines in *Daphnia*. Beyond the effects of climate change on the phenological coupling of trophic levels, climate change is expected to dramatically alter species interactions in lakes, though there is still much uncertainty regarding what the future will look like given the potential for unexpected results.

Social and economic change as a result of food web shifts—Food webs can change as a result of many drivers including biomanipulations, invasive species, and climate change. Structural food web changes can have drastic impacts on lake ecology itself, but these shifts can also ripple throughout human communities reliant on these ecosystems for nourishment, suitable water quality, as well as employment/tourism opportunities causing dramatic social and economic changes. One of the most pronounced examples of this occurred in Lake Victoria, Africa when a large-bodied piscivore, Nile perch (*Lates niloticus*), was introduced in the 1950s. Nile perch have transformed the lake food web as they rapidly consumed native fishes, specifically causing the extinction/near-extinction of numerous endemic cichlids (Balirwa et al., 2003). As a result of the disrupted native ecosystem, many locals were displaced from traditional occupations in the fishing trade or bought into the cash economy to purchase nets capable of catching adult Nile perch. The introduction of Nile perch ushered in a robust commercial fishery, leading to a novel international trade economy that has

further impacted social dynamics in the region. Beyond drastically altering the lake food web, the Nile perch fishery has led to further deforestation in the region, increased conflicts over fish exportation, and has rippled into the illegal trade of wildlife (e.g., bushmeat) as fishery catches fluctuate. Given the demand and reliance on Nile perch, this species has been overfished, which in combination with other ecosystem changes (e.g., water quality declines, nearshore human population growth) has led to further food web shifts and socio-economic changes (Balirwa et al., 2003). People are highly reliant on lakes for numerous services, including nutrition, employment, and recreation. Perhaps it should not come as a surprise that changing food webs can have dramatic consequences for human societies and well-being.

Conclusion

Food webs are a way of representing predator-prey relationships, energy flow, and multi-trophic level interactions in ecosystems. While food webs show the pathways of energy flow in ecosystems, predator-prey interactions simultaneously influence this flow of energy and cycling of nutrients, thereby shaping the productivity and abundance of organisms across multiple trophic levels. The structure of food webs is influenced by both internal and external drivers. Despite their relatively small global coverage, lakes provide disproportionately valuable ecosystem services to humans, which are highly influenced by food web interactions. Many different approaches and perspectives are used to understand lake food webs, including connectance, energetic, and dynamic approaches. In combination with other disciplines, these approaches highlight how food web structure affects community and ecosystem properties of lakes, including the ecosystem services that benefit humans.

Knowledge Gaps

- How can we simplify the vast complexity of natural food webs into something more manageable to inform our understanding and management of these ecosystems?
- How does food web structure and food web complexity in particular influence ecosystem stability and resilience?
- What are the causes and consequences of abrupt shifts in lake ecosystem states?
- What are the consequences of invasive species for lake food webs?
- How do shifting external drivers such as climate interact with changing food webs?
- What are the implications of changing lake food web for the multitude of ecosystem services provided by lakes?
- What is the role of adaptation and evolution in species interactions, and what are the broader food web consequences?
- How do parasitic interactions affect lake food webs?

Section Introduction: Structures and Functions of Inland Water – Rivers

N LeRoy Poff[a,b], [a]Department of Biology, Colorado State University, Fort Collins, CO, United States; [b]Centre for Applied Water Science, University of Canberra, Canberra, ACT, Australia

Rivers are ubiquitous features of the Earth's landscape. They are carved by the runoff from precipitation moving by gravity downhill to the oceans or inland terminal basins. As they flow, they transport sediment (and wood) via erosion, creating dynamic networks of channels and floodplains in which aquatic and riparian species evolve and thrive. Although rivers and streams comprise less than 0.005% of the freshwater on land, they host a greater species diversity per unit area than terrestrial or marine ecosystems. These diverse, dynamic systems provide innumerable goods and services to support human economic activities and societal wellbeing. The future of rivers in a human-dominated world requires that we better understand how they function and what management interventions can contribute to their sustainability.

In this "Streams and Rivers" section of the EIW2, we have collected 36 excellent chapters that help the reader understand rivers as complex and diverse freshwater ecosystems that vary across the landscape due to differences in climate, surficial geology, catchment topography, land cover and evolutionary history of the organisms that comprise these dynamic ecosystems.

These chapters present a variety of perspectives from authors who are experts on the particular chapter content. General conceptual foundations of whole river systems are presented in terms of how river ecosystem structure and function change along the longitudinal profile of a river system (Dodds and Maasri), and how nutrients move from upstream to downstream via water flow and biological uptake and release (Webster, Newbold and Thomas). Rivers also extend periodically outside their normal channels laterally onto with the adjacent land to support riparian ecosystems (Merritt) and diverse and productive floodplains in large rivers (Hamilton). Streams and rivers also have a vertical dimension, with surface water moving into the streambed to the subsurface "hyporheic" zone, where special fauna and important nutrient transformations occur (Lewandowski, Müller and Schulz). The habitats within a river or riparian zone are strongly influenced by the physical nature of the streambed and the dynamic flux of water and sediment, as described in the excellent chapter on fluvial geomorphology (Kondolf and Bizzi). The dynamics of streamflow through river channels, the sources of that variability and how differences in streamflow among rivers can be generalized are treated in a chapter on hydrology (McManamay). Some types of rivers are relatively distinct due to hydrologic or climatic harshness, and examples of these are covered in chapters on high latitude streams (Lento and Culp), alpine streams (Khamis, Brown, Milner, Hannah, Fell), dryland rivers and streams (Compson, Allen, Gao, Hong, Sarremejane, Ruddell, Delvecchia, Burrows, Monk), and intermittent and ephemeral streams (Datry and Stubbington).

Many chapters are included that describe basic biological processes in river systems. For example, algae capture solar energy and convert that, along with dissolved nutrients, via primary production into a fundamental basal food and energy resource (Stevenson). This algal production, along with detritus imported from the terrestrial realm, drives production of consumers and overall ecosystem productivity (Whiles and Patrick). Aquatic organism production can be strongly constrained by the balance between nutrients available and those needed for growth, as described in the chapter on the growing field of stoichiometry (Atkinson, Halvorson, Evans-White, Hopper, Vanni). The interactions between organisms in streams and rivers are often viewed through the lens of communities of species interacting in a food web in streams to mid-size rivers (Thompson) and in large rivers (Thorpe). These interactions may also be mediated through dynamic environmental variation caused by disturbance of the habitat due to hydrologic variation or streambed movement (McIntosh and Barrett). Streams or rivers can recover after disturbance, even catastrophic disturbance, through a process of succession (Milner).

New insights into stream and river ecology over the last decade emphasizes the importance of habitat connectivity in the context of river networks, allowing distant local populations to be connected via dispersal to create metapopulations or metacommunities (Cathay and Brown). This macrosystem perspective (Thorpe) or viewing local system in a regional (network) context is also critical for understanding the resilience of streams and rivers to landscape fragmentation and environmental change (Van Looy, Fuller, Gilvear, Thoms, Wolter).

Streams and rivers suffer many impacts from human activity, often in terms of degraded water quality (Bohenek and Sullivan), and these are covered in chapters on the effects of dams (Schmidt), mining (Clements), and multiple stressors from a variety of pollutants (Birk), including novel stressors such as pharmaceuticals (Rosi). A chapter on urbanization (Walsh) discusses dominant impacts on streams and rivers caused by the world's growing population. Additional threats to river biota and ecosystems are covered in chapters on the spread of non-native species in rivers (Olden, Chen, Garcia-Berthou, King, South, Vitule) and on the growing concerns about climate change and its attendant increase in extreme event frequencies (Tonkin).

To guide management of rivers, the extent of stress or pollution on modifying biological integrity is typically quantified though biomonitoring methods (Hawkins and Carlisle), including novel approaches using "environmental DNA" collected from stream water (Baird, McGee, Compson, Hajibabaei, Robinson, Porter). Many chapters discuss various management actions, including stream restoration in general (Palmer and Laub) and modifying flow releases from dams to obtain partial restoration via "environmental flows" (Arthington). The growing science of dam removal is also presented (Bellmore and Duda), as this avenue of river restoration is increasingly being used. These actions are often grounded in the concern over species loss, as discussed in a chapter on biodiversity conservation in rivers (Linke and Hermoso) and a chapter on the "ecosystem services" provided by rivers (Jähnig, Jardine, Pusch, Wantzen, Dehnhard, Scholz, Tharme, Langhans, Podschun) that are at risk of loss by many human activities.

In sum, these 36 chapters provide the reader of the EIW2 with both a broad and a detailed view of streams and rivers that will advance society's understanding of these complex and ubiquitous inland freshwater systems. On a personal note, I wish to offer my personal thanks to all the contributors to this section—the last 2 years have presented especially challenging circumstances that complicated personal and professional lives. Nonetheless, the authors of these chapters persisted and completed their contributions, with the result being an excellent compilation of contemporary perspectives on stream and river science that speak to the urgency of better managing our inland fresh waters toward a resilient future and for the continuation of all the benefits and opportunities — economic, social, cultural and spiritual — they provide to humanity.

The River Continuum Concept

Walter K Dodds[a] and Alain Maasri[b,c], [a]Division of Biology, Kansas State University, Manhattan, KS, United States; [b]Department of Ecosystem Research, Leibniz Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany; [c]The Academy of Natural Sciences of Drexel University, Philadelphia, PA, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Allochthonous Carbon produced outside the stream in the terrestrial habitat, which falls or washes into the stream.
Autochthonous Carbon produced by primary producers in the stream or river.
Collector-gatherers Animals that collect small organic particles (living or dead) for food.
Ecosystem respiration (ER) The sum of respiration (i.e., the process involving the intake of oxygen and the release of carbon dioxide from the oxidation of organic substances) by all heterotrophs and autotrophs in an ecosystem. Units are in mass per area per time or mass per volume per time.
Filter feeders Animals that collect particles in suspension in the water column.
Functional feeding groups Classification of organisms based on their ecological role, particularly their trophic position in a food web. Often used to classify animals.
Gross primary production (GPP) The total carbon fixation in an ecosystem. It can also be represented by dissolved oxygen flux. Units are in mass per area per time or mass per volume per time.
Invertivores Animals that feed on invertebrates.
Macrophytes Aquatic plants that have adapted to living in aquatic environments.
Net Ecosystem Production The gross primary production (GPP) minus the ecosystem respiration (ER) that indicates net carbon gain in a system. It is sometimes represented as GPP/ER where net carbon gain is represented by values greater than one.
Periphyton The complex film of algae and other organisms attached to solid surfaces in freshwater environments.
Piscivores Animals that feed on fishes.
Planktivorous Animals that feed on plankton, including zooplankton and phytoplankton.
Riparian zone The zone near the edge of a river or stream.
Scraper-grazers Animals that scrape biofilms from solid surfaces, usually periphyton (i.e., attached algae). Also refers to animals that eat macrophytes (aquatic plants). Grazer implies consumption of photosynthetic organisms.
Shredders Animals that break down leaves or wood for nutrition.

Introduction

The River Continuum Concept (RCC, Vannote et al., 1980) is almost a half-century old, and as of September 2021 Google Scholar counts over 12,000 citations and the more restrictive Web of Science lists over 6300 citations. At the core of this concept is the idea that at each specific location in a watershed, inputs from upstream interact with the local terrestrial riparian habitat to control ecosystem characteristics. These interactions then shape river ecosystem metabolism, energetics, and biological communities. Whether considered a milestone in stream ecology that shaped stream ecology research or a concept that needs revision, it has the merit of spurring considerable research, conceptual advance, and debate in stream ecology. Here, we explain the RCC, and how

it has evolved over the years since first proposed by Vannote et al. (1980), including support and critiques. We end with ideas of how researchers might use the concept into the future.

The original concept centered on the continuous connection from a temperate forested high elevation stream flowing through ever-bigger channels into a large lowland river (Fig. 1). The organic material entering from nearby riparian vegetation, the organic material transported from upstream, and the light entering the flowing water driving photosynthesis are the factors that control the sources of carbon and their identity. In small streams with dense canopy cover, the light is low for much of the year, so primary production (autochthonous carbon) is limited and most carbon enters the system in the form of terrestrial leaves, dissolved organic carbon, and other detritus (allochthonous carbon). This leads to a system dominated by heterotrophic respiration (mostly microbial) that relies upon the organic material. In this case, gross primary production (GPP) is low, ecosystem respiration (ER) is high, net ecosystem production is negative, and GPP/ER is less than one. In the middle-sized streams further down the continuum, the stream widens, and light can stimulate productivity. While the light promotes primary production, allochthonous carbon also enters the stream from nearby riparian vegetation and washes in from the small streams above. In this case, GPP rates balance ER, and net ecosystem production approaches or is greater than zero. Note the original paper suggested GPP/ER greatly exceeded one in middle- sized streams, but subsequent research suggests it rarely does by much. Once the flow reaches large rivers, the system is almost completely dependent upon carbon transported from above or gross primary production by any primary producers in the water if turbidity is low enough so that ample light can be transmitted into the river.

This basic pattern in carbon and light supply then controls function and composition of the communities of invertebrates and fishes. The relative dominance of invertebrates is categorized by their functional feeding groups. These include (1) shredders that consume large organic detritus, (2) collector-gatherers that filter or collect smaller particles, (3) scrapers-grazers that consume periphyton or macrophytes, and (4) predators. Changes along the continuum are driven mainly by relative availability of allochthonous and autochthonous carbon sources. In small streams, invertebrate communities rely heavily on allochthonous particulate organic matter, such as leaf litter, decomposed detritus, pollens, and other organic debris, or the microbes on this organic matter. Communities of small streams are, therefore, predicted to be dominated by shredders and collector-gatherers. Shredders process primarily coarse particulate organic matter (>1 mm diameter), while collector-gatherers process the finer fraction of this particulate matter. Both shredders and collector-gatherers depend upon microbial biomass and the byproducts of microbial metabolism for their nutrition. In middle-sized streams, communities shift to dominance by collector-gatherers and scraper-grazers. The development of periphyton as more light reaches the stream in a relatively open canopy characterizing middle-sized streams drives increased relative abundance of grazers. Farther down the continuum, an increase in water turbidity and a sharp reduction of relative importance of locally produced allochthonous detrital coarse particulate carbon are expected. The concept predicts that associated invertebrate communities in these larger systems will be dominated by collector-gatherers including filter feeders.

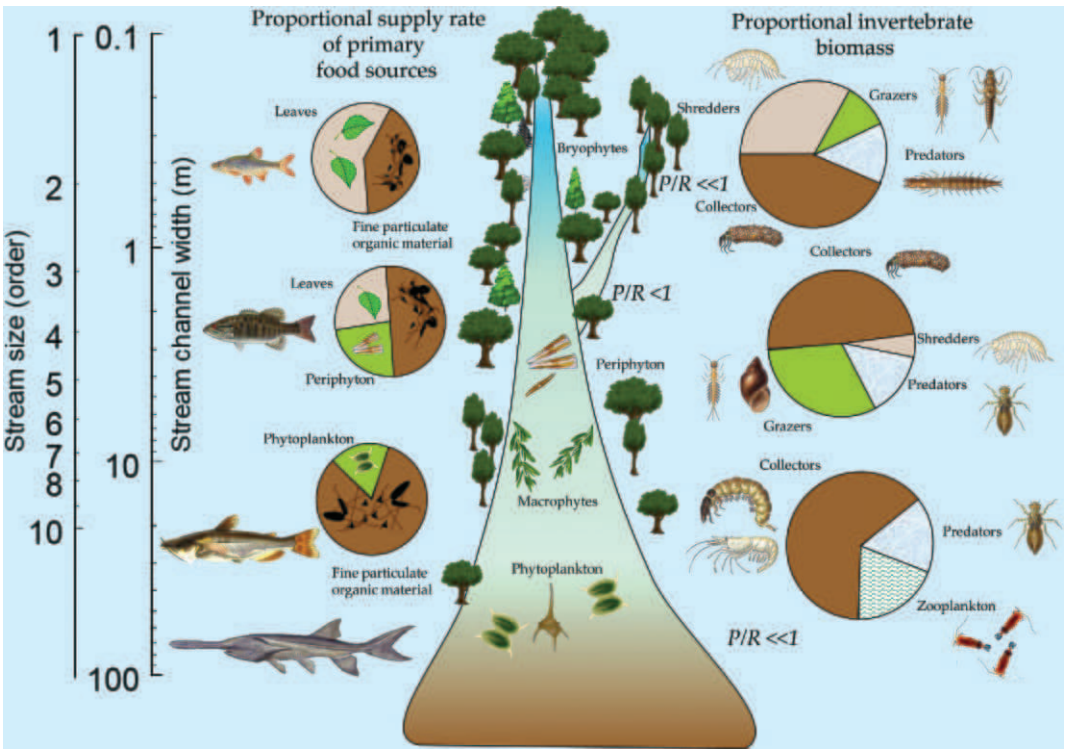

Fig. 1 A diagram of the River Continuum Concept. Modified from Vannote RL, Minshall CW, Cummins KW, Sedell JR and Cushing CE (1980) The river continuum concept. *Canadian Journal of Fisheries and Aquatic Sciences* **37**: 130–137.

The original paper, therefore, argues that the longitudinal pattern in invertebrate communities reflects an adaptation to optimize energy use. Thus, energy in the form of organic carbon that is not used in the upstream parts of the stream moves downstream and the downstream community benefits from it. Stated differently, the invertebrate communities have evolved to efficiently use the balance of organic carbon generated locally (either allochthonous or autochthonous) and that being transported from upstream.

The concept predicts fish communities will be dominated by invertivore species in small streams and headwaters, by invertivores and piscivores in middle-size streams and further downstream along the river continuum. In the largest sections of the river, often associated with low slope, planktivorous species will become more prevalent reflecting the semi-lentic (i.e., lake-like) nature of such waters. Many of the species in large rivers are adapted to high turbidity/low light conditions. The original concept also states that this shift in fish communities reflects changes in affinity to water temperature. Headwater and small stream communities exhibit low diversity and affinity to cool water, while further along the continuum, fish communities are more diverse with increasing affinity to warmer water.

The original concept

The RCC used five components to describe how it should apply to stream ecosystems. Here, we discuss components that "went forward" or received substantial attention in the scientific community, as well as those that were "set aside" or were less commonly examined.

Components that went forward and why

In general, these components went forward because they provided easily testable hypotheses. They are also simpler to understand, so they form the basis of teaching efforts and appeal to a wide range of types of scientists. The common image associated with the RCC found in many textbooks is based on these components (e.g., Fig. 1).

Stream size and ecosystem structure and function

This component is, by far, the most widely examined and has shaped much of the stream ecology research subsequent to the RCC. It stipulates that based on stream size (expressed as stream order) a longitudinal shift in loadings of carbon shape communities of invertebrates and fishes. The ratio of stream GPP/ER characterizes the longitudinal change in carbon inputs. When photosynthesis is the dominant pathway of incoming carbon the GPP/ER is expected to be greater than 1. This component has been tested in multiple ecoregions and on different types of rivers spanning temperate and tropical ecosystems (see, table of supporting case studies below, Table 1). Researchers have also thoroughly examined changes in community composition of fishes and invertebrates and shifts in their trophic guilds to validate the predictions of the RCC. The bioenergetic influences along the river continuum are also widely considered by stream researchers.

Ecosystem processing along the continuum

This component stipulates that unused or partially processed materials in a river ecosystem will be transported downstream where communities are structured to capitalize on the so-called "inefficiencies" of upstream processing. The fate of unprocessed material and the examination of retention, leakages, and downstream adjustments are topics often researched in the context of watershed functioning as a whole.

Table 1 A few important case studies.

Components that were set aside

In general, these concepts are more difficult to understand than those that went forward. They are not as easily tested, as they require long periods of time (e.g., geomorphological change or biological evolution) or space for time substitutions for confirmation. They are not simple to explain graphically and thus have seen less interest in the research and teaching communities.

River ecosystem stability

This component stipulates that ecosystem stability may be viewed as the tendency to reduce fluctuation in energy flow and other variables of the physical system while the structure and function of the biota are maintained. We note that river ecologists and geomorphologists have developed a differing view of "stability" than in some other branches of ecology (e.g., Connell and Sousa, 1983). In general, the idea of a dynamic equilibrium in geomorphology suggests an overarching stability in the face of continuous change that can include catastrophic events such as intense floods (Schumm and Lichty, 1965). This view of a dynamic equilibrium suggests a sort of stability at longer periods used by river geomorphologists that strongly influenced the framers of the RCC. Ecosystem stability is therefore achieved by a dynamic interplay between physical and biological components that change along the river ecosystem from low to high stream orders. In highly fluctuating environments (e.g., fluctuation in temperature, dissolved oxygen concentrations, or water discharge), the biota may assume a critical role in stabilizing the energy flux through an entire system, whereas in highly stable environments the role of the biota in ecosystem stability will be reduced. Only more recently have stream ecologists approached system stability through the concepts of thresholds and alternative stable states (e.g., Dodds et al., 2010). Furthermore, most stream research on stability and disturbance does not directly reference the RCC. Finally, until recently ecologists have not considered stability or dynamic equilibria in the face of global climate change and the prevalence of invasive species that may come to dominate energy flows and change the predictions of the RCC.

Temporal adjustments in maintaining an equilibrium of energy flow

This component stipulates that stream ecosystems will tend towards uniformity of energy flow on an annual basis. Synchronized change in biological communities to temporal patterns of energy sources over an annual cycle controls uniformity of energy flow. Thus, biological systems move towards equilibrium by a trade-off between a tendency to optimize the use of energy inputs and a tendency towards a uniform rate of energy processing throughout the seasons. While this principle has been validated in streams of temperate forested regions (Minshall et al., 1983; Bott et al., 1985), little attention has been given to examining this principle in streams of other biomes. In general, most stream researchers do not produce annual budgets of carbon flux, so few data are available to test this idea. However, longer-term carbon flux estimates are becoming available (e.g., Roberts et al., 2007; Uehlinger, 2006), but only a few are available for larger rivers on an annual basis (e.g., Dodds et al., 2013), and these are not paired with estimates of production by different functional groups of animals. Factors that disrupt systems such that the species evolved in a particular area are no longer as well suited for the habitat (e.g., anthropogenic disturbances, directional climate change, species invasions) will interfere with this "equilibrium."

The invariance and the absence of succession in stream communities

This temporal equilibrium component stipulates that biological systems of each stream order are in equilibrium with the physical system at that point of the continuum. Temporal succession is not explicitly considered under the framework of the RCC, instead, biological systems present only a spatial shift along the continuum. Losses and gains of species occur primarily in low probability cataclysmic events and in response to evolutionary channel development. The lack of observation of successive biological stages is attributed to communities being a continuous heritage of species rather than an isolated temporal composition of species within a sequence of discrete successive stages. Thus, slow evolutionary processes shaping stream channel development are the main drivers of this invariance (or absence of succession) of stream communities at a non-evolutionary period. Little research has examined this principle to date, the main obstacles being the availability of extensive temporal data, and the numerous major alterations that have affected river ecosystems globally in the last century making it challenging to dissociate the contributions of natural and anthropogenic changes to the succession in stream communities.

Critique and support

The conceptual framework of the RCC received both critiques and support since its publication. Several papers supporting the overarching predictions of the RCC appeared soon after the original paper (see table of supporting case studies, Table 1). Minshall et al. (1983) documented the greatest inputs of allochthonous materials in headwaters in four stream networks across the United States. Bott et al. (1985) documented decreases in the relative importance of heterotrophic metabolism relative to primary production in four watersheds across the continental US as predicted, but noted that seasonal variation and that the shift happened at different stream orders. Rosi-Marshall et al. (2016) visited the same Idaho sites used in the previous two studies and re-sampled invertebrates. They found, as the RCC predicts, the greatest amount of reliance on leaf litter in headwaters. However, the authors also noted that there were substantially more autochthonous materials in the guts of stream invertebrates than predicted in the lower order streams. Lately, Curtis et al. (2018), tested the RCC predictions by explicitly linking consumer groups and found that the RCC predictions are integrated into the food webs, transcending, therefore, assemblage boundaries.

The main critiques can be grouped into four major divisions: (1) The limited applicability of the concept arguing that it was developed only for temperate river systems with forested headwaters and rivers flowing in relatively undisturbed landscapes, ignoring, therefore, the complexity of river systems globally. Many argued that the concept applies only to one type of river system excluding, just to cite a few, intermittent rivers, grassland rivers with reduced woody riparian, endorheic rivers, and tropical rivers. (2) The concept failed to integrate lateral habitats and floodplains and their contributions to both river functioning and biodiversity. Critics argued that the relative contribution of lateral connectivity becomes more and more important with increasing stream order and the contribution of lateral habitats in meandering and braided river sections, for example, cannot be ignored when conceptualizing river ecosystems. (3) geomorphological patterns and others that form the template for habitat often do not reliably follow the upstream-downstream continuum of the RCC and local processes may depend more heavily on local conditions than transport from upstream. (4) The concept did not account for the general framework of meta-community theory and identified only local environmental heterogeneity as the main driver for changes in the composition of stream communities.

The first critique, that the RCC only covers temperate forested headwater streams and does not apply to other biomes, is somewhat unfair. The Vannote et al. (1980) paper explicitly said that "At higher elevations and latitudes, and in xeric regions where riparian vegetation is restricted, the transition to autotrophy may be in order 1". This statement acknowledges that the authors understood that the patterns they were describing were potentially biome-specific. However, several critiques and modifications have addressed this issue. Soon after the original publication, Winterbourn et al. (1981) criticized the RCC by showing the limited applicability of the concept to New Zealand river systems with unpredictable rainfall patterns and low forest biomass. Barmuta and Lake (1982) responded to this critique that the lack of invertebrates following the expected patterns in New Zealand rivers could have been related to unusually high disturbance rates in the rivers studied by Winterbourn et al. (1981). Dodds et al. (2004) modified the RCC for application to grassland streams, and this approach was taken further subsequently, to predict the way that biomes modified the predictions of RCC (Dodds et al., 2015). Greathouse and Pringle (2006) studied freshwater invertebrates in tropical streams of Puerto Rico. They found that predators, scrapers, and shredders followed the prediction of the RCC patterns, but that filterers and omnivorous freshwater shrimps did not. They suggested that spatially restricted predation on the shrimps by fishes could explain part of the deviation from the patterns expected by the RCC. Tomanova et al. (2007) found patterns of invertebrate structure and function mostly followed the RCC in Bolivian streams once the corrected for altitude.

The second avenue of criticism, that the RCC failed to integrate lateral habitats and floodplains and their contributions to both river functioning and biodiversity has been discussed by several researchers. Sedell et al. (1989) noted the RCC did not predict the importance of side habitats (e.g., backwaters and weakly connected oxbow lakes) connected to large rivers that are vital habitats for fishes and important locations of high ecosystem productivity. Junk et al. (1989) formalized the idea that large rivers experience high flows that connect lateral habitats to the main channel, further developing ideas of ways that large rivers are not completely explained by the RCC. However, materials carried into lateral habitats can originate from upstream.

The third avenue of criticism, that geomorphological patterns that form the template for habitat often do not reliably follow the upstream-downstream continuum of the RCC, and that local processes may depend more heavily on local conditions than transport from upstream has also received consideration. This avenue relates to the second avenue discussed in the last paragraph. Minshall et al. (1985), further refined by Montgomery (1999), suggested a "process domain" framework could allow the application of geomorphological considerations at various scales to make the RCC more broadly predictive. Thorp et al. (2006) took this idea further in their Riverine Ecosystem Synthesis (RES). They viewed streams as nested hierarchies of patch mosaics, with ecosystem dynamics resulting from a composite of intra and inter patch processes. Functional process zones, as identified in the RES, controlled therefore local processes. They stressed the non-equilibrium processes that result in "quasi-equilibrial metastable states". This synthesis led to 14 predictions on ecological characteristics in streams. This synthesis allows for upstream linkages upon which the RCC depends, but it focuses much more heavily on local conditions and views ecological processes in rivers and streams as substantially more insular than the RCC does. The degree to which local processes dominate relative to control by position in the watershed and location on a continuum from headwaters to large rivers is still an active area of research in stream ecology. More recently, Maasri et al. (2021) and Collins et al. (2018) have shown that despite considering rivers through a discreet model like the RES, the longitudinal and progressive downstream gradient of responses to abiotic and biotic features will be observed in communities and processes, thus forming a partial biotic continuum as predicted by the RCC.

The idea of breaks in the RCC as spawned a number of publications on the river "discontinuum" For example, when a tributary enters a stream, the discharge downstream is abruptly greater (Poole, 2002), and such tributaries create unique habitats above and below the main channel (Benda et al., 2004) disrupting the concept of a smooth continuum. Natural features such as beaver dams (Burchsted et al., 2010), lakes (Jones, 2010), and subsurface stream flow (Di Lorenzo et al., 2013) have all been described as discontinua. These researchers present a view that is closer to the RES than the RCC.

The fourth, and most recent, avenue of criticism states that the RCC failed to integrate the contribution of the theoretical framework of meta-community ecology in explaining changes in communities along the continuum (see review by Doretto et al., 2020). This avenue needs to be considered with respect to the relatively recent rapid development of research in meta-community theory. Meta-community theory postdates the RCC (see, Hanski, 1994, Leibold, 1995, or Leibold et al., 2004), with only a few exceptions referring to the role of dispersal limitation or stochasticity as drivers of ecological communities that can be dated to the early 20th century (Chase and Myers, 2011).

Some further modifications to the RCC have been proposed in addition to the four areas of criticisms to broaden the applicability and scope of inference of the RCC. Statzner and Higler (1985) proposed to simplify the concept and reduce its theoretical ballast by excluding components that are either unexpected, unsupported by evidence, or restricted to particular

geographic areas. Those components dealt mainly with the absence of succession in stream ecosystems, the temporal sequence of species replacement, or longitudinal patterns of biodiversity, shifting, therefore, the RCC towards an energetics based concept, with emphasis on photosynthesis, respiration, and on the status of organic matter and corresponding organization of communities. This suggested simplification was prescient, and Statzner and Higler (1985) suggested dropping the components that we listed above as "not going forward"; it appears that the stream research community has taken this recommended approach for the most part.

The RCC developed in a time when ecologists often focused on "natural" conditions and abiotic and biotic drivers of stream networks as relatively constant over time (e.g., no climate change or invasive species). However, human impact has increased substantially as we move into the Anthropocene. Dams are ubiquitous in watersheds of most areas with human inhabitation, and Stanford and Ward (2001) modified the RCC by considering how human-constructed impoundments disrupt the continuum. While reservoirs strongly influence the continuum, other features can as well. Anthropogenic influences can disrupt or enhance connectivity by activities such as water abstraction drying stream channels, channelization of flows, and construction of impoundments.

Additionally, deforestation, row crop agriculture, and urbanization can lead to large disruptions in the expected continuum by altering flow, riparian conditions, and natural sediment regimes. The RCC does at least provide a framework under which to understand some implications of these changes to river ecosystems.

Conclusion

The RCC has received great attention, in part, because it took a landscape view of how position in the watershed influenced stream ecosystems. River ecologists were primed to receive this view because of the obvious influence of the watershed on aspects such as water quality, discharge, flood intensity, and biotic components (Hynes, 1975). These types of ideas still have relevance. For example, the meta-ecosystem framework (Loreau et al., 2003) was proposed as a new avenue for landscape ecology, but the RCC already fits into that framework in that it includes multiple linked systems that are spatially distributed and have specific interactions based on how they are linked. The second reason that the RCC has been successful is that the components that went forward are conceptually simple and based on obvious abiotic properties such as the fact that stream channels generally get wider further down in the watershed and flow moves materials downstream. The RCC provides testable hypotheses, and they are easy to modify as new approaches have arisen. Even if some of the specifics do not hold (e.g., streams are not all in the temperate biomes originally considered), it is easily modified based on basic geomorphological and ecological principles (e.g., riparian canopies can intercept light, the balance of metabolism in ecosystems, functional adaptations of stream invertebrates) to provide a new framework applicable to local conditions.

Knowledge gaps

- How does the continuum vary with the biomes that rivers and streams are embedded in?
- What is the relationship of the continuum with local processes such as floodplain dynamics and functional processing zones?
- What is the influence of humans on the expectations/predictions of the RCC, including land cover/land use change, climate change, and eutrophication?
- Does biogeography influence the RCC (e.g., do areas with functional groups of organisms with different evolutionary history display different patterns)?
- Do any of the less studied predictions of the RCC hold (e.g., can paleoecology get at the idea of animals in ecosystem optimizing energy flow)?
- How does the RCC relate to meta-community concepts?

The Nutrient Spiraling Concept

JR Webster[a], JD Newbold[b], and SA Thomas[c], [a]Department of Biological Sciences, Virginia Tech, Blacksburg, VA, United States; [b]Stroud Water Research Center, Avondale, PA, United States; [c]School of Natural Resources, University of Nebraska, Lincoln, NE, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Spiraling length The sum of uptake length and turnover length, that is, the total distance a nutrient atom travels as it completes a cycle from mineral form to organic form and back to mineral form. **Turnover length** The average distance a nutrient atom travels in organic form before being mineralized. **Uptake length** The average distance a nutrient atom travels in dissolved, inorganic (mineral) form in the water column before being immobilized by autotrophic or heterotrophic processes.

Introduction

Nutrient spiraling in streams refers to the coupling of nutrient cycling and hydrologic transport. Nutrients do not really "spiral," but the analogy is a useful way to study the dynamics of nutrients such as nitrogen and phosphorus in streams. The concept was introduced by Webster (Webster 1975; Webster and Patten 1979) with the idea that the intensity of nutrient cycling in a stream, or the "tightness" of the conceptual spiral, reflects the activity of streambed biota in capturing, using, and recycling nutrients that otherwise would be carried downstream with the current. Newbold and colleagues (Newbold et al., 1981; Elwood et al., 1983) proposed that this intensity could be expressed as the downstream distance required for a nutrient atom to complete one loop of the spiral, which they termed the spiraling length, S, and which consists of the sum of an uptake length, S_W, and a turnover length, S_B (Fig. 1). In any ecosystem, nutrients in bioavailable forms are used by organisms, pass through food web components, and return to bioavailable forms through excretion and decomposition, thus completing a conceptual nutrient "cycle." In a stream, the flow of water ensures that a nutrient atom on completing a cycle is transported some distance downstream, so that its flow through the ecosystem may better be conceptualized as a spiral, or helix, stretched in the downstream direction.

In all but the largest rivers, most of the biological activity occurs on or in the streambed. Uptake of nutrient from the flowing water by bottom-dwelling organisms slows or even stills the downstream journey of the nutrient. Where a limited nutrient supply supports an active streambed biota, spiraling length is short and nutrient atoms cycle many times within a reach or river network. A large nutrient supply and/or low nutrient demand yields long spiraling lengths and little recycling. The most common practical use of the spiraling concept lies in measuring the portion of the spiraling length termed the uptake length. From a measurement of uptake length, the assimilation of a nutrient by streambed biota can be calculated. Less common in the literature are estimates of turnover length, although notable exemptions exist, many associated with organic carbon turnover (e.g., Newbold et al., 1982; Minshall et al., 1992). This chapter presents the equations underlying the spiraling concept, then turns to the practicalities of measuring spiraling, its application to the modeling of nutrient dynamics, and finally to challenges for future work.

Stream spiraling metrics

For idealized conditions, stream spiraling metrics were defined as follows (Newbold et al., 1983; Newbold, 1992):

Uptake length, S_W, is the distance traveled by a nutrient atom in dissolved, inorganic (or mineral) form before uptake (biological assimilation) and is given by

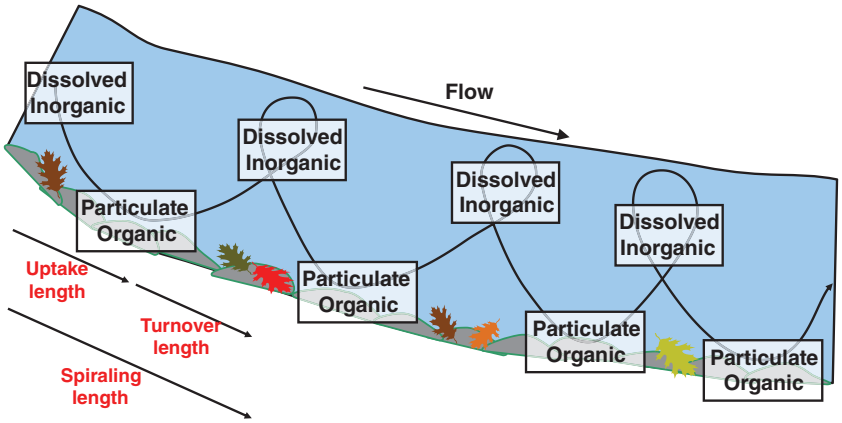

Fig. 1 Nutrient spiraling in streams consists of uptake length and turnover length, which together make up the spiraling length.

$$S_W = F_W/(U * w) \tag{1}$$

in which F_W is the downstream transport of nutrient in a dissolved mineral form available for uptake, U is the uptake flux per unit bed area of stream, and w is the stream width.

Turnover length, S_B is the average distance traveled in biological form, including passage through the food web, prior to mineralization via excretion or decomposition, and is given by:

$$S_B = F_B/(R * w) \tag{2}$$

in which F_B is the downstream transport of nutrient in living or dead organic matter, and R is the flux per unit area of nutrient mineralization, i.e., the return to available form.

The total downstream transport, F, *is* $F_W + F_B$. If we assume that the stream is in steady state and is without lateral losses and gains, then $U = R$ and, combining Eqs. (1) and (2), the spiraling length, S, becomes:

$$S = S_W + S_B = F/(U * w) \tag{3}$$

Eq. (3) expresses the basic idea that spiraling length is the distance of stream in which all of the transported nutrient is cycled, on average, one time.

The simplifying assumptions behind Eqs. (1)–(3) are, in addition to steady state ($R = U$) and the absence of lateral losses and gains, that all of the measured nutrient actively cycles and that all of the uptake, U, is supplied by nutrient in inorganic form. The constraints of these assumptions, together with a number of measurement challenges, have limited experimental measurement of total spiraling length to a single study (Newbold et al., 1981, 1983) in which it was possible to trace injected radioisotope through the food web. This study found that the uptake length accounted for 87% of the spiraling length, suggesting that uptake length alone provides an approximation to spiraling length. However, this study did not quantify storm-related transport of particulates, which would likely have increased turnover length if estimated as a long-term average. However, this work was conducted in a first-order, spring-fed stream and turnover length may account for an increasing proportion of spiraling length as stream size and/or seston concentrations increase. Global budgets suggest that a significant portion of nitrogen and phosphorus exported from rivers to the ocean occurs in particulate forms (e.g., Meybeck, 1982) supporting the hypothesis that turnover length may become increasingly important along the river continuum.

Measuring nutrient spiraling in streams

The uptake length of a single inorganic compound or ion, such as PO_4^{-3}, NH_4^{+1}, or NO_3^{-1}, can be measured by adding the nutrient or an isotopic tracer to the stream and observing its loss from the water column as it travels downstream. Assuming that the nutrient in the water column is well mixed and that uptake by streambed biota removes a constant fraction of the over-lying nutrient per unit distance traveled downstream, the longitudinal loss of added nutrient or tracer, M, can be described by a simple exponential loss function:

$$\frac{dM}{dx} = -k_L M \tag{4}$$

which, upon integration yields:

$$M_x = M_0 e^{-k_L x} \text{or } \ln M_x = \ln M_0 - k_L x \tag{5}$$

where M_X and M_0 are the quantity of added nutrient or tracer x meters downstream and at the addition site, respectively, and k_L is the longitudinal loss rate in units of inverse length. Uptake length (S_W) is equivalent to $1/k_L$.

The uptake flux (U) is calculated from S_W as:

$$U = \frac{QC}{wS_W} \tag{6}$$

where Q is stream discharge and C is the nutrient concentration in the stream water. Of the metrics used to describe cycling in streams, the uptake flux is the most generic descriptor in that equivalent terms exist for all ecosystems.

S_W is often converted to a third spiraling metric, the vertical transfer velocity, using:

$$v_f = \frac{Q}{wS_W} \tag{7}$$

The resulting parameter, a mass transfer coefficient often referred to as the uptake velocity (v_F), describes a theoretical velocity at which nutrients "move towards" locations of assimilation (e.g., stream bed). Solving Eq. (6) for S_W and substituting into Eq. (7) illustrates the relationship between v_F, U, and C.

$$v_f = \frac{Q}{w}\frac{wU}{QC} = \frac{U}{C} \tag{8}$$

Because Eq. (8) indicates that v_F reflects the relative magnitude of biotic use (as represented by U) to nutrient availability (C), some have referred to v_F as a descriptor of retention efficiency (e.g., Davis and Minshall, 1999).

Together, these three terms (S_W, v_f, and U) form what has been referred to as the "metric triad" of dissolved nutrient dynamics (Webster and Valett, 2006). Each metric has its utility in the study of nutrient cycling in streams. U represents a stream's use of nutrients on an areal basis, which facilitates cross-ecosystem comparisons. S_W quantifies the spatial scale associated with nutrient assimilation. Lastly, v_F represents the relative efficiency with which a stream takes up nutrients to which it's exposed. Clearly, no one variable is best suited for the suite of questions surrounding nutrient spiraling and each member of the metric triad has its place in examining solute dynamics in streams.

The simplest method for measuring nutrient uptake is to do a short term nutrient addition. (e.g., Stream Solute Workshop, 1990). For large streams, researchers have used a pulse release technique (e.g., Tank et al., 2008) where a slug of nutrient is added and followed downstream. The problem with both the injection and pulse release techniques is that they raise the nutrient concentration, and if nutrient uptake is a function of concentration, then uptake is not the same as under ambient conditions (Mulholland et al., 1990, 2002; Dodds et al., 2002). It is likely that both methods often saturate uptake. Payn et al. (2005) developed a method of injecting nutrient at different levels and then extrapolating back to the ambient level, but this method had not been used very successfully (e.g., Earl et al., 2006). Covino et al. (2010b) also suggested a method that used the varying concentrations from a slug release, but the downstream concentrations do not reflect the actual concentrations passing over the streambed.

Alternative methods of measuring nutrient spiraling are to use radioactive or stable isotopes. The use of these tracers results in negligible changes in the ambient nutrient level. The problems with isotope methods are the hazards of using radioactive materials and the high cost of obtaining and analyzing stable isotopes. Examples of using these techniques are described below.

Case studies of nutrient spiraling in streams

Elwood, Newbold, Mulholland, and their colleagues used radioactive isotopes (^{32}P and ^{33}P) to measure phosphorus spiraling in Walker Branch, TN (Newbold et al., 1983; Mulholland et al., 1985, 1990). By combining the results from their field studies with a computer model, they quantified phosphorus fluxes through the food web and found that spiraling length varied seasonally, being shortest after autumn leaf fall when decomposing leaves exerted the greatest P demand.

Mulholland et al. (1997) also used radioactive phosphorus to compare the role of hyporheic zones in nutrient dynamics in Walker Branch and Hugh White Creek, NC. As far as we know, this was the last study to use field additions of radioactive materials to study stream nutrient spiraling, although more recent studies have used ^{14}C labeled particles to estimate particle transport distance (e.g., Thomas et al., 2001).

The spiraling concept was the basis of the Lotic Intersite Nitrogen eXperiments (LINX). In LINX1, researchers used 6-wk additions of ^{15}N-labeled ammonium to compare nitrogen processes in 11 predominantly undisturbed headwater streams extending from Alaska to Puerto Rico and spanning desert to tropical forest ecosystems (Peterson et al., 2001; Webster et al., 2003). They found that small streams play an important role in nitrogen removal from the water column and that nitrogen uptake is dominated by biological processes, either heterotrophic or autotrophic.

In the second LINX study (LINX2), ^{15}N-labeled nitrate was used to compare nitrogen processes in 72 streams across multiple biomes and with undisturbed, agricultural, and urban land use (Mulholland et al., 2008). Results showed that nitrate uptake was largely related to instream photosynthesis and that denitrification was related to heterotrophic activity (Hall et al., 2009; Mulholland et al., 2009). Both biotic uptake and denitrification increased with stream nitrate concentration, but the efficiency of uptake

and denitrification declined as concentration increased, reducing the proportion of in-stream nitrate removal. Land use was an important control on nitrate uptake and denitrification, primarily due to its effect on nitrate concentration. Greater agricultural and urban land use also resulted in higher in-stream photosynthesis and consequent greater nitrate uptake.

Models of nutrient spiraling

Studies of stream nutrient spiraling have demonstrated the importance of linking computer models with field research. Civil engineers have long been using models that incorporate biological processes with downstream transport (Streeter and Phelps, 1925). The following are just a few examples of nutrient spiraling models of stream ecosystems. The first stream ecosystem models were used to calculate components of stream dynamics. Webster (1983) used a spiraling model to determine the role of stream insects in detrital processes, and Newbold et al. (1983) developed a model that they used to estimate uptake and turnover lengths of phosphorus. In their study of the Kuparuk River (AK), Wollheim et al. (1999) demonstrated the importance of coupling modeling and field research. Similarly, McKnight et al. (2004) and Gooseff et al. (2004) coupled field studies with computer models to study nutrient dynamics in Antarctic streams. As part of the LINX2 study, Mulholland et al. (2008) used a spiraling model to demonstrate the relative roles of small versus large streams as nitrate sinks. Lin and Webster (2012) fit a model, which included concentration dependent uptake, to the data from the Snake River slug release (Tank et al., 2008). They concluded that fitting release data to a fully dynamic model may be a useful way to understand nutrient dynamics in streams. Recently, Webster et al. (2016) developed a spiraling model, which included nitrogen, phosphorus, and carbon. They used this model to make predictions about nutrient competition and mutualism between stream autotrophs and heterotrophic microbes.

Challenges of stream nutrient spiraling studies

1. Developing methods that are less hazardous and less expensive than radioactive and stable isotopes.
2. Finding tools to study important nutrients, such as base cations and sulfur. Essentially all spiraling research has been with nitrogen and phosphorus, though the original idea for spiraling came from a study of calcium and potassium (Webster, 1975).
3. Separating biotic and non-biotic processes such as sorption to inorganic surfaces and chemical precipitation. For example, Covino et al. (2010a) suggested that physical retention dominated nitrogen retention in a stream in Idaho.
4. Finding ways to separate surface and hyporheic processes (Mulholland et al., 1997). Nutrient retention in a stream may be significantly influenced by hydraulic retention (Valett et al., 1996), which occurs when water leaves the main water column and enters flow that moves more slowly (Morrice et al., 1997). Flow paths of this type extend residence times by prolonging contact between sediment biota and transported materials. Several studies have shown greater nutrient retention is streams with more surface water—hyporheic water interaction (e.g., Martí et al., 1997; Mulholland and DeAngelis, 2000). Thomas et al. (2003) developed a method called the Ratio Partitioning Method to estimate the amount of nutrient cycled through the hyporheic zone.
5. Understanding and modeling the relationship between biotic uptake and stream water concentration. The relationship is probably linear under very low concentrations but follows some saturation function as concentration increases. Lin and Webster (2012) used a Monod function for uptake, and Webster et al. (2016) used a similar function for algal nutrient uptake but modified it with an internal stores limitation (Droop 1973, 1974).
6. Recognition that nutrient spiraling is not as simplistic as defined above. Some nutrients can exist in multiple mineral forms (e.g., nitrate and ammonium), which can have different uptake lengths. Also, nutrients exist in various organic forms, and incorporating the various turnover processes into stream dynamics, including turnover by higher organisms (insects, fish), is a major challenge to stream nutrient studies. While the downstream velocity of nutrients bound in organic particles may be very slow, turnover time can be very long. As a result, turnover length can be long and a major component of total spiraling length (e.g., Dodds et al., 2000).

Conclusions

Streams are longitudinally structured ecosystems connected by the downstream flux of water, solutes, particles, and organisms. Advancing our understanding of stream ecology will require studies that directly address the unique template of stream ecosystems. At the same time, streams are examples of open ecosystems in which questions of general ecological theory can be addressed. The nutrient spiraling concept provides a powerful tool for meeting these challenges.

This is an update of J.P. Bravard, F. Petit, Geomorphology of Streams and Rivers, in Encyclopedia of Inland Waters, edited by Gene E. Likens, Elsevier inc., 2009, https://doi.org/10.1016/B978-012370626-3.00043-0.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Alluvial channel Channel of stream flowing through erodible alluvium (i.e., river transported sediment).
Bankfull flow The flow that just fills the morphological channel up to the banks (sometimes conflated with the flow that occurs as an annual peak every 1.5 years, which is not necessarily equivalent).
Bedrock channel River flowing over fixed bedrock.
Channel incision Erosion of the riverbed and consequent channel lowering.
Channel pattern Form of the river channel as viewed from above.
Effective discharge The flow that transports the most sediment over time.
Episodic channel A channel in Mediterranean or other semiarid climate that goes many years without experiencing channel forming flow, but occasionally experiences a powerful flash flood that is capable of rearranging the bed and banks.
Longitudinal profile Plot of streambed elevation over distance.
River's trajectory The geomorphological river changes that occur over time.
Sediment budget A compilation and accounting for the magnitude and spatio-temporal distribution of sediment sources, sediment transport processes and deposition in a river network.
Sediment caliber The size of sediment particles (clay, silt, sand, gravel).

Water and sediment flow shape rivers

Stream (or "fluvial") geomorphology refers to the forms of rivers and streams, and the processes that create and maintain them. Stream channels and their floodplains are formed by the flow of water and the sediment it transports, both acting on the landscape through which they flow. Streams carry the water and sediment derived from a drainage area or catchment, and the drainage area is the most commonly used measure of the scale of a stream. Streams may also be ranked within the river network by their "stream order," which is determined by the relative number of tributaries that join together to form the stream. A small headwater stream would be a first-order stream, while downstream, a large river might be of fourth or fifth order. A plot of streambed elevation over distance (like a longitudinal slice along the river) is known as a longitudinal profile, while a transect through the river perpendicular to the flow direction is a cross section. Channel pattern refers to the shape of the channel as viewed from above, such as meandering or braided channels, described below.

We can distinguish first between two broad categories of streams: those that flow over bedrock, termed "bedrock channels" and those that flow through erodible alluvium (river transported sediment), termed "alluvial channels," usually flanked by regularly inundated flat surfaces termed "floodplains." The dimensions and shape of alluvial channels depend upon patterns of flow and sediment transport, including the volume and sizes of sediment moved (Church, 2006). Because changes in flow or sediment load can result in changes to alluvial channels, these channels have attracted most attention from researchers and managers. However, many alluvial channels have occasional bedrock outcrops, which can exert strong influence on the channel.

The quest for the channel-forming flow

One of the driving questions in fluvial geomorphology in the latter half of the 20th century was determining the flow that corresponded to the "bankfull" channel, i.e., the flow that just fills the morphological channel up to the banks. The underlying concept of effective discharge was established by Wolman and Miller (1960), who argued that geomorphic work could be estimated as the product of magnitude and frequency. That is to say, we know a big flood can erode, move, and deposit more sediment than a moderate flood, but the moderate floods occur more frequently. So, which moves the most sediment (i.e., has the greatest influence on channel form) over time?

The 1950s and 1960s saw the development of classical concepts in fluvial geomorphology, based on observations in humid Atlantic-climate landscapes and snowmelt dominated rivers of the Rocky Mountains, whose channel dimensions correspond to more frequent floods, often taken to be the Q1.5, which is the flood that occurs (as an annual maximum) 2 years out of three (Leopold et al., 1964), rather than larger floods. For these channels, the Q1.5 was also found to be the "effective discharge," the flow that moves the most sediment over time. Wolman and Miller (1960) used the analogy of a wood-cutting contest among a giant, a man, and a dwarf, with the man—representing the frequent, moderate flood—cutting the most wood over time because he spends more time cutting than does the giant so the cumulative effect of his moderate efforts exceeds the cumulative effect of the giant's stronger but shorter efforts. Over time, the Q1.5 was widely assumed to be equivalent to the "bankfull" flow.

Episodic channels

The notion that the active channel is shaped by the 1.5-year flow is an easily comprehended idea, and one that has clearly fixed itself in the mindset of natural scientists in allied fields and among restoration practitioners (NRC, 1992). However, in climates with more variable hydrology, such as Mediterranean and semi-arid climates, less frequent floods have a greater role in shaping the channel, as discussed by Kondolf et al. (2013). As noted by Wolman and Miller (1960, p.60), "The evidence also suggests that the more variable the regimen of flow of the stream, the larger the percentage of total sediment load which is likely to be carried by infrequent flows." Thus, it is the large, infrequent flood—the "giant"—that will accomplish the most geomorphic work in Mediterranean and semi-arid climates. These have been termed *episodic* channels because they can go for years will little geomorphic work going on, but suddenly in a year with a large flood, large changes result. For example, on the Santa Clara River, California, of the roughly 57.6 million tons of sediment load measured at Montalvo from 1968 to 1975, 55% was moved in only 2 days in the years from 1928 to 2000, and 25% was transported in just 4 days (Warrick, 2002). In this episodic channel, the effective discharge is not the Q1.5. Rather, the channel is formed primarily by larger, infrequent floods (Downs et al., 2013), consistent with the observations of Wolman and Gerson (1978). While smaller features adjacent to a perennial baseflow channel (termed the *lit mineur* in French) can be shaped by smaller, frequent high flows, the overall form of the active channel (the *lit majeur*, Bravard and Petit, 1997) in Mediterranean-climate rivers is shaped by larger floods. Despite Wolman and Gerson's (1978) admonition that in drier climates, it is the larger, less frequent floods that shape the channel, and despite research demonstrating that bankfull channels very frequently did not correspond to Q1.5 (Williams, 1978), the notion that river channels are shaped by the 1.5-year flood became widely accepted, and has been a common basis for stream restoration designs (NRC, 1992).

The ecological implications of episodic channel processes are profound. Unlike the bottomland of a stable, humid-climate river, where a clearly defined channel is flanked by stable stands of mature riparian vegetation, the channel substrate in an episodic river channel is "renewed or rejuvenated abruptly, at intervals shorter than that typically needed for a mature woodland to develop" so that the banks and islands are dominated by early successional-stage vegetation (Hecht, 1994). These channels are typically disturbed at intervals of one to several decades, when they experience sudden influxes of sediment (as from landslides and debris flows) during floods, and especially after wildfires. The valley floor may be reworked beyond the limits of the current riparian vegetation, with erosion commonly eating into the depositional aprons at the toe of slopes. For months or years after such a sediment influx, pools can be filled and riffles buried, but in subsequent years, flows scour out the deposits, and pools reemerge or reform within the rearranged channel (Hecht, 1994). From a flood-risk management perspective, episodic channels present challenges, because floods are so infrequent that inhabitants may not have experienced a flood and do not understand the risks of living in a flood zone, and certainly not the ultra-hazardous flooding that occurs in semi-arid regions (Sanders and Grant, 2020). In many cases, land developers, elected officials, and government agency staff responsible for land-use decisions may not even recognize dry washes as active river channels (Stein, et al., 2011).

River forms and processes

When viewed from above, one of the most apparent differences among alluvial channels is the contrast between single-thread meandering and braided channel patterns (see Fig. 1 for examples). The latter refers to alluvial channels where multiple low flow water channels (i.e., the area where water flows most of the time) exist and one channel is not predominant, in terms of size, over the others. Braided rivers are characterized by relatively high rates of coarse sediment transport, and the islands in between the channels are ephemeral features that change and disappear as the channels shift. Single-thread channels include iconic meandering rivers, which have well-developed bends, with the deepest water, highest velocities (and highest rates of erosion) on the outside of

the bends. The inside of the bend is a site of deposition, with development of a sandy (or gravelly) point bar. The typical meander bend provides a wide range of habitats for aquatic and riparian organisms: at the outside of meander bends are deep pools for large fish and vertical silt banks in which bank swallows make their nests, on the point bar are secondary channels with shallow waters providing habitat to small fish and fresh surfaces on which riparian vegetation can establish.

For decades geomorphologists have asked what drives the fundamental difference in river functioning between single-thread meandering channel and multi-thread systems? The variety of existing river channel patterns and their functioning are nicely summarized in the classification scheme by Church (2006), summarized in the diagram of Fig. 1. This synthesis draws upon prior work by many authors (e.g., Brierley and Fryirs, 2005; Buffington and Montgomery, 2013; Gurnell et al., 2016; Kondolf et al., 2003; Schumm, 1977, 1985). The main logic beyond this scheme is that river forms and patterns are generated by specific drivers, namely: channel gradient, amount of sediment supply, and grain size (caliber) of the sediment supply.

At the top of Fig. 1 we can observe river-beds composed predominantly by cobbles (64–256 mm) and gravels (2–64 mm). In case of limited sediment supplied and greater channel stability, the river will have low sinuosity, single water channel, and alternated exposed sediment bars. Increasing its sediment supply (moving to the right in the diagram in Fig. 1) will develop larger and more frequent central sediment bars, which will divert water in multiple water channels. When one water channel remains larger than the others the river pattern is often referred as wandering. If sediment supply will still increase and channel stability will allow a widening of the active channel, it will develop a fully braided morphology. Similar reasoning applies also for river-bed composed mostly by sediment calibers such as sand (62.5—2 mm) or finer fraction. In this range of sediment fraction sinuosity is more accentuated, and increasing the sediment supply will develop more and more stable exposed sediment bars that will be colonized by stable vegetation. These morphological vegetated units within the channel are termed islands (see Fig. 2 for an example), and if islands are common, the channel pattern is considered anastomosed (see bottom right of Fig. 1).

Sediment supply, the amount of sediment contributed to a river reach from the upstream river network, is influenced by the topography and geology of the river basin, its land uses, presence of dams (which block sediment from moving downstream) and any sediment management measures implemented. Sediment caliber refers to the size of sediment particles (clay, silt, sand, gravel), which in turn affects the mode of transport. For example, gravel moves mostly as bed load (rolling, sliding or bouncing on the river bed), whereas sand or finer sediments move mostly in suspension in the water column. Type of transport and sediment sizes define the fluvial forms that can be generated: gravel-bed rivers develop periodically sequences of pools, areas of deep water and greater erosion (energy build-up due to less friction), and riffles, areas of shallow water created by deposition of coarse sediment during high flows. Whereas in sandy rivers sediment moves downstream through the development of sequences of dunes in the river bed. Channel stability is determined by the sediment caliber, the compactness of the river bed and bank material, and its lithology (rock type). These properties determine the erodibility of the river channel and then how easily it can widen.

Large wood also plays an important role in determining river channel form and nodes of sediment deposition (Wohl et al., 2015). Limbs or entire trees are transported by the flow until they come to rest, often in a debris jam with other such pieces, where they can then induce deposition of sediment upstream and downstream, create deep scour holes, and divert flows laterally. The result is complexity of channel forms and resultant habitats. Conventional river management practices have usually involved

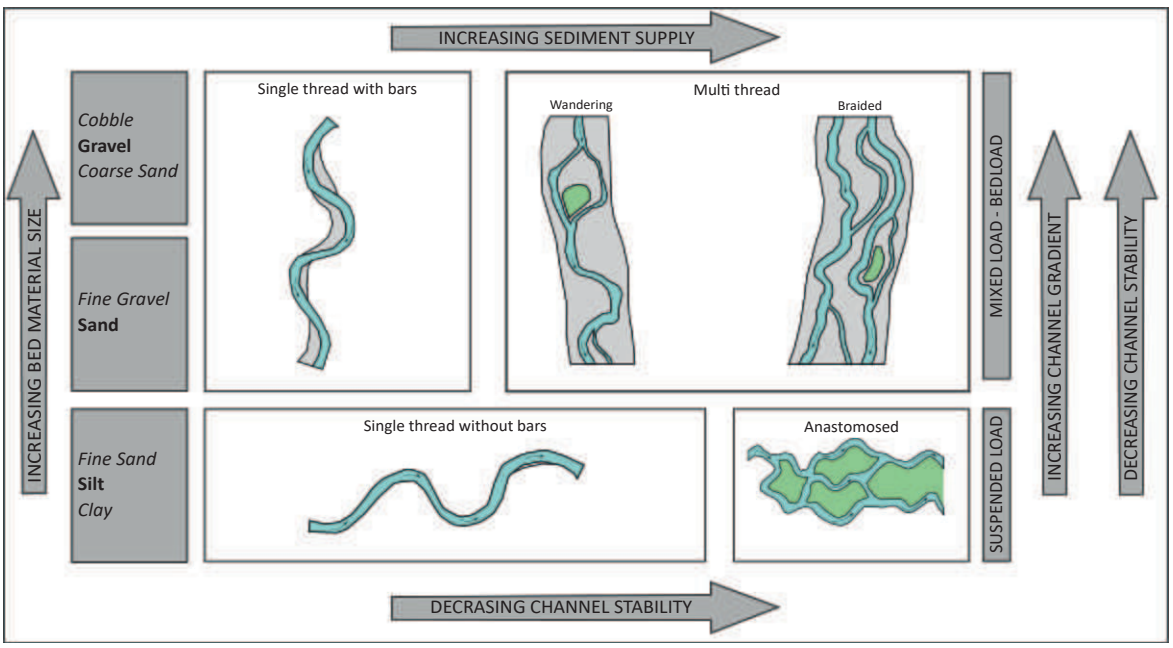

Fig. 1 Diagram showing the association of alluvial river channel form and the principal governing factors. Classically named channel types are located at appropriate positions within the diagram. Grey patches refer to exposed sediment bars within the active channel, whereas green areas to vegetated islands.

Fig. 2 The Tagliamento river in Italy, in a braided reach: water channels, floodplain, active channel, island and hillslope are labeled on the image. The white dashed line represents the area of transition between the two units. View looking upstream. Photo by Simone Bizzi (December 2020).

removal of large wood to reduce the chance of debris jams on bridges and other infrastructure, but with increasing recognition of the importance of large wood for the ecology of many rivers, management is evolving to leave wood in channels to the extent possible.

From a perspective of fluvial geomorphology, a river corridor can range from a narrow bedrock canyon to a wide valley bottom with a floodplain, in which the active channel can migrate up to the confining hillslopes along the valley margins (see Fig. 2). Floodplains are morphological units built of sediment transported and deposited by alluvial rivers. Within the active channel are channels carrying water and unvegetated or sparsely vegetated sediment bars. In other words, the active channel includes all those morphological units which are reworked regularly by frequent floods and for this reason stable and mature vegetation cannot grow because seedlings are regularly scoured by seasonal floods. The floodplain topographic level is typically slightly higher than the top of sediment bars in the active channel. In the area of transition between the active channel and the floodplain (see Fig. 2, the white dashed line between the two units) fine sediments are deposited by regressing floods, which allows younger vegetation to grow and to start creating riparian woods. Some exceptions could be represented by severely aggrading river reaches where for some period the active channel is on average higher than the surrounding floodplain. Over time the river moves laterally building its floodplain. These processes are also specific to every channel pattern and floodplains classification have been proposed as well in literature (Nanson and Croke, 1992). For instance, in case of a single-thread sinuous river, the floodplain is built by migration of a meander bend, which results from erosion of the cutbank and concomitant growth of the opposite point bar and associated overbank deposits. Whereas, in a braided river the floodplain is formed largely by the abandonment and infilling of braid channels.

Quantifying river processes

From an energy-balance point of view, river patterns are the results of a natural necessity to compromise between the available energy to transport sediment, the available material to be transported, the mode by which this material is transported, and the available space to do it (channel stability). Channel gradient determines together with the amount of water flow the energy that a river possesses to transport sediment. It can be expressed very simply as stream power (Bagnold, 1977; Bizzi and Lerner, 2015):

$$\Omega = \gamma\, QS \tag{1}$$

where Ω is the total stream power, γ is the specific weight of water, Q is the water discharge and S is the channel slope. Traditionally, the functioning of an alluvial river channel can be modeled by this simple qualitative statement:

$$\Omega \sim QsD/d \tag{2}$$

in which Qs is the bed material flux, D is sediment caliber and d is the flow depth (Lane, 1955). The relation states that, for given flow energy (Ω), so much sediment of some specified size can be transported. It also recognizes the importance of channel geometry and how that scales with the flow (d). This links to the reasoning about bankfull and effective discharge concepts previously discussed. We could rearrange Eq. (2) to obtain (Church, 2006):

$$Qs/Q = f\,[\rho g d\, S/g(\rho s - \rho)D] \tag{3}$$

with g being the acceleration of gravity, and ρs and ρ are the density of sediment and water, respectively. The term in brackets is an important variable in river hydraulics, the Shields number (Shields, 1936). It is conventionally notated by τ^* and it provides the shear stress imposed by the water flow on the river sediment. Eq. (3) is a sediment transport function, with which we can calculate transported sediment given the hydraulic conditions. It has been proven that when $Q_s/Q \rightarrow 0$, for unconstrained sediment mixture, then $\tau^* \rightarrow 0.045$ (Wilcock and Southard, 1988). This condition defines the hydraulic condition in a river channel which determines the beginning of the sediment transport respect to a given grain size.

The introduced equations state our ability to quantify in physical terms the functioning of river geomorphology as qualitatively described in Fig. 1 and previously discussed. In summary, water discharge determines mostly the channel dimensions (width and depth), slope the rate of energy expenditure, and river morphology is eventually shaped by amount of sediment supply and its caliber. The balance of Eq. (2) governs also the stability of the channel: if river energy is greater than the sediment available to transport there will be a propensity to erosion, whereas if river energy is not enough to transport incoming sediment there will be a propensity toward aggradation. Fluvial forms and river patterns reflect such equilibrium. Step-pools cascades, pool and riffles, and dunes are different modes used by rivers to transfer sediment downstream and dissipate energy in excess based on different sediment calibers and gradient conditions. Indeed, step-pool cascades provide high frictional resistance compared to planar bed channels. Similarly, meanders in lower gradient rivers create greater frictional resistance compared to straight channels. In a context of high sediment supply, increasing the number of incised water channels, toward braided or anastomosed patterns, changes how the flow scales with channel geometry (see Eq. 2) increasing the channel competence, i.e., the ability of the channels to transfer sediment downstream (Nanson and Huang, 2008).

Since alluvial rivers are the result of such sensitive equilibria, changes in flow or sediment regime can induce large changes in alluvial channel form or dimensions. Such changes can result from climatic changes and/or anthropic factors such as land-use changes or dam development. We next provide concrete examples of anthropic disturbances that caused shifts in river patterns. These types of alterations are of critical importance for the environmental quality and ecosystem services a river can provide (Palmer and Filoso, 2009). Channel patterns and their formative processes determine habitats and the availability of specific ecological niches. This means that different river patterns will sustain different types of biodiversity. For instance, dynamic and sediment-rich rivers, such as braided and wandering rivers, support significantly higher biodiversity than less dynamic single-thread rivers that are starved of sediment. It is then of primary importance to study historical patterns of river trajectories (Brierley et al., 2013; Kondolf et al., 2007) and be able to foresee future ones based on expected climatic conditions, anthropic pressures and management measured undertaken. Understanding these fundamental relations also suggest why it is futile to impose a designed channel pattern that is not sustained by current and future water and sediment conditions (Kondolf, 2006).

Anthropic impacts

Changes to the independent variables flow and sediment load

To understand changes in river systems from human impacts, it is often useful to study the system from the perspective of a *sediment budget*, which is a compilation and accounting for the magnitude and spatio-temporal distribution of sediment sources, sediment transport processes and deposition in a river network (Reid and Dunne, 2016). Many human alterations affect the sediment load of rivers. Land use change and poor agricultural practices, road construction, mining, and other land disturbances, especially in steep mountainous and upland areas (Fig. 3) drive increased sediment loads in headwater, sediment producing zones of river basins. Sediment loads from the downstream parts of the basin can also be increased by changes, such as increased erosion from agriculture, or by urbanization and the resulting increased runoff and channel incision, which in turn result in increased sediment loads from channel erosion. Despite widespread increases in land disturbance and consequent increased sediment yields from upland areas, the sediment loads of most major rivers have *decreased* in recent decades. While this might seem counterintuitive given the greatly increased impact of land disturbance in river basins worldwide, it reflects two principal anthropic effects that have reduced sediment loads in river basins world-wide. These are the extent of sediment trapping by dams (Walling, 2006) and the effects of sand and gravel extraction from river channels (Simon and Rinaldi, 2006; Surian and Rinaldi, 2003). The reduced sediment delivery to downstream reaches and coastal areas is increasingly manifest in accelerated coastal erosion and loss of delta lands (Syvitski et al., 2009).

Erosion from the construction of roads has become a significant cause of increased sediment yields, especially in the Global South, where roads have commonly been funded as components of international development projects without fully accounting for their environmental impacts (Sidle and Ziegler, 2012). These impacts are undoubtedly widespread, with impacts on the ecology of receiving waters that are rarely documented (Rios Touma et al., 2020). In the Upper Mekong River basin in China (known as the Lancang), new road construction has been extensive, and has resulted in a roughly 10-fold increase in sediment yields to the river

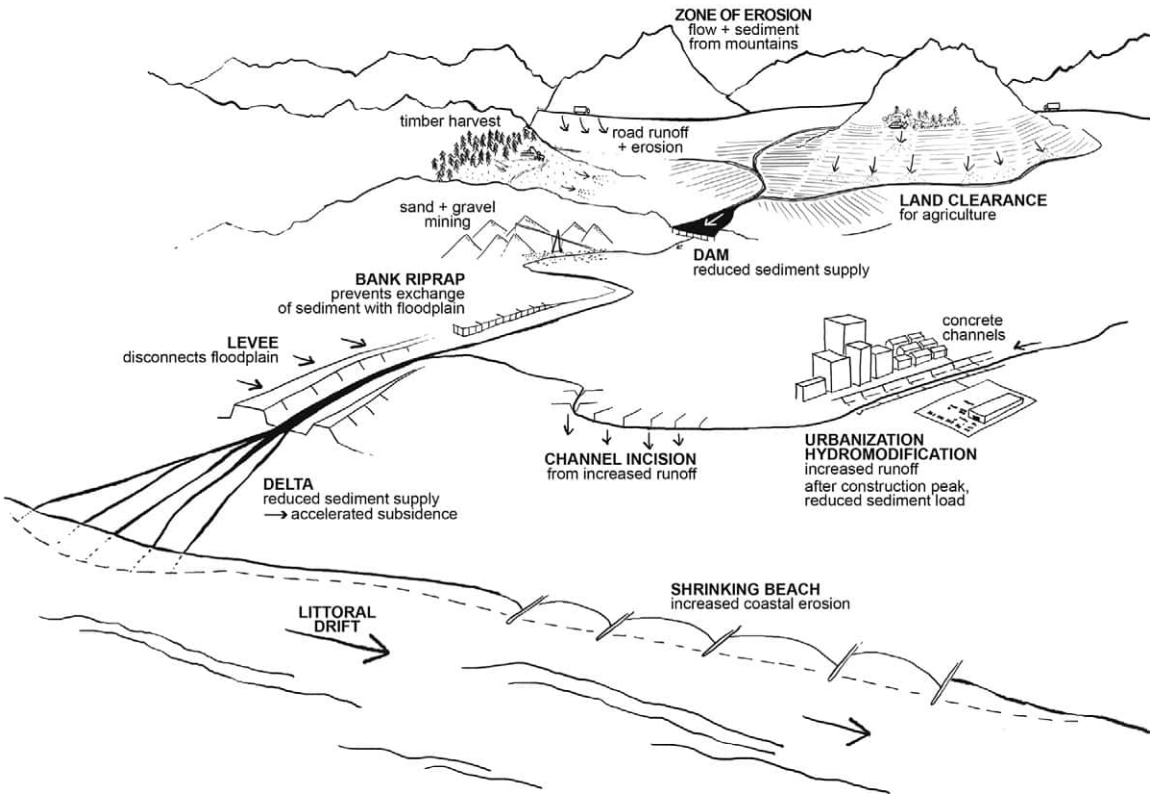

Fig. 3 Human alterations to runoff and sediment load: increasing sediment yields from the upland landscape, sediment trapping above dams, and consequences of sediment starvation downstream. From Kondolf GM and Podolak K (2013) Space and time scales in human-landscape systems. Environmental Management Springer Nature. used by permission of Springer Verlag.

network (Sidle and Ziegler, 2012). Consistent with the sediment trapping by dams described below, however, most of this newly eroded sediment will not move downstream to the Lower Mekong River and Delta in the future but will be trapped in multiple reservoirs downstream.

Urbanization alters runoff from river basins, typically increasing runoff for a given rainfall event, increasing the energy of runoff. The increased runoff means increased erosive potential of streamflow, which results in channel incision, widening, and simplification. In response to erosion, stream banks are commonly armored with rock, concrete, or other protective material. The simplification of channel form resulting from incision, bank erosion, and hardening of banks, results in loss of habitats for aquatic organisms.

Dams typically store water by design and store sediment as an unintended consequence, although some dams have been built as debris basins or sediment-control (*sabo*) dams (Wang and Kondolf, 2014). Dam-induced changes in flow regime are typically accompanied by reductions in the river's sediment load, as reservoirs trap sediment, creating conditions of sediment starvation in the reach directly below the dam. Reservoirs trap 100% of the river's *bedload* (the coarse sediment that moves along the channel bed by rolling, sliding, and bouncing, consisting of gravel and sand), and a varying percentage of the *suspended load* (sand, silt, and mud held aloft in the water column by turbulence), depending on the residence time of water in the dam, and thus on dam design and operation. The storing of water and sediment in the reservoir results in changes in the river flow regime and sediment load and regime downstream of dams, which almost always produce downstream changes in the form of alluvial channels.

Many reservoirs trap sediment but still release flows high enough to transport sediment, thereby creating sediment-starved, or *hungry water* downstream, so-called because these flows still have energy to transport sediment but little or no sediment load, and thus they possess excess stream power (Kondolf, 1997). This excess energy erodes the bed, a process known as channel *incision* or downcutting, which can undermine bridges and other built infrastructure, and scour away sand and gravel bars and riffles, resulting in loss of ecologically important habitats, as documented on the Colorado River downstream of Glen Canyon Dam (Schmidt et al., 1998).

Whether hungry water occurs downstream of dams depends on the balance of water discharge and sediment supply (see Eq. 2). Some river reaches below dams are in sediment deficit, others in surplus (Schmidt and Wilcock, 2008). Reservoirs with large storage to redistribute water between seasons and from one year to the next, commonly reduce high flows, and thus reduce the dynamism of the river channel downstream (Kondolf and Batalla, 2005). Gravel beds formerly mobilized every year or two may go for years without being moved, allowing fine sediments to accumulate within the gravel (clogging) and riparian vegetation to establish within the active channel, restricting flows to a narrower conveyance path, and scouring the low-flow channel (Kondolf and Wilcock, 1996).

By controlling a wide range of floods, large reservoirs can reduce the magnitude, duration and frequency of floods experienced by the downstream channel—with consequences for fluvial processes downstream. Dam-reduced flood flows may be incapable of transporting sediment delivered to the river by tributaries, inducing channel aggradation and potentially increasing flooding risk.

The ecological consequences can be profound. The complexity of alluvial channel forms depends upon the availability of coarse sediment (sand and gravel) that compose bars and riffles. In reaches starved of sediment by upstream dams, sand and gravel are transported downstream without being replaced, resulting in loss of gravel and sand bars, riffles, and beds, and with them, loss of channel complexity, resulting in a simplified "bowling-alley" channel form lacking in habitats needed for fish and invertebrates.

To mitigate dam-induced impacts on sediment transport and channel geomorphic processes, controlled high-flow releases designed to mimic the action of natural floods are increasingly required in hydroelectric licenses for dams and as part of programs to restore river functions (Williams, et al., 2019). These deliberate, high-flow releases constitute one component of environmental flow requirements for the maintenance of aquatic and riparian habitat. They reflect an evolution of environmental flow requirements from simple minimum flows to include periodic high flows to mimic flood effects on channels or on ecological processes (Kondolf and Wilcock, 1996; Poff et al., 2017). While terminology varies (e.g., "flushing flows," "channel maintenance flows," and "morphogenic flows," see Loire et al., 2021), the need for periodic high flows to accomplish geomorphic goals and to maintain the functionality of the sediments as physical habitat for stream organisms has been widely recognized (Yarnell et al., 2015).

However, even if a post-dam flow regime were to mimic precisely the pre-dam flow regime, the river system would be severely altered by the loss of its sediment load (Kondolf and Wilcock, 1996; Wohl et al., 2015). Thus, to prescribe most beneficial morphogenic flows for a given river, it is critically important to take into account the sediment load available to the reach downstream of the dam, such as sediment supplied from downstream tributaries (e.g., Grams et al., 2013). Increasingly, partial restoration of sediment load is prescribed along with morphogenic flows (Kantoush and Sumi, 2011; Kondolf, 1997; Tena et al., 2012).

Direct channel modifications

Among human activities resulting in direct modifications to river channels, dredging and channel straightening for navigation or flood control are among the most pervasive and severe. For navigation, a relatively straight, deep channel is ideal, and many rivers have been turned into such canals to allow navigation. To straighten the river's course, meander bends may be mechanically cut off and the river rerouted through a straight channel. Similarly, to improve flood control, many river channels have been straightened and dredged. Such simplified channel forms can be disastrous ecologically, as they do not provide habitat for fish and other organisms (Brooker, 1985). For flood control, many rivers have been lined with dikes to prevent floodwaters from flowing out onto floodplains, disconnecting river channels from their floodplains (Tockner and Stanford, 2002) and causing severe reductions in river-floodplain productivity (Bayley, 1995).

In addition to bank hardening undertaken in response to erosion induced by urbanization (discussed above), banks are hardened even when the erosion is perfectly natural, such as on the outside of migrating meander bends, to protect poorly-sited infrastructure, dwellings, and even undeveloped rural land whose owners do not want to see their pastures eroded. This has resulted in bank hardening ranging from engineered riprap, masonry, or concrete structures to informal dumping of rubble, debris, and even abandoned vehicles down banks to slow erosion. Bank hardening measures also include some that are mislabeled as "green" because they involve boulders and large wood (especially root wads), which are claimed as "natural materials" but whose use in these contexts is typically far from natural in that they prevent natural channel migration, and in many cases the boulders would not naturally be found in these channels. All these measures to harden banks take a toll on river ecology, by preventing the erosion, deposition, and channel migration processes that lie at the foundation of healthy river systems, and by directly replacing natural banks with artificial structures. For example, along the Sacramento River, vertical banks found along the outsides of meander bends (maintained in vertical profile by frequent toe erosion) provide habitat for bank swallows, but at many sites, banks have been riprapped, eliminating this habitat (Wright et al., 2011).

Rivers are also dredged to mine sand and gravel for construction aggregate, resulting in direct modifications to channel form, not only in the reach directly affected by the dredging, but also in reaches up and downstream. Channel incision propagates upstream from instream mines via regressive erosion (headcut migration) and downstream via sediment starvation (as coarse sediment is trapped in the mining pit) (Kondolf, 1994). Both navigational dredging and mining can trigger instability in river systems. For example, on the Apalachicola River, Florida, attempts to excavate and maintain a 3-m deep navigational channel in a loose sand bed resulted in collapse of the banks of the dredged channel, which triggered instabilities throughout the river system (Light et al., 2006). Mining of sand and gravel from the bed of the Douro River in Portugal resulted in the collapse of the Entre-Os-Rios Bridge during a subsequent high flow, killing 59 people (Antunes do Carmo, 2021).

Implication for management

Fluvial geomorphology expresses river forms and processes as the results of specific drivers: the geological, hydrological and ecological conditions of the river corridor but also how this is managed. Rivers are influenced not only by what occurs within the river corridor but also at the scale of the catchment, such as changes in land uses and climate change (Darby et al., 2016). We have discussed how river functioning depends upon the balance between water and sediment fluxes and how these determine different

channel patterns. The legacy of such factors, i.e., the historical trajectories of climate, geology, ecology and human disturbances co-exist and determine what is termed the river's trajectory: the geomorphological river changes that occur over time. Most rivers are dynamic by nature, and it is only through human intervention that we attempt to create more stable conditions, which in the long run very often do not work. From a river management point of view, it is meaningful to look at changes that have occurred in the recent history (10–100 years) because these define the starting conditions affecting future river trajectories. For instance, at the beginning of the 20th century many north Italian rivers showed braided patterns which shifted to single-thread meandering morphology due to reduced sediment load caused by sand and gravel mining and by land use changes following the second world war (Surian and Rinaldi, 2003). With controls on instream mining, some of these rivers have started to show signs of recovery toward multi threads system (Bollati et al., 2014; Surian et al., 2009). In the French Alps for similar reasons during the second half of 1900s, many braided rivers have transformed its pattern toward more single thread morphology (Piégay et al., 2009). In the latter half of the 19th century, some rivers in northern California became braided due to dramatically increased sediment loads caused by hydraulic mining for gold (Gilbert, 1917). In the Bega River catchment, NSW, Australia, significant geomorphic changes to rivers have occurred post European colonization (after 1850s), including widespread channel erosion and sediment mobilization (Brierley et al., 1999). River management must not only understand current conditions but also to investigate recent historical processes, and based on that, foresee future river geomorphological trajectories in terms of channel pattern dynamics and their sensitivity to changes by future climate and human disturbances (Bizzi et al., 2021; Downs et al., 2013; Fryirs, 2017). Over the last decades a number of river geomorphic analysis frameworks have been proposed to implement such visions in Europe (Gurnell et al., 2016; Rinaldi et al., 2013), Australia (Brierley and Fryirs, 2005), and Asia (Blue et al., 2013). These frameworks support river managers in reading river systems to interpret current fluvial processes and foresee future ones based on alternative management scenarios proposed.

Geomorphic analysis of river system must be tuned with ecological management targets and objectives: indeed, geomorphic processes shape habitats and ecological niches (de Jalón et al., 2016). Nonetheless, very often ecological targets defined for river management purposes fail to properly incorporate the concept of river geomorphic trajectories in their definitions and may adopt a static vision of river morphology and habitats (Belletti et al., 2015; Friberg, 2014). To develop a dynamic vision of river systems and translate that into implementable management schemes and measures, where ecological and geomorphic processes are investigated and interpreted on common basis, is a challenge for river management of the future. It is also a requirement to pursue a sustainable and healthy environment where human needs are wisely weighed with a scientific and appropriate understanding of river functioning.

Hydrology and Classification of Rivers for Management

Ryan A McManamay, Department of Environmental Science, Baylor University, Waco, TX, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Bankfull flow The maximum discharge a channel carries. On average, these flows generally occur every 1–2 years, although this varies by region and climate.

Baseflow Flow within river channels sustained by groundwater contributions from infiltrated precipitation.

Clustering Process of grouping objects of similar properties into categories. Clustering may involve the use of multivariate statistical procedures.

Deductive hydrologic classification Grouping rivers or watersheds based on generalizing landscape or climate features into regions, where the variation in physical properties of the landscape or climate are hypothesized to approximate hydrologic variation. Deductive reasoning generally follows a stepwise rationalization process where generalizations (e.g., landscape and climate influences hydrology) are used to infer a logical conclusion (e.g., landscape regionalization approximates hydrologic types).

Discharge A volumetric flux of water in river channels. Typically measured as $ft^3\ s^{-1}$, $m^3\ s^{-1}$, or ls^{-1}.

ELOHA (ecological limits of hydrologic alteration) A framework and methodological process for defining environmental flow standards for groups of rivers within regions. The central premise for identifying standards is using flow alteration-ecological response relationships to determine socially acceptable "limits" to hydrologic alteration (see Poff et al., 2010).

Environmental flows The quantity, timing, and quality of flows required to sustain freshwater and estuarine systems, and the humans that rely on those systems (Annear et al., 2004).

Flood frequency The number of occurrences of a flood event of a given magnitude within a specified time period.

Floodplain Portions of river valleys extending laterally and at higher elevations from river channels (bankfull areas) inundated periodically by flood events.

Flow duration curve (FDC) A non-linear relationship depicting the percentage of time a flow of a given magnitude is equaled or exceeded.

Hydrologic classification The process of grouping rivers into categories based on similarities in hydrologic behavior or hydrologic variability.

Hydrologic statistics Metrics used to summarize temporally variant measures of discharge into consolidated forms.

Hydrologic variability The spatially and temporally dynamic changes in discharge in rivers over multiple spatial and temporal scales.

Hydrology (of rivers) Study of the dynamic volumes of water within fluvial channels. Hydrology, more broadly, is the study of the movement of water across landscapes.

Inductive hydrologic classification Grouping rivers or watersheds into categories based on generalizing direct measures of discharge and hydrologic variability. Inductive reasoning used emergent properties of direct observations (e.g., discharge from gages) to make generalizations (e.g., hydrologic classes).

Natural flow regime The natural variation in the magnitude, timing, duration, frequency, and rate of change in discharge in rivers and streams, where natural refers to absence of human influences (e.g., dam regulation, withdrawals). See Poff et al. (2007).

Return interval Analogous to flood frequency, the period of time a flow a given magnitude is expected to re-occur.

Runoff Volume of water draining a given area of land or catchment over a specified time period.

Storm hydrograph A visual depiction of discharge changes over time immediately preceeding, during, and following a precipitation event.

Stream order A stream classification approach using a discrete numerical depiction of stream size. Integers (0,1,2) represent incrementally increasing sizes of streams where 0 is a headwater, 1 is 1st order, etc.

Surface flow (also stormflow) The portion of discharge or runoff resulting from precipitation flowing overland to river channels.

Introduction

Rivers are dynamic ecosystems. From the vantage point of a riverbank, one can see continuous physical movement of water as turbulent riffles, undercurrents in pools, and eddies. The downstream transport of water and other materials along an elevational gradient is the primary function of river systems and the key factor that distinguishes rivers from other ecosystems. While a seemingly simple concept, water molecules flowing downstream may have originated as rain or snow days or months ago and traversed hundreds of kilometers above and below ground. The rate at which those molecules arrived in the river depend upon climate, geology, soils, groundwater, vegetation, and, of course, humans. Rivers not only connect longitudinally disparate landscapes, but they also vertically interact with subsurface areas underlying channels, as well as creating lateral connections to the adjacent landscape during floods. These connections change from minutes to decades, depending on the dynamics of flowing water in rivers, generally termed *river hydrology*.

Hydrology is the master variable of river systems (Power et al., 1995), organizing the morphology of river channels, mobilizing sediments, scouring floodplains, influencing the physiochemical properties of water, and shaping the fluid and riparian environment in which aquatic organisms' life histories have adapted (Poff and Ward, 1990). Each river has a unique hydrologic regime that varies interannually, seasonally, and daily (Fig. 1). Organisms inhabiting these systems are sustained by the natural variability in hydrology across different temporal scales (Poff et al., 1997; Bunn and Arthington, 2002). Despite these unique hydrologic signatures, rivers draining landscapes with similar climate, geology, and topography tend to display reoccurring patterns in hydrology; these repeatable patterns have supported the development of hydrologic classifications, where streams are grouped according to similarities in hydrologic behavior. Hydrologic classifications have provided insights into regionally distinct hydrologic regimes important in organizing ecological communities (Poff and Ward, 1989; Olden et al., 2012; McManamay et al., 2015a).

Aside from improving the fundamental understanding of the importance of naturally variant hydrologic regimes on sustaining ecological communities and ecosystem functions, hydrologic classifications have also proven useful for managing flows in river systems altered by human disturbances. In the last 25 years, considerable research has been devoted to understanding relationships between river hydrology and ecological patterns, including the development of hundreds of indicators or statistics aimed to reduce the dimensionality of hydrologic patterns and the creation of hydrologic classifications to generalize patterns in hydrologic behavior. In this chapter, I will provide a broad background of the principles of river hydrology. These principles are carefully selected to provide the reader with a broad, yet relevant, background in order to appreciate the justification behind the growth of research in hydrologic statistics and hydrologic classifications in advancing the fundamental understanding of river behavior as well as their use in environmental management.

The water cycle and river discharge

Rivers, in their simplest form, are channels that carry water downhill. However, the volume of water flowing at any point in a river is the accumulation of a multitude of processes occurring just meters to hundreds of kilometers upstream. Indeed, how the water arrived within the river channel can be complex and determines the river's morphological organization and its hydrologic behavior. River systems, i.e., entire networks of rivers and their tributaries, follow a nested organization where small headwater systems join to form larger systems, and so on. To systematically characterize these patterns, Strahler (1964) developed a stream ordering system, known as Strahler orders, where two headwaters (0-order) join to form a 1st order streams, and where two 1st order streams join, a 2nd order stream emerges, and so on; however, the junction of a 0 order and 1st order does not result in a 2nd order, nor does the junction of a 1st and 2nd order result in a 3rd order system. Although the Strahler order is limited to a discrete numerical depiction of stream size, stream orders and spatial dendritic patterns of tributary branching can be useful in regional comparisons of stream densities, which provide an indication of the role of climate and geology have organized basins and how much water channels carry water downhill (Strahler, 1964; Selby, 1985).

A fundamental law of river organization is that as stream order increases, so does watershed area (or catchment area), i.e., the area of the landscape that drains towards a channel. Larger areas of the landscape receive more cumulative precipitation, which generally yields more water (although rare exceptions to this rule depend on the underlying structure of bedrock lithology). However, not all that precipitation will reach the river system, and the resulting water that does eventually arrive in channels, termed runoff, does not arrive all at the same time. At any point in time, the volumetric rate of water draining the landscape and resulting in surface water in a river, or discharge (Q), is a function of a balanced water budget (Fig. 2):

$$\Delta S = P - Q_s - E - I_v - Q_b \tag{1}$$

where ΔS represents the positive or negative change in storage in the watershed over a time period. In natural watersheds lacking human disturbances, ΔS at any instant is comprised of changes in water in soils and groundwater. Precipitation (P) that exceeds the infiltration capacity of soils results in surface runoff (Q_s). The remaining portion of precipitation that infiltrates the soil ($P - Q_s$) is available to vegetation and evaporated (E) or infiltrates to deeper soil horizons beyond the roots of vegetation (I_v), termed the vadose zone. This water eventually enters groundwater, termed groundwater recharge, which eventually enters streams as surface flow or base flow (Q_b). Total discharge in river (Q_R) is the sum of Q_s and Q_b. By replacing and rearranging terms in the above equation, Q_R can be calculated as:

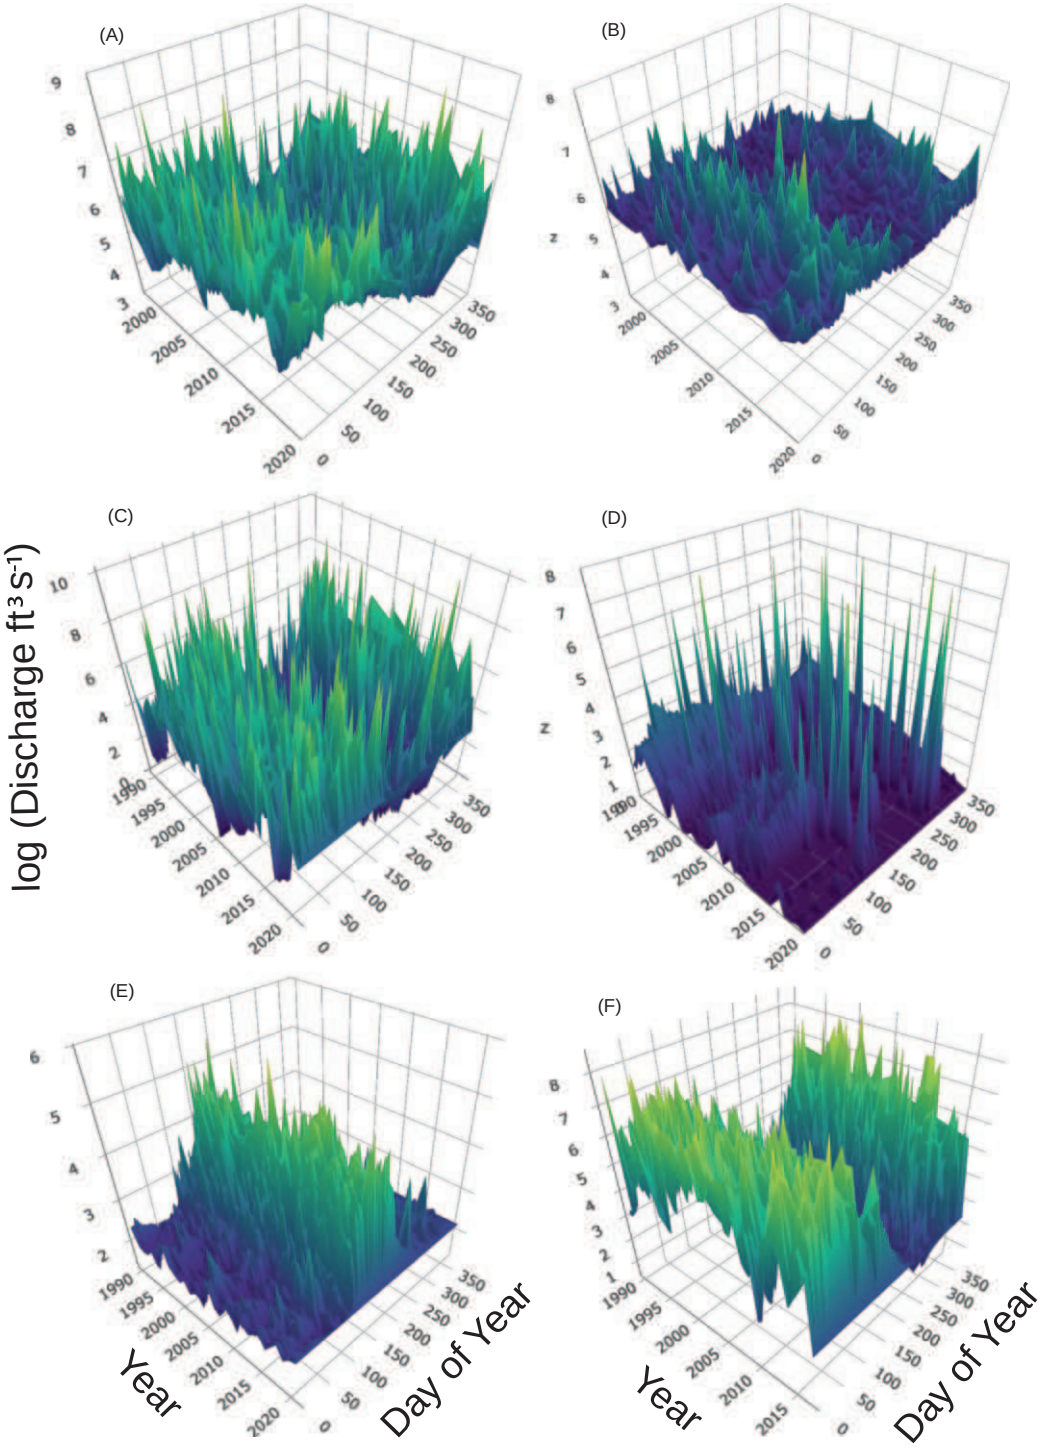

Fig. 1 Interannual, seasonal, and daily variation of different hydrologic regimes across the United States. (A) Valley River at Tomotla, North Carolina (USGS gage 03550000), (B) Pine River near Hoxeyville, Michigan (USGS 04125460), (C) Dutch Creek at Waltreak, Arkansas (USGS 07260000), (D) North Concho River near Carlsbad, Texas (USGS 08134000), (E) South Crow Creek near Ronan, Montana (USGS 12375900), (F) Redwood Creek near Blue Lake, California (USGS 11481500).

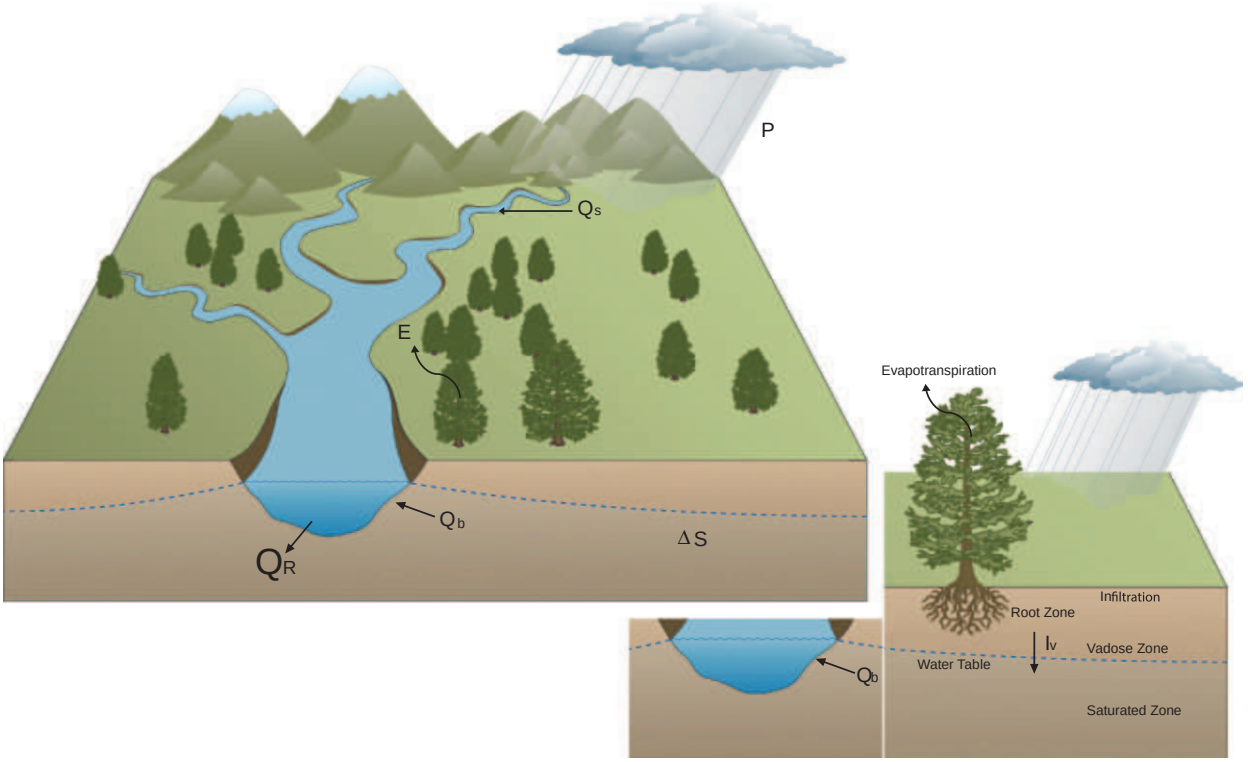

Fig. 2 Water budget and contribution to river hydrology. See text for definition of terms. Base conceptual diagrams were modified from original versions, which were courtesy of the Integration and Application Network, University of Maryland Center for Environmental Science (ian.umces.edu/symbols/).

$$Q_R = P - E - I_v - \Delta S \tag{2}$$

The above equation can tell us a great deal about temporal variation in discharge for individual rivers, but also regional-to-global hydrologic variation. Regions vary extensively in the magnitude and seasonality of precipitation, which generally governs annual and interannual patterns in discharge. In humid regions with sustained rainfall throughout the year or significant portions of the year, rivers continually have surface flow—these are termed perennial rivers. In contrast, intermittent streams drain landscapes in arid regions and may have no discharge for portions of the year. A third major type of river or stream is called ephemeral channels, which are channels smaller than headwater systems that convey water only during rainfall. Whether precipitation is rain or snow defines the periodicity in high-flow conditions following snowmelt. In some high-elevation mountainous regions, such as the Rocky Mountain region of the United States, the majority of annual precipitation occurs as snow during a portion of the year and accumulates as snowpack, eventually melting and forming large spring freshets (peak floods). Snowmelt infiltrating soils then sustains baseflow during periods of the year with little precipitation.

Aside from major climatic differences among regions, hydrology varies with geology, soil characteristics, and vegetation. The amount of precipitation infiltrating soils and eventually entering groundwater depends upon soil texture, which generally refers to soil porosity and water-holding capacity, whereas the amount of precipitation reaching the vadose zone and the time it resides there (i.e., ΔS) depends on evaporation, soil depth, and lithology of underlying bedrock. Bedrock that is impenetrable to water (e.g., granite) forms distinct saturated zones and water tables, whereas porous bedrock (e.g., limestone) yields complex subsurface hydrology with less predictable behavior following precipitation. In some regions with deep aquifers, the exchange between surface and deep groundwater is not well known and may be measured on the order of centuries rather than days. Evaporation is portioned into precipitation that evaporates from the surface of the soil or vegetation and the part of infiltrated precipitation transpired by vegetation. The type and density of above-ground vegetation not only influences evaporation but also infiltration. Vegetation intercepts precipitation, termed throughfall, slowing the rate at which precipitation falls to the land surface. Vegetation cover lessens the velocity and impact of precipitation with soils, increasing the soil and water contact time, and increasing infiltration.

The same drivers of regional differences in discharge patterns also influence how an individual river responds to variation in annual (Fig. 3A) or seasonal (Fig. 3B) precipitation or a single precipitation event—termed a storm hydrograph (Fig. 3C). During a rainstorm, surface runoff (Q_s), also called overland flow, drains the landscape quickly, corresponding to rapid increases in discharge. Once rainfall subsides, river discharge decreases, but at a much slower rate. The leading and trailing edges are referred to as rising and falling or receding limbs, respectively, of a storm hydrograph. The rainfall entering groundwater takes on the order of days to months following precipitation, to emerge as surface flow (Q_b). Hence, a storm hydrograph can be separated into surface (Q_s) and

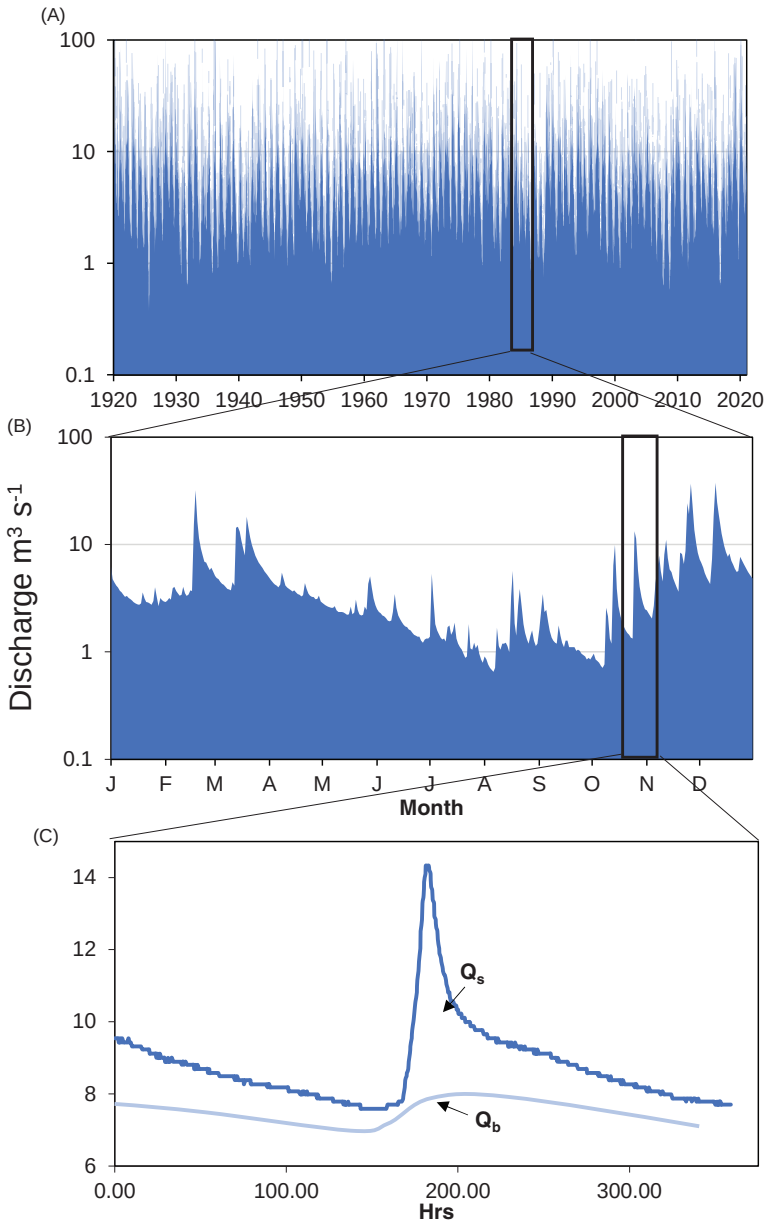

Fig. 3 Hydrologic variation over multiple temporal scales in the Valley River, North Carolina, USA (USGS 03550000). Variation is captured over (A) inter-annual, (B) seasonal, and (C) daily time scales.

baseflow (Q_b) components (Fig. 3C). Hence, most of time, flow within river channels is sustained solely by baseflow. The shape of storm hydrographs, the peak magnitude and rise and fall rates, indicate a great deal about a river's watershed characteristics, particularly geology and soils, and the overall response to precipitation. Additionally, individual storm hydrographs are closely related to seasonal and annual hydrographs for a river system (Fig. 3A–C).

River hydrographs, on daily to annual time scales, are predictable for many regions, although that predictability is shifting with climatic change. This predictability forms the basis of the discussion of river classification and its importance in later sections. Indeed, human societies have grown to depend upon this seasonal predictability for important services, such as dam operations, irrigation, and cooling for electric power generation. Extremities in climate, however, including excess rainfall or extended dry periods, induces unpredictable extremities in hydrologic patterns. For instance, 8 days of heavy rainfall during Hurricane Harvey in Texas exceeded 152 cm (60 in.) in some locations, inducing record breaking peak floods in at least 40 rivers and costing a cumulative of $125 billion in flood damages (Watson et al., 2018). In contrast, California's 5-year drought (2012–16) resulted in $10 billion worth of losses arising from water shortages to six major sectors of the state's economy and placed vulnerable aquatic species at increased risk of extinction (Lund et al., 2018).

Measuring river discharge

Understanding river channel geometry is critical to measuring discharge. River discharge and other materials in transport are conveyed through channels. The dimensions and stability of river channels are partially governed by the geological and topographic setting but otherwise are related to the magnitudes and frequency of water volumes carried downhill. Flowing water constantly carves the river channel, eroding and carrying sediment and materials; however, the channel shape remains relatively constant as materials from upstream replenish sediments as others are eroded. Hence, the river is said to be in dynamic equilibrium (Leopold, 1994). The maximum discharge a channel carries is termed the bankfull flow (Fig. 4). Bankfull flow frequency varies among regions but, on average, these flows generally occur every 1–2 years (Foster, 2012), although this varies by region and climate (Fig. 4). The frequency and magnitude of bankfull discharge is critical for maintaining channel dimensions and shape. Floods, then, are flows that exceed the bankfull capacity of a river channel and enter the floodplain. Floodplains may have multiple tiers, where lower floodplains are inundated annually or semi-annually and upper floodplains are inundated during less-frequent but larger events (Fig. 4).

Discharge is related to the cross-sectional area of water within a channel or, in situations where overbank discharge exceeds the channel's carrying capacity, within a floodplain. Discharge is a measurement of flux, or volume per unit time; therefore, to calculate discharge for a given cross-sectional area, an *estimate* of water velocity is required. Indeed, most methods that measure velocity are estimates, as river hydraulics are complicated by channel roughness, a term describing irregularities in channel geometry arising from variation in substrate size or obstructions to flow, such as boulders or logs. Roughness induces friction and turbulence, which creates highly variant velocities across a stream channel. If river channels consisted of perfect trapezoids or half-circular pipes, estimates of velocity and discharge would be far more reliable. In fact, some approaches to measuring discharge use weirs or other structures to constrain flow a known area to accurately characterize geometry and velocity.

Measuring river discharge can be generally classified into two approaches: instantaneous field measurement and automated or continuous measurements. Although continuous measurements are ideal, this approach requires more equipment, maintenance, and expense. Additionally, continuous measurements are reliant upon many initial and recurring instantaneous field measurements for equipment calibration and continued operation. Instantaneous field measurements represent a single discrete measurement of discharge in time. The wetted width of a channel is measured using a field tape and split into equidistant subsections (generally 10 to 20 sections) (Fig. 4). For each subsection, depth and velocity are measured and their product (width X depth X velocity) is discharge for that section. Discharges for all subsections are then summed to yield total river discharge. Velocity is measured using a velocity or current meter mounted to a wading rod (e.g., Fig. 5A), and there are generally two main types of instruments: a mechanical current meter or electromagnetic sensor. Mechanical current meters consist of metal cups that rotate around an axis, where the revolutions directly translate to current speed, whereas electromagnetic sensors measure voltage arising from conductive

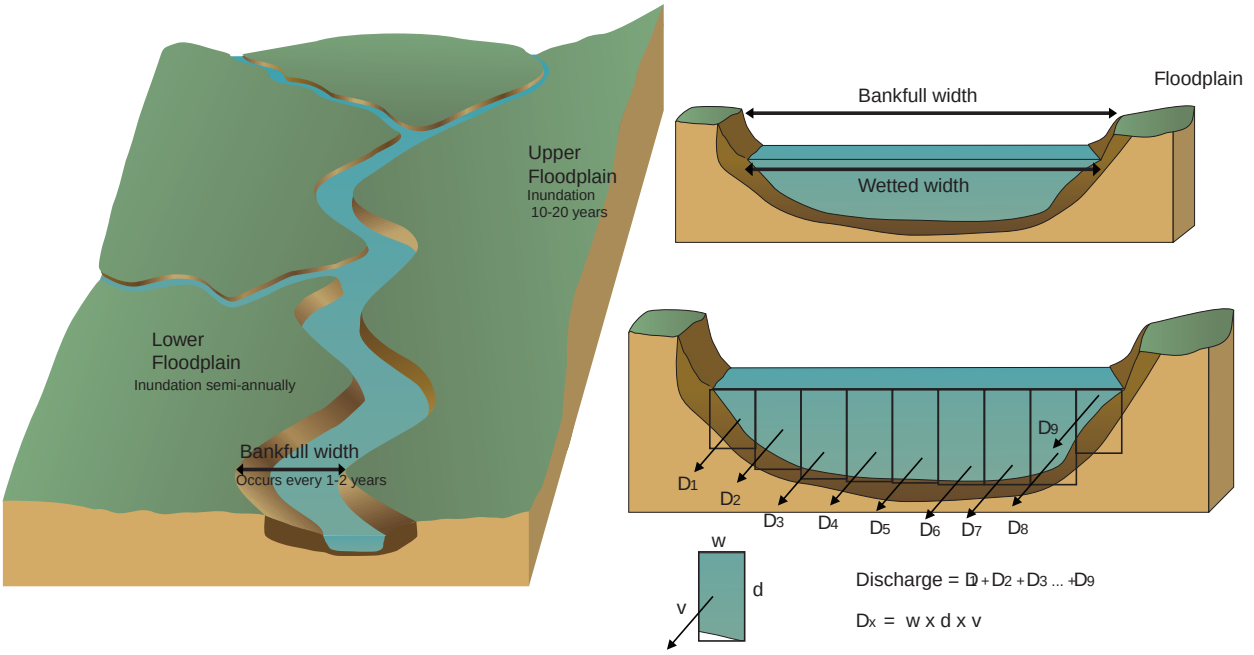

Fig. 4 Channel and floodplain morphology of a river and relations with discharge. Bankfull width is the maximum carrying capacity of a river channel before flows enter the floodplain. Bankfull flows occur, on average, every 1–2 years, whereas lower and upper floodplains may be inundated every 1–20 years. Discharge measurements rely on discretizing the channel cross section into equal subsections where width, depth, and velocity are measured. The sum of these products is discharge for a river at a given point in time. Base conceptual diagrams were modified from original versions, which were courtesy of the Integration and Application Network, University of Maryland Center for Environmental Science (ian.umces.edu/symbols/).

fluids moving through a magnetic field to calculate current velocity. Current velocity varies considerably vertically within the water column, where surface velocity is higher compared to velocity near the streambed, where friction with the streambed slows the velocity. Hence, velocity is commonly measured at 60% of the depth (from the surface) for each subsection, as this generally represents the average current velocity of the entire water column (assuming a logarithmic velocity profile). Due to advances in technologies, the most modern approaches to measuring discharge in the field make use of an Acoustic Doppler Current Profiler (ADCP) mounted to a small watercraft and pulled across the entire channel (Fig. 5B). ADCP instruments use a doppler effect to measure the speed of particles in the entire water column and the cross-sectional depth, voiding the need for manual measurements. Because ADCP instruments measure the current speed across the entire water column and provide continuous depth profiles, these techniques are more accurate in measuring discharge, particularly in larger and deeper streams and rivers.

Translating field-based measures of discharge into continuous readings by automated equipment requires another important field measure, river stage, which is the height of the surface water from a selected location within a river's cross-section. Therefore, stage is completely relative to an individual reach within a specific river. Assuming the cross-section of the stream reach remains constant (which is not always a reasonable assumption), then the stage of the water column can be used to infer discharge based on a stage-discharge curve. Stage-discharge curves represent a relationship between stage and discharge developed from repeated instantaneous field measurements for a given cross-section. As you can see from the stage-discharge relationship (Fig. 6), discharge increases on a log-scale as stage increases; hence, peak floods that inundate floodplains have far more uncertainty (larger log values), as they are inherently difficult to measure accurately in the field. Automated equipment typically measures stage, or pressure, at high temporal intervals and uses the stage-discharge relationship to infer discharge. However, river channels are dynamic and shift regularly, which requires repeated field measurements to adjust cross-sectional profiles and take new stage-discharge readings. Examples of automated equipment to measure water height include floats or pressure transducers housed within small buildings or structures (Fig. 5C–F). The United States Geologic Survey (USGS) has operated over 25,000 stream gaging stations in rivers across the US and Puerto Rico; however, slightly more than 10,000 are currently operating (Fig. 7). Most of these structures are equipped with satellite communication instruments to transmit data to and from satellites and receivers (Fig. 5E and F), and eventually display real-time data on the internet (waterdata.usgs.gov/nwis/rt). In small watersheds, weirs or flumes of precise cross-sectional areas (e.g., v-notch weir) use a small dam to control and measure stage and discharge (Fig. 5D).

Deluge of discharge data—Characterizing river hydrology with statistics

Instantaneous field measurements take considerable time and effort to produce one discharge measurement for a point in space and time. Despite all the effort, those measurements only apply to a single reach within a river and may not coincide with important events, such as peak flood magnitudes, especially if conditions were unsafe to sample or if the event occurred outside of routine sampling. In comparison, consider the 10,000 USGS stream gaging stations in current operation (Fig. 7), most of which provide real-time data at 15-min to 1-h intervals. The continuous measurements from all those gages results in 3,650,000 daily averages or 87,600,000 hourly measurements for 1 year, all provided in real-time. Now, if you consider that many of these gages have been in operation for >15 years, that results in >1 billion observations! This volume of data present new opportunities but also create challenges, such as how to summarize the data to characterize hydrologic patterns in meaningful ways.

Variation in river discharge is generally represented by five components that organize riverine ecological processes: the magnitude, frequency, timing, duration, and rate of change of flow (Poff et al., 1997). Considering all these facets of a river's hydrologic regime, however, can be overwhelming, especially in managing river flows to support natural ecosystem function and human demands. To simplify this complexity and utilize information-rich discharge data, much work has been devoted to summarizing discharge into hydrologic statistics or indices. Summarizing discharge patterns into statistics is important for advancing our fundamental understanding of how river ecosystems are organized, by simplifying hydrologic patterns or making ecohydrological processes easier to discern. Hydrologic statistics also provide practical information for society. For instance, several

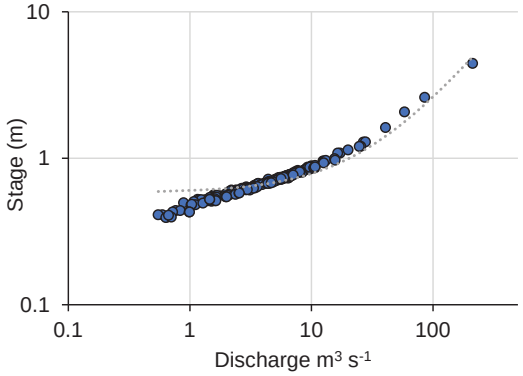

Fig. 6 Stage-discharge relationship for the Valley River at Tomotla, North Carolina (USGS gage 03550000).

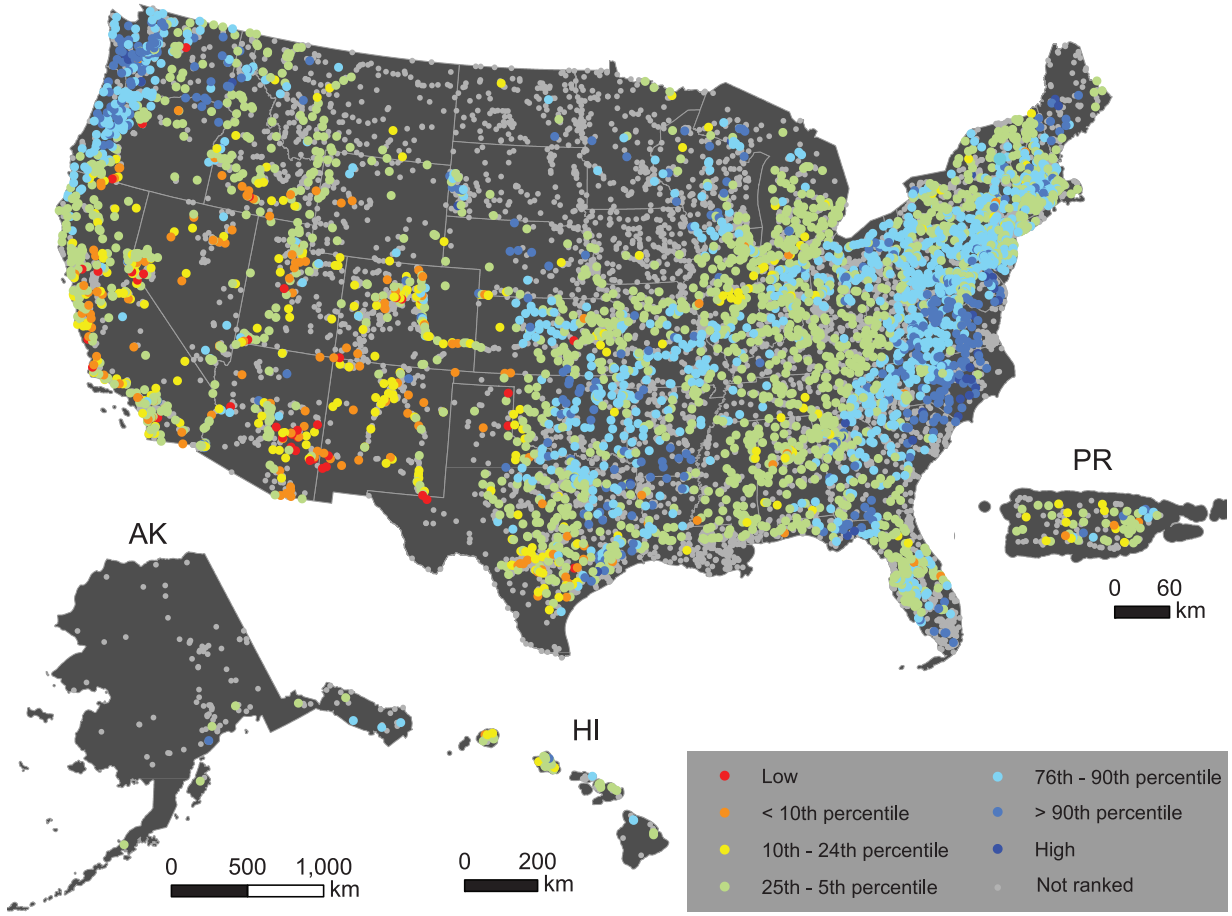

Fig. 7 United States Geological Survey (USGS) stream gaging stations currently in operation and ranked (via percentiles) according to their most-recent discharge value relative to their own 30-year discharge record.

hydrologic statistics have been used as guiding principles or generic thresholds to set water policies or standards for rivers to prevent excessive use of water or protect sensitive ecological components. Hydrologic statistics have also been used for designing infrastructure resilience in light of the variability of flows in rivers. Suppose a state department of transportation desires to build a new road requiring a bridge over a stream, or a developer desires to build a new water supply reservoir to meet growing population demands. In either case, the infrastructure design and materials need to withstand the disturbance of potential peak floods or prevent the occurrence of a dry reservoir. Although one strategy might be to "over-engineer" the infrastructures for the worst possible scenario, seemingly small increases in the size and volume of materials can exponentially increase the cost. Hence, accurate statistics of discharge are important for balancing financial expense with risks to human safety or risk of financial losses from infrastructure failure. One such statistic is peak flood frequency, which represents the return-interval (RI) of a flood of a given magnitude. Suppose the stream has a nearby gaging station with 105 years of discharge data (which is not uncommon) and engineers wanted to design the infrastructure to withstand a 500-year flood event. To calculate peak flood frequency, the peak discharge would be calculated for each year of data and the 105 observations would be ranked from smallest to largest. For each peak flood observation, RI is calculated using the following:

$$RI = \frac{n+1}{m} \tag{3}$$

where n is the total number of observations ($n = 105$) and m is the rank of a given observation (Leopold, 1994; Lundgren, 1986). A flood frequency curve can be generated by plotting peak flood magnitude versus the return interval in years (Fig. 8A), and the predictive relationship can be used to estimate the maximum magnitude of a flood event likely to occur within 500 years. The reciprocal of RI ($\frac{m}{n+1}$) is the probability that a given flood event will occur. For instance, in our observation dataset, the 100-year flood event has a rank $m \sim 1$, which corresponds to 0.01, or a 1% probability of exceedance. The problem with estimating a 100-year flood event with our dataset is that we only have 105 years of observations and hence, only one 100-year event. Using the

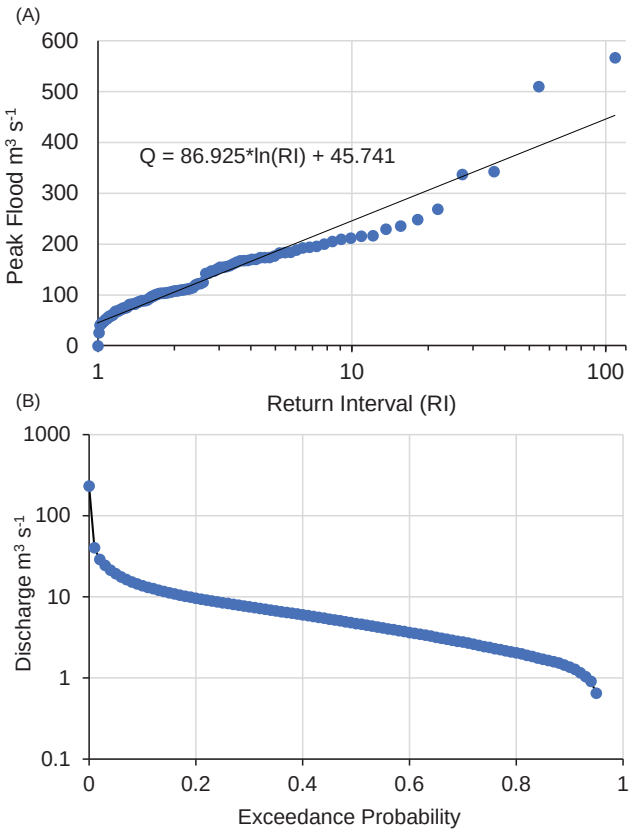

Fig. 8 Examples of hydrologic statistics including (A) peak flood return interval, and (B) a flow duration curve.

same dataset to estimate a 500-year flood events becomes even more uncertain, and in some situations, the uncertainty dramatically increases if the stream of interest does not have a gaging station. In these cases, discharge from the nearest neighboring gage is used and adjusted based for differences in drainage area.

Similar to flood-frequency curves, a flow-duration curve is typically generated from daily discharge values over the entire period of record for a stream gage (Fig. 8B). Percent exceedance values (1–100%) are calculated from daily average flow observations where the 1st percentile discharge value indicates that only 1% of daily flows exceed that value (e.g., daily maximum), whereas the 99th percentile value indicates that discharge exceeds such a value 99% of the time (e.g., the daily minimum). Flow duration curves represent daily discharge magnitudes plotted against percentiles (Fig. 8B). The distribution of values within flow-duration curves provides important information about hydrologic behavior, such as the stability of flows through the year or disparity between high- and low-flow magnitudes. Flow-duration curves also provide important information for water use planning, such as whether a stream can sustain certain human services, such as water withdrawals or hydropower generation. Flood-frequency and flow-duration curves are just two examples of the hundreds of statistics used to summarize discharge patterns.

The large number of hydrologic statistics emerged with the aim of being "ecologically-relevant," i.e., those flow events having relevance to ecological processes. To protect river ecosystems from excessive withdrawals for human use, especially during naturally occurring low-flow periods, statistics were designed to characterize minimum-flow conditions within rivers, such as average August or September flow, which commonly coincides with dry periods in North America. Another commonly used low-flow statistic is 7Q10, the lowest 7-day average flow that occurs (on average) once every 10 years or has a recurrence interval of 10 years. The minimum flow paradigm became a widely accepted and instream flow management approach for mitigating or preventing situations of withdrawals and dam regulation or setting flow regulations and policies (Tennant, 1976; Annear et al., 2004). Unfortunately, river managers became overly reliant upon the minimum flow paradigm, which was neither generally not protective of a river's dynamic flow regime nor useful for characterizing hydrology in ways meaningful to general ecological condition or to species the regulations were aimed to protect.

During the late 1980s through mid-1990s, a growing appreciation of the multi-dimensional nature of river hydrologic regimes (e.g., Poff and Ward, 1989; Poff, 1996; Richter et al., 1996) eventually gave rise to the natural flow regime paradigm, which was a framework to approach river management through holistic consideration of all five flow regime components (Poff et al., 1997). During this paradigm shift, a multitude of new and informative hydrologic statistics emerged to characterize discharge in ecologically meaningful ways (Poff and Ward, 1989; Poff, 1996; Richter et al., 1996, 1997; Olden and Poff, 2003). Among these

included the Indicators of Hydrologic Alteration (IHA), a series of 32 indices that summarized biologically relevant aspects of hydrology at daily to intra-annual scales (Richter et al., 1996). Measures of variation or dispersion in each IHA statistic resulted in 64 total indices (Richter et al., 1997). The IHA statistics were eventually incorporated into open-access software and designed for comparing human-altered hydrologic regimes with pre-altered or ideal natural conditions to inform flow management (Richter et al., 1996). To date, almost 2000 hydrologists, ecologists, researchers and water resource managers worldwide have used the IHA software to evaluate hydrologic alteration due to anthropogenic disturbance (TNC, 2018). More studies of various river systems and contexts demanded new hydrologic statistics specifically designed for associating discharge with ecological dynamics of interest or measuring unique situations of hydrologic alteration. Some of the various studies documenting these hydrologic statistics are provided in Table 1. Recognizing the challenges associated with the growing number of indices and selecting appropriate statistics for ecohydrology studies, Olden and Poff (2003) conducted a review documenting 171 hydrologic indices summarized from daily discharge records. They found that many of the indices were redundant or displayed multi-collinearity and that the 64 IHA indices explained the majority of multivariate space represented by all 171 indices. Even still, the number of hydrologic indices continue to grow, including those that characterize hydrology on sub-daily time scales (e.g., Bevelhimer et al., 2015). Most recently, Eng et al. (2017) calculated 612 daily hydrologic statistics for hydrologic classification and supporting future studies in hydroecology. Carlisle et al. (2019) later used these statistics to relate with measures of biological integrity to understand how anthropogenic modifications of stream flow have affected stream health.

Hydrologic signatures and classification

The previous section gave a high-level background of hydrologic statistics and their utility in decomposing thousands of discharge observations into a series of statistics meaningful for many applications, such as infrastructural engineering, setting water policies, or explaining complex ecological patterns. However, as Olden and Poff (2003) suggest, the pursuit of ecologically meaningful statistics has resulted in an over-abundance of indices, which has created new challenges of selecting the most appropriate and informative measures to guide river flow management. Considering the contextual specificity of river ecosystems in different climatic and physiographic settings with divergent riverine ecological communities, the over-abundance of indices adapted for each unique application should not come as a surprise. As Poff et al. (2007) describes, each river is characterized by a natural flow regime, a hydrologic signature unique to that river system (Fig. 1). Looking back at Eqs. (1) and (2), we notice that there are several variables that influence discharge, and there are many factors that influence each variable: climate, geology, topography, soils, and vegetation. Suppose for simplicity's sake that each factor is represented by several major categorical types, and there are a myriad of combinations of factor types that generate hydrologic variability in rivers. For instance, there are 6 generally recognized global climate regions (Mason et al., 2016), ranging from polar to tropical areas, and 12 textural types of soils (USDA, 2017), ranging by combinations of clay, silt, sand, and loam. The world is generally comprised of 5 major vegetation communities or biomes (forest, grassland, tundra, desert, and ice) (Bowman and Hacker, 2021) and 5 topographically variant landforms: plains, plateaus, mountains, valleys, and canyons (Page, 2015; Mason et al., 2016). Additionally, there are over 7000 lithostratigraphic units representing different geological bedrock and surficial deposits of the world (Kirkham et al., 1995; King and Beikman, 1974a,b), although these can be coarsened into 8 very simplified types (Kirkham et al., 1995). Assuming each type equally contributes to

hydrologic variation, then a product of all these types results in 18,000 possible combinations, or unique, hydrologic types. As other examples, there are roughly 178,000 sub-basins across the world, where sub-basins are analogous to medium-sized river basins (Lehner and Grill, 2013), and there are at least 8.5 million river reaches globally with an average length of 4.2 km (Linke et al., 2019). If we assume each sub-basin or reach has its own unique hydrologic regime, then this suggests that the world has hundreds of thousands to millions of hydrologic signatures.

This immense variation, however, poses clear challenges to managing environmental flows in rivers. Particularly, there is a great need to generalize hydrologic behaviors and relationships with ecological processes in order to set water standards or general rules of thumb that protect the hydrologic components most critical to sustaining ecosystems. Classification systems help to consolidate variation in hydrologic regimes by generalizing rivers that behave similarly hydrologically. In doing so, hydrologic classifications provide management units, where types of rivers can be managed as a group rather than the individual hydrologic uniqueness of every river (Arthington et al., 2006). An overly simplistic classification might be grouping streams that have perennial, intermittent, or ephemeral flow, described in the "Water Cycle" section. However, this would provide little protection of variant seasonal or even interannual hydrologic patterns. In contrast, setting water policies for even 1000 different hydrologic types would be too complex for effective river management. Despite millions of hydrologic signatures unique to each river, river systems display reoccurring patterns in hydrologic regimes that predispose them to classification. The multi-collinearity and redundancy among hydrologic indices (Olden and Poff, 2003) further suggest that the dimensionality of multivariate measures of discharge can be dramatically reduced, specifically through clustering of hydrologic indices into groups or classes of hydrologic variation.

In the past 30 years, many hydrologic classifications have been developed to provide a fundamental understanding of hydrologic regime diversity (e.g., Poff, 1996) or to support environmental flow management (e.g., McManamay et al., 2012a) (Table 2). In a review of hydrologic classification efforts, Olden et al. (2012) distinguished two general approaches: deductive and inductive techniques. Deductive techniques use regional boundaries or grouping of environmental variations to infer regions of

Table 2 Examples of deductive and inductive approaches to hydrologic classification and a hybrid approach between the two.

Study	*Region*	*Spatial Resolution*	*Method*
Deductive			
Auerbach et al. (2016)	Ecuador	Small to large basins (100–600 km^2)	Used topographic, climate, soils, and land cover variables summarized in basins using Ward's hierarchical agglomerative clustering procedure and gap statistic for selecting optimal groups
Wolock et al. (2004)	United States	Small watersheds (200 km^2)	Ordination (principal component analysis) and clustering using a minimum variance criterion and the nearest neighbor chain algorithm
Snelder et al. (2005)	New Zealand	Stream Reaches	Hierarchical method where river segments were classified into groups for a number of different layers, each with different criteria
Inductive			
Archfield et al. (2014)	United States	Stream Gage	Used seven "fundamental daily streamflow statistics" characterizing the distribution of hydrology in a Ward's hierarchical agglomerative clustering procedure
Baker et al. (2004)	Midwestern United States	Stream Gage	Maps of four hydrologic groups were produced by partitioning gages by quartiles of values in Richard-Baker Flashiness Index
Haines et al. (1988)	Global	Stream Gage	Hierarchical clustering with average linkage procedure
Hughes and James (1989)	Victoria Australia	Stream Gage	Ordination via principal component analysis followed by hierarchical clustering using the average linkage procedure
Kennard et al. (2010)	Australia	Stream Gage	Used 120 hydrologic metrics in a non-hierarchical clustering using fuzzy partitioning Bayesian mixture algorithm
McManamay et al. (2012a,b)	Southeastern United States	Stream Gage	Used 66 hydrologic metrics in a k-means clustering procedure
McManamay et al. (2014)	United States	Stream Gage	Used 110 hydrologic metrics in ordination via principal components analysis followed by Gaussian mixture modeling with Bayesian parameter estimation
Monk et al. (2006)	United Kingdom	Stream Gage	Wards agglomerative hierarchical clustering procedure
McManamay and DeRolph (2019)	United States	Stream Reach	Clustering results for gages from McManamay et al. (2014) were used in a random forest model to map hydrologic classes to stream reaches
Poff (1996)	United States	Stream Gage	Using 10 metrics in a hierarchical clustering (density linkage) procedure
Puckridge et al. (1998)	Global	Stream Gage	Ordination via hybrid multidimensional scaling followed by hierarchical clustering using average linkage
Liermann et al. (2012)	Washington, United States	Stream Reach	Non-hierarchical clustering using fuzzy partitioning Bayesian mixture algorithm to classify gages to hydrologic groups. Predictive model was then used to assign gages to stream reaches
Hybrid approach			
Ouellet Dallaire et al. (2019)	Global	Stream Reaches	Average discharge, discharge seasonality, and hydrologic variability were simulated in WaterGap model (Döll et al., 2003) and then both supervised and unsupervised classification approaches were used to cluster streams

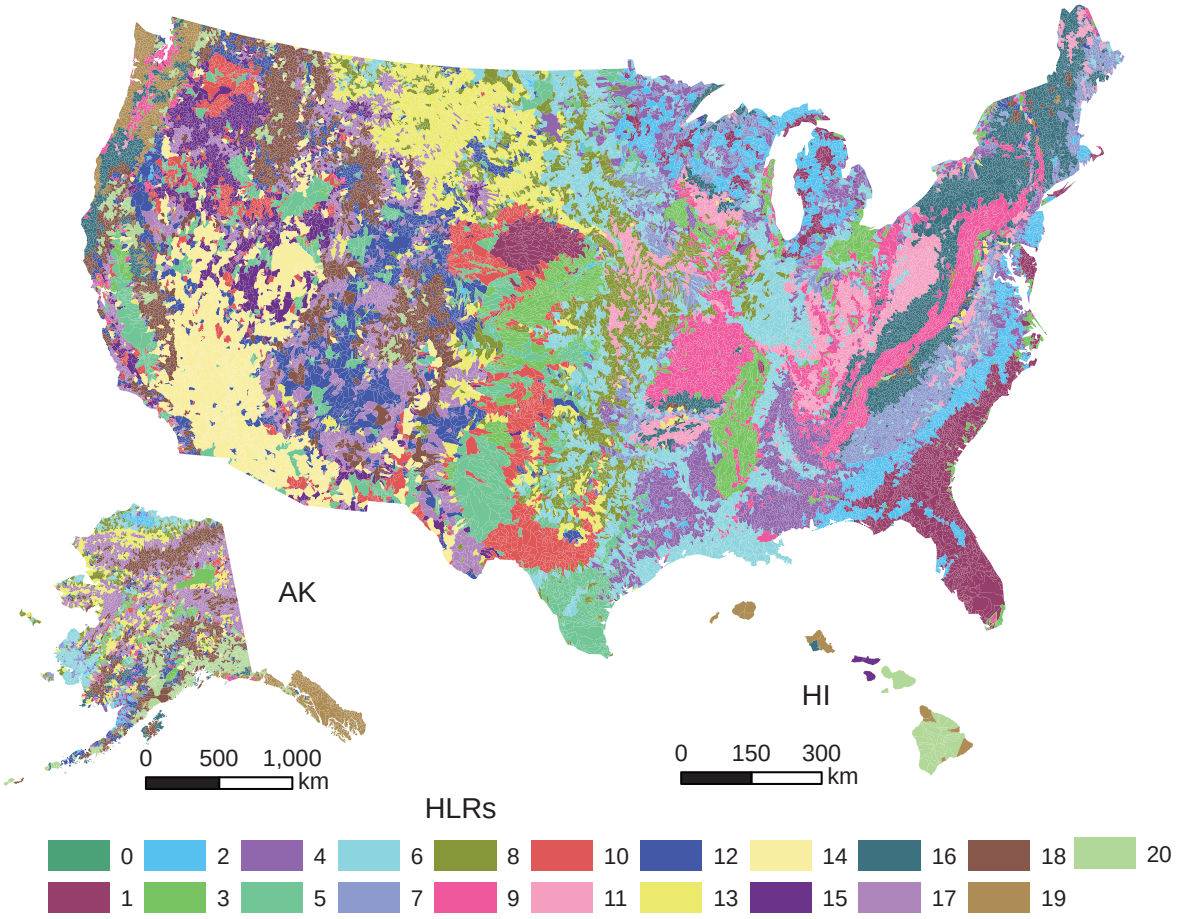

Fig. 9 Hydrologic landscape regions from Wolock et al. (2004) as an example of a deductive hydrologic classification technique.

similar hydrologic regimes, whereas inductive techniques directly use empirical hydrologic data to develop classifications (Olden et al., 2012). Deductive approaches rely on the logic of regionalization and best professional judgment, either assuming hydrology is similar within regional boundaries (Omernik, 2004) or that the variation of hydrologically relevant environmental variables (e.g., climate, soils, etc.) serve as reliable surrogates of hydrologic variation (e.g., Wolock et al., 2004; Snelder et al., 2005, 2011). Deductive approaches may be advantageous where crisp regional boundaries are preferred (Wolock et al., 2004), or in situations where hydrologic information is limited or unavailable (Auerbach et al., 2016). As an example, Wolock et al. (2004) assembled seven hydrologically relevant landscape attributes for over 40,000 small catchments in the US and then used principal components analysis and hierarchical clustering to yield 20 Hydrologic Landscape Regions (HLR) (Fig. 9). HLRs were used to stratify nationwide water quality study site locations by areas of similar hydrologic settings (Wolock et al., 2004). River systems are longitudinally organized into nested watersheds and tend to display hydrologic "inertia" despite flowing through different hydroclimatic regions (McManamay et al., 2012a). Because rivers may transect multiple regions, deductive regionalization may not accurately represent streamflow patterns, unless environmental attributes are structured according to relative importance of governing hydrology and developed a river reach-scale (McManamay et al., 2012b). Snelder et al. (2011) assembled climatic variables within nested watersheds of individual stream reaches to produce a deductive classification of rivers in New Zealand; this approach is presumed to more accurately represent differences in hydrologic regimes than regionalization approaches, as it was generated at the river-reach scale.

In comparison, inductive approaches rely on direct observations of discharge, and generally follow a stepwise procedure of summarizing streamflow records into statistics and then clustering streams based on correlative structure of hydrologic metrics (Olden et al., 2012). Inductive hydrologic classifications have been developed for individual states of the US (Kennen et al., 2007, 2009; Turton et al., 2008; Liermann et al., 2012), regions (Sanborn and Bledsoe, 2006; Chinnayakanahalli et al., 2011; McManamay et al., 2012a,b), continents (Kennard et al., 2010; McManamay and DeRolph, 2019), and the world (Haines et al., 1988; Ouellet Dallaire et al., 2019). Because inductive classifications are based on empirical observations of streamflow, they more accurately distinguish hydrologic regimes than regionalization or environmental surrogate approaches (McManamay et al., 2012b); however, until recently, inductive approaches were limited to locations with streamflow observations, leaving many ungauged rivers without

hydrologic class membership. Advances in geospatial datasets and statistical modeling (e.g., machine learning) have provided new opportunities to extrapolate class membership to ungauged river systems (e.g., Liermann et al., 2012; McManamay and Derolph, 2019), which is discussed below. Inductive classifications vary in the composition of hydrologic indices used to represent hydrologic variation, the statistical decomposition approach to reduce multicollinearity and dimensionality, and the clustering procedure to develop groups, all of which influence the classification outcome and interpretation of hydrologic regimes. Clustering procedures have varied from hierarchical or agglomerative statistical approaches (e.g., Poff, 1996; Monk et al., 2008; Archfield et al., 2014), to k-means procedures (Poff and Ward, 1989; Snelder et al., 2009; McManamay et al., 2012a,b), to "fuzzy" partitioning methods using Bayesian mixture modeling algorithms (Kennard et al., 2010; Liermann et al., 2012; McManamay et al., 2014) (Table 2). Ward's agglomerative procedure has been the most used statistical approach and is commonly preferred, as it yields interpretable results, clean cluster membership (not fuzzy membership), and cluster membership robust to the order of observations (compared to non-hierarchical approaches) (Olden et al., 2012). Aside from the choice of clustering algorithm, another important, yet rarely discussed, decision that noticeably influences clustering outcomes is whether to standardize magnitude-related hydrologic metrics according to river size. Standardizing metrics typically consists of dividing all magnitude-related variables by mean or median annual flow or drainage area prior to clustering (e.g., Poff, 1996; Kennard et al., 2010; McManamay et al., 2014). In the case of unstandardized approaches, raw values of metrics are used in clustering procedures (e.g., Archfield et al., 2014). Leaving magnitude-related metrics unstandardized results in classes influenced by drainage area, whereas metric standardization ensures class distinction is based on relative variation in hydrologic regimes. In the latter case, rivers of varying size may share similar cluster membership based on similarities in hydrologic behavior or signatures, regardless of the differences in flow volumes. Once standardized hydrologic classifications are developed, highly predictable relationships between drainage area and flow magnitudes can be developed (e.g., McManamay, 2014; McManamay et al., 2013).

Numerous examples of both deductive and inductive approaches are provided in Table 2. As mentioned previously, one of the past limitations of inductive approaches was that they were limited to only locations of empirical observations of streamflow, leaving many rivers without class membership; however, multiple recent approaches have used predictive models to extrapolate hydrologic classes from stream gages to ungauged reaches (e.g., Kennard et al., 2010; McManamay et al., 2014; McManamay and DeRolph, 2019) (e.g., Fig. 10). These approaches take advantage of compilations of geospatial climate and landscape variables summarized for the entire stream network draining to each river reach. For example, there are over 2.6 million stream reaches within the NHDPlus V2 dataset for the conterminous United States (CONUS) (EPA, 2020). For every NHDPlus stream reach, large suites of variables (climate, topography, geology, soils, and land cover) have been summarized for the entire drainage area upstream of each reach (e.g., StreamCat dataset, Hill et al., 2016). This provides a tremendous resource for extrapolating hydrologic class membership to all streams within a region. Recently, McManamay and DeRolph (2019) leveraged the StreamCat dataset within a predictive model to extend hydrologic class membership to all 2.6 million stream reaches in the CONUS (Fig. 10). Ouellet Dallaire et al. (2019) used a novel hybrid deductive-inductive approach to yield a global stream classification product at a river reach scale (Fig. 11). Rather than generate empirical hydrologic classes to extrapolate to ungauged reaches, the authors used synthetic estimates of mean monthly flow and flow variability from hydrologic models (Döll et al., 2003; Lehner et al., 2008) to cluster river reaches into hydrologic types (Fig. 11).

Applying hydrologic classifications to river management

Significant effort has been devoted to the science of developing hydrologic classifications, including the selection of reference-quality stream observations, hydrologic metrics, and clustering procedures (see examples in Tables 1 and 2). Despite this tremendous volume of research, far less effort has been devoted to the application of hydrologic classifications to advance the science of environmental flows; however, those efforts have increased considerably in recent years. Poff and Zimmerman (2010) suggest that the successful development of environmental flow standards requires regional specificity and context, perhaps partially addressed through hydrologic classifications.

Arthington et al. (2006) originally conceptualized hydrologic classifications as the basic management unit for developing environmental flow standards, specifically by providing a stratified approach to examine how river hydrology and ecological communities respond to human-induced hydrologic alteration. As a consensus among many international scientists, the Ecological Limits of Hydrologic Alteration (ELOHA) framework was proposed as a synthesis of science and techniques for determining environmental flow needs for rivers at regional scales (Poff et al., 2010). ELOHA constituted a paradigm shift in the approach to environmental flow management by focusing on defining environmental flow standards for groups of rivers rather than recommendations for individual systems. The central premise of ELOHA is developing flow alteration-ecological response relationships for each hydrologic class within a region; this information base is then used to by stakeholders to determine socially acceptable "limits" to hydrologic alteration and establish environmental flow standards for each hydrologic type. Since its conception, the ELOHA framework has been formally applied in at least 20 US states and several other countries, including the United Kingdom, Tanzania, South Africa, Australia, China, Colombia, and Mexico (TNC, 2020; Kendy et al., 2012; Liermann et al., 2012; McManamay et al., 2013; Mackay et al., 2014; Tavassoli et al., 2014; Martin et al., 2015).

Applications of the classification-based ELOHA process vary depending on the environmental flow management needs for different regions. Examples of studies include the following: examining whether dam regulation alters streamflow differently depending on hydrologic class membership (McManamay et al., 2012c; Mackay et al., 2014); evaluating associations between

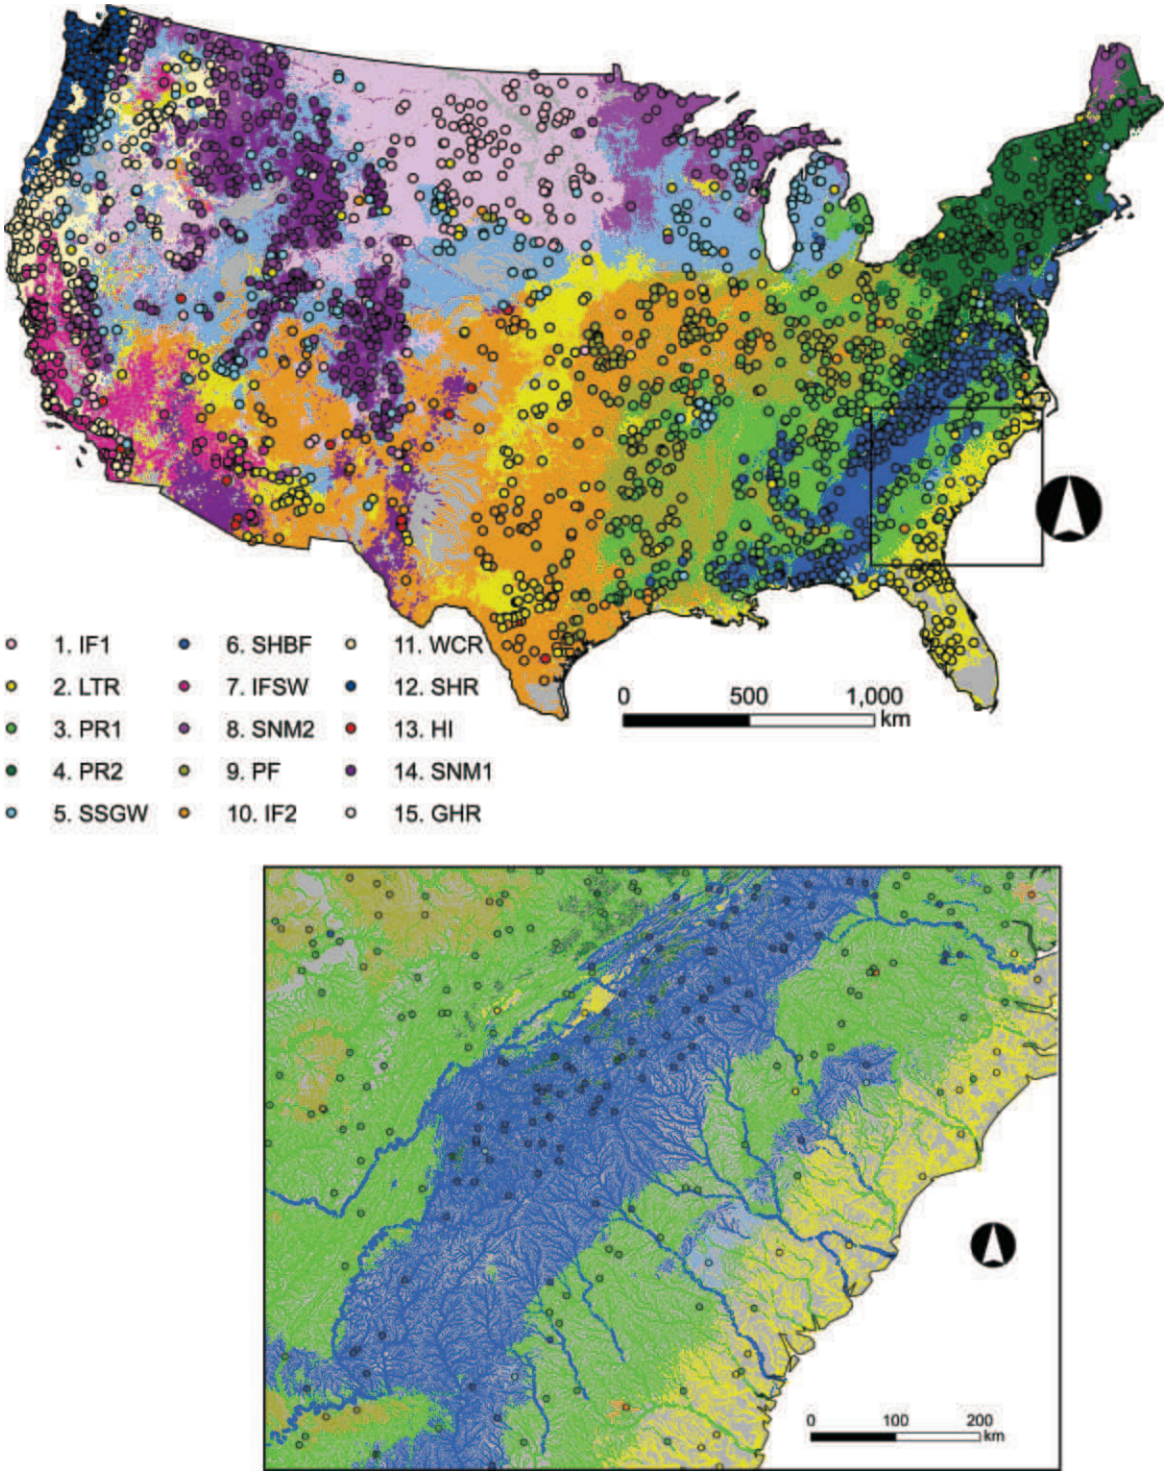

Fig. 10 Hydrologic classification at the stream reach level for the United States developed by McManamay and DeRolph (2019). An inductive approach was used to classify discharge statistics from stream gages into different groups. Predictive models were then used to extrapolate group membership to all streams based on climate and landscape characteristics.

hydrologic classes and community ecology patterns (McManamay et al., 2015a); determining how hydrologic regimes and variation may shift in light of climate change (Liermann et al., 2012); quantifying "ecological limit functions" specific to ecoregions (as opposed to hydrologic classes) (Knight et al., 2014); and testing ELOHA in prescribing flow restoration measures in dam regulated rivers (McManamay et al., 2013, 2015b). The science of environmental flow development continues to rapidly advance and ELOHA applications are still ongoing. More research is needed to understand how generalities in hydrologic behavior can be used to inform regional environmental flow standards.

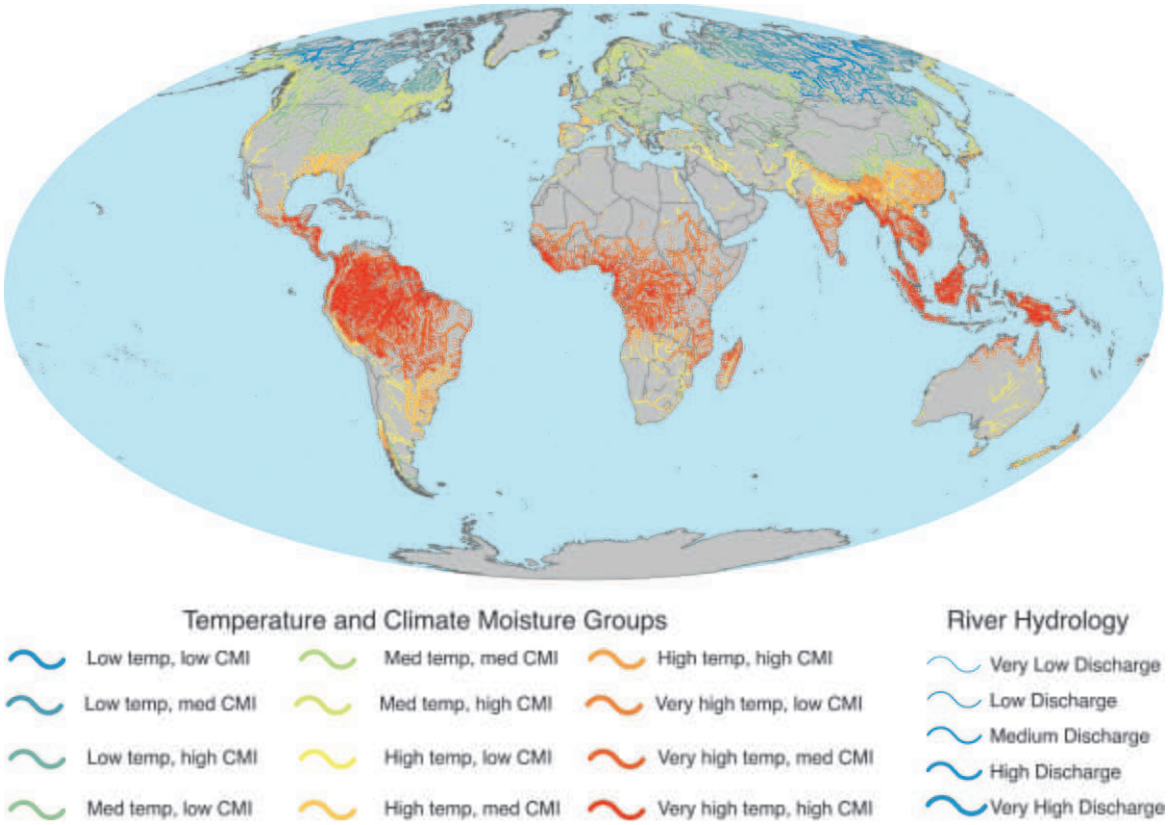

Fig. 11 A hybrid inductive-deductive hydrologic classification approach for streams of the world taken by Ouellet Dallaire et al. (2019). Streams were classified according to climate and hydrologic properties. Climate included temperature and climate moisture index (CMI). The WaterGap model (Döll et al., 2003) was used to model discharge in order to develop the river hydrology classification.

Riparian Zones

David M Merritt, National Stream and Aquatic Ecology Center, U.S. Department of Agriculture Forest Service, Fort Collins, CO, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Allochthonous External organic carbon contributed to an aquatic ecosystem (often from riparian areas).
Alluvial Material deposited as a result of fluvial processes.
Anoxic Soils with low levels of oxygen due to submergence and microbial oxidation-reduction processes.
Colluvial Deposits of rock, sediment and debris from side slopes resulting from gravitational delivery.
Endorheic basins Drainage basins that terminate in the interiors of continents into wetlands, lakes or mudflats rather than oceans or larger rivers. Endorheic basins are also called closed, terminal and internal basins.
Environmental flows The timing and quantity of stream flow required to sustain freshwater and estuarine ecosystems and the human livelihoods and well being that depend on these ecosystems.
Fluvial Of, relating to, or produced by flowing water.
Hydrophytic A plant that is adapted to living either in waterlogged soil or partly or wholly submerged in water.
Hyporheic Subsurface alluvial, saturated zone driven by groundwater that is connected to surface flows.
Process domain Spatially identifiable areas characterized by distinct suites of geomorphic processes in which ecological community structure and dynamics respond to distinctly different disturbance regimes.
Riparian Areas along/adjacent to stream channels and influenced by streamflow and fluvial processes associated with river flow and sediment regimes, surface and groundwater interactions, and region-specific disturbance regimes, species pools, and climates and geologies.
Riverine Aquatic and riparian ecosystems occurring along streams and rivers and influenced by streamflow volumes, stream processes, and human influences.

Introduction

The intent of this chapter is to define riparian ecosystems and to describe their range, distribution, extent and diversity of forms and functions worldwide. This section will briefly describe the processes governing aquatic and riparian (together "riverine") forms and functions, highlight natural and human-caused threats to them, their conservation, as well as discuss scientific opportunities in the field of riparian ecology. Riparian is derived from Latin word *riparius* (feminine *rīpāria*, neuter *rīpārium*) meaning "of or belonging to the bank of a river." Riparian areas are features of the landscape that are adjacent to rivers and streams and governed by river hydrology and associated fluvial processes. For the purpose of this overview, the banks and floodplains of flowing water (lotic) systems such as rivers, streams and spring outflows that are influenced by processes associated with open channel flow (fluvial) are considered riparian. Marshes, wet meadows, pond and lake margins not associated with flowing water may share many of the patterns, processes and functions of riparian ecosystems but are not considered riparian.

In addition to forming networks of various forms (e.g., dendritic, trellised, parallel, pinnate, etc.) that drain water, mineral sediment, wood and other organic material and dissolved compounds (and propagules) from watersheds, streams, rivers and their riparian zones perform many valued ecological and societal functions and services. Riparian ecosystems are among the most complex and diverse ecosystems on Earth, yet occupy only roughly 3% of the Earth's land surface, though this varies significantly from region to region (Lehner and Doll, 2004) (Fig. 1). Riparian habitat, which is typically distinct from and more productive and

physically and biologically diverse than adjacent upland habitats on all continents, represents a transitional zone, or ecotone, bridging uplands and aquatic habitats, and performs functions and supports ecosystems that are uniquely riparian compared to adjacent uplands (Naiman and Décamps, 1997; Sabo et al., 2005; Ward and Tockner, 2001).

Many riverine functions valued by humans are performed by riparian areas, which provide sites for detention, storage, uptake and biochemical transformation of a range of minerals, chemical compounds and organic material—performing water purifying processes (Wohl, 2021). Most often flowing through the lowest position in any landscape, river channels collect water, sediment, seeds and vegetation propagules, wood and other materials from surrounding landscapes. Riparian areas provide habitat for wildlife, carbon, nutrients, and channel maintenance functions, such as stabilizing banks and influencing hydraulics and sediment mechanics (Merritt, 2020). Riparian vegetation governs vertical and horizontal habitat structure, generates and delivers organic material which, along with autochthonous production, provides the basis for aquatic food webs. Further, the rich diversity of vegetation in riparian areas provides pollen, nectar, shelter, cavities, nest sites, wood inputs to streams, nutrient uptake, sediment detention, bank stabilization, thermal regulation, and microclimatic drivers that collectively contribute to the functions, values, and

biotic diversity of these areas (Baruch et al., 2021; Merritt and Bateman, 2012). Whereas larger flowing rivers serve as valuable transportation corridors for humans, and for many aquatic and amphibious species, adjacent riparian zones also serve as corridors for movement, resting sites for migratory species, and permanent or seasonal habitat for myriad organisms. Riparian areas and their health may be assessed through quantifying bird, arthropod (e.g., spider and butterfly), plant species richness, and overall diversity and community composition.

Riparian areas exhibit functional connectivity: (1) longitudinally, in an upstream to downstream dimension, connecting otherwise disconnected landscape elements and two way exchanges between the interiors of continents and oceans; (2) laterally through seasonal and/or permanent interaction with floodplains and valley bottoms outside of the river channel itself through exchanges of water, sediment, carbon and other chemical compounds and biotic components; and (3) vertically, extending from deep confining bedrock into the hyporheic zone (groundwater interacting with the river) and fluvial sediments, and up through the vegetation canopy into the atmosphere. As with all other ecosystem types, the fourth dimension considered important for riparian areas is change through time, which may be accelerated and dramatic along rivers, particularly in alluvial river systems, which may have high turnover of substrate, channel forms, and vegetation and other biotic patterns compared to other non-fluvial ecosystems.

Because riparian areas are typically transitional areas that span an aquatic to terrestrial gradient, components of many terrestrial ecosystems occur in riparian areas and this transition between riparian and adjacent uplands may advance and recede through time. Riparian areas vary as a function of climate, structural and Quaternary geology, evolutionary history, position within in channel networks, and direct and indirect human influences, and it is difficult to make broad generalizations or singularly describe riparian areas globally. Further, descriptions of patterns and processes in riparian areas must be placed within the context of the appropriate spatial scale. Riverine ecosystems are hierarchically organized from whole networks within large watersheds exceeding 7 million km^2 to sub-watersheds smaller than 1 km^2 representing a range of stream and river sizes. Within sub-watersheds, segment-scale valley and channel forms occur, and are comprised of reaches, sub reaches, geomorphic units, and at the smallest scale, microhabitats (<1 m^2) (Frissell et al., 1986). Each level in the continuum of scales in this nested organization is to some degree, governed by processes acting at the higher spatial scale. Riparian areas are a function of all processes occurring at each of these scales throughout a watershed and stream network. Therefore, understanding and interpretation of processes or patterns occurring at a microhabitat or reach scale must be considered with an understanding of processes occurring throughout the network, adjacent uplands within the watershed, and with an awareness of historical legacies, both natural and anthropogenic (Fig. 2).

It is with this definition of riparian ecosystems, and in the context of their diversity of form and function, that we consider the processes and patterns that all riparian ecosystems in the world share and what makes riparian areas distinct from other freshwater and terrestrial ecosystems.

Redrawn and modified from Montgomery DM (1999) Process domains and the river continuum. *Journal of the American Water Resources Association* 35: 397–410.

Riparian ecosystems

Physical attributes of riparian ecosystems

The primary drivers of and constraints upon river processes include climate and geology. Climate determines the amount, timing, form (glacial melt, snow, rain, groundwater, etc.), and seasonal variability of water availability, governing hydrologic regime and geology and recent geologic history sets the template upon which water and sediment is routed. For example, rivers that flow through broad low gradient landscapes have distinct physical forms, riverine ecosystems, and functions compared to those that flow through (and perhaps carve) canyons or glacial valleys. Rates of chemical and physical weathering, solar radiation, temperature and atmospheric demand for moisture and are also governed directly or indirectly by climate. However, the routing of this water, the drainage network of watersheds, and channel geometry and geomorphic processes are conditioned by geology, both ancient and recent (i.e., <90 K years ago).

Globally, there are over 11.8 million kilometers of streams and rivers, a vast majority of these watercourses are ephemeral (flowing for part of the year) or intermittent (flowing for only part of their length) (Grill et al., 2019). Riparian areas and the river floodplains they occupy range from a few meters wide in headwater reaches to 250–330 km wide on deltas of very large rivers such as the Nile and Amazon, respectively. Estimates of the extent of river floodplains on Earth are on the order of 4 million km^2 (Lehner and Doll, 2004). In flowing from mountains and higher elevations on continents to the sea, streams increase in streamflow and volume of mineral sediment, dissolved compounds and organic material, whereas channel particle size and river channel gradient decrease. Headwater and mountain streams are typically higher gradient and erode and transport sediment (as transport capacity typically exceeds supply of sediment), transitional reaches largely transport sediment; and depositional reaches along larger (higher order) streams have lower gradients and may terminate in larger order streams, estuarine deltas, or endorheic basins in the interiors of continents. Timing and volume of flow and sediment and the hydraulic complexity of streamside and floodplain habitats are intimately tied to the structure, form and function of riparian areas.

The combination of climate and geology (and dominant geomorphic processes occurring) along a particular river reach or within a hydroclimatic regime are referred to as process domains (Montgomery, 1999)—suites of characteristic disturbance and recovery cycles governed by the dominant geomorphic processes. Different process domains have characteristic magnitude, frequency and duration of the physical ecological disturbances and periods of recovery, which influence riparian areas. Process domains vary in ecologically important ways along the course of a river and throughout a catchment. For example, in mountainous areas, colluvial inputs along confined canyons may dominate, whereas alluvial processes dominate along higher order, lower gradient reaches further downstream in a watershed (Friedman et al., 2006). Study of process domains reveals that along rivers, the main geomorphic units relevant to riparian ecosystems are hillslopes, channels and floodplains. The influences of geomorphic processes acting at these scales define the process domain and influence riparian functions and patterns (Fig. 2).

Valley morphology (gradient, lateral confinement, and form) and subsurface sediment stratigraphy and physical properties of valley fill also control surface water and groundwater patterns and their interactions (Fig. 3). Geologic controls on down valley and vertical groundwater movement have been shown to drive changes in the presence and productivity of key riparian trees (Harner and Stanford, 2003; Stanford and Ward, 1993; Wohl, 2021). Transitions from wide valleys with deep alluvial fill to narrow bedrock-constrained reaches result in upwelling of alluvial groundwater and nutrients, creating conditions that support productive riparian forests that may be absent or sparse in wider valley sections with deeper groundwater (Fig. 4).

Worldwide, many distinct forms of rivers have been recognized, each varying from ecoregion to ecoregion and position in the watershed from headwaters to terminus. The range of forms of high gradient streams include straight, cascade, plane bed, pool-riffle, and step-pool (Montgomery and Buffington, 1997) whereas lower gradient channels may take on braided, anastomosing, anabranching, and meandering pool-riffle forms (in order of decreasing channel gradient) (Leopold and Wolman, 1957; Tooth et al., 2008) (Fig. 1). Riparian vegetation establishment, survival, physiognomy, community composition, age-class structure and diversity all vary as a function of channel form, surface and groundwater hydrology, the frequency, intensity, form, and frequency of

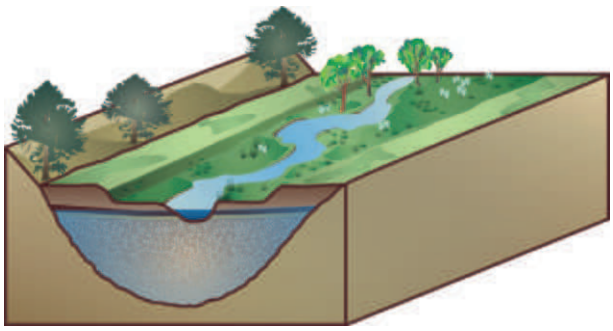

Fig. 3 Block diagram showing the three-dimensional nature of riparian areas. The diagram highlights the interconnectivity between the surface flow in the stream channel, the groundwater system, and the interface between floodplain sediments (and their stratigraphy) and the deeper alluvium (hyporheic zone). Zonation of vegetation from hydrophytic disturbance-tolerant plants near the channel to upland conifers along the valley perimeter is illustrated. A fourth dimension is change through time, which may be event-driven (flood and fluvial disturbance) or gradual (channel migration) and is accelerated in riparian areas.

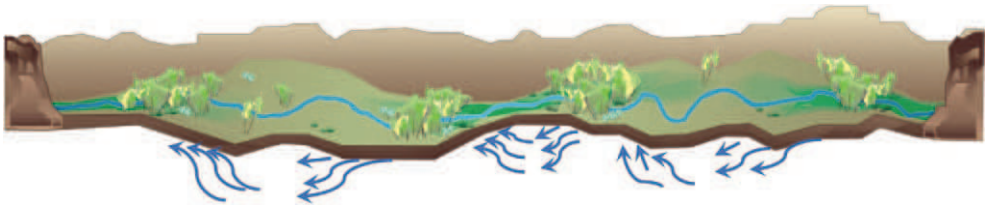

Fig. 4 Oblique view of a reach of river with alternative narrow and wide valley walls. Blue arrows indicate upwelling of groundwater along gaining reaches where groundwater is forced toward the rhizosphere of plants and downwelling along losing reaches. Studies show that primary productivity (growth rate) and nitrogen content of riparian trees are higher in areas of upwelling when compared to areas of downwelling. This higher growth rate is attributed to higher water availability along upwelling reaches and an order of magnitude greater concentrations of nitrate and soluble reactive phosphorus in these areas compared to losing reaches. Hyporheic flow enhances tree growth and leaf quality, thereby influencing soil and aquatic food webs of alluvial floodplains. From Harner MJ and Stanford JA (2003) Differences in cottonwood growth between a losing and a gaining reach of an alluvial floodplain. *Ecology* 84: 1453–1458.

disturbance. Meandering rivers may migrate back and forth across river valleys through time through the process of cutbank erosion and point bar extension. As point bars are often bare and seasonally inundated, these areas serve as sites where pioneer plant species may colonize. The presence of plant stems facilitates accelerated rates of sediment deposition and bar extension. As channels migrate and bars aggrade, arcuate bands of even aged vegetation may form in a successional sequence away from the channel as former bars aggrade to become floodplains—far from and at higher elevations above bars in the active channel.

The formation, maintenance, abandonment and destruction of channels and floodplains resulting from deposition and scour, result in floodplains, braidplains, and fluvial features that may be expressed on the surface as meander scrolls, chutes, oxbow lakes, abandoned floodplains as well as various subsurface stratigraphic features that are ecologically important. Deposits reflect past fluvial processes and may result in layering or lenses of sediment which influence the movement of groundwater, capillary rise, aeration and anoxia, soil chemistry, and the availability of moisture and nutrients to plants. Former low energy, slackwater areas such as those upstream from beaver dams or other obstructions to flow, backwaters and oxbow lakes resulting from the meandering process and abandonment of former channels, and overbank flood deposits may result in lenses or veneers (of various depths and volumes) of fine sediment with high water holding capacity. When buried by subsequent deposits, stratigraphic series are formed, imparting a diverse three-dimensional subsurface microhabitat into which plants may root and vegetation and habitat mosaics form.

River hydrology is influenced by a combination of surface and groundwater interactions. Seasonal and interannual patterns of hydrology along rivers are driven by the sources of moisture driving flow and flow regime. Sources of moisture include snowmelt, convective, frontal or monsoon rainstorms, groundwater discharge and any combination of these as influenced by localized and upstream climate and topography. The major streamflow components that are essential to riparian ecosystem functioning include low flows or base flows, intermediate and extreme peak flows, spates and small flow pulses, rates of change, number of peaks, and interannual variability in these components. Variations in climate, geology and landscape patterns result in regionally distinct natural flow (McManamay and DeRolph, 2019; Poff et al., 1997) and sediment regimes (Wohl et al., 2015) resulting in characteristically-timed flow components, rates of change, annual averages and extremes in streamflow and sediment entrainment, transport and deposition. Sediment regime is also key and is driven by geology, vegetation cover of uplands, and driving variables (such as overland flow) that connect uplands to valley bottoms and riparian and aquatic systems. Classifications of flow regimes of rivers highlights the regional heterogeneity that contributes to beta diversity of channel forms and processes, disturbance regimes, and aquatic and riparian ecosystems across continents (Mcmanamay and DeRolph, 2019).

Three of the most important functions of riparian forests and floodplain vegetation include: (1) supporting high species diversity through providing complex and productive micro and macro habitats, (2) influencing fluvial processes through providing substrate stability (roots), serving as roughness elements (stems, canopy, large wood) which affect fluvial processes and sedimentation in riverscapes, and (3) influencing primary productivity, biogeochemical processes, nutrient and carbon dynamics on floodplains and in aquatic habitat.

Biological attributes of riparian ecosystems

The tremendous variety of species utilizing and dependent upon riparian areas among rivers worldwide include combinations of upland, transient (annual, opportunistic, and colonizing/pioneer species) along with uniquely riparian, wetland and upland species. Species unique to riparian areas include those possessing adaptations enabling them to tolerate transient periods of flooding, drought and fluvial disturbance (Merritt et al., 2010). Water availability is generally higher in riparian zones, but it fluctuates seasonally as a function of surface flow, local and basin-wide weather patterns and groundwater regimes. The selective pressures associated with life in riparian areas have resulted in plants, insects, and animals with unique sets of physical and physiological adaptations (Lytle and Poff, 2004). The seasonal variability in hydrologically dynamic riparian systems can result in anoxia and drought along river margins over the course of a season, requiring sessile organisms such as plants to either tolerate such diverse stresses, develop adaptations (through natural selection) to survive them, or to avoid them all together (Grime, 1979). These suites of adaptations reoccur in riparian habitats worldwide, generating characteristic vegetation with similar physiognomies on depositional sandbars, in side channels and floodplain depressions, and in transitional areas near the riparian-upland transition (Lytle and Poff, 2004; Merritt et al., 2010) (Fig. 1).

Functional groupings (also known as guilds) of riparian species provide insight into the selective pressures associated with life in riverine habitats, often resulting through convergent evolution in unrelated species with similar sets of physical and physiological traits in different regions and continents (Merritt et al., 2010). Such traits may include the synchrony of phenology (e.g., timing of emergence, flowering, dispersing seeds) with components of the flow regime (Mahoney and Rood, 1998), the ability to tolerate fluvial disturbance (resprout ability/vegetative reproduction, adventitious rooting following burial, furrowed bark to resist abrasion) (Karrenberg et al., 2002), and the ability to disperse propagules along waterways (hydrochory) to enhance both dispersal distance and delivery of propagules to suitable habitats (Nilsson et al., 2010) and other riverine-specific adaptations.

Whereas ecologists have noted a trade-off between productivity and species diversity in terrestrial plant communities, riparian areas often exhibit both high diversity and high productivity due to a variety of interrelated factors associated with water availability, fluvial disturbance and rapid rates of decomposition and nutrient cycling (Araujo Calçada et al., 2015). Vegetation, habitat, species distributions and diversity vary in predictable ways longitudinally along a river's course and laterally from channel to uplands, as will be discussed below. Some fundamentals of these relationships will be discussed with examples from different riparian ecosystems from around the world.

Longitudinal connectivity and patterns of riparian diversity

There is no universal pattern of change in riparian biodiversity along longitudinal gradients traversing headwaters to terminus along river corridors. Some studies have shown that plant diversity peaks in intermediate reaches of large boreal rivers draining from the Scandic Mountains to the Baltic coast in Sweden (Nilsson et al., 1994). This pattern is attributed to the accumulation of propagules as a function of downstream distance (and the coalescence of water-transported seeds from tributary inflows to the mainstem) and to habitat heterogeneity that provides a combined boost in concentrations of microhabitats and potential species richness (Jansson et al., 2000). Higher plant species biodiversity in middle reaches of rivers flowing into the Baltic Sea in Sweden was shown to result from complex microhabitats associated with the transition from formerly glaciated landscapes to those that had once been submerged by a previously higher sea-level that resulted in deposited beach sediments and paraglacial substrates (Renofalt et al., 2005). Transition zones tend to have higher diversity due to the high concentration of habitats (habitat heterogeneity) in these areas (Tockner and Ward, 1999). In China, riparian plant species richness was shown to increase in a downstream direction along the Beijiang River (Zhao et al., 2018), whereas the San Pedro River in Arizona, United States exhibited highest richness at intermediately disturbed sites (Lite et al., 2005). In other river systems, diversity may be highest in headwaters or at the terminus and diversity can be elevated at tributary junctions (Osawa et al., 2010) and areas with shallow or upwelling groundwater (Fig. 4) (Jansson et al., 2007).

The lack of a globally consistent pattern of diversity varying along longitudinal gradients within river basins is in part due to the importance of local (reach and segment-scale) controls on species richness and to the variety of climates and geologies that river systems traverse (Kuglerova et al., 2015). Diversity throughout a river network is fundamentally limited by the regional species pool and a function of the magnitude, frequency and duration of disturbances (intermediate levels of disturbance have been associated with high species richness across taxa), the distributions of resources (water and nutrients), and the heterogeneity of habitats. Insect, bird and mammal diversity has been shown to track habitat heterogeneity, which stems from diversity of form and function of riparian vegetation. As a consequence, longitudinal patterns of diversity of insects and animals along riparian corridors are concordant with species and structural diversity patterns of riparian vegetation. Riparian trees serve as an important link between subsurface and surface hydrology and nutrient dynamics on floodplains, "affecting multiple trophic levels across aquatic and terrestrial food webs" (Tibbets and Molles, 2005).

Riparian areas have been shown to be relatively invasible by non-native species, and non-native species play a significant role in riparian plant communities from tropical to temperate zones. Among the factors identified to explain invasibility of plant communities include richness of incoming propagules (species pool), the presence of recruitment sites, and sites in which "harsh" environmental stressors are uncommon (Zefferman et al., 2015). Harsh habitats include sites with one or more abiotic stressors, including low levels of limiting resources, temperature extremes, and mechanical disturbance. For plants, limiting resources include nitrogen, phosphorous, oxygen and water and other factors that can contribute to harsh habitats include the presence of toxins in the soil. Indeed, the frequency of invasive plant species tends to be lower at colder temperature extremes such as high elevations and latitudes for plant communities (Zefferman et al., 2015). Mechanical disturbances that remove biomass and cause mortality may also be considered a stressor for individuals occupying such sites, but the bare, moist, sunny sites that are created from such disturbances along rivers serve as important areas for colonization by native and non-native species alike. Because disturbance and propagule delivery increase as a function of downstream distance, higher order streams are generally more susceptible to invasion than smaller, higher elevation streams.

In many parts of the world, rivers and riparian zones have been shown to be corridors of plant invasion. Examples of invasives that have become dominant in areas once introduced include northern hemisphere *Salix* spp. in Australia, Eurasian *Tamarix* spp. in western North America, south-eastern Australian *Acacia mearnsii* in South Africa, Himalayan *Impatiens glandulifera* in Europe, and Mexican-Central American *Leucaena leucocephala* throughout Indonesia. Invasive mammals in riparian areas may also have significant impacts on rivers and their riparian ecosystems. For example, nutria (*Myopotamus coypus*) introduced from South America into the southeast United States, North American beaver (*Castor canadensis*) introduced to southern Chile, and North American mink (*Neogale vison*) in northern Europe have had impacts on river channels and habitats and compete with native species for resources and space. Many successful non-native colonists are pre-adapted to the conditions along river margins where they are introduced, whereas others tend to succeed (or become dominant) in response to alteration of natural processes that support native

riparian vegetation (e.g., human development, flow alteration, climate change) (Merritt and Poff, 2010). In some cases, invasive species influence biodiversity through becoming dominant (even forming monocultures), whereas in other areas they may enhance local diversity by coexisting with native species.

Because riparian corridors traverse an elevational gradient and many larger rivers cross multiple ecoregions (climates and geologies), riparian areas contribute to regional and continental-scale beta diversity. In the Pacific Northwest of the United States, nearly two thirds of all plant species within one catchment were found in the riparian corridor, which occupies less than 10% of the catchment area (Naiman et al., 2005). According to other reports, all seasonally flooded floodplain forests in the Amazon basin may harbor about 53% of the 6727 estimated Amazonian tree species (Luize et al., 2018), and about 30% of the 1400 vascular plant species in the flora of France occurs along the Adour River riparian corridor in France (Décamps et al., 1995). It has been suggested that riparian zones increase regional diversity 50% or more by harboring distinct and unique species assemblages, rather than simply adding more species, when compared with surrounding uplands (Sabo et al., 2005).

Riparian areas also serve as important corridors, stopover sites and breeding areas for migratory species. Tropical birds travel hundreds of kilometers to breed in temperate riparian zones. Many species of birds migrate from tropical Africa across the Sahara to riparian areas in Europe to nest. Hundreds of species of neotropical birds from Central and South America migrate north to North America to forage and breed during summer months. One south to north trending river, the San Pedro, is among the most bird-diverse rivers in North America serving as a migratory, foraging, and nesting sites for over 400 species of birds (more than 45% of the total number of birds in North America) over the course of a season. Nearly 400 species of birds migrate along the East Asian Flyway to utilize temperate and arctic riparian areas as stopover and nesting sites. In addition to the habitat structure provided by riparian forests, the adjacency to open water and the diversity of food resources make riparian areas important stopover and nesting sites for birds. Recently, the exceptional nutritional value of emergent aquatic arthropods (rich in omega-3 fatty acids) has been recognized for its role in avian nutrition, nourishing birds during migration and enhancing breeding success (Twining et al., 2016).

High diversity in riparian areas stems from the dynamic fluvial environment that may result in mosaics of habitat, gradients of disturbance and resource availability, the presence of multiple age classes of vegetation and a variety of landforms across valley bottoms, provisions and habitat that attracts resident and migratory fauna, and the cycles of disturbance and recovery in river bottomlands (Fig. 1).

Lateral connectivity and patterns of riparian diversity

Another characteristic of riparian areas is distinct zonation of species and growth forms occurring in bands radiating out from aquatic to terrestrial areas. Transverse (cross valley) patterns of plant zonation are a common feature of riparian vegetation. Depending on climate and surrounding uplands, hydrophytic (water-loving, anoxia tolerant) and disturbance-tolerant vegetation typically occupy the zone nearest the channel, sub-shrubs and shrubs occur at intermediate distances, shrubs and trees at further distances and upland vegetation at the furthest extremes from the channel (Fig. 5). The process of meandering may also result in zonation of vegetation that corresponds to successive stages of riparian colonizers of bars, as they age and facilitate aggradation, floodplain formation and abandonment.

Distance away from and elevation above river channels are associated with a number of interrelated abiotic processes that may account for variation in vegetation. Vegetation zonation may be striking because of observable differences in plant physiognomy (height, leaf size, color, morphology, etc.), life-stage or age-class patterns. Species-specific flooding requirements explain patterns of zonation in vegetation along river margins. Moving from a river channel to upland generally reflects a moist-to-xeric gradient in soils, with decreasing anoxia and increasing depth to groundwater, decreasing intensity, frequency and duration of flooding and flow-related mechanical disturbance, with decreasing ice and debris scour and wave action, changes in nutrient and light availability, humidity, accumulation of litter, organic material and plant propagules, and with fining of substrate grain size from high to low energy fluvial habitats. Interspecific competition is more intense and facilitation less common as a function of distance from and elevation above a river channel towards the uplands. These biotic processes have been proposed as a major influence contributing to vegetation zonation and the associated lateral pattern of habitat variation along rivers.

Along active channels that have periodically disturbed sites, certain plant species have adaptations to disperse widely and colonize bare, moist, recently disturbed habitats. Many of these disturbance-adapted species release seeds in synchrony with the descending limb of the hydrograph so that the availability of sites suitable for germination and recruitment is maximized (Mahoney and Rood, 1998). The reproductive phenology of pioneer riparian tree species relative to the timing of seasonal floods around the world, root morphologies for water acquisition, and sexual versus vegetative reproductive strategies provide some examples of trait convergence relative to flow attributes/components. Riparian poplars (*Populus* spp.) and riparian willow species (*Salix* spp.) in western North America and river red gum (*Eucalyptus camaldulensis*) and swamp paperbark (*Melaleuca rhaphiophylla*) in Australia have phenological adaptations and release short-lived seeds for a short period of time in synchrony with the recession of floods and the availability of new sites to colonize. The capacity to produce roots that exploit the phreatic zone (aerated soils above the water table) exemplifies the convergence of root morphologic traits in phreatophytes in the northern (many species of Salicaceae and the mesquites *Prosopis* spp.) and southern hemispheres (e.g., *Eucalyptus sideroxylon*). Another example of trait convergence due to similar selective pressures across rivers of the world is selection for rapid life cycle and annual growth form in plants associated with areas experiencing frequent, channel forming fluvial disturbances. Sandbar and other sites with frequent turnover of substrates have distinctive colonizers and similar growth forms and habits worldwide (e.g., low drag, prostrate or flexible stems, water-dispersed seeds, short life cycle). These areas are often colonized by opportunistic annuals and species with rapid life cycles, and are thus often

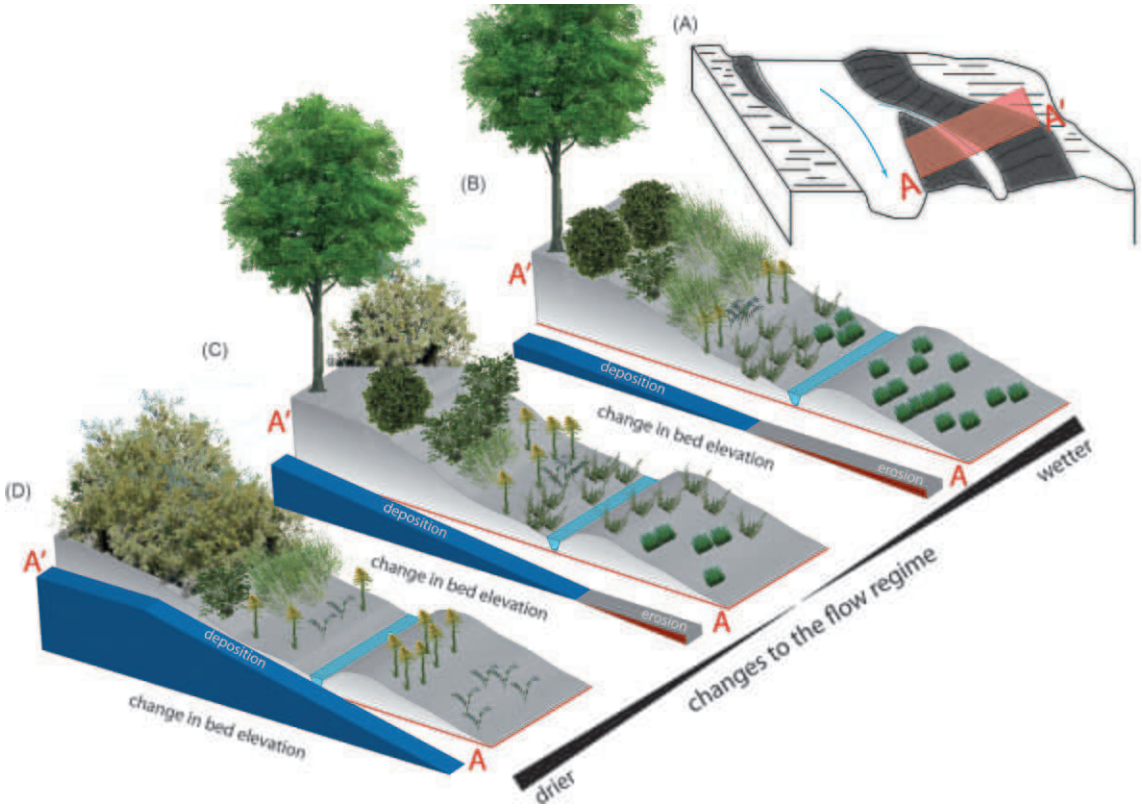

Fig. 5 For ecological plant guilds that respond to water availability and fluvial disturbance gradients, analyses indicate that the distribution of morphological traits—and therefore the plot-scale biotically controlled topographic response—can be predicted on the basis of these abiotic gradients. For a hypothetical section (A), where a steep gradient in water availability (high to low, A to A′) exists, ecological plant guilds trend from hydric to mesic to xeric (C). The flexural rigidity of the ecological guilds increases from A to A′. Observations from three flood events showed that deposition increased with increasing stem flexural rigidity. With a shift in flow attributes, the distribution of ecological guilds, morphological plant traits, and the topographic response change; (B) changes that may result from a drier flow regime and (D) changes that may result from a wetter flow regime. In (B)–(D), changes in bed elevation are indicative of an increased likelihood of either aggradation (plant-induced sediment deposition) or degradation (plant-induced sediment erosion). From Diehl RM, Merritt DM, Wilcox AC, and Scott ML (2017) Applying functional traits to ecogeomorphic processes in riparian ecosystems. *BioScience* 67: 729–743.

sites where non-native, generalist species may become established. In contrast, vegetative and perennial reproductive strategies are commonly found along relatively stable channels with less seasonal flow variability.

Species adapted to specific hydrograph attributes are particularly vulnerable to changes in streamflow regime. Flow alteration may decouple certain life stages (e.g., flowering, seed dispersal, colonization, growth) through de-synchronizing flow events from life histories that have evolved to them. In the tropical floodplain rivers around the world, fish and floodplain vegetation have coadapted a mutualistic relationship to seasonal flooding and floodplain inundation. Approximately 182 species belonging to 32 families of freshwater fishes consume and disperse the fruits and seeds of over 600 neotropical plant species in tropical floodplain rivers worldwide (Correa et al., 2007). In many floodplain rivers, fruiting phenology of tree species is synchronized with the annual flood cycle, fish swimming onto the floodplain when inundated and eating fruit and seeds fallen on the floodplain (Kubitzki and Ziburski, 1994). Over fishing in tropical rivers may lead to functional extinctions of frugivorous fish mutualists and cascade to extinctions of plants, resulting in ecosystem-level change in floodplain forests (Araujo et al., 2021). Other plants disperse seed in synchrony with hydrograph components to enhance water dispersal (hydrochory) and deposition along river margins (Nilsson et al., 2010). Conceptual models have been developed that can inform flow managers to accommodate key life history traits, such as seed deposition in suitable sites on receding waterlines along river margins, that may rely upon historic patterns of seasonal hydrographs. One such model that has been used to design hydrographs downstream from dams is the "recruitment box model" (Mahoney and Rood, 1998), which integrates suitable recruitment sites with river stage (level) decline to identify streamflow regimes that enhance the likelihood of survival. It is well understood that flows that may benefit one species, may be harmful to others, highlighting the role of interannual variability in accommodating a wide range of species over time, enhancing "temporal diversity" of riparian floodplains (Tonkin et al., 2021). The ability of highly specialized riparian species to adapt to changes in flow and sediment regimes in rivers resulting from slow-paced climate change will vary by species, their phenotypic plasticity, range of variation in populations, and other genetic factors.

Threats to riparian ecosystems

Riparian areas are subjected to all of the natural stressors that other ecosystems are faced with including wildfire, grazing and herbivory, animal activities, pathogens, insect herbivores and parasites, introductions of non-native species, and changes in weather conditions. Further, long-term changes imposed by climate change, such as shifts in the timing and volume of runoff, groundwater patterns, air and soil temperature, and the concentration of atmospheric carbon, also influence riparian ecosystems and their inhabitants. Though rivers and riparian ecosystems may adjust slowly to changes imposed by changing climate through gradual directional shifts in species distributions and adjustments of channel form, direct human effects on rivers are global in scale and may be extensive, severe and abrupt.

Threats to the functioning, diversity and characteristics of riparian areas include several direct human-caused stressors, the most pervasive one being water development: water diversion, dam construction and water storage, and surface and groundwater pumping. Dams fragment formerly connected rivers longitudinally as well as altering the flow and sediment regime, indirectly affecting lateral connectivity (Nilsson et al., 2005). The effects of dams on flow, sediment, carbon and propagule regimes can extend downstream for hundreds of kilometers and result in changes in channel morphology, floodplain formation and connectivity, and interrupting the life history requirements of riparian species adapted to natural flow regimes.

Worldwide, there are currently more than 45,000 dams above 15 m high, mostly in the northern hemisphere, capable of collectively storing greater than 6500 km^3 of water—about 15% of the total annual river runoff globally (Nilsson et al., 2005). Today, only 37% of rivers longer than 1000 km remain free-flowing along their entire length and only 23% of rivers draining to the sea remain uninterrupted to the ocean (Grill et al., 2019). In addition to the known effects that storing water and sediment behind impoundments has in altering downstream timing and volume of water and sediment delivery, dams affect geomorphic and biological processes which have direct effects on the functioning, physiognomy and species composition of riparian ecosystems. Changes in streamflow can decouple important life cycle stages of flow-adapted species from suitably timed flow attributes. In dam-regulated systems, small changes in the management of daily and seasonal flow release operations can result in recoupling of important life stages and flow regime, restoring key elements of riparian ecosystems that were compromised by dam operations (Rood et al., 2003).

Water storage reservoirs also submerge riparian zones and floodplain inhabitants upstream from impoundments, completely eliminating them from such systems. For example, the World's largest hydroelectric dam (Three Gorges) was recently constructed in China and displaced 10 million human inhabitants of the floodplain along with extensive riparian and floodplain habitats and the arthropods, birds, amphibians, reptiles and other mammals that once occupied these now-submerged riparian habitats. The shift from formerly lotic systems to lentic ones upstream from dams, often with sterile shorelines (or "bathtub rings") most often results in reduced biological diversity. Dams fragment rivers affecting riparian vegetation and associated riparian arthropods and animals through fragmenting the downstream dispersal of seeds and propagules and altering sediment, nutrient, organic material and water movement through watersheds.

Other stressors to riparian areas include those that directly affect soils and vegetation within the floodplain, channel and corresponding riparian zones, such as livestock, native ungulate and insect grazing, forestry and fuels reduction, fire, human encroachment (development, roads, levees, channelization, draining floodplain soils, agriculture, harvesting), in-channel mining operations for precious metals, gravels and aggregates, and fossil fuels, dredging and management of channel form for timber floating and transportation routes, large wood removal and the effects of off-channel land, vegetation, water management and development within watersheds. Most large European rivers have been disconnected from their floodplains, straightened, and simplified from their natural form. Most rivers are constrained to a narrowed floodplain between rigid dikes, with former floodplains landward of the dikes converted to agricultural land. This has resulted in floodplain forests being designated one of the most endangered ecosystems in Europe.

Though new dam construction has become less frequent in many developed countries of the world, dam construction remains high in developing countries such as China, India, and countries throughout Africa and South America. Developed countries of the world are currently in a renaissance of advancing the science of river management and river and riparian restoration having been through eras of extensive dam building and river channelization in the past and better appreciating the negative ecological effects of such development on rivers and their floodplains and riparian forests.

Conservation of rivers and riparian areas

Recognition of the widespread negative effects human development has had on riparian ecosystems worldwide over the past few centuries, and the continued threats to them has led to policy and legislation to protect remaining free-flowing rivers and functioning riparian ecosystems, and to better manage and to restore rivers and their riparian ecosystems in developed and developing countries. Legislative protections for rivers include the Wild and Scenic River system (Wild and Scenic Rivers Act 1968) and protections under the Clean Water Act (1972) in the United States, the inclusion of inherent rights of rivers to flow incorporated into the constitution of South Africa, the European Union Water Framework Directive to manage freshwater resources, and case-by-case protections funded from local or international sources often to protect sensitive species or biological diversity.

A small percentage of the linear distance of the World's rivers falls under protection on most continents. In the United States, only 0.25% (20,453 km) of rivers (and 0.4 km on either side of the river) are designated Wild and Scenic and some of them lie along dam-regulated river reaches. In Europe, the Water Directive Framework provides non-binding recommendations for protection of rivers and riparian areas, but there is no equivalent of Wild and Scenic Rivers protection throughout Europe, though individual countries including Slovenia, Finland, Sweden, and Spain have legal protection for rivers and their riparian areas that specifically aim at protecting their free-flowing character (Schäfer, 2019). One of the longest rivers in South America, the Orinoco River, supports vast riparian forests and charismatic species such as parrots, giant anaconda, crocodiles and river dolphins and is under heavy threat of human development. In such cases where there is no federal protection, global non-profit groups such as World Wildlife Fund may support local efforts to raise community awareness and protect such systems.

Riparian restoration efforts range from small, reach-scale efforts to larger, watershed and segment-scale efforts including pollution remediation, environmental flow management, riparian and floodplain rehabilitation, protected buffers—widths of riparian vegetation, targeted fish recovery and the removal of dams, diversion structures, culverts and other barriers to passage (Bernhardt et al., 2007). Riparian restoration can broadly be classified as active or passive, and most projects include a combination of approaches (Wohl et al., 2005). Active restoration methods include de-channelizing stream channels, recontouring channels and floodplains, mechanical soil disturbance and active planting of riparian vegetation, removing levees and laying banks back to allow for stream-floodplain interaction, deconstruction of development within active floodplains, removal or reduction in invasive species and reintroducing desired plant species.

Passive restoration approaches include changes to land and water use in a basin that may result in restored water, sediment and carbon regimes. A rapidly developing form of passive restoration is managed restoration of streamflow components that restore some defined geomorphic and ecological purpose downstream from dams. "Environmental flow" management has gained popularity and sophistication in the past couple of decades and has resulted in the restoration of native riparian vegetation and floodplain forests, in many cases without compromising water storage, power generating capacity and other intended utilities of dam operations (Tonkin et al., 2021). Guidelines for determining environmental flow needs range from those targeting single organisms such as riparian poplars (*Populus* spp.) (Lytle and Merritt, 2004; Rood et al., 2005) to multi-taxonomic approaches (Shafroth et al., 2010; Tonkin et al., 2018) and from the reach to segment and watershed scales (Poff et al., 2010; Webb et al., 2015).

Restoring streamflow components downstream from dams can be very effective for reestablishing desired processes in dam-impacted riparian ecosystems and re-synchronizing tightly coupled biotic and streamflow interactions. However, dams inhibit the passage of mineral sediment, and carbon (including leaves, wood and propagules), so restoring many processes cannot be accomplished through environmental flow prescription alone. In the rare situation in which there is a natural source of significant sediment inputs downstream from a dam, timing prescribed flows to coincide with sediment inputs such tributaries can be effective at restoring sediment deposits such as bars and river margin beaches (Melis, 2011), which serve as sites for vegetation colonization and establishment.

A combined form of passive and active restoration involves implementing environmental flows after conducting active restoration to floodplains to restore pre-development channel forms. Another hybrid approach to riparian restoration that is gaining popularity primarily in the United States, Europe and Australia is dam removal. Dam removal requires decommissioning and deconstructing dams, recontouring of river channels and possible eradication of invasive species and reintroduction of desirable ones, resulting in a restoration of natural flow, sediment and carbon regimes. Over 2300 dams have been removed in the United States since 2016. Over the past 20–25 years, at least 5000 small dams, weirs and culverts have been removed from rivers in France, Sweden, Finland, Spain and the United Kingdom.

As most of the world's major rivers have been affected in some way by direct and often deliberate human activities and by indirect and unintended factors (such as climate change and invasive species introductions), there are great opportunities to recognize the value of and to protect those last remaining free-flowing rivers on earth. The communities, floodplain forests and meadows, complex fluvial settings and mosaic of micro-habitats along free-flowing rivers represent a natural heritage that can be used to set goals for restoration of impacted streams. Free-flowing rivers can serve as sentinel rivers, natural laboratories where an understanding of the complex interactions between flow and the evolutionary history of the biota of sites can be better understood and applied to river management elsewhere.

Opportunities for future research in riparian and riverine ecology

The field of riparian ecology has advanced rapidly in the past several decades. Early advances include an expanded view from river reaches existing in isolation to an understanding of the river as a continuum of energy, carbon, and discharge cascading along the river network (Vannote et al., 1980). In the 1990s, the four dimensional nature of river systems, lateral floodplain connectivity and the ecological importance of the dynamic nature of riverine ecosystems emerged with concepts such as the three-dimensional nature of riverine connectivity (Gregory et al., 1991), the flood pulse (Junk et al., 1989), and the natural flow regime paradigm (Poff et al. 1997). These concepts distinguished rivers from other freshwater systems and provided a foundation in the importance of process and connectivity in the functioning of riverine ecosystems.

River and floodplain connectivity includes surface-water interactions with hyporheic zone (connected groundwater systems) (Stanford and Ward, 1993), the exchange of nutrients, water, and materials between aquatic and riparian systems (Baruch et al., 2021), and the movement of organisms (including non-native species) along dendritic networks of stream channels. In recent

decades, the role of floodplain inundation for soil microbial processes, decomposition, mycorrhizae and nutrient dynamics has been recognized (Beauchamp et al., 2006; Molles et al., 1998). The importance of reciprocal relations between sediment, vegetation and floodplain processes has been recognized (Corenblit et al., 2007; Merritt, 2020) and deterministic models developed to better predict the consequences of varying water and sediment regimes to channel evolution and form (Diehl et al., 2018). Intellectual developments such as the probabilistic river concept (Graf, 1984) and the concept of the normative river (Stanford, 1997) have also contributed to an advanced understanding of river function and process and our approaches to restoration, decision-making, modeling and management.

Despite this progress, a recent meta-analysis of the scientific trajectory of riparian vegetation studies (Dufour, S et al., 2019) revealed a lack of a well-identified scientific community in the peer reviewed published literature that focuses on riparian ecology, specifically on riparian vegetation. The authors suggest that by its very nature, riparian ecology is a diverse, interdisciplinary science that includes varied fields of knowledge. Indeed, the study of any riparian ecosystem requires an understanding of geology, groundwater-surface water hydrology, geochemistry, hydraulics, sediment mechanics, fluvial geomorphology, and the range of disciplines involved in understanding the biology of the system from microbial to evolutionary. Further, the reciprocal relations between vegetation, wildlife (e.g., beavers, hippopotamus, Crocodilia (alligators, caiman and crocodiles), fish, etc.) and channel form and process must also be considered. Climate change and non-stationarity must also be at the forefront when interpreting process-pattern relations, establishing realistic reference conditions, and transferring understanding of one system to the next in riparian studies.

Though many challenges remain in our understanding of riverine systems and the interdependency between riparian and aquatic ecosystems, advances in remote sensing, geographic information systems (GIS) technology, and light detection and ranging (LIDAR), laser surveying instruments, and structure from motion have rapidly advanced mapping of valley bottoms, floodplains, fluvial features, and riparian areas worldwide. Satellite imagery and thermal sensors, aerial and ground-based LIDAR technology, small aircraft and unmanned aerial vehicles (or drones), and advances in other remote sensing tools have enhanced the mapping and characterizing of riparian ecosystems, aquatic habitat, and vegetation patterns.

The application the stable isotopes of nitrogen, hydrogen, carbon and other elements has now been widely used to determine the sources of water utilized by riparian plants over time (Busch et al., 1992; Schook et al., 2020) and to determine how carbon cascades from organism to organism throughout riparian and aquatic ecosystems (Baruch et al., 2021). One such study found that the carbon from riparian trees comprised about 25% of the carbon in large predatory fish through the transfer from allochthonous inputs from leaf fall, into aquatic invertebrates and ultimately into the biomass of fish (Baruch et al., 2021). Other isotope studies have identified higher growth rates of riparian trees due to the influence of marine-derived nitrogen fertilization by grizzly bears (*Ursus arctos horribilis*) that consume anadromous salmon (*Oncorhynchus* spp.) which have migrated hundreds of miles from the sea to spawn in inland streams (Naiman et al., 2000).

New and emerging modeling techniques and tools will enable us to better understand cause and effect in riparian ecosystems, make better, science-based management decisions, and to forestall extinctions and further losses of some of the most biologically diverse and functionally rich terrestrial ecosystems on earth.

Conclusions

Riparian zones stand out as striking ribbons of green traversing arid landscapes and serve as more subtle centers of diversity and productivity through temperate, humid and more lushly forested upland systems. Public appreciation of rivers, and policies and laws that inform management, sustainability and protection of them has never been more important than it is now. Climate change and human population growth are exerting increasing pressure on freshwater resources and leaving systems vulnerable to unprecedented extremes in hydrologic events (droughts and flooding). With most of the world's rivers impaired to some degree directly or indirectly by humans, and an onslaught of new development proposals such as micro-hydropower, pump storage facilities, and water diversion on lower order streams and massive mainstem dams on some of the largest river systems in the world, diversity of the world's riparian areas could see a continued decline in coming decades.

Preservation of extant free-flowing rivers requires deliberate action. Science-informed management of rivers, an engaged and energetic public and politicians, and a social river ethic aimed at preserving water in streams is necessary to protect these diverse ecosystems. Myriad organisms rely on rivers to complete their life cycles and maintain their existence at local, regional, and intercontinental scales. Managing rivers with a recognition of the importance of key components of historic seasonal flow regimes as well as historic sediment, carbon and nutrient regimes is key to supporting dynamic floodplain processes, riparian mosaics, structurally and compositionally complex floodplain forests, groundwater systems and the diverse interdependent systems that they support.

Knowledge gaps

- Deterministic models that predict geomorphic change in rivers in response to changes in water and sediment regimes would facilitate more reliable models of riparian vegetation change. Integrated models that incorporate the reciprocal relations between vegetation and river channel change would further refine our predictive abilities.

- How the distribution of the range of riparian ecosystem forms and functions will change as a function of direct and indirect effects of changing climate patterns. For example, direct effects include changing atmospheric temperature, CO_2 levels and cascading changes to the hydrologic cycle. Indirect effects of global change include landscape-scale changes in upland vegetation composition and cover, rates of decomposition and biochemical processes, rates of chemical and physical weathering, extreme events (e.g., temperature and precipitation), landscape sediment yield, and shifts in the state (frozen or liquid) and temporal delivery of water and its effects on surface and groundwater patterns.
- The role of water storage reservoirs and regulated flow releases as a tool that could be strategically used for mitigating (and providing resilience to) the effects of climate change on river and riparian ecosystems.
- The role of rivers and riparian zones in resistance and resilience to climate change relative to upland ecosystems. The role of riparian ecosystems to serve as corridors (providing thermal refugia) facilitating the range shifts of organisms in response to global change.
- The relationships between species diversity and trait functional diversity and the functioning and resilience of riparian ecosystems. The rate of evolutionary change in different taxonomic groups of riparian organisms relative to the rate of climate change.
- Methods for engaging the public and policy makers in understanding how important functioning and connected rivers and riparian areas are in providing ecosystem services and supporting biodiversity.
- The ability to coordinate complex social and legal systems with our understanding of the requirements of riparian ecosystems to balance climate change, continued human water development and uncertainty and prevent further degradation, loss of natural heritage and extinction of riparian species. Through dam management, conservation, water right transfers, and other creative means, developing techniques to most efficiently distribute water to human water users while ensuring biologically important flows in key stream reaches.

Flood Plains of Large Rivers☆

Stephen K Hamilton, W.K. Kellogg Biological Station, Michigan State University, Hickory Corners, MI, United States; Cary Institute of Ecosystem Studies, Millbrook, NY, United States

This is an update of S.K. Hamilton, Flood Plains, in *Encyclopedia of Inland Waters*, Elsevier Inc., Edited by: Gene E. Likens, 2009, https://doi.org/10.1016/B978-012370626-3.00052-1

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Abandoned floodplain A floodplain that has become isolated from the main river and is no longer subject to inundation by that river. Abandoned floodplains may still be flooded by water from local rainfall and stream inputs. They typically lie on fluvial terraces that are sufficiently elevated to be out of reach of flooding from the main river, although they often drain to the river via streams.
Active floodplain A floodplain that is subject to inundation by the main river at least occasionally and often every year.
Alluvial fill Sediment deposited by flowing water, generally over a long period of time. Floodplains tend to lie on alluvial fill.
Anastomosed channel A river reach where flow is divided into two or more interconnected channels with floodplain between the channels. Usually more stable that a braided channel.
Blocked-valley lake Lakes that have formed in tributary valleys now back-flooded by the main river, often resulting in a dendritic form. In the central Amazon floodplain, such valleys were carved out at lower relative river levels, possibly in the late Pleistocene when sea levels were lower, then have not filled in with sediment as the main river channel subsequently accumulated alluvial fill (Latrubesse, 2012). Their water levels are controlled by the main river but through-flow of sediment-laden river water is restricted by the lake morphology and/or inputs of local streams.
Braided channel A river reach with multiple interconnected channels separated by small islands. Usually characterized by dynamic geomorphology due to erosion and deposition.
Flood pulse Periodic inundation and drainage of floodplains, particularly along large rivers where inundation may last for weeks to months. The Flood Pulse Concept articulates the importance of the natural flood regime to the ecology of floodplains along large rivers.
Oxbow lake (Billabong) A U-shaped floodplain lake formed when a meander of a river channel is cut off from the main channel flow. Oxbow lakes may be connected to the river all year, usually only on one end, or can be completely isolated from the river except when intervening floodplain is inundated. In Australia the term "billabong" is commonly used.
Point bar An alluvial deposit that has accumulated on the inner side of curve in the river.
Run-of-river reservoir A reservoir in which dam operations do not result in large variation in water level and volume, such that river inflows are approximately equal to outflows except on short time scales.

Introduction

Floodplains are often defined as land that is seasonally or episodically inundated by overflow from river channels, and people in urbanized areas often think of floodplains in terms of potential flooding hazard to life and property. Farmers around the world recognize that floodplains can provide particularly fertile croplands or pastures. In contrast, ecologists view floodplains as a

☆*Change History*: October 2020. SK Hamilton. Revised text in general, plus addition of new sections as prescribed in the instructions. Title changed from that suggested in letter of invitation. References now cited throughout text. Replaced Figure 8. Revised text in response to the review by the Subject Editor, LeRoy Poff. Glossary and Further Reading section have been added.

distinctive, often highly productive wetland ecosystem that harbors unique combinations of biodiversity and contributes to ecosystem services by virtue of the hydrological connectivity with rivers. Floodplains can exist anywhere in a river network, but they are often particularly well developed—and have longer and more predictable periods of inundation—in the lower reaches of larger rivers (Scott et al., 2019). Larger rivers tend to flow across more level terrain, facilitating the accumulation of sediment deposits to form floodplains, and in many cases their valleys and deltas have filled with sediment in reaction to the global rise in sea level since the last glaciation (e.g., Day et al., 2008; Syvitski et al., 2009). This chapter focuses on floodplains associated with large rivers.

The aforementioned definition of floodplains belies their spatial complexity. Many floodplains along large rivers are mosaics of distinct wetland systems that include areas flooded by local precipitation and stream inflows, often in distinct locations or times compared to inundation by riverine overflow. Topographic variation across floodplains, even over scales of <1 m, produces a continuum of flood regimes, akin to the flow regime concept widely applied to stream and river research (Poff et al., 1997; Bunn and Arthington, 2002). The resultant spatial and temporal gradients in hydrological dynamics and water sources can strongly affect the structure and function of the floodplain ecosystems (e.g., Battaglia and Sharitz, 2006; Ferreira-Ferreira et al., 2015). Floodplains along larger rivers also commonly contain water bodies that are permanent or semipermanent, including floodplain lakes and channels, as well as shallow wetlands (sometimes called backswamps) in the lowest lying parts of the floodplain that may retain water all year (e.g., Sippel et al., 1992; Hamilton et al., 2007; Emmerton et al., 2007; Day et al., 2008).

The occurrence and patterns of seasonal or episodic inundation strongly affect the ecology of large river floodplains, including both the aquatic and terrestrial biota, and explains their high biodiversity (Junk et al., 1989; Lewis Jr. et al., 2000). The Flood Pulse Concept articulates the myriad ways in which inundation regimes of large river floodplains determine their ecological structure and function, and how the biota are adapted to cope with and often depend on long-lasting flood pulses common to the largest river systems.

Examples of floodplain environments

Remotely sensed images of contrasting types of flood-plain environments are depicted in Figs. 1–7. Images of four large South American floodplains (Amazon, Madre de Dios, Pantanal, and the Llanos de Moxos), as well as the Cooper Creek system in Australia (Figs. 1–5) depict the diversity of landforms, water bodies, and vegetation in large floodplains with minimal human disturbance. Examples where floodplain hydrology has been strongly altered are shown for the Kalamazoo River (Fig. 6) and the Mississippi River (Fig. 7). The ensuing discussion will refer to these images. In addition, photos of many of these sites appear in the online Floodplain Photo Gallery see (Supplementary Material in the online version at https://doi.org/10.1016/B978-0-12-819166-8.00091-8).

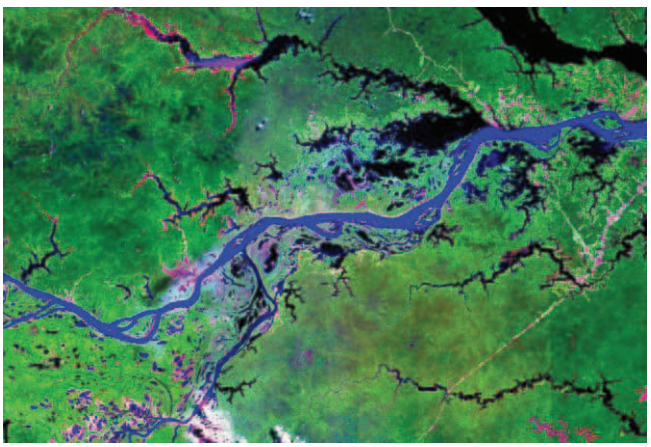

Fig. 1 Amazon River (locally known as the Rio Solimões in this reach) and its fringing floodplain up river of the city of Manaus and the confluence with the Negro River. This image covers land extending about 240 km in width. The Negro River is visible in the upper right. The main river channel contains high inorganic turbidity (blue) and clearer waters on the floodplain as well as in the Negro River are dark (due to lack of turbidity). The floodplain here shows diverse geomorphic features, including numerous lakes, most conspicuous of which are the dendritic blocked-valley lakes (defined in Glossary). Blocked-valley lakes along the main Amazon River normally maintain a hydrological connection with main river all year. Image coordinates are 61.20 W, 3.61 S. Image shows Landsat 7 ETM+ data (bands 7, 4, 2) from the Geocover 2000 data set, obtained from NASA World Wind version 1.3.

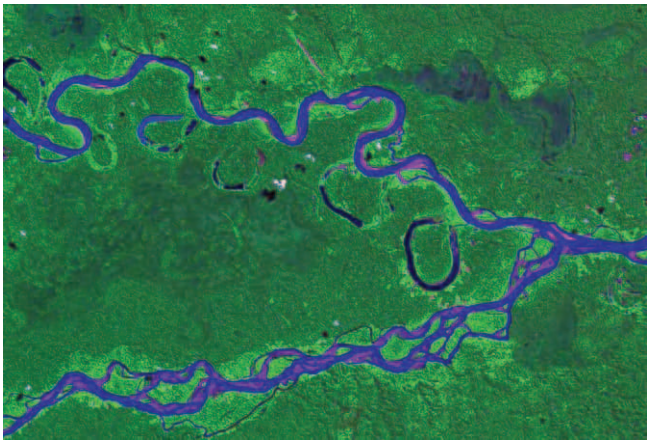

Fig. 2 Madre de Dios River (upper) and its tributary the Inambari River (lower) in the Peruvian Amazon basin. This image covers land extending about 29 km in width. The river channels contain high inorganic turbidity while some oxbows contain clearer water and hence appear darker. Lighter green areas are vegetation in early successional stages following fluvial disturbance. The floodplain along the Madre de Dios contains oxbow lakes in various stages of separation and infilling. Much of the Inambari floodplain occurs as islands and bars along the highly braided channel. Between the two rivers is an extensive interfluvial backswamp, and in the upper right the darker blue areas are palm swamps lying on fluvial terraces. Image coordinates are 69.83 W, 12.70 S. Image shows Landsat 7 ETM+ data (bands 7, 4, 2) from the Geocover 2000 data set, obtained from NASA World Wind version 1.3.

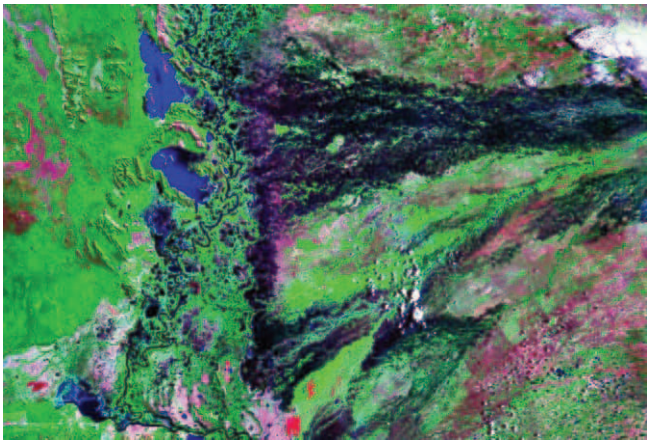

Fig. 3 Floodplains of the upper Paraguay River and tributaries in the central Pantanal (Brazil and Bolivia). This image covers land extending about 200 km in width. The floodplains here include the fringing floodplain of the sinuous Paraguay River (running from north to south), large turbid lakes with permanent connectivity to the river, and seasonally flooded savannas of the Taquari River alluvial fan, which covers the right side of the image. Lower lying areas of the fan are subject to backwater effects from the Paraguay River, making them appear dark in this image. Image coordinates are 57.14 W, 18.51 S. Image shows Landsat 7 ETM+ data (bands 7, 4, 2) from the Geocover 2000 data set, obtained from NASA World Wind version 1.3.

Geomorphological processes on floodplains

Much attention has been paid to the study of fluvial geomorphology, including the ways in which the action of moving water interacts with sediment deposition and erosion and vegetation to produce a variety of floodplain landforms (reviewed by Dunne and Aalto, 2013). Floodplains are built of alluvial fill that normally originates as sediments carried by the main river and deposited as point bars along the migrating channel, and/or during overbank flooding (Meade, 2007; Trimble, 2010). Hydrologists refer to bankfull discharge as the river discharge above which the floodplain becomes inundated (Leopold, 1994). In large river floodplains the concept of bankfull can be difficult to apply, however, because much water enters and exits the floodplain via low areas or discrete openings in the levees, as described later. Many rivers reach bankfull at least annually, but inundate their floodplains less frequently, whereas others inundate their floodplains every year, sometimes in multiple events.

River valleys commonly have one or more abandoned floodplains lying on elevated terraces that are normally above the present-day reach of riverine flooding. Such terraces may still contain wetlands and permanent water bodies that reflect their fluvial origin (e.g., Hamilton et al., 2007). Wetlands on such terraces may be sustained by groundwater and surface runoff emanating from adjacent uplands in addition to direct precipitation inputs. For example, terraces containing palm swamps that retain surface water all year are visible to the north of the Madre de Dios River just above its confluence with the Inambari River in Peru (Fig. 2).

Larger flood events can be particularly important in sculpting the surface geomorphology of floodplains. Fluvial deposits can be highly heterogeneous and subject to constant change in active floodplains along rivers with high sediment loads (Constantine et al., 2014), as for example, in the floodplains close to the Madre de Dios River and on islands in the Inambari River in Fig. 2. Fluvial landforms tend to become smoothed out over time, as may be reflected by increased distance from or, in the case of terraces, elevation above the main river. Erosion of elevated features and infilling of depressions contribute to the long-term homogenization of floodplain surfaces. Yet even in humid tropical climates, traces of the geomorphic features produced by fluvial action may remain visible for tens of thousands of years (e.g., Llanos de Moxos of Bolivia in Fig. 4).

Elevated strips of land known as levees often border the river channel and reflect the higher rates of sediment deposition where the river water first decreases in velocity as it exits the channel. Successively formed, concentric levees and swales may form meander scrolls. In some floodplains, these are created by the meandering of smaller channels within the floodplain rather than by the lateral migration of the main channel (Mertes, 2000).

Floodplains can be readily classified based on their hydrology and geomorphology, and several schemes have been proposed that apply to particular regions (e.g., Brinson, 1993; Junk et al., 2014). Floodplains can be broadly classified as fringing floodplains (i.e., found along the banks of rivers), coastal deltaic floodplains (formed where rivers meet lakes or the ocean), and internal deltaic floodplains (formed internally where a tributary meets a larger river and is subject to backwater effects). Some river channels, particularly those with braided morphology such as the Inambari River of Peru in Fig. 2, have much of their floodplain on

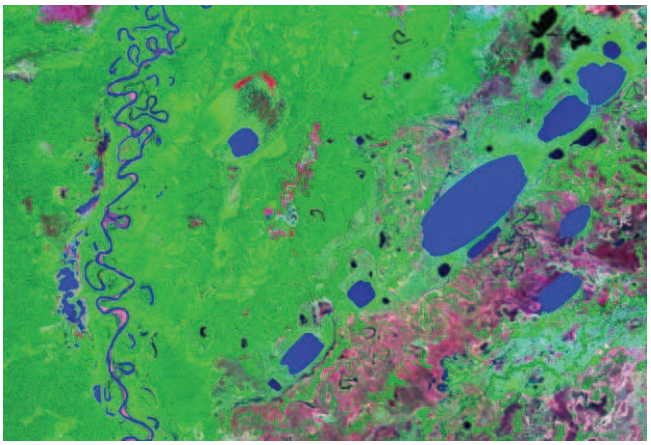

Fig. 4 Savanna floodplains of the Llanos de Moxos (also spelled Mojos) in the upper Amazon Basin in Bolivia. This image covers land extending about 108 km in width. The meandering Beni River with numerous oxbow lakes flows from south to north. The floodplain here reveals topographic features created by past fluvial activity. Superimposed on this landscape are strikingly regular depressions filled with shallow turbid water; these lakes have been attributed to subsidence patterns reflecting lineaments in the basement rock far below the alluvium. Image coordinates are 67.20 W, 13.99 S. Image shows Landsat 7 ETM+ data (bands 7, 4, 2) from the Geocover 2000 data set, obtained from NASA World Wind version 1.3.

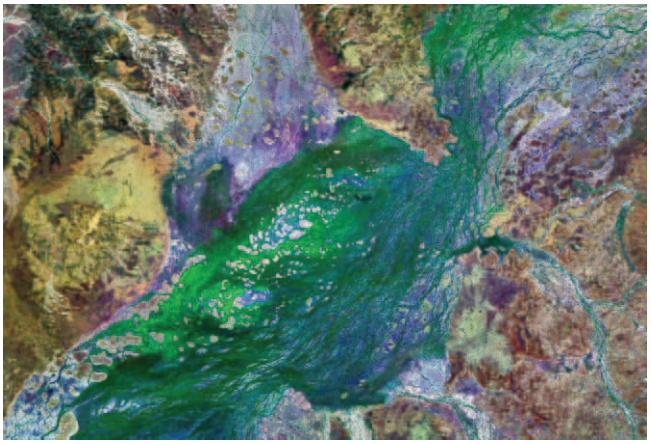

Fig. 5 Floodplains and river channels of Cooper Creek near Windorah (Queensland, Australia). This image covers land extending about 136 km in width. The floodplains were relatively vegetated lands in this image because they recently had been inundated, providing soil moisture for growth of herbaceous plant cover. Surrounding uplands are semiarid, sparsely vegetated shrublands and grasslands. The floodplain here receives river water through a complex system of anastomosed channels that are mostly dry in between the occasional flows. A few deeper channel reaches hold water between flows and are known as waterholes; these are too small to resolve here. Image coordinates are 142.47 E, 25.56 S. Image shows Landsat 7 ETM+ data (bands 7, 4, 2) from the Geocover 2000 data set, obtained from NASA World Wind version 1.3.

Fig. 6 Hydrological alterations to the floodplain along the Kalamazoo River (Michigan, United States). This image covers land extending about 11 km in width. The reservoir in the lower part of this view was created by impoundment of the main channel for hydroelectric generation. Downstream is a diked area where water levels are managed for wildlife. The remaining floodplain is covered by deciduous forest and retains an approximately natural flood regime because this and other, upstream reservoirs are managed as run-of-river (i.e., they do not vary much in water levels over the year). Image coordinates are 85.94 W, 42.57 N. Image source: U.S. Geological Survey digital aerial photography (DOQQ) taken in March 1999, obtained from NASA World Wind version 1.3.

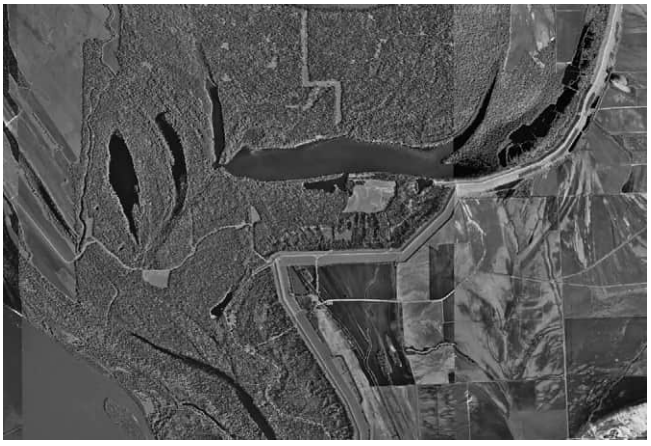

Fig. 7 Hydrological alterations to the floodplain along the Mississippi River (northeastern Mississippi east of Helena, Arkansas, United States). This image covers land extending about 9 km in width. Much of the floodplain here has been disconnected from the river by dikes and is used for agriculture; other parts are deforested but not diked. Oxbow lakes are visible in the forested parts; topographic floodplain features can also be seen in cleared and diked areas. Image coordinates are 90.51 W, 34.59 N. Image source is U.S. Geological Survey digital aerial photography (DOQQ) taken in April 2001, obtained from NASA World Wind version 1.3.

mid-channel bars and islands, and smaller channels can become isolated from the flow and exhibit lake-like conditions at lower discharge. Wetlands that resemble riverine floodplains but may not be subject to direct inundation by river water include floodplains on fluvial terraces, and poorly drained plains adjacent to rivers that tend to become flooded with local runoff during the wet season. Examples of the latter include much of the land in images of the Pantanal (Fig. 3) and Llanos de Moxos (Fig. 4).

Hydrology of floodplains

By definition, floodplains share the characteristic of being subject to inundation, but key hydrological features of inundation are highly variable. The timing, frequency, and duration of inundation can be collectively considered as the hydroperiod or flood regime. In many kinds of floodplains, there is a range of flood regimes depending on the land surface elevation with respect to the river. Subtle differences in topography can result in considerable differences in hydroperiod with corresponding variation in soil moisture and ecological characteristics, particularly when the range of inundation depth is relatively small.

Where riverine overflow and/or river-level backwater effects control water levels on the floodplain, river discharge often dictates timing and predictability of inundation, while depth and routing of flow within the floodplain reflect its geomorphology and vegetation. Larger river systems tend to have broader and more predictable flood peaks because their large drainage basins integrate the smaller-scale spatial variability of individual precipitation events. The presence of extensive floodplains or water bodies along larger rivers attenuates the flood pulse downstream.

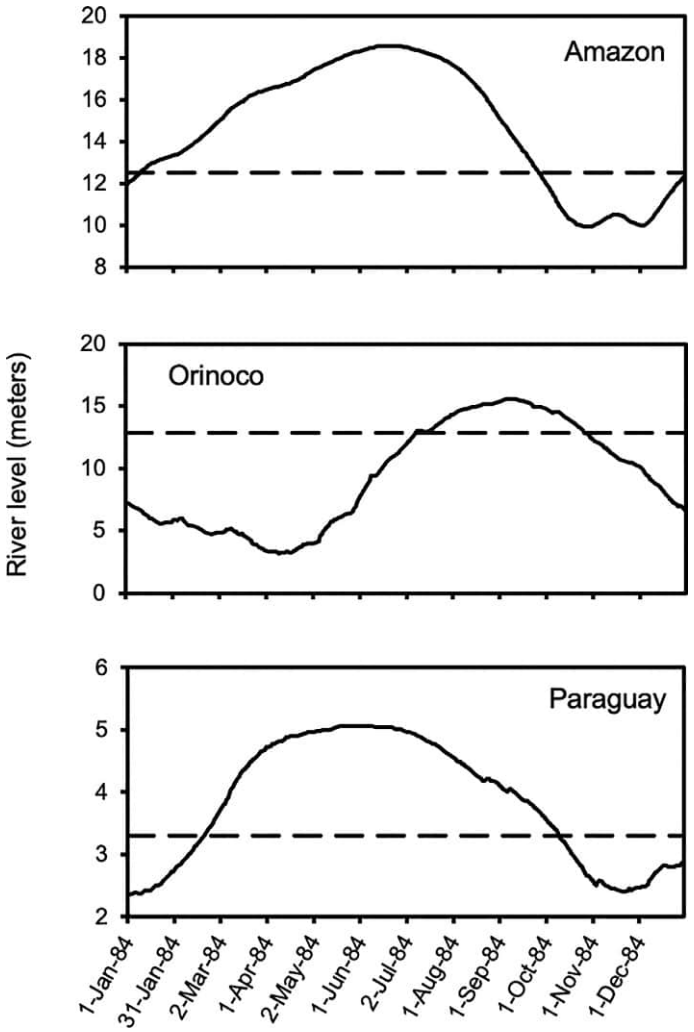

Fig. 8 Daily river level measurements for the year 1984 from the Amazon River (Rio Solimões at Manacapuru, Brazil), the Orinoco River (Ciudad Bolívar, Venezuela), and the Paraguay River in the southern Pantanal (Corumbá, Brazil). Dashed lines show approximate bankfull stages, above which the adjacent floodplains become inundated with river water. These flood regimes are essentially natural with no significant upstream regulation. Data collected by the Brazilian Agência Nacional de Energia Elêtrica (Amazon River), the Venezuelan Ministerio del Ambiente y de los Recursos Naturales Renovables (Orinoco River), and the Brazilian Navy (Paraguay River).

Particularly attenuated and prolonged flood pulses are observed in large, mostly unregulated river systems of South America, where the floodplain typically is inundated once per year, lasting for months and covering much of the floodplain with water to depths up to several meters (Hamilton et al., 2002). Fig. 8 shows examples of daily river water level measurements from three large rivers with extensive floodplains—the Orinoco, Amazon, and Paraguay rivers of South America. In the vicinity of these measurement sites, the Orinoco has the least extensive floodplain relative to its discharge, while the Paraguay River has the most extensive floodplain (these data come from the southern Pantanal in Brazil: Fig. 3). In each case, the inundation lasts for months, with the most protracted inundation in the savanna floodplains of the Pantanal where standing water often persists for more than 6 months of the year, but in some years of markedly lower rainfall (e.g., 2020) most of that land can become dry. These river systems and their floodplains are so large that the passage of the flood wave through the system takes months, resulting in a time lag between the wet season runoff and the inundation of the floodplain. This time lag reaches 4–6 months in the case of the southern Pantanal (Hamilton et al., 1996).

At the other extreme are floodplains that typically are inundated for only a few days or weeks per year. Examples shown here include the Madre de Dios River (Figs. 2 and 9), which drains mountain and lowland landscapes in Peru, and the Kalamazoo River (Figs. 6 and 10), which drains a lowland glacial landscape in southern Michigan, United States. In both of these river systems, the timing and duration of floodplain inundation are highly variable. In a particular year, inundation can occur several times or not at all. The tropical Madre de Dios responds to rain events in the Andes as well as the lowland plains. The temperate Kalamazoo River responds to rain events but also to snowmelt and rain on snow, which produce a higher proportion of overland runoff in a landscape where rainfall infiltrates the soils during most of the year (Hamilton, 2015). Most floods in the Kalamazoo River occur

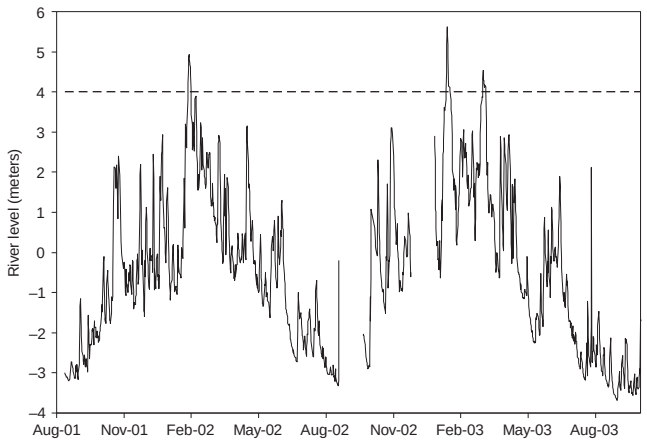

Fig. 9 Daily river level measurements over two annual cycles from the Madre de Dios River above the confluence with the Los Amigos River in Peru. This river drains Andean mountain and lowland environments, and has a natural flow regime. Dashed line shows approximate bankfull stage, above which most areas on the adjacent floodplains become inundated with river water. Data collected by the Centro de Investigación y Capacitación Río de los Amigos (CICRA), operated by the Amazon Conservation Association.

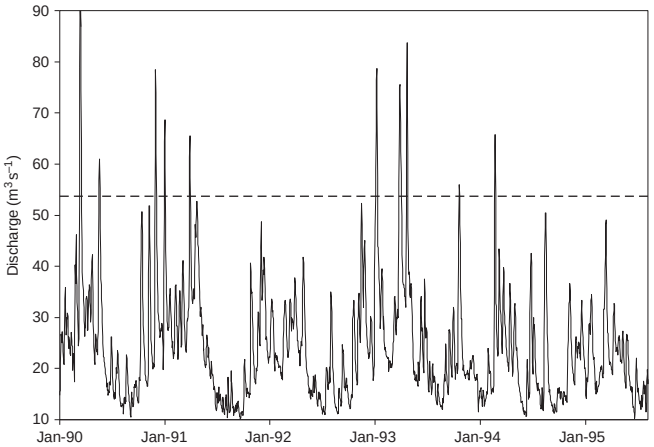

Fig. 10 Daily river level measurements over six annual cycles from the Kalamazoo River (Battle Creek, Michigan, United States). Reservoirs and urbanization have a small effect on the flow regime of this river. Dashed line shows approximate bankfull stage, above which most areas on the adjacent floodplains become inundated with river water. Data collected by the U.S. Geological Survey.

during cooler months (especially March and April) when biological activity is relatively low, and the mean number of days flooded. per year is only eight, with substantial inter-annual variability. Summer flooding has recently increased in the Kalamazoo River floodplain in response to intensification of rain events.

Even brief flooding can be important as a geomorphological force, but from an ecological perspective, brief and unpredictable floods may act more as a disturbance that limits the plant and animal life rather than benefits it. In cooler climates, the timing of the inundation is critical as well. Some large boreal/arctic rivers that flow in a northerly direction, such as the Mackenzie River in northwestern Canada and the Ob and Yenisei rivers in Siberia, exhibit spectacular flood pulses as the river breaks through ice in the spring (Pavelsky and Smith, 2004).

The most variable river discharge regimes, and hence the most unpredictable flood pulses, occur in certain dryland rivers such as Cooper Creek and the Diamantina River in the endorheic Lake Eyre basin of interior Australia (Fig. 5), which tend to flow only when monsoons bring heavy rainfall far into the continent (Puckridge et al., 1998). In these semiarid environments water limits biological activity most of the time, and hence inundation of extensive floodplains and anastomosed channel systems can be important in stimulating aquatic and terrestrial primary production despite its erratic and ephemeral nature (Bunn et al., 2006). Permanent waters in these systems are known as 'waterholes', which are particularly deep channel reaches of restricted length that hold water long after the river has ceased to flow and most of the channels have dried, thereby serving as important refugia for the aquatic biota, including invertebrates and fishes.

The routing of flood waters across floodplains is complex and often changes over the course of the flood event. Commonly, water first enters the floodplain through low breaks in the levees known as crevasse splays, and this water may follow floodplain

channels for some distance before spreading out into backswamps or lake basins. Water also commonly backs up through downstream openings, for example, through the lower end of tributaries or oxbow lakes that are connected with the channel. Thus, floodplain inundation commences before the levees become submerged. At the highest river stages, most or all levees may be underwater, and bulk water flow across the floodplain proceeds generally in the downriver direction.

Although the water that inundates floodplains does not necessarily originate from overbank flow of the main (also called mainstem) river, the river may control water levels by backwater effects. Locally derived water entering from lateral tributaries can be impounded temporarily by river flood waters, or travel down the floodplain as deferred flow before mixing with the main river. In extensive floodplains such as the Pantanal, the flood waters can be derived entirely from delayed drainage of precipitation falling directly on the floodplain. Groundwater inputs from adjacent uplands also can be important, especially in smaller floodplains or in floodplain wetlands lying close to the upland boundary. Such inputs may maintain a high water table, and thus create wetland conditions for most or all of the year. These distinct sources of flood waters often differ in chemistry and suspended matter, enhancing the biogeochemical and ecological heterogeneity across floodplains (McClain and Naiman, 2008).

Freshwater rivers near their confluences with the sea can have floodplains subject to tidal control of water levels, superimposing a short-term cycle of variability on longer-term, discharge-driven flood pulses. Examples include the Amazon and Orinoco deltas, where freshwater discharge is high enough to prevent seawater intrusion yet tidal fluctuation can be observed for considerable distances upriver (~200 km for the Orinoco and ~800 km in the Amazon). In contrast, rivers with little or no dry-season flow can experience substantial intrusion of seawater in their lower reaches (Berger et al., 2019). In such river systems, seemingly modest changes in relative sea level can alter the zone of seawater influence, producing dramatic implications for the river and floodplain ecosystems. Sea level rise associated with climate change increasingly will pose a threat to many low-lying floodplain (and other kinds of coastal wetland) ecosystems that contain freshwater in close proximity to the coastal zone (White and Kaplan, 2017). Conspicuous stands of dead trees resulting from the dual stresses of higher water levels and saltwater intrusion, often called "ghost forests," are increasingly common along the Atlantic and Gulf coasts of North America (Kirwan and Gedan, 2019).

Floodplain Lakes

More or less permanently flooded depressions on the floodplain that are deep enough to have open water at least seasonally often are called floodplain lakes, although floodplain water bodies typically exist as a continuum in area and depth from what would normally be called wetlands to lakes (Downing et al., 2006). There is no universal definition that distinguishes a lake from a wetland and usage of 'lake' or comparable terms varies regionally. Commonly water bodies that are called lakes have an open-water area for most or all of the year, which distinguishes them from entirely vegetated wetlands. Their open-water areas may not fill with aquatic vegetation even though they can be quite shallow at low water, which can be a result of the changing water levels and low light penetration. Interannual variation in the flood regime can produce striking changes in the proportions of open water and emergent or floating vegetation. Although they are often small in area, floodplain lakes are one of the most abundant types of lakes in the world, particularly in the tropics where large, unregulated floodplain rivers remain (Lehner and Döll, 2004). Very large lakes are associated with some floodplains, such as the Grand Lac on the Mekong River, though these may have a distinct geomorphological origin.

Floodplain lakes are formed by a variety of processes, including the isolation of main channel meanders (oxbows), formation of swales between successive levees, subsidence of alluvial fill, and permanent flooding of incised tributary valleys. Examples of each of these are visible in Figs. 1–7. Floodplain lakes may be permanently or seasonally connected to the *main* river, and the connections can be broad or very restricted. Lakes that become seasonally isolated from the *main* river may become perched at higher elevations than the river level as the river falls, and they may accumulate water of local origin during the phase of isolation from the river, often maintaining a stream that drains to the river.

Lakes typically occupy a minority of floodplain area but this depends on the geological history of the floodplain. Sometimes subsidence or back-flooding exceed rates of new alluvial deposition (accretion), producing lakes that cover much of the backswamp areas. Tectonic processes that cause subsidence, tilting, or uplift of basement rock can create areas of permanent flooding on floodplains (Dunne and Aalto, 2013).

Most kinds of floodplain lakes are no deeper than the *main* river, and they can become very shallow during low water. During periods of isolation or at least minimal through-flow of river water, they can be rich in phytoplankton, although in many cases they become shallow enough that sediments are resuspended by wind-induced turbulence and inorganic turbidity greatly restricts underwater light availability (e.g., the large oval lakes in the Llanos de Moxos: Fig. 4). During inundation they receive through-flowing river water and this may drastically reduce the water residence time to the point where plankton growth is suppressed by flushing and the water chemistry of the lake increasingly resembles that of the river (e.g., Hamilton and Lewis Jr., 1990; Melack and Forsberg, 2001).

Functions of floodplains

The permanent and temporary aquatic environments of floodplains along large rivers are locations for a number of important ecosystem processes, or functions, which provide values and services to people.

Floodplains tend to be highly productive ecosystems and have long been utilized for production of food and fiber and harvest of wild plants and animals. Perhaps the greatest contrast in productivity between uplands and floodplains occurs in dryland regions, but even in humid climates the floodplain is often desirable for farming and livestock production.

The temporary residence of water on floodplains can be an important hydrological function because it delays the passage of flood waters through the fluvial system. This delay tends to attenuate the flood peak downriver, reducing peak water levels (Lininger and Latrubesse, 2016), which often is advantageous to riverside communities and floodplain agricultural activities. Passage of river water through floodplains can significantly enhance evapotranspirative losses, which in dry regions may be viewed as negative, but this also may increase groundwater recharge, a positive service for water-limited regions. Some floodplains overlie extensive alluvial aquifers and these can provide a readily accessible water supply that is recharged by seasonal flood pulses.

Passage of river water through floodplain environments changes its content of dissolved and suspended matter, which can affect the composition of riverine exports. Suspended sediments tend to show net loss by deposition, whereas nutrients may show net retention or transformations. Concentrations of certain pollutants, particularly those associated with particulate material (e.g., trace metals) as well as labile nutrients (e.g., nitrate), are often greatly reduced in water passing through floodplains. High rates of primary production can result in net export of organic matter back to the river, although floodplains can evidently act as either a net source or sink for riverine organic carbon, based on the few available comprehensive carbon budgets for floodplains (Sjögersten et al., 2014).

Under certain circumstances, water quality can be diminished by passage through floodplains. Strong oxygen depletion upon initial inundation of some tropical floodplains is known to result in fish kills (e.g., the Pantanal in Brazil: Hamilton et al., 1997). In coastal plains of tropical Australia, initial contact of flood waters with acid sulfate soils can cause marked decreases in pH and result in aluminum toxicity for fishes (Townsend, 1994). Such leaching effects usually diminish as the floodplain is increasingly flushed by flood waters.

Extensive floodplains can be important as sources of greenhouse gases to the atmosphere. It remains uncertain whether floodplains tend to be net sources of sinks of atmospheric carbon dioxide, but like other wetlands they certainly tend to be net sources of methane while they are wet, and they may be important sources of nitrous oxide as well, particularly in regions with nitrogen pollution. Tropical floodplains are a globally significant source of methane emission to the atmosphere because of their extensive area and high biological activity (Sjögersten et al., 2014).

In rivers with extensive floodplains that are inundated for relatively long periods, much of the primary and secondary production in the overall river-floodplain system can occur in the floodplains. The Flood Pulse Concept articulates how large river floodplains serve as the locus of biological production in the river system, supporting rich aquatic and terrestrial biodiversity including economically and culturally valuable fisheries (Junk et al., 1989; Tockner et al., 2000).

Human modification of floodplain hydrology

The age-old proclivity of humans to control river systems, combined with our ever-increasing technological ability to do so, has made floodplains one of the most altered aquatic ecosystems. River regulation, mainly through construction of dams, has strongly impacted flood regimes of rivers across all spatial scales, and even many of the largest rivers of the world have been regulated to some degree (Ward and Stanford, 1995; Vörösmarty et al., 2010; Grill et al., 2015, 2019). Construction of new dams on large rivers, particularly in the Tropics, is ongoing and expected to increase in the future (Zarfl et al., 2014; Winemiller et al., 2016).

Impoundments tend to create permanently flooded reservoirs in place of seasonally flooded lands (Fig. 6), and in many cases, they alter the discharge regime and often the water quality and temperature well downstream. Dams and reservoirs block longitudinal migration of riverine fishes and other aquatic animals, and fish passage structures are often inadequate. Reservoirs often trap a large fraction of the riverine sediment load, leading to geomorphological destabilization of the river-floodplain system downriver of the dam (e.g., Kondolf et al., 2014) and potential nutrient impoverishment of downstream water bodies and floodplains (Forsberg et al., 2017). Dams operated for hydroelectric generation may impose highly unnatural, short-term fluctuations in water levels (known as hydropeaking: Moreira et al., 2019), while those operated primarily for agricultural irrigation tend to change the seasonality of river flow in addition to removing water from the system for consumptive use.

Modification of river channels to facilitate navigation usually impacts floodplains by altering the relation between water levels and discharge. Removal of natural barriers to navigation can entail dredging, channel straightening, and excavation of rock outcrops. All of these measures tend to enhance flow conveyance and diminish the backwater effect that produces overbank flooding (Hamilton, 1999). Construction of navigation locks may have similar effects as dams. Low-head navigation dams that allow passage of flood waters, such as those on the upper Mississippi River (United States), are less damaging but still create extensive permanently impounded areas at low water levels (Sparks et al., 1998; Schramm et al., 2015).

Floodplains have often been isolated from their *main* rivers by construction of dikes, commonly for the purpose of farming the land (see Mississippi River example in Fig. 7). Such land can be highly productive but may require costly measures to remove or control water, and over time land subsidence, loss of fertility, and occasional incursion of flood waters can detract from its sustainability. Nonetheless, agriculture on converted floodplains has played an important role in many societies and continues to be significant throughout the world. In some regions, floodplains have been extensively mined for clay, sand or gravel, gold, or diamonds, a provisioning service that is sustainable only if subsequent floods replenish the material that is removed.

Aquatic ecosystems on floodplains are also impacted by urban and agricultural development in the upland watershed, which results in alterations to the flow regime and water quality of the main rivers (Bayley, 1995; Vörösmarty et al., 2010). Runoff is

intensified by impervious surfaces and stormwater runoff drainage in built areas, and by land clearing and wetland drainage for agriculture. Nutrient loading to rivers and their floodplains increases with development, although the floodplain biota can have a large capacity for nutrient uptake and retention, and the nutrient removal as water flows across intact floodplains can be viewed as a valuable ecosystem service.

Conclusions

Floodplains of large rivers are a unique and valuable class of wetlands that are important for biodiversity and ecosystem services. These ecosystems are often complex mosaics that reflect spatial and temporal variability in flood regimes, which in turn are due to topography, water sources, and vegetation. Many of the world's large floodplain systems have been altered by human activity, particularly river regulation by dams and isolation of floodplain lands from river connectivity to permit agricultural use. Yet examples of unregulated rivers with extensive floodplains remain, particularly in less developed parts of the world.

Knowledge gaps

- How will climate change and the consequent altered precipitation and river flow regimes affect floodplains and the ecosystem services they provide?
- How will new dam construction affect the remaining unregulated large rivers, and what can be done to mitigate the impacts?
- Can we restore floodplains that have been historically disconnected from rivers by dams and levees?

Glossary

Biogeochemistry Processes and conditions that can be described by biological, geological, and chemical processes and conditions all together.
Breakthrough curve Plot of the concentration of a substance (natural or artificial) against time; important parameter of tracer tests.
Ecosystem services The benefits an ecosystem offers to humans.
Hydraulic gradient Difference between the hydraulic head at two points, divided by the distance between these two points.
Hydraulic head Pressure head of the water at a given elevation.
Hyporheic exchange flux (HEF) A parameter for the amount of water that enters and leaves the hyporheic zone per time unit.
Hyporheic zone (HZ) The upper streambed where surface water and groundwater meet (different definitions exist, Introduction).
Hyporheos Fauna of the hyporheic zone.
Interface The area where different compartments are connected and interact with each other.
Residence time Time a water parcel or substance spends in a defined volumetric space.

Introduction

Historically, research on groundwater and surface water was separated in different disciplines; their connectivity and water exchange are still current research topics. In streams, the groundwater-surface water interface is known as hyporheic zone (HZ). The term "hyporheic" was first mentioned by Orghidan (1955) as a "new habitat" at this interface. Nevertheless, a re-thinking considering groundwater and surface water as a "single resource" began much later (Winter et al., 1998). The term "hyporheos" is derived from the Greek words hypo (beneath) and rheos (flow/stream) and summarizes the organism community inhabiting this zone. However, different disciplines use different definitions for the HZ, and sometimes they even differ within the same discipline (Lewandowski et al., 2019). Biologists, for instance, identify the HZ based on its characteristic community of organisms. Hydrologists often define the HZ based on flow paths beginning and ending at the sediment-water interface. Biogeochemists delineate the

HZ based on a minimum percentage of surface water (e.g., 10%, Triska et al., 1989) present in the subsurface. Groundwater-surface water interfaces exist in other aquatic systems as well. They can, for example, be found at the groundwater-lake water as well as groundwater-seawater interfaces.

The aim of this chapter is to introduce the reader to the current knowledge about HZs and the most important hydrological and biogeochemical processes taking place within the HZ. Moreover, this chapter introduces measurement and modeling techniques used in lab, mesocosm, field, and modeling studies to investigate hydrological and biogeochemical processes in the HZ. The HZ's extraordinary importance and vulnerability to human disturbance is highlighted. Furthermore, we present up-to-date research fields and major, current knowledge gaps.

Characteristics and processes of hyporheic zones

Hydrological processes

The HZ is formed at the interface of surface water and groundwater. Due to substantial differences in physical parameters between these two compartments, the HZ is characterized by strong biogeochemical gradients. Usually, fast-flowing, air-temperature-influenced surface water mixes with slowly flowing, thermally-stable groundwater.

Differences in hydraulic heads between two locations in relation to their distance are called hydraulic gradients (Fig. 1A). The hydraulic gradient between surface water and groundwater determines the main flow direction. If the hydraulic head of the surface water is below the hydraulic head of an adjacent groundwater body, groundwater exfiltrates into the surface water ("gaining river" or "upwelling") (Fig. 1B). If the hydraulic head of surface water is higher than the hydraulic head of groundwater, surface water infiltrates into the aquifer ("losing river" or "downwelling"). In arid regions, low groundwater tables cause the rivers to completely disconnect from the aquifer (Fig. 1B).

Darcy's law can be used to determine flow velocities and volume fluxes in the HZ based on hydraulic gradients. The volume flux, or discharge Q ($m^3\ s^{-1}$), which passes the cross-sectional area A (m^2) in a porous medium, is proportional to the hydraulic gradient, termed i, which is calculated by the hydraulic head difference Δh (m) of two locations with distance L (m):

$$v_f = Q/A = v_a/n_e = k_f * i = k_f * \Delta h/L$$

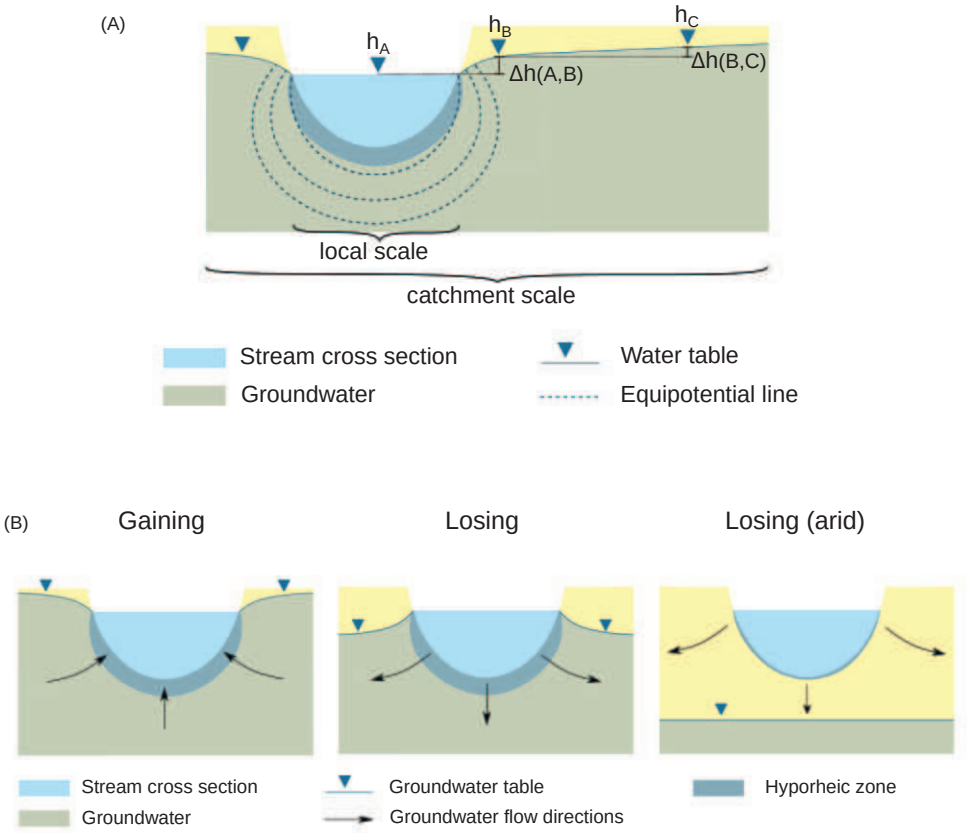

Fig. 1 Schematic representation of (A) hydraulic heads (h) and difference in hydraulic heads (Δh) on a local and catchment scale, and (B) gaining and losing rivers, and losing rivers in arid regions with flow directions in the hyporheic zone and the adjacent aquifer.

The quotient of Q and A is the so-called Darcy velocity v_f (m s^{-1}) which can be transformed into the distance velocity v_a (in m s^{-1}) by division through the flow effective pore space n_e (m^3 m^{-3}). The saturated hydraulic conductivity k_f (m s^{-1}) (also known as permeability coefficient) quantifies the water permeability of the aquifer material. The hydraulic conductivity depends predominantly on the particle sizes of the aquifer material and can be determined either directly by Darcy experiments (manually or with a KSAT device, company: Meter Group, Germany) using undisturbed sediment samples collected in cylinders, by pumping tests, by slug tests or indirectly by means of a grain size analysis. Depending on grain size, hydraulic conductivities vary over several orders of magnitude and are divided into classes ranging from "highly permeable" ($>10^{-2}$ m s^{-1}) over "permeable" (10^{-4}–10^{-6} m s^{-1}) to "impermeable" ($<10^{-8}$ m s^{-1}).

Following Darcy's law, hydraulic gradients at the streambed's sediment surface cause hyporheic exchange flux (HEF), i.e., flux of surface water into the hyporheic zone and back into the overlying water body (Fig. 2). HEFs control transport, residence time, and distribution of dissolved oxygen, nutrients, and contaminants in the hyporheic zone. They are spatially and temporally dynamic and are related to local pressure differences, large scale head differences, hydrological conductivity and porosity of the sediment (Krause et al., 2011).

Varying surface water discharge or groundwater table fluctuations can result in a shift between downwelling, neutral or upwelling conditions. Consequently, the percentage of surface water or groundwater in the HZ changes and even the extent of the HZ is altered. Intense hyporheic exchange occurs at sediment ripples. These streambed features can be highly dynamic and can migrate downstream with alternating celerity (i.e., the speed of motion of that feature) depending on the surface water velocities (Wolke et al., 2019).

Biogeochemical processes

The HZ is a bioreactor with microbes controlling the biogeochemical processes and main ecological functions (Krause et al., 2011). Naegeli and Uehlinger (1997) determined the contribution of hyporheic respiration to up to 96% of the overall ecosystem respiration, underlining the importance of the biogeochemical processes in the HZ as part of river ecosystems. In the HZ, biogeochemical processes are closely coupled to hydrological processes. Groundwater and surface water may differ greatly in their chemical composition including nutrients, organic matter, pollutants, dissolved oxygen concentration, and other redox indicators such as iron, manganese, sulfate or nitrate. Therefore, distinct biogeochemical gradients develop in the zone where groundwater and surface water mix. Microbes play a key role in the formation of these gradients. Close to the sediment surface, oxic conditions and aerobic biogeochemical processes dominate. Along a flow path, aerobic microbes consume oxygen, nutrients, and dissolved organic carbon supplied by the surface water. This eventually leads to anoxic and nutrient-depleted conditions as well as anaerobic processes and related microbial communities further down along the pore water flow path (Fig. 3).

In addition to a changing chemical milieu, biomass and productivity of the streambed community decrease with increasing depth (Peralta-Maraver et al., 2018). The HZ and its biogeochemical gradients provide diverse ecological niches for a variety of organisms and make the HZ a biological hotspot in a river. HEFs through ripples or dunes are often spatially heterogeneous and temporally variable, resulting in different residence times and turnover of solutes in the hyporheic zone (Krause et al., 2011).

Due to temporally varying environmental conditions, the biogeochemical zonation of the HZ is dynamic. Temperature is a major driver of biogeochemical processes and varies both seasonally and in the course of a day. Diel temperature fluctuations might alter oxygen saturation of surface water and diel light cycles alter oxygen production and consumption at the sediment surface and within the HZ.

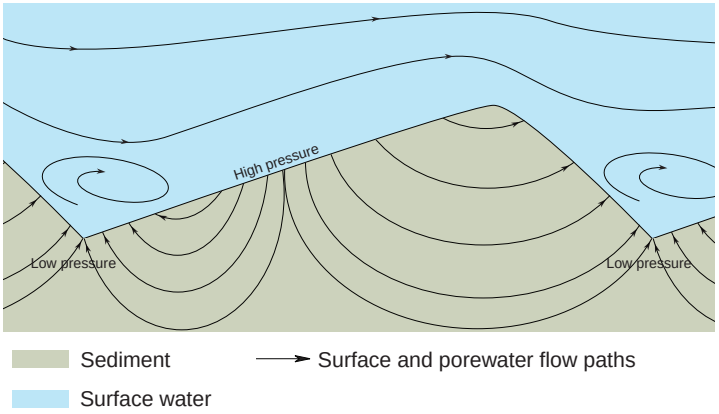

Fig. 2 Hyporheic flow paths in dune-shaped bedforms that can occur in sandy streambeds. The flow paths result from pressure differences at the sediment surface. The flow direction is from high pressure to low pressure zones.

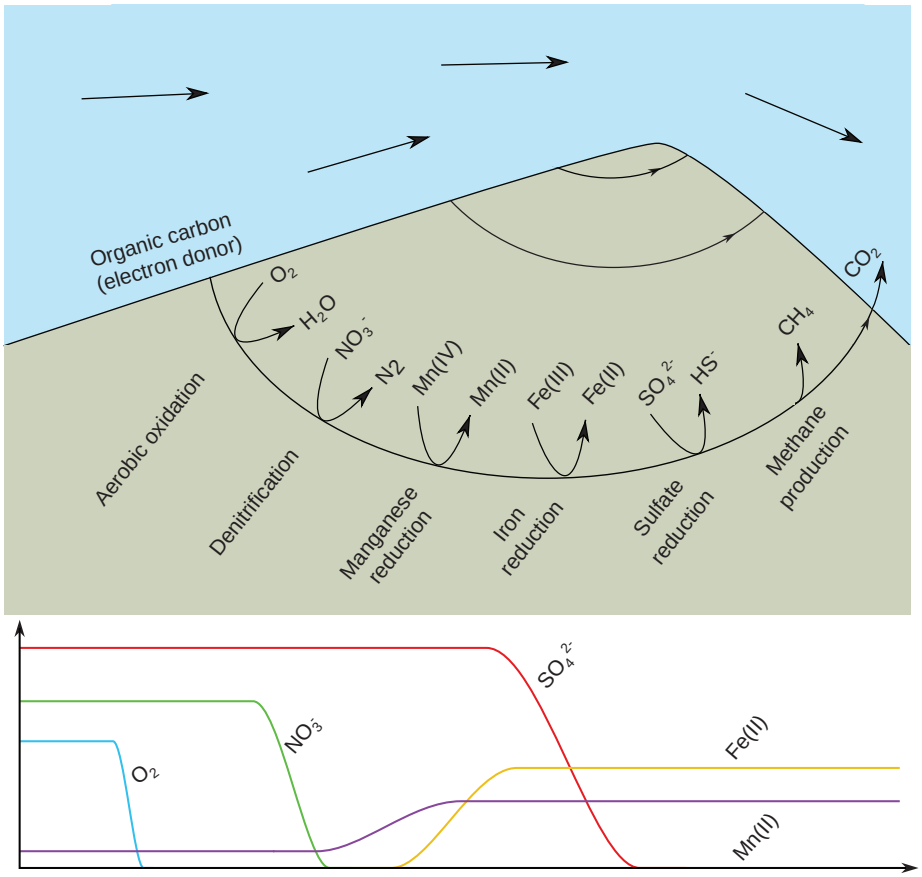

Fig. 3 Schematic figure visualizing the redox sequence along a flow path through a ripple or dune. The lower panel shows schematically the resulting concentration patterns along the flow path.

Importance and vulnerability of the hyporheic zone

Ecosystem services provided by hyporheic zones

HZs provide a diverse number of ecosystem services. Diverse microbial communities promote cycling of carbon (C) and high attenuation rates of the nutrients nitrogen (N) and phosphorus (P). Ammonium and phosphate might be released due to the mineralization of organic matter in the HZ. In addition, the weathering of bedrock and the reductive dissolution of iron-bound P under anoxic conditions might release phosphate. However, HZs might also be sinks for nutrients. P might be bound to iron(oxy) hydroxides under oxic conditions or removed by other compounds. Uptake of P by biomass might also be a relevant removal process. In anoxic hyporheic sediments, denitrification might remove nitrate by conversion to N_2 but sorption and assimilation are additional removal processes of inorganic nitrogen. However, oxidation of ammonium in the oxic part of the HZ causes formation of nitrate (nitrification) (Lewandowski et al., 2019).

Elevated concentrations of iron, manganese, zinc, copper and lead in rivers, lakes and groundwater are usually due to mining-related contamination. In general, the HZ can contribute to the attenuation of metals under conditions with high oxygen concentrations and a high pH but can also release sorbed or precipitated metals if conditions change to anoxic and a low pH (Gandy et al., 2007).

The HZ is also a hotspot for the attenuation of contaminants in rivers. This attenuation is promoted by bedforms on the sediment surface (Boutron et al., 2011), as they increase the hyporheic flux and therefore the water volume flowing through the HZ increases. Trace organic compounds such as pharmaceuticals, industrial compounds, personal care products or pesticides have several degradation pathways, among which microbial degradation and sorption are the most important ones in the hyporheic zone. For many polar trace organics, microbial degradation is the major attenuation process while sorption can also play a significant role for non-polar substances. For many polar trace organics, the upper centimeters of a riverbed are the zone where attenuation is most efficient. This is due to the presence of easily degradable organic matter and oxic to suboxic redox conditions close to the sediment surface (Schaper et al., 2018).

Moreover, the HZ has a filtering capacity for natural and anthropogenic suspended particles (e.g., microplastics), despite the low density of some of those particles (Drummond et al., 2020). Even though filtration is positive from the perspective of surface water

quality, filtration can have severe negative impacts on other ecosystem services: e.g., colmation reduces HEFs and results in alteration of the hyporheos community (Descloux et al., 2013). Furthermore, particulate matter might be toxic itself or might carry sorbed contaminants that might harm the biota inhabiting the HZ.

The HZ is considered a refuge for aquatic organisms, such as juvenile fish (Benjankar et al., 2016), amphibians, or invertebrates. It offers a habitat protected from strong currents in the surface water, temperature extremes, droughts and predators. Surface water entering the HZ provides organisms with oxygen and nutrients while water returning from the sediment back to the surface water removes biological waste products from the HZ. Salmon, for example, dig nests in gravel sediments of HZs for spawning. The resulting structure of the nest and increased hydraulic conductivity around the eggs enhances hyporheic exchange and the oxygen supply to the eggs (Tonina and Buffington, 2009).

Vulnerability

In the HZ, diverse hydrological and biogeochemical processes are in a vulnerable balance. One of the biggest threats to a functioning HZ is the decrease of its permeability combined with a decline in hyporheic exchange. Clogging of the top layer can occur due to inputs of fine sediment into streams by anthropogenic activities such as mining, agriculture, urbanization or dam construction (Hancock, 2002). Clogging can also result from the absence of higher discharge, e.g., natural flow regimes, that would regularly break up the river bed and flush fine sediment downstream (Schälchli, 1992). Moreover, clogging and a decrease in hydraulic conductivity can result from an increase in nutrients stimulating algal blooms and biofilm growth at the sediment-water interface (Boulton, 2000; Hancock, 2002).

A straightened river loses many of its diverse structures that promote hyporheic exchange. These structures include meanders, pools, or obstacles such as large rocks or woody debris. Especially in urban areas, river construction leads to obstructed river banks and sealed riverbeds that, in extreme cases, may completely eliminate the HZ. Nevertheless, river construction can also create obstacles which force water flow into the sediment and increase hyporheic exchange (Crispell and Enreny, 2009).

The input of anthropogenic substances has consequences for all types of organisms throughout the food web. Increased concentrations of heavy metals or other contaminants result in toxic conditions for many organisms (Courtney and Clements, 2002). Hyporheic microbial communities, for example, react to a change in the chemical milieu through altering their composition and performance (Danczak et al., 2016; Febria et al., 2010; Nelson et al., 2019). If the contaminant is toxic for invertebrates which dig in the sediment or graze on microbial biofilms, the extinction of those organisms could also lead to a decrease of hyporheic flow (Hancock, 2002).

Artificial discharge and resulting water temperature fluctuations might impact the HZ. They can be caused by infrastructures, including hydropower and waste water treatment plants, irrigation practices, etc. Those fluctuations may alter the physiochemical conditions of the HZ and, hence, impact the habitat of organisms living in and on the sediment (e.g., for hydropower plants: Bruno et al., 2013).

Methods

Choosing the right research approach

The available techniques to study the processes in the HZ are manifold. When planning an experiment, the research question or hypothesis is the basis for selecting the appropriate methods, temporal and spatial scales. One of the main challenges in hyporheic research is the overlap of spatial heterogeneity and temporal variability (Fig. 4, "Characteristics and processes of hyporheic zones" section). For instance, groundwater is usually characterized by temporally rather constant chemical compositions while spatially chemical compositions can be very heterogeneous due to slow mixing rates. In contrast, surface water bodies are characterized by spatially rather homogeneous water composition as mixing rates in streams are fast but the temporal variability is high. In the HZ, as the transition zone between groundwater and surface water, the water composition is both temporally variable and spatially heterogeneous even though the temporal variability of the surface water body might be damped. Consequently, HZ research must account for both spatial heterogeneity and temporal variability.

Given this complexity, another important aspect of experimental planning is determining the level of simplification acceptable to answer the research question. Generally, experimental studies can be divided into field, mesocosm, and laboratory studies (Fig. 5). Field studies are conducted in real and complex river systems, including all involved and non-separable processes with their spatial heterogeneities and temporal variabilities. In contrast, in batch or column experiments in the laboratory, many parameters can be controlled well. Although simplification helps to focus on single processes and differentiate their individual impacts, important links to other processes or parameters present in reality might be missed. Artificial river channels (i.e., flumes) and other mesocosm experiments are in between the complexity of field sites and the simplicity of batch and column experiments as some parameters can be controlled but others cannot. Laboratory studies and mesocosm studies have the advantage to allow for statistical replication, which is hardly or not at all possible in field studies.

Besides experimental studies, another possibility to study hyporheic processes are models. Models can either be used for pure modeling based studies or they can complement experimental investigations. Modeling studies allow for controlling parameters and can cover a large range of complexity and realism. While models always simplify reality, they make it possible to narrow down value ranges of parameters which are either hard to measure or cannot be measured at all.

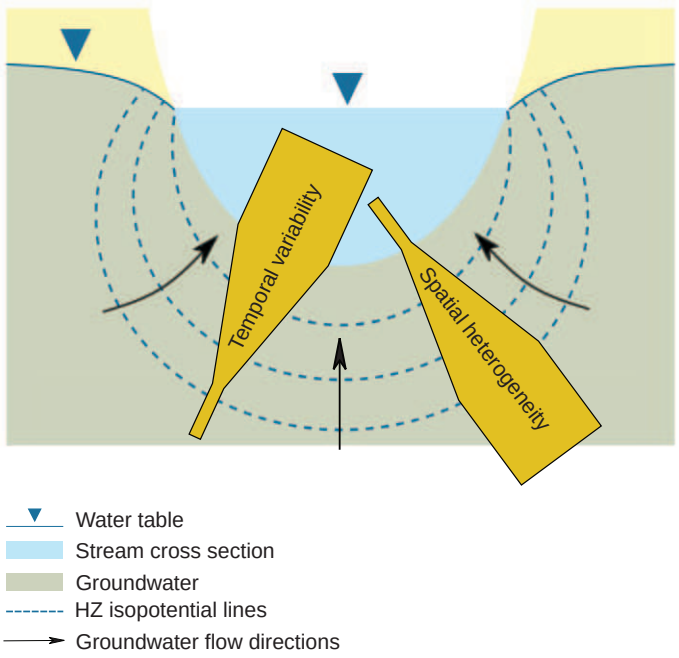

Fig. 4 Schematic overview over temporal variability and spatial heterogeneity at the groundwater-surface water interface. Width of yellow polygons represents degree of heterogeneity/variability.

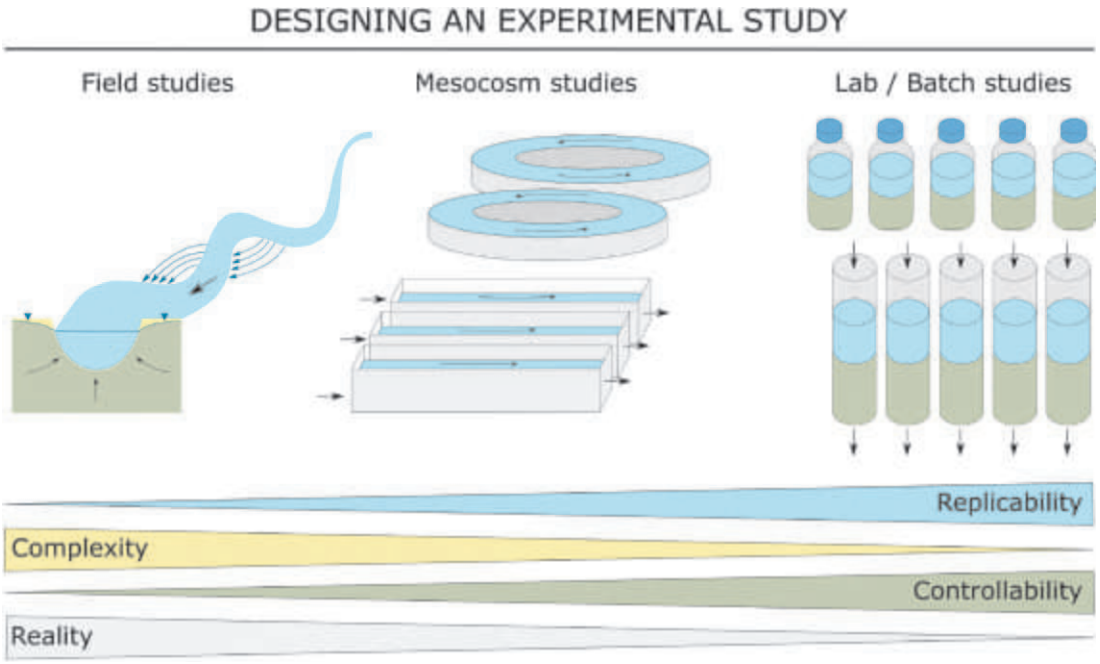

Fig. 5 Schematic overview of different forms of experimental studies, i.e., field, mesocosm, and lab/batch studies, and their variability in replicability, complexity, controllability, and closeness to reality.

Methods to study hydrological processes in the HZ

In the following, we present frequently used lab, mesocosm and field methods to investigate hydrological processes in the HZ. Understanding of these processes is an important prerequisite for assessing biogeochemical processes and contaminant degradation.

Methods used in laboratory and mesocosm studies

Laboratory methods for investigating hydrological processes include batch tests and column experiments. Column experiments are conducted to study flow in sediments collected in the field or in artificial sediments with known grain size distribution and grain shape. Hydrological column experiments are often combined with conservative tracer tests (Section "Methods used in field studies" below). Hydrological processes investigated in mesocosm flume studies include the characterization of hyporheic flow paths and HZ extension, turbulent water flow and the water-sediment interface including erosion and deposition of sediments.

Methods used in field studies

Field methods to study hydrological processes in the HZ examine pore water flow direction, quantity and velocity. Methods based on Darcy's law use observation wells, so called *piezometers*, i.e., tubes with a filter screen at the lower end. They are installed in the streambed or aquifer to measure hydraulic heads either manually with dip meters or as time series by pressure loggers. Hydraulic head differences between wells or/and the water table of the river can indicate vertical or horizontal flows. *Seepage meters* are large cylinders with one open side that is pressed into the sediment. Groundwater exfiltrating within the seepage meter is collected and its volume used to calculate the exfiltration rate (Lee, 1977). *Heat-Pulse-Sensors* determine the 3D flow direction and velocity in the HZ using temperature breakthrough curves. A heating element introduces a short heat pulse into the sediment which travels then through the sediment and is detected by temperature sensors placed around the source (Angermann et al., 2012).

Natural temperature differences between groundwater and surface water can also be used to quantify exchange rates and record spatial flow patterns in the HZ. While groundwater temperatures fluctuate only slightly over the course of the year, surface water shows daily temperature fluctuations and is often significantly colder than groundwater in winter and significantly warmer in summer. *Temperature lances* with multiple temperature sensors record temperature profiles in the water column and in different depths of the sediment. Mathematical models, e.g., VFLUX (Gordon et al., 2012), are then applied to calculate vertical fluxes in the HZ. *Fiber-optic distributed temperature sensing (FO-DTS)* uses long fiber optic cables located at the sediment-water interface that determine temperature changes along the fiber. Deviations from the stream water temperature indicate that cooler or warmer groundwater (depending on the season) is entering the stream (Gaona et al., 2019). In *thermal infrared imaging (TIR)*, a camera records an image of surface water temperatures. The exfiltration of warm or cold groundwater in winter or summer, respectively, might cause visible signals in the TIR image and thus allows for a fast and easy localization of exfiltration zones (Hare et al., 2015).

Electric resistivity tomography (ERT) is a non-contact method that provides information on the subsurface sediment matrix or subsurface flow if combined with an electrically conductive tracer (Ward et al., 2010). With one pair of electrodes, electric current is injected into the ground and the electric potential difference is measured with another pair of electrodes. The resulting data allows conclusions about hydraulic conductivities. *Hydrograph analysis* (Bayou et al., 2021) of surface water flow is based on the proportion of base flow, often groundwater, and event flow from precipitation or snow melt, in a river. A *water mass balance* between two gauging stations at a river can determine groundwater ex- or infiltration by detecting higher or lower discharge at the downstream station, respectively.

Tracers are another useful tool to study surface water-groundwater interactions. They are divided in *natural and artificial tracers*. *Stable water isotopes* naturally occur in certain ratios of heavy to light isotopes. This ratio is altered by different processes such as evaporation or precipitation. As these two processes mainly influence surface water but not groundwater, the isotopic signal of those two water bodies differs and can be used by mixing models to determine the contribution of them both (Sklash and Farvolden, 1979). If the *electrical conductivity* of groundwater and surface water differs, this parameter can also be used to examine interactions of the two water bodies in the hyporheic zone. For a period of several days, *radon* gas can be used to calculate the age of water (Bourke et al., 2014). Radon is produced by the decay of radium, which naturally occurs in rocks, and has a half-life of 3.8 days. It occurs in groundwater but rapidly degasses from surface water. Therefore, elevated radon concentrations in surface water indicate nearby exfiltration of groundwater into the surface water body. In contrast to natural tracers, *artificial tracers* are injected into the system to study hydrological processes by looking at breakthrough curves at certain locations of the system. Conservative tracers such as salt (NaCl), bromide, lithium, and artificial dye tracers, such as rhodamine WT; fluorescein and uranine, are applied to investigate flow paths and times, discharge or mixing of different water bodies. Salt requires larger amounts, because of higher background concentrations, but can be easily measured as electrical conductivity. The other tracers require only small amounts, but are more elaborate to be detected.

Methods used in modeling studies

Models are nowadays generating a large part of HZ research. Boano et al. (2014) extensively reviews modeling studies conducted over the history of HZ research and divides mathematical models into two groups: physical and phenomenological models. Physical models use the "physical principles of mass and momentum balance" as a basis. These physical models are used to predict transport and residence times of water and dissolved compounds in streambeds and are suitable to examine the relative importance of factors and processes regulating flows at the groundwater-surface water interface (Boano et al., 2014). Phenomenological models are models based on the phenomenological description of the surface water-groundwater system (Boano et al., 2014), e.g., transient storage models by e.g., Bencala and Walters (1983) and Runkel (1998). Phenomenological models are often applied to reach scales and calibrated by field tracer tests, e.g., OTIS by Runkel (1998) and Boano et al. (2014).

The determination of groundwater upwelling and downwelling can be determined by modeling hydraulic heads (Cardenas and Wilson, 2007) or by assessing phase shift and amplitude damping of diel temperature signals along a profile in the sediment by Dynamic Harmonic Regression using the VFLUX method (Gordon et al., 2012).

Methods to study biogeochemical processes in the HZ

Biogeochemical processes in the hyporheic zone are a crucial part of the functionality of this interface. Based on sediment and hydrological characteristics, different redox zones develop. These zones can be either stable or dynamic and regulate all other biogeochemical processes. These processes can be nutrient cycling or attenuation of contaminants, among others.

Methods used in laboratory and mesocosm studies

Batch tests are used to determine specific biogeochemical features of hyporheic sediments or pore water. Examples are sorption and desorption processes or the impact of e.g., organic matter on the attenuation of contaminants or microbial metabolism. Compared to batch tests, *column experiments* are more realistic as they can feature pore water flow through the columns. Adjusting flow velocities and resulting redox conditions in the sediment allows for analyzing the influence of these parameters on the biogeochemical processes. Biogeochemical processes can be examined by comparing input and output concentrations, by measuring concentration gradients over depth, or by using reactive tracers (e.g., resazurin) as surrogates for the compound or microbial biota of interest. To capture more reality, *mesocosm* studies are used. Examples are many, but include flumes with either circular or straight channels to study for instance how surface water flow velocities affect dissolved O_2 in the sediment (Wolke et al., 2019) or how trace organic compounds (TrOCs) are degraded in the riverbed (Jaeger et al., 2021).

These setups can be equipped with a wide range of measurement devices. Sensors combined with data loggers can automatically record, for example, temperature, pH, O_2, electrical conductivity, and some solutes. *Microsensors*, for instance used by De Falco et al. (2018), are used to measure depth profiles of O_2, redox potential, pH, etc. in the hyporheic zone. Due to their small size in the μm range, depth profiles can be recorded with minimum disturbance of the sediment. 2D measurements of O_2, CO_2 or pH are possible with *planar optodes (solute imaging)* installed at a transparent wall of the studied system and associated excitation light sources combined with a camera (Wolke et al., 2019).

As microbes are a major factor determining biogeochemical processes, microbial communities in the hyporheic zone can be of interest. While *genetic analysis* like sequencing disentangles the composition of microbial communities by their genome, tests such as *community-level physiological profiling* (Weber and Legge, 2010) separate microbes into functional groups based on metabolic similarities on microplates. Microbial activity can be measured using *smart tracers* e.g., resazurin (Knapp et al., 2018).

Methods used in field studies

Field studies investigating biogeochemical processes in the hyporheic zone often focus on nutrient cycling, contaminant attenuation or transport processes of compounds. Many techniques introduced in Section "Methods used in laboratory and mesocosm studies" can also be used in the field. In addition, taking samples to be able to analyze the water composition in the laboratory is often required. A number of such sampling methods are explained below.

Mini piezometers (Martinez, 2009) are miniatures of groundwater observation wells with a small diameter down to 2 mm. Due to their small diameter, peristaltic or syringe pumps are used for sampling. The pumping rate must be very low to avoid pumping induced surface water intrusion to the sampling port. *Multilevel piezometers* consist of a bundle of tubes with sampling ports located at different depths in the sediment. This allows for simultaneous pore water sampling from several depths within the sediment. *Pore water samplers* (also called peepers, dialysis samplers or diffusion samplers) consist of a plate with chambers at regular intervals. The chambers are filled with deionized water and covered with a semi-permeable dialysis membrane (Hesslein, 1976). Peepers are installed vertically in the river bed, usually with an exposure time of 14 days. Solutes diffuse through the membrane until concentration equilibrium is reached between chamber and surrounding pore water. *Seepage meters* can not only be used to quantify the volume flux but also to determine the quality of exfiltrating groundwater. The water collected can be used for analytics but precaution needs to be taken against oxygen contamination of anoxic sample water (Lee, 1977; Downing and Peterka, 1978).

Methods used in modeling studies

HEFs cause high spatial heterogeneity of hydrological and biogeochemical conditions in river sediments (Boano et al., 2014). They strongly control biogeochemical processes in the HZ (Krause et al., 2011) by, for example, supplying nutrients, organic carbon, and oxygen. As mentioned earlier, complexity occurs by spatial heterogeneity in groundwater-surface water interaction. This complexity

forms a great challenge for modelers. According to Boano et al. (2014, p. 644), "no current model considers this full range of coupled physical and biogeochemical complexity" and up to date most models focus on single processes, scales or connections of interest. Models that integrate hydrological and biogeochemical processes focus on single streambed formations and are strongly simplified if applied to reach or stream network scales (Boano et al., 2014). Existing models include models on hyporheic transport of solutes (such as metals, Boano et al., 2014), models of HEF and the deposition of fine particles (e.g., Preziosi-Ribero et al., 2020), models on microbial metabolism (Boano et al., 2014), metabolic models combined with HEFs (e.g., Caruso et al., 2017), generally reactive transport models (e.g., Runkel, 2010), and transient storage models (e.g., Salehin et al., 2003).

Knowledge gaps

- Coping with the challenge of spatial heterogeneity of sediment composition and temporal fluctuations of porewater composition
- Flow path determination in HZs as basis for understanding of biogeochemical processes
- Dynamic flow paths changes and changing residence time distributions
- Influence of discharge dynamics (natural, e.g., rainfall or artificial, e.g., hydropower plant) on hyporheic exchange fluxes, biogeochemical and microbial processes in HZs
- Effects of moving bed forms on hydrological and biogeochemical processes and microbial respiration in the HZ
- Improvement of micro sensors for minimum disturbance of sediments needed
- Further development of sensors and measurement techniques
- Reactive transport in streams and their HZs, i.e., linking hydrology with biogeochemistry, especially for analysis of contaminant attenuation and transport
- Hyporheic microbial community composition and its impact on biogeochemical processes and contaminant degradation
- Further development of smart tracers to investigate microbial activity
- Contribution of the HZ to total greenhouse gas (GHG) emissions of a river

Conclusions

The HZ is nowadays a widely studied river compartment involving many different disciplines. Recent HZ research explored a huge diversity of hydrological and biogeochemical processes occurring in the HZ. The advancing knowledge of the HZ unravels the extraordinary importance of this interface and of the ecosystem services it provides. It offers filtration of surface water and habitat for juvenile fish, invertebrates and microorganisms. Microorganisms building up as biofilms are crucial for the nutrient turnover in a river. They offer great potential for organic contaminant attenuation through microbial degradation. The HZ is a vulnerable system which is threatened by river engineering, clogging and consolidation of the sediment, artificially altered discharge regimes, modified temperatures, and increased pollutant or nutrient loads. The latter two are leading to an increased oxygen consumption and subsequent oxygen depletion in the HZ. This might result in a reduction of the self-purification capacity of streams.

Hyporheic studies apply a variety of methods depending on the aspect or question examined. Unfortunately, previous studies revealed that several parameters, e.g., hyporheic exchange fluxes (HEF) or hydraulic conductivities, differ significantly depending on the method applied. Therefore, it is recommended to apply multiple methods giving information about the same target compound in each study to be able to compare their results. Furthermore, a detailed documentation of the applied methods is important for later use of data and comparison between studies. Future work on method standardization is recommended to improve comparability. As hyporheic processes (e.g., flow, transport, transformation) are closely linked to each other, it is furthermore recommended that future studies use a combination of different methods (field, lab, models) and scales (spatial and temporal). One of the main findings of HZ research is the close coupling of biogeochemical processes to hydrological processes. In other words, the knowledge of flow paths is essential for understanding biogeochemical processes.

This chapter showed the extraordinary importance of the hyporheic zone as part of the surface water-groundwater continuum. Further research is necessary to enhance our knowledge about the HZ to acknowledge and promote its ecological importance. Future research should increasingly involve water resource managers, authorities, the public, and other stakeholders to better protect and use this resource.

Algae and Primary Production of Streams and Rivers Ecosystems☆

R Jan Stevenson, Department of Integrative Biology, Michigan State University, East Lansing, MI, United States

This is an update of R.J. Stevenson, Algae of River Ecosystems, in *Encyclopedia of Inland Waters*, edited by Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00142-3.

This article was reviewed for the *Encyclopedia of Inland Waters*, Second Edition by Section Editor LeRoy Poff.

Glossary

Allelopathic Types of interactions among organisms generated by one organism that secretes chemicals that affects another organism with potentially positive or negative effects.
Allochthonous Matter originating from outside the ecosystem.
Autochthonous Matter origination from within the ecosystem.
Autogenic Means self-produced or self-generated, rather than determined by other organisms or habitat scale drivers of physical and chemical conditions.
Benthic algae Algae that in association with surfaces in aquatic ecosystems (the benthos). Some are microscopic (microphytobenthos, or biofilm) and some are large enough to see strands of cells without a microscope (microphytobenthos).
Epiphytic Refers to living on plants.
Functional redundancy Refers to the ability of different species to perform the same function in an ecosystem, such as primary production or nutrient cycling. If there is sufficient functional redundancy of species in a regional species pool, then ecosystem functions can be maintained with modest changes in environmental conditions if rates of changes in those conditions allow sufficient time for immigration and reproduction.
Metaphyton Algae that are occupy the water column that can determine their distribution and are therefore relative stationary in location by entangling with substrata on the bottom of the habitat or potentially attaching to substrata.
Photoinhibition Low levels of light have positive effects on photosynthesis, but high light intensities can cause negative effects organisms that increase with higher and higher light intensities.
Phytoplankton Algae that are suspended in the water column that cannot determine their distribution and float wherever currents take them, which is typically downstream.

Introduction

Algae in rivers occupy two distinct habitats, the benthos and water column. Benthic algae are algae attached to or associated with substrates in streams and rivers. Thus, periphyton and biofilms (microphytobenthos), macroalgae (macrophytobenthos), and metaphyton are benthic algae. Phytoplankton are suspended in the water column. The amount of these algae and their function and biodiversity varies greatly among different types of streams and rivers and with time. River ecosystems, broadly defined, include all flowing water sections within a watershed, streams, and rivers, and may be bordered or interrupted by lakes, reservoirs and wetlands. Groundwater connections are also important parts of river ecosystems that affect algae.

☆*Change History*: October 2021. R Jan Stevenson updated text, added two new figures, deleted one figure, deleted one table, and added new references.

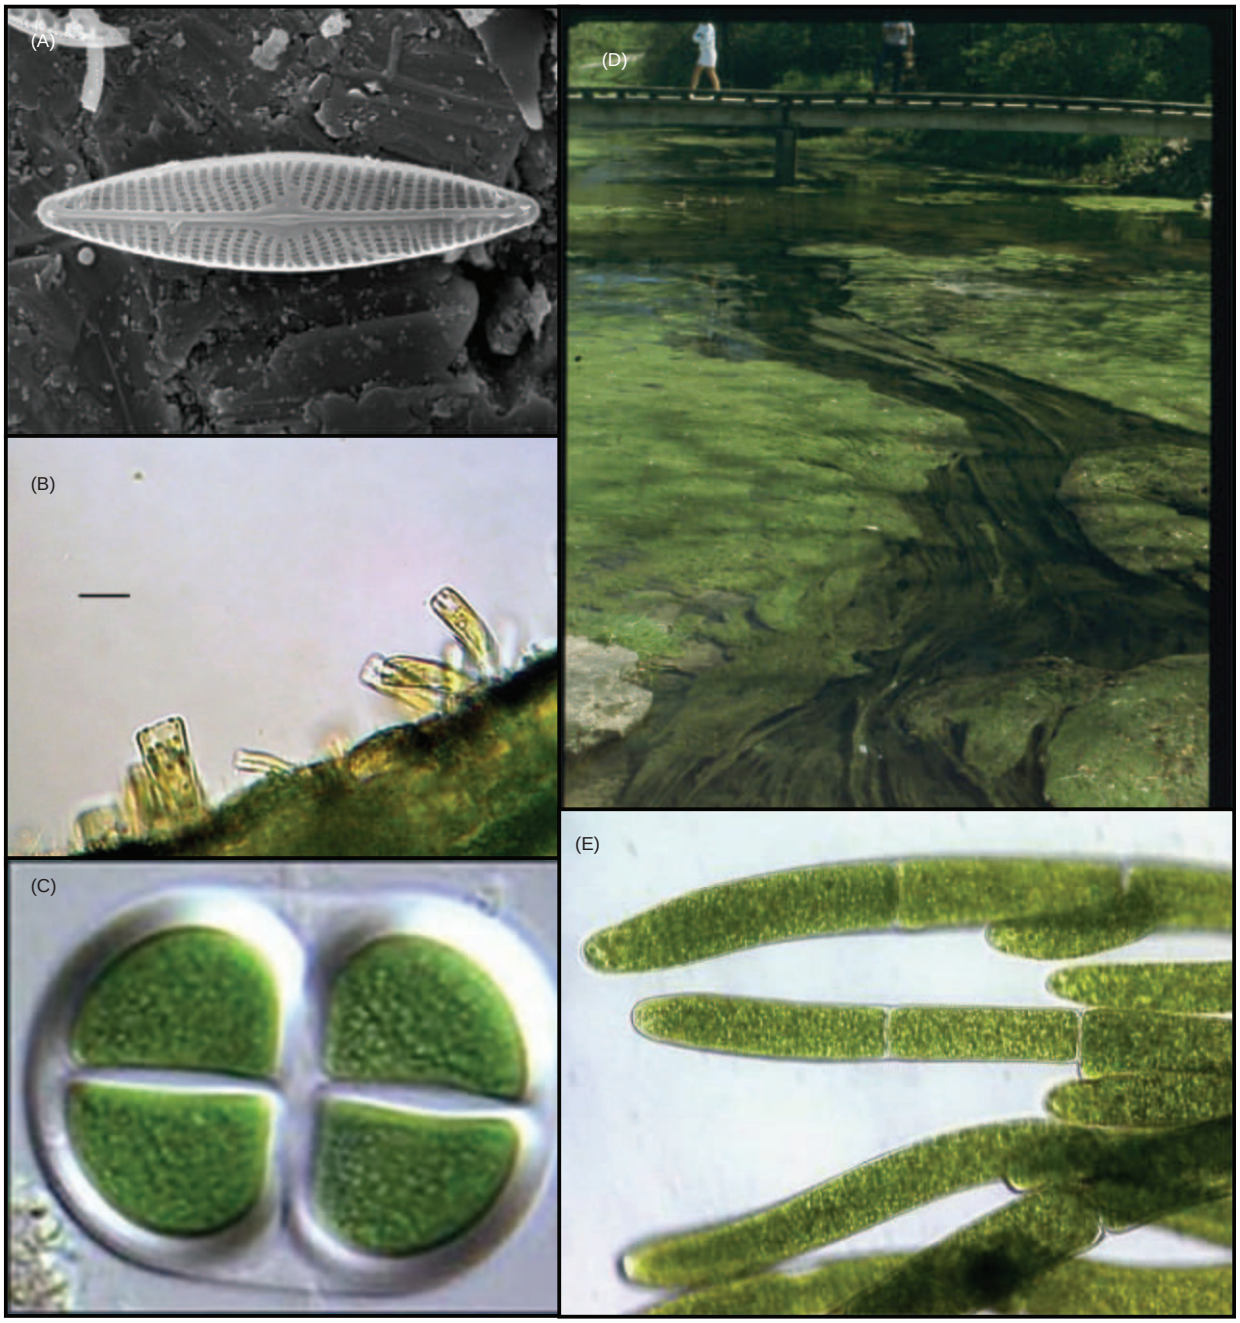

Fig. 1 Three common types of algae in rivers and streams: (A) glass cell wall of a diatom viewed by scanning electron microscope; (B) photomicrograph of diatoms with golden brown pigments attached to the cell wall of a green alga; (C) photomicrograph of a cyanobacterium; (D) photograph of filamentous green algae in a stream; (E) photomicrograph of a filamentous green alga, Cladophora that is in the stream (D).

Taxonomic and morphological diversity of algae varies among habitats and seasonally within rivers as well as among rivers with different environmental conditions. Species composition varies in most river ecosystems from diatom-dominated benthos and phytoplankton during winter and spring to a varying diversity of green algae and cyanobacteria during warmer seasons (Fig. 1). However, a wider diversity of almost all kinds of algae—euglenoids, reds (Rhodophyta), crytomonads, chrysophytes, xanthophytes, dinoflagellates, and even browns (Phaeophyta)—can be found in rivers. Size of these organisms varies from less than 5 μm for small diatoms and chrysophytes in the plankton to meters in length for some filamentous green benthic macroalgae. Morphologically, algae occur as unicellular, colonial, and filamentous forms in both benthic and planktonic habitats. Both unicellular and colonial flagellates use flagella to move vertically in the plankton. Unicellular diatoms may use their raphe and filamentous cyanobacteria move through sheaths in benthic habitats. Many planktonic species rely simply on water currents or periodic resuspensions to maintain sufficient exposure to light to survive.

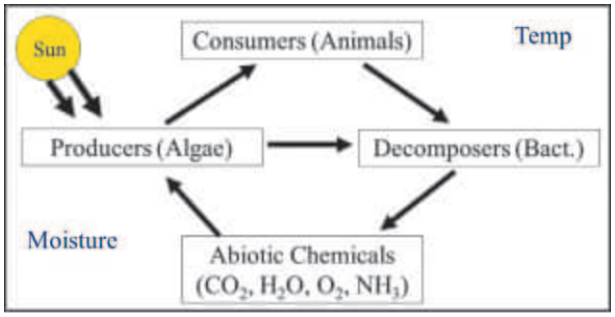

Fig. 2 Basic food web illustrating role of algae as primary producers in relation to consumers (herbivores and predators) and decomposers (bacteria and fungi).

Despite the great variation in algae of rivers and the complexity of factors that affect them, we have learned much about the environmental factors that regulate the processes that control algal biomass, diversity, and function. For example, floods and grazing invertebrates can reduce algal biomass, reduce primary production, and shift species composition to flood- or grazer-tolerant organisms (Power and Stewart, 1987; Steinman et al., 1987; Biggs, 1988; Grimm and Fisher, 1989; McCormick and Stevenson, 1989). Whether or not floods and grazing invertebrates are important in river ecosystems is determined by the climate, geology, and resulting hydrology of the ecosystem (Frissell et al., 1986; Biggs, 1995b; Riseng et al., 2004). In this chapter, I will use a hierarchical conceptual framework for the factors that affect algae in rivers and streams. This framework will help organize the interrelationships among factors that regulate the complex patterns of algal biomass, function, and biodiversity and thereby, will help predict or generate hypotheses to explain patterns of spatial and temporal variation of algal attributes within and among ecosystems. Ultimately, this broader conceptual model will help us predict longer term changes in algae of river ecosystems and how human activities can be managed to solve and prevent environmental problems.

Algae are important elements of river ecosystems and important determinants of the goods and services provided by rivers. Algae are important in the food web in terms of primary production, biogeochemical cycling, and habitat formation and alteration (Fig. 2; see review in Stevenson et al., 1996; Allan and Castillo, 2007). Algae transform sunlight and CO_2 via photosynthesis (i.e. primary production) into sugars. Algal photosynthesis is responsible for the oxygen in every other breath a human takes, although admittedly most of that comes from oceans and not rivers and streams (Field et al., 1998). Algae consume large amounts of nutrients from rivers and streams to combine with the sugars made in photosynthesis to produce amino acids, proteins, lipids, and nucleic acids that are needed for algal reproduction. In food webs, algae can be consumed by herbivores or decomposed by bacteria. In general, microalgae are consumed by aquatic herbivores, mostly insects. In contrast, most macroalgae and plants, which are also important primary producers in some rivers and streams, are more directly decomposed by bacteria and fungi because few aquatic herbivores are adapted to eat it. In addition, algae secrete great amounts of polysaccharides that are used by bacteria and even help bacteria decompose other more recalcitrant organic matter (Wyatt et al., 2012; Danger et al., 2013). Remineralization of nutrients from organic matter occurs by many processes which enable completion of the nutrient cycle as algae again take up nutrients, bind them with sugars from photosynthesis and make cell components for reproduction.

Algae support human wellbeing by producing food and cleaning water for drinking. Excess algae in rivers cause many problems by altering physical habitat and depleting dissolved oxygen supplies. This affects biodiversity and productivity of rivers. Algae can also cause taste, odor, and toxicity problems in drinking water supplies and foul the pipes and filters of water users. So understanding algal ecology is important for managing river ecosystems to protect the goods and services that rivers provide.

Factors affecting algae in rivers and streams

Both benthic algae and phytoplankton in rivers live in highly variable habitats. To help understand how algae are regulated by their environment, we should focus our attention on algae at a specific location. There we find five fundamental processes affecting how much and which algae occur in that location: immigration, reproduction, grazing, emigration, and death (Fig. 3; Stevenson, 1997). Immigration of cells or groups of cells into the space provides the initial colonists as well as ongoing replacement for cells that are continuously leaving the habitat via loss factors, such as grazing, emigration (drifting and sinking), and death. Reproduction by cells within that location, as well as immigration, affects accrual positively. Algal metabolic processes, such as photosynthesis, respiration, and nutrient uptake, directly affect reproduction. These fundamental processes determine the structure of algal communities in rivers: the biomass of individual species as well as all algae at a location, and therefore species composition.

Both abiotic and biotic factors either directly or indirectly regulate the five fundamental processes of cell accrual. These include: (1) light intensity and duration, (2) nutrient concentration, and density of grazers, bacteria, and viruses that have direct effects, as well as (3) flood frequency, (4) climate and (5) geology that have more indirect effects. Many patterns are possible because they depend on the relative magnitude of each of the biological processes and their many direct and indirect environmental determinants. Relating patterns in algal biomass and species composition to the biological processes and environmental factors in rivers requires, in most cases, application of non-equilibrium models in algal ecology.

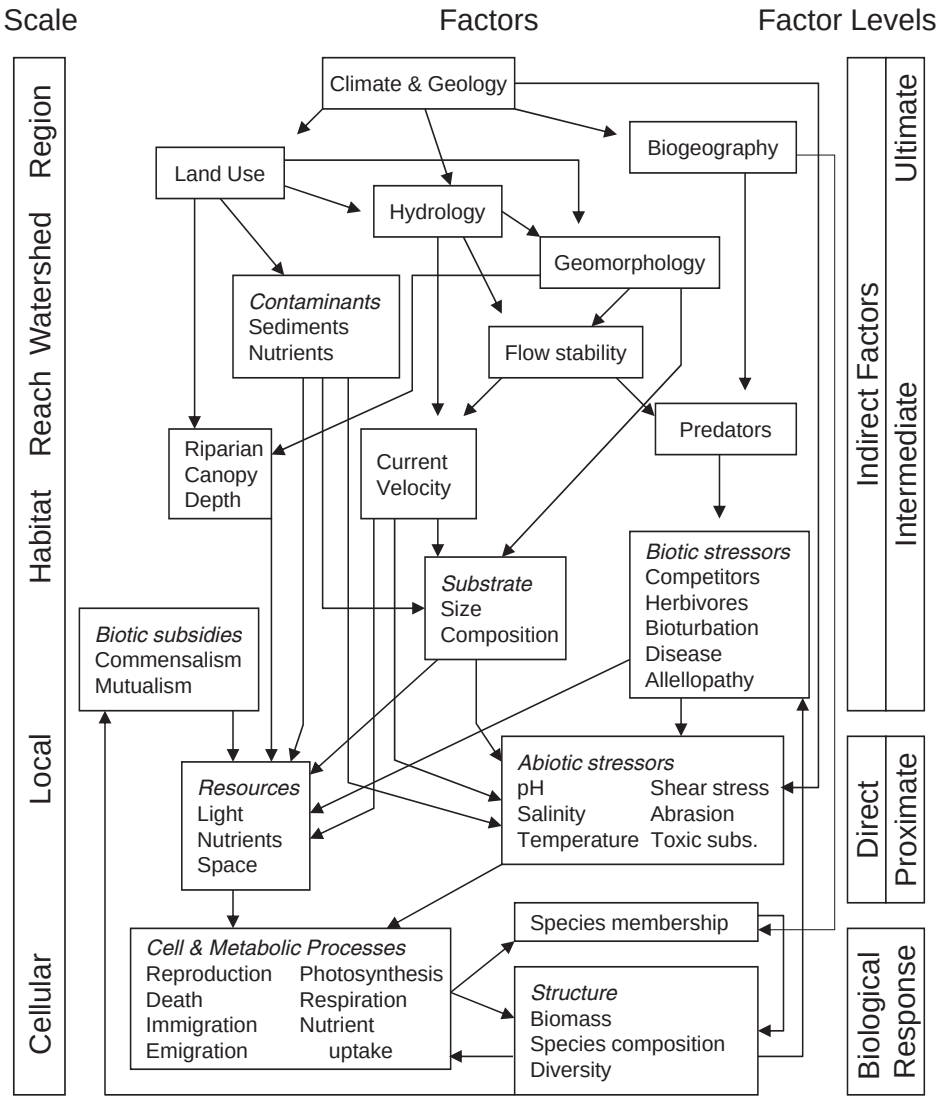

Fig. 3 Hierarchical interrelationships among proximate, intermediate and ultimate determinants of benthic algal structure and function. The relative spatial scale is shown at the left. Modified from Stevenson, 1997.

Factors that regulate algae in rivers operate at different spatial and temporal scales (Fig. 3). The processes of accrual and losses of cells at a specific location operate at the cellular or local spatial scale and reflect the biological responses to other ecosystem factors that are regulated at larger spatial and temporal scales. Abiotic factors that directly affect algae include both resources and stressors, such a nutrients and light versus pH, salinity, shear stress, and heavy metals. Biotic factors can also be classified as positive or negative, and they include commensalistic and mutualistic interactions, as well as competition, predation, disease, and allelopathic interactions. At the habitat scale, riparian canopy, current velocity, and substrate presence and size affect algae, but primarily by mediating the direct biotic interactions, resources, and stressors. At watershed and regional scales, climate and geology ultimately regulate land use, hydrology, and geomorphology of rivers. They also regulate species biogeography and their availability to colonize rivers. The spatial and temporal hierarchy of these factors will regulate the complexity of possible interactions and facilitate understanding and prediction of local conditions and resulting algal structure and function in rivers and streams.

Local abiotic factors

Resources

Algal reproduction can be regulated by light, nutrients, and space. A variety of metabolic processes have similar functional responses to light intensity and nutrient concentration. Metabolic rates increase relatively rapidly in response to light and nutrient increases at low levels of resource availability, but eventually saturate at high levels of resources and respond little to further increases (Fig. 4A). Light has the possibility of having an additional negative effect at very high intensities due to photoinhibition processes (Boston and Hill, 1991). Light intensity strongly regulates photosynthetic rates and carbohydrate synthesis. Nutrient concentrations regulate their uptake rates, use in protein and lipid synthesis, and cell reproduction (Bothwell, 1989; Rier and Stevenson, 2006).

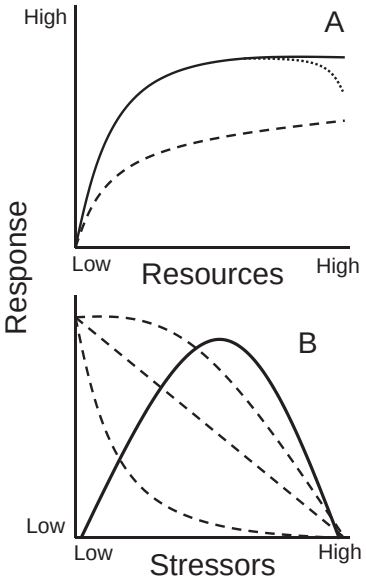

Fig. 4 Responses of algae to abiotic factors. (A) Resources have asymptotic responses with rapid increases to saturating levels (solid line). Light can have a negative effect at very high levels (dotted line). Density of algae reduces supply rates and response of algae to given resource levels (dashed line). (B) Stressors negatively affect algal processes either non-monotonically like temperature (solid line) or monotonically (family of dashed lines), when there is no positive effect at low levels of stressors.

Variation in light and nutrients does affect algal biomass, metabolism, and species composition in streams and rivers (Biggs and Close, 1989; Guasch et al., 1995; Rosemond et al., 2000). High light intensity and nutrient concentrations are required for accrual of high algal biomass on substrata or in the water column. Although reproduction or algal growth saturates at low light and nutrient levels, self-shading and reduced nutrient transport (when eddy mixing and diffusion are less than nutrient uptake rates) limit resource supply at the local scale as algae accumulate on substrates (Stevenson and Glover, 1993). For example, phosphorus limitation of thin biofilms of diatoms requires concentrations lower than 5 $\mu g\ L^{-1}$ PO^4-P, whereas 30 $\mu g\ L^{-1}$ is required to saturate growth of thicker mats (Bothwell, 1989). As algal biomass increases, more light as well as nutrients are required to produce the metabolism, growth, and accrual of high biomasses in relatively short periods of times (Hill and Boston, 1991; Dodds et al., 1999). However, high algal biomasses can accumulate over longer periods of times at lower light and nutrient concentrations in hydrologically stable habitats, such as some springs, where disturbance does not interrupt accumulation processes. Thus, this process-based approach helps us understand how we can have high algal biomass at intermediate as well as high nutrient concentrations.

Experiments using nutrient diffusing substrates and dosing in experimental streams show that both nitrogen and phosphorus can limit algal growth in streams (Fairchild et al., 1985; Bothwell, 1989; Pringle, 1990; Rier and Stevenson, 2006). There is also some evidence that micronutrients can limit growth of some algae that need large amounts of an element for enzymes in critical processes, such as Fe availability for nitrogen fixation by cyanobacteria. In published meta-analyses of this research with benthic algae, the trend is for about half of all streams being nutrient limited, and of those streams that are nutrient limited, a quarter are limited by P, a quarter are limited by N, and about half are co-limited by both N and P (Francoeur, 2001). In streams with high accumulations of diatoms, Si may become limiting for both benthic and planktonic algae. Nutrient ratios have been used successfully to predict which lakes are limited by N or P, but this approach has not been as successful in streams where nutrient concentrations in the water column are highly variable, supply rates may differ with time, groundwater supplies are not often accounted for, and differential cell leakage of N versus P over time may increase relative N demand.

Much less is known about space limitation than nutrients and light. Space limitation has not been evaluated well because it is difficult to isolate space versus density-dependent interactions. Space limitation applies most directly in the case of algae that must attach directly to substrates, such as the diatom *Cocconeis*. Space becomes an indirect factor or resource when algal biomass accumulates on substrata and reduces light and nutrient supply rates to cells in benthic algal mats. Space limitation can be relieved for algae in general when epiphytic microalgae can grow on macroalgae, such as *Cladophora*, but some species may be excluded from this extra space because they cannot attach well to *Cladophora* even though they can attach to benthic mineral substrates.

Species composition as well as biomass and function vary among rivers, corresponding to differences in light and nutrient concentrations (Kelly, 1998; Pan et al., 1999). Species require different amounts of nutrients and light to survive. Thus, low levels of nutrients and light constrain species membership to those species that can survive in these resource-stressed habitats. High nutrients or light enables species with requirements for high resource levels to colonize a habitat with high nutrient or light. Some experiments, theory, and now some field evidence suggest that tradeoffs for species do exist between being able to grow fastest in low and high nutrient concentrations, which would help explain the dramatic changes in species composition along nutrient gradients.

Diversity is complexly related to resource availability. As resources increase, more algal species can invade and successfully reproduce in the river based on physiological requirements (Passy, 2008). Evenness of species abundances change non-monotonically with increasing nutrients, from low to high to low evenness as nutrient concentrations increase. Evenness is low in low nutrient conditions because only a few species are adapted to grow well in low nutrient concentrations. As nutrients increase, more species can invade the habitat and their growth rates increase faster than species adapted to low nutrients; therefore, evenness of species abundances is highest when evenness of reproduction rates of species are highest. At high nutrient concentrations, growth rates and species abundances become uneven again as some species can grow faster than others in high nutrient concentrations. Many models predict that numbers of species (richness) would follow the same pattern as evenness along resource gradients. These models predict richness would increase as the habitat became more available to more species, i.e. the species that require higher nutrient concentrations to reproduce sufficiently fast to persist in the habitat. Species richness could decrease in high nutrients conditions because one or more resources became depleted, competitive relationships shift, and some species are competitively excluded. Observations of this pattern have not been satisfactory because estimating species richness of organisms is difficult in habitats where they are so abundant and difficult to observe.

Stressors

Stressors are environmental factors that can have negative effects on metabolism and other attributes of species' performance. Stressors affect reproduction according to one of two groups of response functions (Fig. 4B). One group consists of negative linear and non-linear responses in which there is no or very little positive effect of a stressor on species performance. Fine sediments that bury cells and toxic inorganic and organic substances are examples of factors with monotonic negative effects. Suspended sediment has strong indirect effects on phytoplankton, by reducing light transparency. Temperature and the ionic factors (salinity, pH, and alkalinity) produce non-monotonic effects on species performance. Algal performance is optimal at some intermediate level of these factors because high and low levels of temperature, salinity, pH, and alkalinity limit species performance for one reason or another. Temperature, for example, stimulates metabolism as temperature increases from relatively low to intermediate levels as kinetic energy and metabolic rates increases. However, high temperatures denature enzymes and reduce metabolic function. Salinity, pH, and alkalinity probably affect enzymes and enzyme-mediated processes most, for which an intermediate condition is optimal for species.

Because almost all algal species are negatively affected by sediments and toxic substances, biomass of algae can be negatively affected by these stressors. Similarly, the negative effect of high temperatures is "toxic" for most algae above 30 °C, except for some cyanobacteria that tolerate temperatures as high as 55 °C in hot springs. So high temperatures may reduce algal biomass, as low temperatures may. However, algal species are adapted to an unusually wide range of pH, alkalinity, and salinity, so that biomass is only affected by the ionic factors in extreme conditions. Throughout much of the range of the ionic factors, species composition differs with varying ionic factors, but functional redundancy is able to maintain community-level reproduction and biomass.

Local biotic factors

Biotic factors can have positive or negative effects on algae in rivers (Fig. 3). We know relatively little about commensalistic and mutualistic interactions, but some examples do exist. One example of commensalisms would be the attachment of some benthic diatoms on stalks of other diatoms, which provides an advantage to species that can attach to stalks and has little negative effect on the stalked diatoms. Diatoms with endosymbiotic cyanobacteria provide an example of mutualistic interactions (DeYoe et al., 1992; Peterson and Grimm, 1992). Of the negative interactions, much more is known about herbivory and competition versus allelopathic interactions and disease-like effects of fungi, bacteria, and viruses. Many have hypothesized that the latter two biotic stressors should have great effects in dense microbial assemblages like benthic algae. They are known to be important in lake and ocean phytoplankton. Unusual white circles in periphyton with high numbers of bacteria and fungi indicate "disease," but little investigation has pursued this line of research.

Competition is probably a more important determinant of algal biomass, function, and species composition for benthic algae than for phytoplankton. Phytoplankton seldom accumulate to sufficiently high densities to deplete nutrient concentrations in rivers because of the relatively short hydrologic residence times of these organisms in their habitat. However, competition may be important in very slow flowing, lake-like rivers where residence time is sufficiently high to deplete nutrients or light by biological uptake or shading. These are the processes that are thought to be important in benthic algal communities (McCormick and Stevenson, 1991). If species membership is constrained to diatom dominated communities, peak biomass of communities may be constrained by light and nutrient depletion. We know that light and nutrient availability within benthic algal mats decreases with increasing density; less light penetration and decreasing nutrient transport rates and cell nutrient content have been documented as diatom biomass increases on substrata. Per capita rates of metabolism and reproduction decrease with increasing benthic algal biomass. Species composition changes with increasing biomass of diatoms on substrata. All indicate autogenic changes in environment that are consistent with strong competitive regulation of benthic algal communities (Peterson et al., 1994).

Herbivory is also an important determinant of algae in rivers (McCormick, 1994; Lamberti, 1996). It is more frequently important for benthic algae than phytoplankton because of the lack of time for zooplankton to accumulate in the water column of rivers. Low disturbance frequency by floods and drought is important for determining whether herbivory is important for benthic algae, too. When river conditions allow herbivores to accumulate to high densities, they can regulate biomass, function, and species composition of benthic algae in rivers. The importance of zebra mussels in some rivers is a good example of herbivores affecting

river phytoplankton, but examples of zooplankton regulation are not common (Smith et al., 1998). Filter feeding invertebrates like blackflies and net-spinning caddisflies may also be important regulators of suspended algal abundance in streams, but this is not well understood.

Aquatic insects, snails, and some fish consume benthic algae, but aquatic insects and snails are the most important in most situations. Protozoa have also been shown to consume benthic algae (McCormick, 1991), but their importance does not seem to be as great as the much larger cased caddisflies, mayflies, and snails that graze algae from substrata. These invertebrates can constrain diatom biomass to very low levels. Many of them can consume filamentous green algae during early stages of growth, but not after filaments have exceeded the size that can be controlled, largely because of the small size of herbivores and their mouthparts. Herbivores seem to avoid consumption of filamentous cyanobacteria, pushing it back from actively grazed areas or knocking it off the substrate. In addition, they selectively graze overstory versus understory diatoms (stalked and filamentous forms versus tightly adnate and prostrate forms). Although grazers consume algae, not all are killed. Estimates of algae passed alive and viable through guts of aquatic invertebrates often exceed 50% (Peterson, 1987; Peterson et al., 1998). In a sense, grazing of cells removes cells from the substratum and either causes death or emigration of the cells downstream when they are egested alive. Because of the importance of grazing as a process of removing algae from a location and conceptually within food webs, it merits inclusion as one of the five fundamental processes.

Bioturbation is another process that affects benthic algal biomass accumulation. Invertebrates, fish, and terrestrial animals are common sources of disturbance of benthic algae as they move through streams. Diel patterns in algal drift are observed in some streams that correspond to the dawn and dusk activity patterns of aquatic invertebrates (Stevenson and Peterson, 1991). Paths of disturbed benthic algae in shallow riffles can be observed in deeper upstream-downstream channels where fish have moved from pool to pool. Movement of fish in pools disturbs the development of periphyton and clouds the water. Raccoons and larger animals, such as manatees, crocodiles, hippopotamus, and humans probably have great effects on benthic algae when moving; but these effects have not been quantified.

Habitat scale factors

Riparian canopy, depth, substrate, and current velocity vary among habitats within a reach and have indirect effects on the five fundamental algal processes (Fig. 3). Covariation among depth, substrate, and current velocity are regulated by the riffle-pool structure carved in most rivers. Coarser substrates are found in the shallow, high velocity riffles. Finer substrates are found settling in the deeper, slow velocity pools. Riparian canopy and depth regulate light availability, whereas current velocity and substrate have relatively complex effects that warrant further discussion.

Substrate is very important for algae as a stable surface for attachment and growth and potentially as a source of nutrition. Some algae have special morphological adaptations for attaching to substrata, such as the raphe and mucilaginous stalks and tubes of diatoms. Many filamentous green algae produce specialized cells that attach to a substrate and then form filaments when they divide. The species composition of true river phytoplankton, i.e. not just benthic algae dislodged from substrata and suspended in the water, is very different than the benthic algae. Surprisingly, the adaptations that so clearly separate species occurring in the phytoplankton and benthos are poorly understood, except for benthic algae and not phytoplankton having morphological adaptations that enable their attachment to substrata. Given the great differences in habitat conditions when suspended in the water versus attached to substrata, such as greater ranges in current velocity and denser packing of cells for benthic algae, great physiological differences must accompany these morphological adaptations.

For benthic algae, size, roughness, and nutritional value of substrata may have great effects (Stevenson and Hashim, 1989; Schneck et al., 2011). The smallest substrates, silt and organic sediments, are smaller than the smallest algal cells. So, organisms that live in this habitat tend to be large and motile, such as the diatoms *Nitzschia* and *Surirella* or the flagellated euglenoids. Sands, slightly larger and inert, are large enough for attachment by small diatoms in streams. During hydrologically stable periods, other algae can colonize sands, but only small diatoms can survive in the crevices of individual sand grains when the sands tumble across the bottom of streams. As rock substrates become larger, they tend to become more resistant to hydrologic disturbance. Almost all pebble and larger substrates can support diverse diatom assemblages. As substrates become larger and more stable, they can support luxurious growths of filamentous green algae that require longer stable periods for colonization by spores and growth of filaments. Woody debris and plants are other common substrates in rivers, and both may have nutritional properties that affect algae. Wood provides nutrition to bacteria, which may actually have a negative effect on benthic algal colonization because of competition with bacteria for nutrients (Tank and Dodds, 2003). Plants leak nutrients that become available to epiphytic algae attached to them (Burkholder et al., 1990).

Current velocity has watershed- and habitat-scale effects on algae. For phytoplankton, current velocity determines residence time of water and algae in the river and the time for cells to accumulate (Reynolds and Descy, 1996; Yang et al., 1997). For benthic algae, increases in current velocity during rain events may be sufficient to scour algae from stable substrates. Higher velocities can disturb the substrate in riffles and cause severe scouring of algae from substrates (Biggs and Thomsen, 1995). The time between scouring events provides the time for recovery of benthic algal communities (Biggs, 2000). Thus, variations in current velocity at the watershed scale determine the frequency and intensity of disturbance and are important, ultimate determinants of non-equilibrium ecological dynamics of algae in rivers.

The habitat-scale effects of current velocity on benthic algae are relatively well understood, compared to effects on river phytoplankton. Eddy mixing of the water column surely slows sinking of phytoplankton and shear in the water column may

reduce nutrient depletion in waters surrounding cells. One of the important premises of current effects on algae is that, in still waters, algae develop nutrient-poor shells of waters around cells. This shell develops because nutrient uptake rates from waters around cells exceed diffusion rates of nutrients into the shell. Water near surfaces, whether cell or substrate surfaces, has different physical properties than water away from these surfaces. Although measurements of nutrient concentrations in these 1–2 um thick layers around cells has not been practical, many observations between current velocity, metabolic rates, and transport of nutrients through periphyton mats indicate that these shells do exist. Thus, as current velocity around cells increases, the shearing of layers of water around cells increases and disrupts this layer of nutrient-poor (and potential waste-rich) water from around cells, thus increasing nutrient delivery.

Habitat-scale effects of current velocity on benthic algae have both positive and negative effects. While the shear stress of current velocity decreases immigration rates and likely increases emigration rates from habitats with moderate and fast current velocities, the increased physical mixing of water through attached masses of microalgae or macroalgae stimulates metabolic rates (McIntire and Phinney, 1965; Stevenson, 1984). Concentration gradients in micro- and macroalgal communities can cause severe nutrient depletion within this microhabitat. Assuming a common 10–30 cm s^{-1} range in velocities from slow (pool) to fast (riffle) current habitats, profound differences in current effects on immigration and reproduction help relate the patterns of benthic algal colonization after flood disturbance to these processes. Initially, algal biomass and accrual rates will be slower in riffles than pools because immigration is the dominant process affecting colonization when algal biomass on substrates is low, for example $5–10 \times 10^3$ cells cm^{-2}. As more cells accumulate, reproduction becomes more important than daily immigration of cells and the positive effects of current outweigh the negative effects (Stevenson, 1996). So, we eventually observe higher algal biomasses in riffles than pools, even though that pattern may not be evident immediately after flood-related disturbances.

Reach to regional scale factors

Whereas reach or segment scale factors (such as hydrology, channel geomorphology, flow stability, and stream size) interact to shape habitat structure and local abiotic conditions, regional processes associated with climate, geology, and biogeography regulate the more general spatial and temporal patterns of algae in rivers (Fig. 3). Climate and geology also affect human activities in watersheds, which have profound effects on contaminants in streams, channel geomorphology, and hydrology. Extensive discussion of human effects on algae in rivers is beyond the scope of this chapter. Here, I want to synthesize the review of algal ecology in rivers by describing three common large-scale patterns: seasonal and longitudinal patterns of phytoplankton in rivers, algae and the river continuum hypothesis, and the effects of disturbance on benthic algal-grazer interactions.

Phytoplankton in rivers has a distinct longitudinal pattern that varies in magnitude with seasonal variations in discharge (Stevenson and White, 1995; Reynolds and Descy, 1996). Suspended algal densities are usually low in headwater sections of rivers and largely composed of algae that have emigrated from benthic substrates and are entrained in the water column. As water flows downstream, species better adapted to life in the water column immigrate into a mass of water and stay in it as it moves downstream. Gradually, as the river becomes larger, fewer benthic species are suspended in the water than planktonic species. The longer that mass of water resides in the river before reaching a lake, estuary, or ocean, the higher the biomass of algae in the water column will become. More phytoplankton accumulates in rivers of geologic regions where rivers have low gradients versus those with high gradients. Climate determines the time of year and the extent of hydrologically stable periods when algae can accumulate in streams. In climates with periodic storms during the dry season, high discharge events may disrupt the development of phytoplankton communities. During long dry and hot periods, high and often problematic biomasses of algae can develop with sufficient quantities that deoxygenation occurs and toxic algae accumulate.

The river continuum hypothesis (RCC, Vannote et al., 1980; see Dodds and Maasri this volume) proposes the ecology of rivers is regulated by upstream-downstream patterns in the hydrogeomorphology and connectivity within rivers. Although originally defined for free-flowing rivers in temperate climates with forested landscapes, the model has been adapted for dammed rivers and many ecological regions. The original model described how narrow streams in forests would be covered by a riparian canopy that would limit light, and therefore, algal production. As streams became wider downstream, light would become more available and benthic algae would be able to accumulate. Correspondingly, the base of the food web was predicted to shift from allochthonous detritus in the headwaters to autochthonous primary production in the mid-reaches of the river. Farther downstream as algae became entrained in the water column and depth increased, autochthonous productivity in rivers would shift from benthic to planktonic algae. Although this upstream-downstream pattern in hydrogeomorphology and connectivity may vary greatly among regions, it tends to vary with climate and geologic conditions of a region, and to some extent with local landscape conditions. Most differences occur in headwater regions where the river may not have accumulated sufficient erosional power or geology constrains their ability to carve channels and broad floodplains. Headwaters vary from springs arising in deserts to high gradient channels in mountains or low gradient channels emerging out of wetlands. Each of these provides a different starting point in downstream regulation of the ecology of rivers and very different environments for algae.

One of the challenges for understanding the ecology of algae in streams has been understanding the relationship between resource availability and disturbance intensity. This challenge underpins: (1) the prediction of top-down or bottom-up regulation of river food-webs, (2) relationships between nutrients and algal biomass for management of these important contaminants of streams, and (3) biodiversity of algae in streams. Increases in nutrient concentrations should result in an increase in algal biomass of streams. Increases in hydrologic stability also should result in increases in algal biomass of streams because algae have, on average, longer periods of time to accumulate between disturbances. Thus, in streams that are relatively hydrologically stable, we

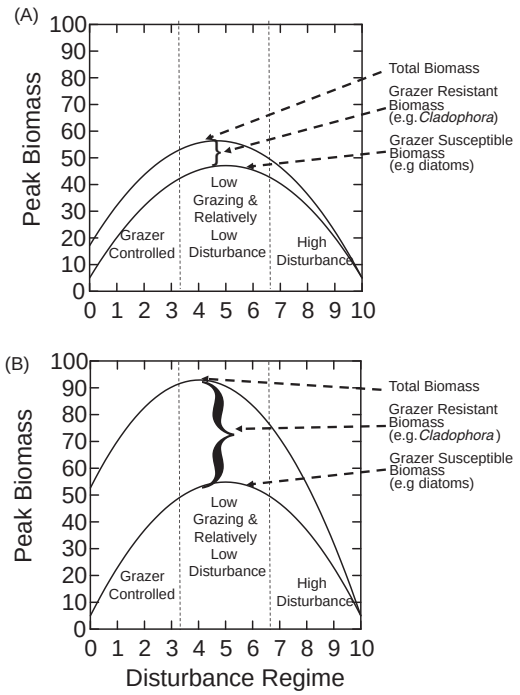

Fig. 5 Conceptual model of effects of physical disturbance regime on peak biomass of grazer susceptible algae, grazer resistant algae (such as *Cladophora*), and all benthic algae in relatively low (A) and high (B) nutrient conditions. Grazer density is hypothesized to be high in low disturbance regimes, where grazers regulate accumulation of grazer-susceptible algae (such as diatoms). In high nutrients and low disturbance, grazers cannot regulate density of grazer resistant forms, such as *Cladophora*. Grazer density decreases with disturbance (Riseng et al., 2004) and enables accrual of both grazer-susceptible and resistant forms in habitats with intermediate levels of disturbance. In high disturbance, accrual of both grazer-susceptible and grazer-resistant forms are constrained by physical disturbance. From (Stevenson et al., 2006).

should have greater responses of algae to nutrients than in frequently disturbed streams. This is what we see in New Zealand streams where hydrologic stability ranges from great to average on the global scale (Biggs, 1995a,b). However, in the middle of North America, we see the opposite end of the disturbance continuum. Algae in low disturbance streams respond relatively little to increases in nutrient concentrations compared to relatively high disturbance streams in this region. Here, accrual of algae is constrained by high grazing pressure in hydrologically stable streams (Riseng et al., 2004, 2010). Flood and drought disturbances in relatively hydrologically variable streams of this region constrain grazer abundances, so grazers no longer regulate algal biomass in the most hydrologically disturbed regions of central North America—which compared to the global range of possibilities, is only intermediate on the hydrologic disturbance scale (Stevenson et al., 2006). Globally, we find complexity arising from the non-linear and multi-trophic level effects of disturbance on algal-resource interactions. Herbivores and disturbance constrain algal response to nutrients in the most highly hydrologically stable habitats and the most hydrologically variable habitats, respectively; and algae respond most to nutrients at intermediate levels of disturbance when they have sufficient time to recover from disturbance, but not so much time that invertebrates can also recover and consume the algae (Fig. 5).

Summary

Interactions between algae and their environment are complex, yet predictable based on accurate linkage of processes, scale of determining factors, and algal attributes. Although much is yet to be understood about algae in rivers, we have learned much by a marriage of three basic scientific approaches: large-scale field observations from environmental monitoring projects, experiments, and process-based models. Study of algae in rivers provides a model for how to understand complex systems that are tightly coupled to human effects on the environment.

Knowledge gaps

1. Future work in rivers should address:
   a. the importance of the biodiversity of river algae and ecosystem function,
   b. how ecological systems respond to environmental change,
   c. the role of dispersal in ecological resilience and stream restoration and
   d. the importance of algae in ecosystem goods and services

2. The lessons that we have learned in the study of algae in rivers should be applied to studies of algae in other habitats as well, such as:
   a. wetlands,
   b. terrestrial habitats in rainforests, and
   c. the arctic tundra.

Glossary

Allen Curve A plot of numbers in a cohort vs. individual growth; the area under the curve is proportional to secondary production.
Allen's Paradox An imbalance between estimated predator consumption of prey and prey production whereby estimated prey production does not appear sufficient to support local predator production.
Annual P/B Annual production to biomass ratio, which is related to individual growth rate.
Cohort A group of individuals that begin life (hatch or are born) at about the same time.
CPI Cohort Production Interval correction, which is used to standardize a secondary production estimate to 1 year; used for animal species with life cycles that are less than or greater than 1 year.
Production efficiency *Net production efficiency* is the efficiency of an animal at converting assimilated materials into tissue production; *gross production efficiency* is the efficiency at converting ingested materials into production.
Secondary production Tissue elaboration by heterotrophs regardless of fate (e.g., whether it is eaten, dies, is molted, etc.)
Voltinism Life cycle length relative to a year; a *univoltine* taxon has a 1 year life cycle.

Introduction

Secondary production is the generation of tissues by heterotrophs, regardless of the fate of the generated materials; death, consumption by predators, molting, etc. do not matter, as the tissue was produced at some point before any of those occurred. Secondary production is ultimately the result of a series of ecological efficiencies, starting with the assimilation efficiency (AE) of consumed food, and then the efficiency at which assimilated materials are converted to production, or net production efficiency (NPE). The overall efficiency of conversion of ingested materials to production is the gross production efficiency, or GPE. These efficiencies, and thus secondary production, are influenced by a wide range of intrinsic and extrinsic factors spanning scales from individuals and populations, to communities and habitats, to regional climate differences. Secondary production has been referred to as the "ultimate dynamic variable" because it integrates all elements of fitness, including abundance, biomass, growth, survival, and other important population metrics in to one value (Benke, 1993). Secondary production studies draw upon elements of both population biology and ecosystem ecology (Benke and Whiles, 2011).

The two main components of secondary production are biomass and individual growth rate. As such, biomass can be considered a predictor of secondary production in some cases, but not in cases where there is great disparity between biomass and individual growth rate. For example, high biomass of adult unionid mussels in a mussel bed in a river would not necessarily translate into high production because of slow individual growth rates of the long-lived adult mussels. Conversely, moderate levels of biomass of dipteran (true flies) Chironomidae larvae in sediments of a stream pool can result in relatively high production because of rapid individual growth rates. Thus, the occasional use of biomass as a proxy for production can be inaccurate; however, empirical estimates of production, rather than application of statistical models based on biomass, temperature, and literature values of P/B, are better. Obviously, the highest production estimates are associated with animals with both high biomass and high individual growth rates.

The annual production to biomass ratio (mean annual production divided by mean annual biomass), a measurement of turnover, is a proxy for individual growth rate. Annual P/B values vary tremendously across stream-dwelling taxa as a function of individual growth rates and life histories. Small, rapidly growing taxa often have annual P/B values that exceed 10, and in some extreme cases exceed 100. In contrast, slower growing species may have values around 1–2, and even <1. Many univoltine stream invertebrate taxa with moderate growth rates have annual P/B values ~5–6. Annual P/B values can be used to estimate actual tissue turnover times by dividing the number of days in a year by the P/B. For example, a stream invertebrate with an annual P/B of 5 will have a tissue turnover rate of 365/5 = 73 days for complete turnover of the tissues as the individual grows.

Methods for estimating secondary production

Despite some of the challenges of generating secondary production estimates, stream ecologists have recognized the importance of these estimates for decades. Overall, there is a strong bias toward aquatic habitats in the secondary production literature (Benke and Whiles, 2011), and this is likely related to interests in fish production for food and sport, and the associated production of fish food. Accordingly, development of many of the methods for estimating secondary production were based in aquatic habitats and focused on fishes and their prey (Ricker, 1946, 1975; Waters, 1977). In fisheries, secondary production methods often focus on mass-balance bioenergetic approaches based on metabolic and ecological efficiency estimates for organisms. Here, we focus on more general, ecosystem energy flow approaches that are commonly used for studies of invertebrates and that dominate the literature on secondary production in streams. Along with invertebrates, these approaches have also been applied to fishes (Huryn, 1996) and amphibians (Colón-Gaud et al., 2009) in streams.

While many relatively simple methods for estimating primary production exist, and thus primary production estimates for streams are relatively common, estimates of secondary production, particularly for whole communities, are limited. Estimates of secondary production require estimates of abundance and biomass through time, size-specific individual mass, and depending on the method, growth rates or population age or body size structure estimates through time. As such, secondary production estimates for systems that are difficult to sample (e.g., large rivers) and for taxa with rapid generation times (e.g., many small invertebrates) or complex life cycles that include metamorphosis and/or resting stages (e.g., many insects and amphibians) are limited in the stream ecology literature. However, if the proper information is available, reasonably accurate estimates of secondary production for many systems and taxa can be easily generated.

The common methods for secondary production studies in streams track changes in density and individual mass in a cohort (Benke and Huryn, 2017). The relationship between cohort density and individual mass over time can be depicted with an Allen curve (Allen, 1951) (Fig. 1). This curve shows production of a cohort for a given time interval (the trapezoid underneath the *Allen curve* defined by rectangle A + triangle B in Fig. 1), which is the biomass produced by those that survived (A) and those that died (B) over the sampling interval. Total production by the cohort is the total area under the Allen curve. The Allen curve is useful for visualizing secondary production. For example, if there were no mortality over time, secondary production would be the entire area of the plot underneath the dotted line in fig. 1.

The area representing biomass production under an Allen curve during a time interval can be estimated from densities and individual mass by multiplying the average number of individuals during the time interval by the change in individual mass:

$$\frac{N_t + N_{t+1}}{2}(W_{t+1} - W_t)$$

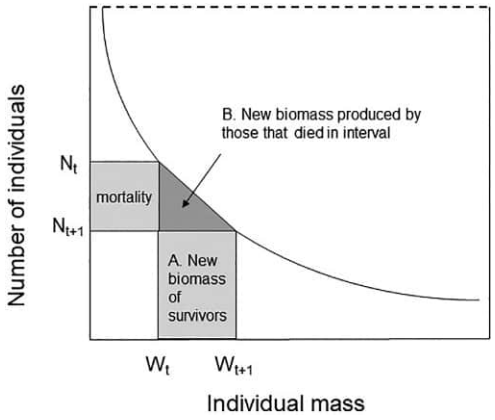

Fig. 1 An Allen curve showing relationships between abundance of individuals in a cohort and individual size over time. N is number and W is individual weight or mass; subscript t and t + 1 indicate points in time. Rectangle A and triangle B together represent production for the time interval depicted. If there was no mortality over time, secondary production would be the entire area of the plot underneath the dotted line.

Total Mg m^{-2} $year^{-1}$							256.0

This species has a 1-year life cycle. Dates are days when samples were collected; May is the start date because this is when recently hatched larvae first appeared. Maximum larval size was estimated at 14.8 mg on April 27, but densities at this time were ~0.

Data are from Ross DH and Wallace JB (1981) Production of brachycentrus-spinae ross (trichoptera, brachycentridae) and its role in seston dynamics of a southern appalachian stream (USA). *Environmental Entomology* 10: 240–246.

Where N_t is the number of individuals at the beginning of the time interval and N_{t+1} is the number at the end of the interval; likewise, W_t is average individual weight at the beginning of the interval and W_{t+1} is average individual weight at the end. This yields production for a given time interval; total production is the sum of the interval values (Table 1). This method for estimating production is called the *increment summation method* (Waters, 1977; Benke and Huryn, 2017). It is one of the so-called cohort methods and is considered relatively accurate but can only be used when a cohort can be followed through time; this is often not possible because of sampling design and/or life history characteristics (e.g., rapid, asynchronous development of cohorts in a population).

The instantaneous growth method can often be used when cohorts cannot be followed. Only estimates of interval average biomass and individual growth rate are needed for this method. Biomass estimates are easily obtained from field measurements but overlapping generations and/or rapid generation times can make estimation of growth rates difficult. Approaches include laboratory rearing studies, caging individuals in the field, or marking and recapturing individuals, all of which can generate reliable individual growth rate estimates. Changes in individual weight over time are then used to estimate instantaneous growth as follows:

$$G = \frac{\ln(w_{t+1}) - \ln(w_t)}{t}$$

where G is the instantaneous growth rate, W_t the individual weight at the beginning of the interval, and W_{t+1} the individual weight at the end of the interval. The instantaneous growth rate has the units of $time^{-1}$, with time usually in $days^{-1}$.

Once G and average biomass for the interval is obtained, interval production is estimated as:

$$P = G * \overline{B} * t$$

Where P is interval production, $\overline{B}$ is average biomass during the interval, and t is time.

As an example, for the first interval of May 18—June 1 from Table 1:

$$G = \frac{ln(0.057) - ln(0.021)}{14} = 0.0714/\mathrm{d}$$

Using biomass estimates for the same interval (9.44 mg m^{-2}), production for the interval was $P = .0714 * 9.44 * 14 = 9.43$ mg m^{-2}. This method requires less detailed information and is easier to calculate, but production estimates using the instantaneous growth method are generally considered less precise than those obtained using cohort approaches such as the increment summation method. In this case, the estimates for the first sampling interval obtained with the instantaneous growth and increment summation methods are close, but this is not always the case.

The size-frequency method has become increasingly common for estimating secondary production because it can be used in situations when cohorts can or cannot be followed. This method involves constructing an "average" cohort from sampled size

classes, much like population ecologists use in constructing life tables (Benke, 1979). Subsequent calculations are similar to those of the increment summation method, except that interval production estimates, which in this case are size class intervals, are multiplied by the total number of size classes because they are not actually being followed through time. The production estimates for each size class interval are then summed to estimate total annual production for taxa with 1 year life cycles. Those with shorter or longer life cycles can be expressed as production over the length of the life cycle, or they can be standardized to 1 year using a cohort production interval (CPI) correction (Benke, 1979). The CPI is obtained by simply dividing 1 year by the length of the life cycle, generally in months. For example, a taxon with a 10 month life cycle would have a CPI correction of $12/10 = 1.2$, so the production estimate for this taxon would be multiplied by 1.2 to estimate annual production. Details on the size frequency method and other production methods are presented by Benke and Huryn (2017).

Estimates of the CPI should be as accurate as possible given that the CPI can greatly influence annual production estimates. The most accurate CPI estimates come from detailed studies of life histories in the habitats sampled or similar habitats.

Statistical considerations

Replication and statistical analyses are inherently limited in secondary production studies, particularly in lotic systems that vary over time and are difficult to replicate. While in some cases, such as experimental manipulations in artificial streams, replication can be achieved and parametric statistical approaches applied. An unsatisfying end result of many secondary production studies is a single value with no associated error estimate. As such, alternative methods to estimate error in secondary production estimates have been developed, and these generally involve bootstrapping, which is a non-parametric re-sampling procedure. For this procedure, all data are randomly resampled with replacement until multiple (often 1000 or greater) data sets are produced. These are then used to produce vectors of estimates for each parameter (e.g., abundance, biomass, production), and then a mean and confidence interval are calculated. Huryn (1996) provides some details on these procedures.

Spreadsheet based methods are commonly used for estimating secondary production and performing bootstrap analyses, but some investigators have developed R code for both. Venarsky et al. (2018) provide descriptions of R code they used for both secondary production estimates and bootstrapping procedures to examine stream invertebrate production along a stream disturbance gradient in the US Rocky Mountains.

Production and energy flow food webs

Secondary production estimates, along with the ecological efficiencies discussed earlier in this chapter, can be used to examine energy flow paths and the trophic basis of production. Using these estimates, the amount of food consumption required to sustain the observed level of production estimated. For example, a population of detritivorous stream insects with 5 g m^{-2} y^{-1} production, and an assimilation efficiency of 20% and net production efficiency of 50%, consumes $5/(0.2^{*}0.50) = 125$ g m^{-2} y^{-1} of detritus. This information is obviously valuable for examining how invertebrates and other animals contribute to important ecosystem processes such as decomposition and energy flow.

Fecal particles are important components of stream food webs, and these same efficiencies can be used to estimate egestion by a population. For the detritivorous insect population example used above, egestion would be $125 * 0.8 = 100$ g m^{-2} y^{-1} of fecal material, which could contribute greatly to the pool of fine particulate organic material in the stream food web. The 0.8 used in this equation is simply the inverse of the assimilation efficiency (100%—20% = 80%, or 0.8 egested). The low assimilation efficiencies and high consumption and egestion rates of detritivores such as these make them strong contributors to energy flow in streams.

Trophic basis of production values can be used to construct quantitative food webs and analyze energy flow through ecosystems. Such analyses have been used to examine energy flow patterns in systems ranging from tropical headwater streams (Frauendorf et al., 2013; Mello et al., 2020), temperate forested and grassland streams (Benke and Wallace, 1980; Huryn, 1996; Stagliano and Whiles, 2002), and mid to large sized rivers (Cross et al., 2013).

Reported variation in population and whole community secondary production

Compared to other ecosystem functions, such as primary production, which are routinely measured in running waters, secondary production has received relatively little attention. The most recent meta-analyses of published values that explicitly evaluated variation among stream invertebrate populations was published almost three decades ago (Benke, 1993). However, whole community estimates of secondary production have received more recent treatment in the literature (Huryn and Wallace, 2000; Patrick et al., 2019). Using these references as guides, supplemented with some additional sources, here we summarize what is known about variation in estimates of biomass, production, and P/B ratios at the population and community levels. Summarizations of population level estimates are derived from the database assembled by Benke (1993), with additional relevant observations added to provide context regarding developments since then. Summarizations of community level estimates are derived from Huryn and Wallace (2000) and Patrick et al. (2019).

At the population level, estimates of production, biomass, and P/B ratios vary widely within and among taxonomic groups and functional feeding groups (Table 2). For example, among phyla, the mollusks have highest reported mean production (12,553 mg ash-free dry mass (AFDM) m^{-2} $year^{-1}$) and biomass (7073 mg AFDM m^{-2}), but values within this phylum vary widely, ranging from 0.39–659,499 mg AFDM m^{-2} $year^{-1}$ for production and 0.15–160,651 mg AFDM m^{-2} for biomass (Table 2). When population estimates are viewed as simple averages, biomass rankings from highest to lowest are Mollusca > Annelida > Arthropoda > Platyhelminthes, mean production estimates are Annelida > Mollusca > Arthropoda > Platyhelminthes, and P/B ratios are Arthropoda > Annelida > Platyhelminthes > Mollusca. This gives the impression that mollusks and annelids make up the majority of biomass and production in running waters. However, anyone who has conducted work in these systems would rightly view this conclusion as suspect. Biases in the types of studies that are included in the dataset skew the results. Non-arthropod groups are often ignored in studies of invertebrate secondary production, and estimates are usually undertaken only when they obviously make up a large and important part of biomass and production. For example, some of the highest reported invertebrate production estimates come from studies quantifying the effects of the invasive New Zealand mud snail (*Potamopyrgus antipodarum*) on streams in Wyoming (Hall et al., 2006).

Comparative estimates among taxa within Arthropoda may be more meaningful because these are more frequently undertaken by investigators. Across studies, crustaceans have the highest mean reported annual production (Isopoda ~3257, Amphipoda ~8703 mg AFDM m^{-2} $year^{-1}$), followed by Diptera (2605 mg AFDM m^{-2} $year^{-1}$) and Trichoptera (1773 mg AFDM m^{-2} $year^{-1}$). A similar pattern is apparent for annual biomass estimates with the highest mean values again coming from crustacea (Decapoda ~684, Isopoda ~623, Amphipoda ~1879 mg AFDM m^{-2}) followed by Diptera (363 mg AFDM m^{-2}) and Trichoptera (386 mg AFDM m^{-2}). However, patterns of P/B ratios, which reflect individual growth rates, diverge significantly from biomass and production patterns, with highest mean values for Diptera (~29) and Ephemeroptera (~15), and the next highest mean value dropping to ~6 (Megaloptera). These mean values only represent what is typical, not what is possible. For example P/B ratios as high as 222 have been reported for Diptera in the Chironomidae tribe Chironomini in the Ogeechee River (Hauer and Benke, 1991).

Reported values for functional feeding groups (Cummins, 1973) from all reported population data skew heavily toward highest biomass and production estimates for the collector-filterer group, reflecting high reported values from filter feeding bivalves in the Mollusca (Table 2). When summarization is restricted to Arthropoda, collector filterers still comprise the largest share of production (~2995 mg AFDM m^{-2} $year^{-1}$) and mean biomass (410 mg AFDM m^{-2}). Collector-gatherers, predators, scrapers and shredders comprised notably smaller amounts of biomass and production, on an order of 0.125 × – 0.25 ×. Again, these general patterns must be viewed in context of the dataset and are not fixed rules. For example, groups such as shredders, which in many systems represent a minority of biomass and production, may comprise significant proportions of biomass and production in forested headwater streams (Benke, 1993).

Similar to the reported variation in biomass and production estimates at the population level, there is a wide range of variation in reported values of biomass and production at the whole community level. Reported annual production ranges from 3.6–13.3 g AFDM m^{-2} $year^{-1}$, biomass ranges from 3.1–10.0 g AFDM m^{-2}, and whole community P/B values range from 1.0 to 1.9. It is worth noting the highest whole community production values reported in Patrick et al. (2019) are a good deal lower than the highest population level estimates reported in the literature. Whole community estimates are less frequently undertaken than population level estimates, and thus these estimates fail to capture the possible extremes. Additionally, estimates from unusual habitats such as artificial lake outflow streams (e.g., Voshell, 1985) were excluded from the analysis. However, the dataset is useful for making meaningful comparisons among streams and rivers to better understand the dominant drivers of variation in secondary production.

Drivers of variation in secondary production

Secondary production is dependent on the factors that limit individual and population growth rates, including food availability and quality, habitat features, environmental conditions, biotic interactions, and the frequency and intensity of disturbance. At the whole community level, Patrick et al. (2019) found that the frequency of low flow events and water temperature were the key factors influencing global variation in secondary production in running waters (Fig. 2). Production rates generally increased with water temperature, likely due to positive relationships between temperature and growth rates. In contrast, production decreased with the duration of low flow events each year in streams, likely due to such disturbances causing organism mortality and reducing resource and habitat availability. A number of other factors in the analyses appeared important but could not be effectively evaluated given the limitations of the dataset.

For example, food availability was not reported for the majority of studies reviewed in Patrick et al. (2019), but this is likely an important factor (Wallace et al., 1997; see "Case studies" section below). The most commonly reported resource, coarse particular organic matter (CPOM), was reported in only ~1/3 of studies, but for that subset of studies it explained 32% of the variation in whole community production and 47% of the variation in whole community biomass. It is likely that CPOM was reported in cases where the investigators thought it important to measure and that similar general relationships could be expected for predictors like algal biomass or seston quality and volume. Indeed, some of the highest reported values of production come from filter-feeding communities associated with lake outflow streams that are fed by a constant stream of high-quality phytoplankton and zooplankton produced in the epilimnion of the source lake (Voshell, 1985). High production estimates also come from open-canopy, arid land streams in Arizona that have high algal production when the water is flowing (Fisher and Gray, 1983). Similarly, Finlay (2011) reported the impact of human activities in a watershed was associated with significant increases in GPP and by extension

Table 2 Biomass, production, and P/B estimates by Order, Phylum, and functional feeding groups (FFG) calculated from the meta-analysis dataset used by Benke (1993).

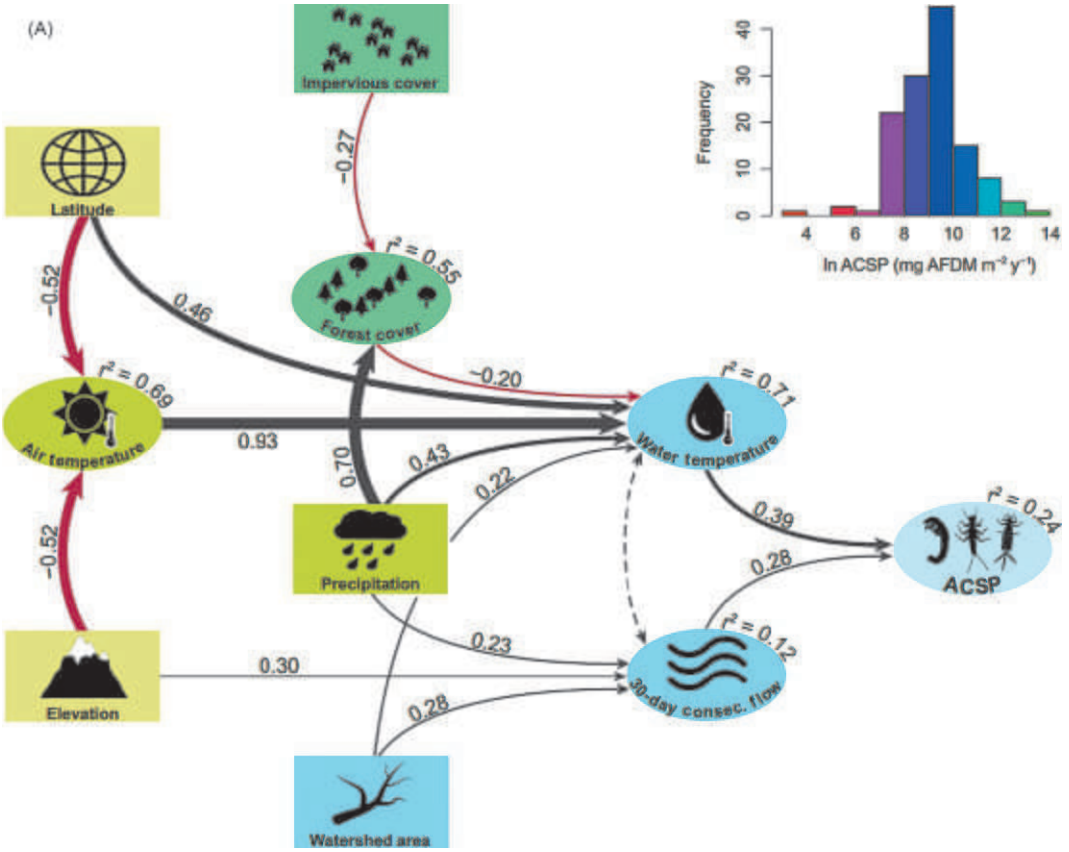

Fig. 2 Structural Equation Model of annual community secondary production (ACSP) in streams and rivers in the United States. Exogenous variables are indicated by rectangles, and endogenous variables are represented by ovals. Coefficients of determination (r^2) are shown for all endogenous variables, and standardized path coefficients are shown for all modeled relationships. Positive and negative effects among variables are depicted by black and red arrows, respectively, with arrow widths proportional to effect sizes (i.e., path coefficients). Significant covariance between mean annual water temperature ("Water temperature") and the minimum average discharge that persists for 30 consecutive days ("30-day consec. flow") is depicted by a dashed double-headed arrow. All relationships are significant at $P = .05$. Inset histograms show the distribution of natural log (ln)-transformed ACSP at U.S. and global scales. Reproduced with permission from AAAS.

invertebrate secondary production due to increased nutrients and light driving bottom-up processes. Further evidence for the importance of food resources comes from Benke's (1993) reported relationships between discharge and the proportion of production attributable to each functional feeding group (Fig. 3). As stream size increases, shredder production decreases, scraper and collector gather production follows a hump shaped pattern, and filter feeder and predator production increases. These patterns largely conform to expectations of the River Continuum Concept and are driven by longitudinal shifts in resource availability for these functional groups (Vannote et al., 1980).

Habitat stability is another general category that is only partially explored in Patrick et al. (2019). The overwhelming importance of low flow events as a universally important predictor of secondary production makes logical sense and the mechanism can be extended to consider other factors that were not available. For example, substrate stability is a very good predictor of secondary production when it has been explicitly considered. Benke et al. (1984) found that secondary production of communities associated with stable large woody debris (snags) was 5–6× times higher than that in the nearby unstable sand substrate in low gradient, Coastal Plain streams in Alabama (Benke et al., 1984). The negative impacts of occasional anthropogenic disturbances may also be considered in this conceptual framework. For example, punctuated or press disturbances in the form of contaminants from mine drainage reduced secondary production in comparison to reference streams (Carlisle and Clements, 2003).

Biotic interactions such as predation and competition may also limit secondary production. The best evidence for this comes from case studies of secondary production of invasive species that have no natural predators, diseases, or parasites in the introduced range. Extremely high rates of secondary production of New Zealand mud snails in Wyoming streams exemplify this (Hall et al., 2006). Left unchecked, mud snails can reach levels of biomass and annual production that rival the highest estimates in the literature. If we assume that reported explosions in abundance are correlated with biomass, the wealth of literature examples of population explosions of invasive species in streams and rivers may serve as additional examples of secondary production unchecked by predation, competition, and/or pathogens in native ranges.

Beyond empirically tested hypotheses of variation in secondary production, there are some patterns that have been observed across types and sizes of streams that speak to mechanism. Benke (1993), Finlay (2011), and Patrick et al. (2019) all observed a

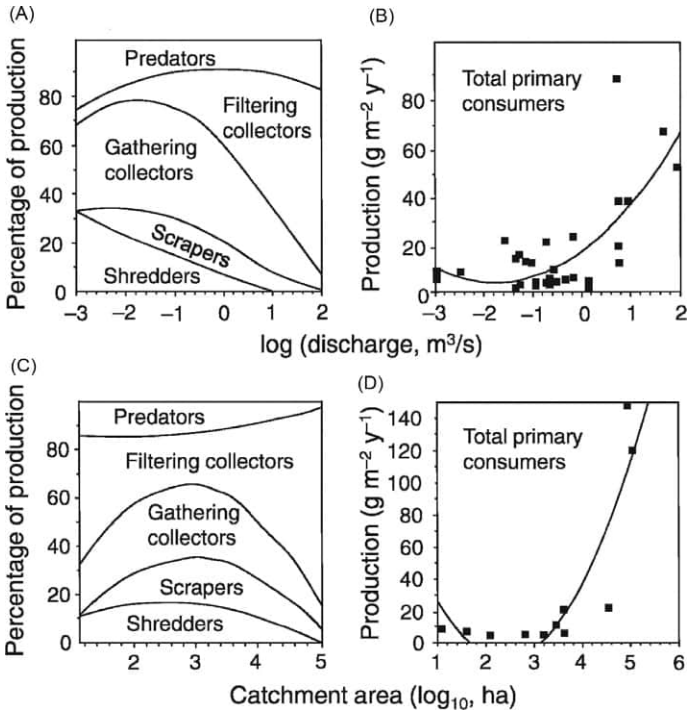

Fig. 3 Relative production (percentage of P) (panels A and C) and total production fitted to 2nd degree polynomials (B and D) of functional feeding groups along a river continuum (Benke and Huryn, 2010). Total primary consumers include all functional feeding groups except for predators. Data are from a meta-analysis by Benke (1993) (A and B) and (Grubaugh et al., 1997) (C and D). general pattern of increasing secondary production with increasing stream size (Table 3). Finlay (2011) attributed this pattern to increased probability of anthropogenic impacts, such as nutrient loading that increases production. However, Patrick et al. (2019) observed that as streams increase in size, water temperature increases, while the intensity of low flow events decreases. The actual mechanism is likely a combination of these factors, with larger rivers tending toward both greater nutrient loading but also more stable flow regimes and more moderate temperatures that enhance production. At larger scales, secondary production estimates also vary among ecoregions of the world (Benke, 1993; Patrick et al., 2019). Dry and humid temperate ecoregions have been observed to have higher whole community production and biomass than humid tropical and polar regions. However, P/B ratios reported from humid tropical regions are higher than the other biomes, a pattern likely linked to higher individual growth rates in warm tropical stream waters.

Case studies

Detritus availability in headwater streams; bottom-up controls on secondary production

Some of the most important studies regarding the secondary production of invertebrates in streams took place at the Coweeta Long Term Ecological Research Site in the Blue Ridge Mountains of North Carolina, United States. Among these, a unique, reach-scale litter exclusion study performed by Wallace et al. (1997) serves as an important case study for understanding bottom-up effects on secondary production. Investigators began monitoring the abundance, biomass, and production of stream invertebrates in two comparable fishless headwater streams in 1992. After 12 months, the investigators set up exclusion nets over the top and sides of 180 m reaches of one of these streams (hereafter the treatment stream) to prevent fall leaf litter from entering the stream directly or through lateral movement (Fig. 4). For the next 3 years, they observed the effects of the litter exclusion on the abundance, biomass, and production of the animals by monitoring both the treatment and the reference streams. In mixed substrata (the dominant cobble, pebble, gravel, and sand/silt substrates of the streams), they observed a continual decline in total secondary production in the treatment stream while production actually increased each year in the reference stream (Fig. 4). The declines were most strongly reflected in detritivores that eat large particles (shredders, collector-gatherers) and the predators that consume these groups. In contrast, communities on moss-covered bedrock that mostly feed on fine particles showed no discernable difference between the treatment and reference streams. This classic experiment clearly demonstrates that resource availability can limit production of primary consumers, and that this limitation can cascade up to secondary consumers that depend on them as prey.

Examining the Allen paradox; top-down and bottom-up processes and production

During the mid-20th century, research on the secondary production of streams that supported trout came to the puzzling conclusion that observed invertebrate production was insufficient to support the production of the trout populations that lived in those streams (Allen, 1951). This phenomenon came to be known as the Allen Paradox (Hynes, 1970). Huryn (1996) examined these same streams to re-evaluate the paradox and today we now recognize that the solution to the Allen Paradox can be found in the combination of several factors: (1) Secondary production estimates are prone to error, (2) trout populations are supported not only by secondary production of surface dwelling benthic invertebrates but also allochthonous inputs of terrestrial insects as well as secondary production occurring in the hyporheic zone, (3) only a relatively small portion of secondary production needs to escape predation and reproduce to maintain invertebrate populations in streams. Huryn (1996) conducted a detailed study of New Zealand trout streams and calculated production estimates for surficial invertebrates, hyporheic invertebrates, and terrestrial insects falling into the stream. He also estimated the energy needs of the resident trout populations. He concluded that the mean estimates yielded a surplus of zero (Fig. 5), but that it was likely that his production estimates underestimated surplus production by as much as 20%. Notably, terrestrial inputs made up roughly 20% of available food resources, with a 95% confidence range of 10–37% of available food resources. This study both resolved the Allen Paradox and demonstrated the importance of terrestrial prey inputs into streams, which are linked to riparian habitat quality, for supporting the production of higher trophic levels (Huryn, 1996).

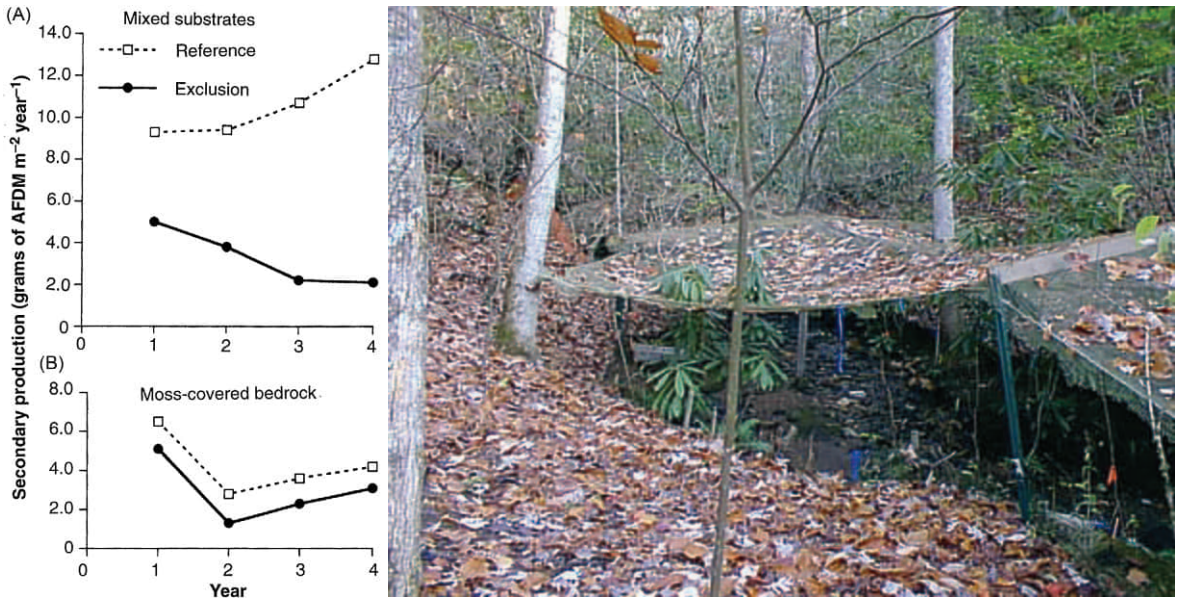

Fig. 4 Experimental set-up and annual secondary production estimates from Wallace et al. (1997) (left). Benthic invertebrate production estimates. Year 1 was the pre-treatment year followed by 3 years of litter exclusion. Data are shown for (A) mixed substrate habitats in the reference and litter exclusion streams and (B) moss covered bedrock outcrop habitats in the same streams (right). Depiction of the canopy erected to prevent litter from entering the stream. Reproduced with permission from AAAS. Ecological responses to loss of a dominant consumer group: Biotic interactions and secondary production

As catastrophic, disease-driven amphibian declines moved through the mountains of Central America in the early 2000s, a group of biologists began looking at ecological responses to the losses of amphibians at multiple scales, from plots and chambers to reach-scale production and metabolism (Whiles et al., 2006). Following the loss of tadpoles, including taxa that were abundant grazers and detritivores in these systems, Colón-Gaud et al. (2009) found that overall patterns of secondary production did not change as dramatically as expected, with no large compensatory increases in grazing or detritivorous groups that hypothetically competed with tadpoles for food. While large-bodied grazing insects did show some increases, production of small-bodied grazers such as mayflies declined with amphibians, as did shredders. Small-scale manipulations demonstrated that these patterns in production were linked to positive effects of tadpoles on some insect groups; tadpoles facilitated small-bodied grazing mayflies by removing sediments overlying the periphyton the mayflies feed on (Ranvestel et al., 2004). It was later discovered that tadpoles also facilitated leaf shredding insects by enhancing microbial activity and abrading and penetrating the tough tropical leaves with their rasping mouthparts (Rugenski et al., 2012). While many secondary production studies focus on top-down and bottom-up controls, or responses to physicochemical gradients, this study showed that biotic interactions, in this case facilitation, can also influence patterns of community production. This series of studies also illustrates the power of using small-scale manipulations in conjunction with reach-scale production estimates to identify mechanisms underlying patterns of production.

Future directions

One of the greatest issues standing in the way of further synthesis and enhancing our theoretical understanding of secondary production in flowing waters is simply lack of data. Benke (1993) was based on 159 studies, 40 of which were whole community estimates from different rivers and streams. Patrick et al. (2019) was based on whole community estimates from 164 different rivers and streams. This indicates that conservatively there have been 4.5 new studies on whole community secondary production coming out each year. Furthermore, Benke (1993) pointed out several specific areas where more data were needed, such as larger rivers (>10 m^3 s^{-1} discharge) and low latitudes ($<30^o$); unfortunately these data limitations persist, with only five estimates from Patrick et al. (2019) from tropical regions and only four estimates from 8th order or higher rivers (Tables 3 and 4). The literature bias is even greater when biogeographic location is considered. There are almost no estimates from Africa and Asia and relatively few estimates from South America. The literature bias remains centered on wadeable streams, primarily in North American and Europe, the majority of which are temperate and forested.

The challenge is not an easy one to address using existing methods. While Benke and Huryn (2010) report that estimating secondary production is easier today than in decades past, it remains a tedious, laborious, and often expensive process. As long as high-quality estimates require monthly sampling visits to field sites and long hours of tedious laboratory work identifying, enumerating, and measuring all collected individuals, the rate of advancement in this area will remain slow and geospatially limited to areas that are close to research groups with easy access to field sites. Considering this, methodological advances in measuring secondary production to reduce the cost and time required are a laudable research goal that could potentially advance the field in the long run. Refinement and application of approaches being developed in other disciplines such as using machine learning

and image analyses of samples to rapidly classify and measure invertebrates may make these methods more cost effective and efficient in the future. Development of statistical approaches that reduce frequency of sampling required to develop defensible estimates would also cut down on time and labor in the field and laboratory.

Our understanding of the drivers of secondary production has come a long way in recent years, but much remains to be done. Unlike primary production, which is easily measured in the field and laboratory and lends itself to experimental manipulation, secondary production has proven to be a much more challenging response variable to study. All areas of general theory concerning ecosystem functioning could stand to be more thoroughly tested with secondary production. For example, one topic that has received very little attention is the importance of biodiversity to secondary production. Theory predicts that as biodiversity increases, secondary production should also increase. This relationship can be related to factors such as complementarity and facilitation among co-occurring species, and sampling effects whereby the odds of having highly productive taxa in a community increase with richness. However, little support exists for this in streams (but see Statzner and Resh, 1993, Pollock, 2008), and some of the highest secondary production estimates come from relatively low diversity systems (e.g., Voshell, 1985; Hall et al., 2006). Furthermore, Finlay (2011) reports covarying patterns of biodiversity declining and secondary production increasing as rivers get larger. It seems likely that this pattern can be reconciled by the covarying pattern of anthropogenic impacts both reducing diversity while increasing nutrients and food availability, but it speaks to a larger issue regarding a need for independent assessment of the relative importance of, and interaction between, the various drivers of secondary production. While additional studies are needed to fill current gaps, there remains an open opportunity for synthesis of the work that has been done that goes beyond recent publications. An exhaustive review of published population level estimates of secondary production, coupled with geospatial data and causal network analysis, would greatly enhance our understanding of the drivers of secondary production and provide a useful resource for advancing theory and statistical tools for understanding secondary production and energy flow in running waters.

Glossary

Assimilation efficiency (AE) The efficiency at which a consumer digests or incorporates consumed elements into its metabolic pool. Defined as assimilation rate divided by consumption rate of a particular element.

Consumer-driven nutrient dynamics (CND) Direct and indirect effects of consumers on nutrient cycling within their environment.

Egestion The release of materials or elements as fecal matter. These elements have been ingested, but not assimilated.

Elemental imbalance The degree of elemental mismatch (ratio of C:nutrient, e.g., C:N or C:P) between consumer elemental demands and the elemental contents of their food resources.

Excretion The release of dissolved materials or elements. These elements have been ingested and assimilated but are not used for growth or storage.

Functional feeding group (FFG) A behavioral classification scheme that categorizes organisms based on feeding acquisition strategy.

Gross growth efficiency (GGE) The efficiency at which a consumer converts consumed elements into new biomass, defined as growth rate divided by ingestion rate for a particular element.
Growth rate hypothesis The hypothesis that organisms with higher growth rates have an increased demand for ribosomal RNA production to sustain rapid growth, and thus have higher phosphorus (P) concentration in their tissues.
Luxury consumption An organism's ability to assimilate and store excess available elements within tissues.
Nutrient spiral The cycling of nutrients in streams as they are assimilated from the water column into benthic biomass, temporarily retained, and mineralized back into the water column in a downstream trajectory that resembles a spiral.
Stoichiometric homeostasis The ability of an organism to maintain relatively constant internal tissue stoichiometry despite variation in the stoichiometry of its resources.
Threshold elemental ratio (TER) Resource ratio at which consumer growth switches limitation between two different elements.

Introduction

The role organisms play in biogeochemical processes has become central to our understanding of ecosystem function. All organisms are made of elements in varying proportions. The relative rate of supply of these elements in the environment and the degree to which the ratio of these elements is constrained or flexible within organisms have fundamental consequences ranging from cellular-level processes to the ecosystem. Ecological stoichiometry (ES) is a general framework that follows the law of conservation of mass and has been used to understand the balance of multiple key elements (traditionally carbon (C), nitrogen (N) and phosphorus (P)) in ecological interactions and processes (Sterner and Elser, 2002). ES has been used to model the coupled flow of multiple elements between organisms and their environments and has enhanced our understanding of two main areas in aquatic ecology: resource quality effects on consumer growth and consumer-driven nutrient dynamics (CND). Using mass balance principles to track pools and fluxes of elements from the cellular to ecosystem level, ES enables predictions of relationships among the elemental composition of consumers, their food resources, their waste products (i.e., excretion and egestion), and how other organisms (i.e., microbes and autotrophs) use these waste products to support growth (Frost et al., 2006; Schiettekatte et al., 2020).

Many core concepts of ES were originally derived from pelagic systems (open waters of lakes and oceans), focusing on interactions between zooplankton and their phytoplankton resources (Sterner, 1990; Sterner and Elser, 2002). However, recent work has applied ES concepts to advance understanding of stream organisms and ecosystems (Maranger et al., 2018; Cross et al., 2005; Atkinson et al., 2017). Compared to pelagic systems, streams are characterized by unidirectional water flow and stronger interactions between the water column and the benthos, both of which strongly influence the transfer of elements between biota and their environments. For example, streamflow converts nutrient cycles into "spirals" between biota and the environment, and nutrient spiraling is controlled by stoichiometric constraints on organisms (Newbold et al., 1981; Schade et al., 2011). Because of their close proximity to terrestrial systems, basal food resources in streams also encompass a wide range in quality, from low-quality allochthonous detritus (e.g., tree leaves and woody tissues) to high-quality autochthonous benthic algae and macrophytes (e.g., higher quality resources have a lower C:nutrient; e.g., lower C:N or C:P). Below, we review principles of ES as they relate to organism-nutrient relationships in streams, emphasizing principles of organism homeostasis and physiology (Fig. 1), patterns in stream food web stoichiometry (Fig. 2), and scaling from organisms, to communities, to ecosystem-level processes like nutrient cycling (Fig. 3). We close by summarizing knowledge to date (Fig. 4) while highlighting knowledge gaps on this topic.

Nutrient uptake and homeostasis in autotrophs versus heterotrophs

Within the context of ES, homeostasis refers to an organism's ability to maintain a relatively constant nutrient content or ratio in its tissues over short time scales (e.g., hours or days) (Sterner and Elser, 2002). Broad groups of organisms have distinct elemental compositions in their body tissues, with autotrophs having higher intraspecific variability (i.e., lack of homeostasis) than heterotrophs (Persson et al., 2010). Autotrophs obtain energy (mostly sunlight) and nutrients from different, uncoupled sources within their environment. As a result, autotrophs have distinct strategies to store these resources, as the availability of one resource does not guarantee availability of another one (Frost et al., 2005). These resource uptake strategies are often linked to storage capacity and therefore to plasticity in cellular, and hence organismal, stoichiometry. Due to their ability to store nutrients, C:N:P ratios in tissues of autotrophs vary greatly with available nutrient ratios, indicating a high flexibility in chemical composition and a lack of homeostasis (Stelzer and Lamberti, 2001; Hill et al., 2011). This adaptation allows autotrophs to store cellular nutrients when in excess, a process called luxury consumption. However, the response of benthic periphyton elemental composition to the availability and ratios of dissolved nutrients in stream water is complicated by concomitant shifts in algal species composition (Stelzer and Lamberti, 2001). Further, while aquatic macrophyte stoichiometry is partially driven by background nutrient concentrations, taxonomic identity is a stronger driver (Cedergreen and Madsen, 2003; Demars and Edwards, 2007), highlighting the role of homeostasis in generating interspecific variation among autotrophs (Nifong et al., 2014).

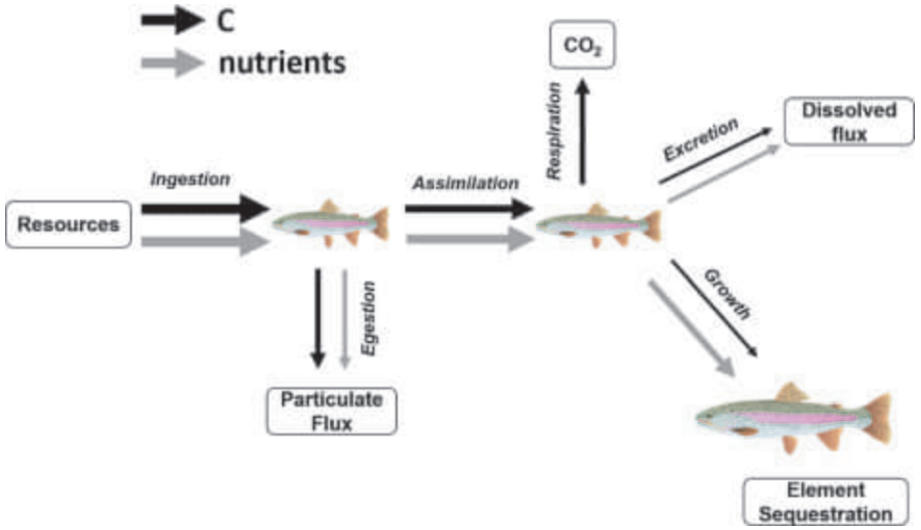

Fig. 1 Heterotrophic animal consumers ingest resources that vary in elemental composition (C:nutrient). The body elemental composition and nutrient storage capacity govern the amounts of C and nutrients heterotrophic animals assimilate. Post-assimilation, heterotrophs regulate internal body composition by preferential mineralization and excretion of the element in excess to maintain growth. As the degree of limitation varies among consumers due to feeding status and structural demand, there is interspecific variation in sequestration and nutrient recycling.

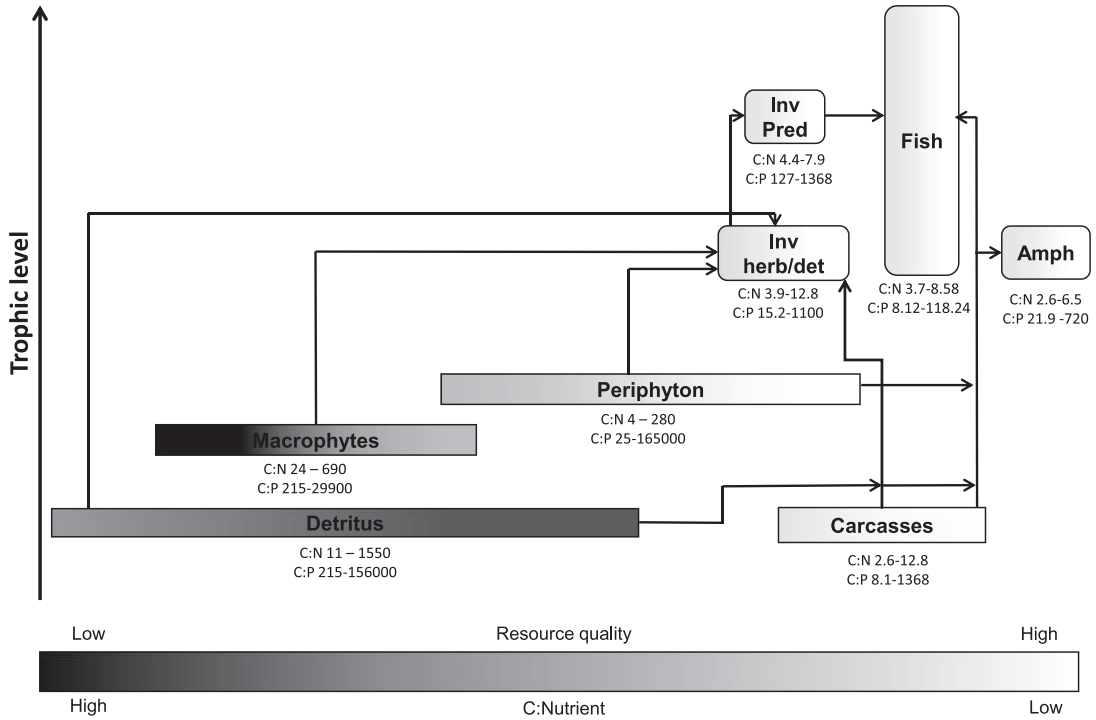

Fig. 2 Conceptual food web illustrated in the context of stoichiometric mismatches such that animals (rounded boxes), basal resources (sharp boxes) and their degree of shading reflects the C:nutrient (C:N or C:P) of each food web compartment. Solid arrows represent consumptive interactions and the flow of energy and elements up trophic levels. Detritus combines wood and leaves from Cross et al. (2005), and the width of each box represents the relative stoichiometric variation within each compartment. Mismatch between consumer and food source is reflected by the horizontal distance (left to right) between consumer and food sources. Resource stoichiometry values are based on ranges reported in Cross et al. (2005) and animal stoichiometry values are from Vanni and McIntyre (2016). "Inv pred" indicates invertebrate predators. "Inv herb/det" combines stoichiometry values for herbivores and detritivores insects. "Amph" indicates amphibians. "Detritus" combines wood and dead leaves.

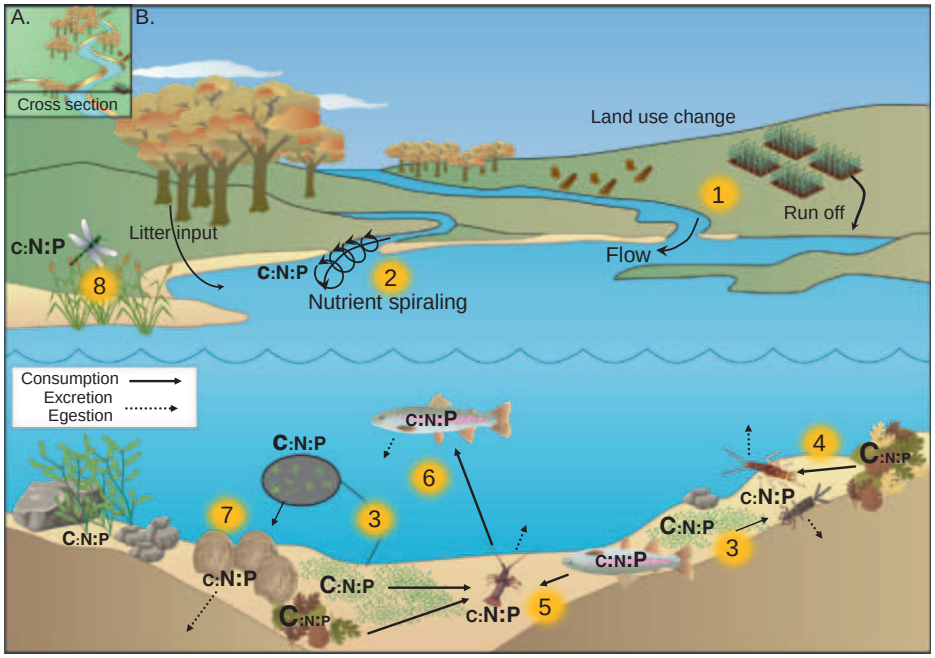

Fig. 3 (A) Aerial view of a stream. (B) Cross section view of inset illustrating a simplified diagram of a stream food web showing stoichiometry of compartments. Relative elemental size reflects differences in composition. (1) Streams integrate nutrients from their watershed. Land use changes impact nutrient loading that can shift food resource stoichiometry. (2) Unidirectional downstream flow converts nutrient cycles into spiraling that flow between biomass and the abiotic environment. (3) Biofilm and seston stoichiometry are generally plastic and determined by ambient conditions and biofilm is generally higher quality (lower C:nutrient ratio); grazer-biofilm mismatch is lower than shredder-leaf litter stoichiometric mismatch. (4) Leaf litter is typically recalcitrant (high C:nutrient ratio)—shredders have a greater elemental imbalance. (5) Omnivores can exhibit compensatory feeding (e.g., feeding on nutrient-rich decomposing animals) to reduce mismatch. (6) Predators have a lower stoichiometric mismatch. Mobile predators can translocate nutrients. (7) Filter-feeders are mismatched with food source and translocate materials from the water column to the benthos. (8) Aquatic insect emergence links aquatic and terrestrial ecosystems as nutrient and energy subsidies. (9) Unidirectional downstream flow converts nutrient cycles into spiraling that transitions between benthic biomass and the abiotic environment.

Heterotrophs, including bacteria, fungi, and animals, are generally more homeostatic than autotrophs in their elemental ratios, resulting in more constrained elemental body composition and nutrient storage capacity (Persson et al., 2010). As heterotrophs take up, transform, and store nutrients through consumption, metabolism and growth, the elemental composition of their resources dictate the efficiency of uptake and resultant release of elements in waste products (Fig. 1; Mooshammer et al., 2014; Manzoni et al., 2017; Schiettekatte et al., 2020). Heterotrophs typically rely on C-rich resources in comparison to their body composition, with important implications for performance and subsequent trophic dynamics; for example, herbivores may be limited by the amounts of N or P they can assimilate from C-rich autotroph tissues (Hessen and Anderson, 2008). Heterotrophs deal with these imbalances with a wide range of pre- and post-assimilation strategies. Pre-assimilation strategies include selective ingestion such as preferentially feeding on nutrient-rich resources (Hood et al., 2014) and regulating their body elemental composition via selective assimilation, the process by which organisms digest and acquire nutrients into their metabolic pool (Clissold et al., 2010). Post-assimilation, organisms regulate internal body composition by preferential mineralization and excretion of the element in excess (Fig. 1; Dalton et al., 2017). The degree of homeostasis, and the roles of these regulatory processes in maintaining homeostasis, vary across taxonomic groups and trophic levels.

Although evidence suggests that animals are relatively homeostatic in terms of body elemental composition, microbial heterotrophs (bacteria and fungi) have a more variable degree of homeostasis. While historically thought to be inflexible in their internal nutrient content, recent research has highlighted that both bacteria and fungi are flexible in their P content (Scott et al., 2012; Gulis et al., 2017). Aquatic fungi can be relatively homeostatic with respect to their C:N ratio (~11:1), but non-homeostatic with respect to C:P and N:P (Gulis et al., 2017). Dissolved N greatly enhances fungal growth rate and production, but has little effect on C:nutrient stoichiometry. In contrast, dissolved P does not seem to affect fungal growth and production, yet it controls fungal biomass C:P and N:P. The proposed mechanism dictating alteration of C:P and N:P ratios in fungi is luxury P uptake and storage (as polyphosphate-P) during periods of high P availability. Bacteria also exhibit substantial plasticity in cellular P contents, with the capacity to grow with extremely P-deplete tissues, as well as store excess P via luxury consumption (Scott et al., 2012; Godwin and Cotner, 2015). The ability of bacteria and fungi to flexibly immobilize and store excess P may alter nutrient flow through aquatic food webs and affect ecosystem functioning.

Animal body nutrient composition, an indicator of an organism's relative demand for nutrients, is relatively homeostatic and is a product of multiple ecological, evolutionary, and environmental factors (Fig. 1; Persson et al., 2010, Sterner and Elser, 2002). Structural characteristics, such as P-rich bones or N-rich carapaces, are often phylogenetically conserved and can contribute

substantially to the nutritional makeup and demands of an animal (Leal et al., 2017a,b). Ecological (e.g., diet) and environmental (e.g., temperature) factors influence physiological processes and also affects body nutrient composition. For example, rapid growth rates during early stages of development or among species with fast turnover rates (i.e., r-selected species) have been correlated with high levels of P-rich ribosomal RNA and consequently high body P demand (i.e., growth rate hypothesis; Sterner and Hessen, 1994; Meunier et al., 2017). The premise that animal nutrient contents vary across species, but remain relatively static within species, led to the concept of the threshold elemental ratio (TER; Urabe and Watanabe, 1992; Frost et al., 2006). The TER predicts the elemental ratio at which growth limitation switches from one element to another (generally C:nutrient), signifying the C:nutrient ratio for optimal consumer growth. TER models for animals have been modified over time to include variable assimilation efficiencies of limiting elements and metabolic loss terms. (i.e., animals need C not only to build tissues, but also for respiration; Fig. 1) which has improved estimates of animal element demand (Doi et al., 2010; Halvorson et al., 2015; Moody et al., 2019; Schiettekatte et al., 2020). As a result of variable TERs, the degree of limitation varies among consumers, generating interspecific differences in nutrient recycling rates and overall ecosystem-level effects.

Stream food webs: Patterns and mismatches across trophic levels

Basal resources

The energy base of ecosystems affects both stream food web structure and biodiversity (Wallace et al., 1997; Cross et al., 2007). Stream ecosystems are generally supported by two major resource types: (1) "green" or autochthonous resources, such as benthic algae and macrophytes, and (2) "brown," generally allochthonous (terrestrial) detrital resources in the form of coarse particular organic matter (CPOM; e.g., leaves and wood) and fine particulate organic matter (FPOM; e.g., feces, soil, leaf litter fragments) and their associated fungal and bacterial communities. Basal resource availability can vary temporally (e.g., autumn leaf fall), and spatially as a result of stream size (i.e., River Continuum Concept, Vannote et al., 1980) and interactions with the adjacent floodplain (i.e., Floodpulse Concept, Junk et al., 1989). Here we highlight the controls on "green" and "brown" resource stoichiometry for stream consumers (Fig. 2).

Autochthonous/green resources

Generally, autochthonous resources such as benthic algae are a higher quality food resource than allochthonous detritus because the N and P content of living plant material tends to be higher than that of detrital leaves and wood (Evans-White et al., 2005; McManamay et al., 2011). Previous work has indicated that light, nutrient availability, and flow interactively affect both water column and benthic algal stoichiometry (Dickman et al., 2006; Kohler et al., 2012). Specifically, enhanced nutrient availability decreases C:nutrient ratios while light increases C:nutrient ratios (Dickman et al., 2006; Sanches et al., 2011), and variation in flow impacts stoichiometry of primary producers by shaping algal community structure and influencing nutrient flux (Dodds and Biggs, 2002; Francoeur and Biggs, 2006). In terms of nutritional quality, macrophytes tend to be intermediate between algae and allochthonous detritus, as indicated by higher C:nutrient ratios in macrophytes (Fig. 2), large quantities of cellulose and lignin, and decreased digestibility of proteins compared to algae (Demars and Edwards, 2007; Cebrian, 1999). Macrophytes, however, can also provide substrates for periphyton and bacterial colonization (Dodds and Biggs, 2002; Vadeboncoeur et al., 2006) and make significant contributions to the detrital pool (Wallace and O'Hop, 1985; Minshall, 1978).

Allochthonous/brown resources

While terrestrial plant litter is of poorer quality than autochthonous algal-based resources, the former is often the dominant energy input to many stream communities supporting "brown" food webs. This is especially true among low-order streams in temperate forested ecosystems (Webster and Meyer, 1997; Rosi-Marshall and Wallace, 2002; Vannote et al., 1980) where a suite of detritivores and microbial decomposers process this allochthonous material (Marks, 2019; Cummins and Klug, 1979). Allochthonous detrital matter differs greatly in chemical composition from autochthonous resources, having greater amounts of refractory compounds and higher C:nutrient ratios, making it a lower-quality food source for consumers (Rosi-Marshall and Wallace, 2002; Allan and Castillo, 2007). Detrital stoichiometry changes as this material is processed, through animal feeding (e.g., shredding) and colonization of detritus by nutrient-rich bacteria and fungi increasing CPOM nutritional quality for subsequent consumers (Grattan and Suberkropp, 2001). Shredding of large particles into smaller particles (FPOM) by physical abrasion and animal feeding also increases surface area (Anderson and Sedell, 1979), facilitating further microbial colonization by bacteria and fungi, increasing N and P contents (Ferreira et al., 2006; Manning et al., 2015), and thus lowering C:nutrient ratios (Cross et al., 2003; Atkinson et al., 2009). As a result, CPOM tends to be of poorer quality (highest C:nutrient ratios) compared to FPOM (Cross et al., 2005). However, this may be partly driven by low C content of FPOM, as CPOM can actually exhibit higher N content than FPOM (Farrell et al., 2018).

Consumers

Since primary consumers have lower C:nutrient contents than the basal food resources upon which they feed, there can be differential imbalances in green- versus brown-based food webs (Cross et al., 2003; Evans-White and Halvorson, 2017), with implications for consumer performance and subsequent trophic dynamics. Primary consumers in streams span a large breadth of feeding strategies categorized into functional feeding groups (FFGs) and since basal resources vary in quality, FFGs vary in their

nutritional imbalances (Fig. 2). Below we highlight what is known regarding feeding strategies and dietary mismatches in four broad trophic groups: herbivores, detritivores, omnivores, and predators.

Herbivores

Herbivores in streams comprise several FFGs including scrapers, which graze on benthic algal biofilms, and collector gatherers and collector-filterers, which feed on both autotrophic and detrital resources. Herbivores can have strong top-down controls on autotrophic production by constraining total autotroph biomass (Lamberti et al., 1995; Hillebrand et al., 2004) and altering community composition through selectively feeding on more palatable species or removing overstory taxa (Rosemond et al., 1993; Feminella and Hawkins, 1995). The degree of stoichiometric mismatch between herbivores and their resources determines assimilation efficiencies and growth, with multiple studies indicating that herbivores that ingest algae or macrophytes with high C:nutrient ratios have lower assimilation efficiencies and growth rates (Stelzer and Lamberti, 2002; Fink and von Elert, 2006; Hillebrand et al., 2004). Elevated concentrations of available (dissolved) nutrients can both increase autotroph growth (Rosemond et al., 1993) and nutrient content (Hessen et al., 2002), which can reduce nutritional imbalances for herbivores. In addition, beyond active selection of high-quality resources (e.g., Rosemond et al., 1993), herbivores may employ compensatory feeding to respond to nutrient-deficient basal resources (Plath and Boersma, 2001; Liess, 2014).

Detritivores

Several FFGs, such as shredders and collector-gatherers, use predominantly terrestrial-derived detrital resources and have greater stoichiometric constraints relative to herbivores (Fig. 2; Tant et al., 2013; Farrell et al., 2018). The overall lower nutrient content and high recalcitrance (e.g., lignin) of detritus (Cross et al., 2003; Chapin et al., 2002) relative to algae may result in lower detritivore assimilation efficiencies (AE) and lower gross growth efficiencies (GGEs, i.e., growth rate divided by ingestion rate) relative to herbivores (Halvorson et al., 2015; DeMott et al., 1998). Several mechanisms can explain how detritivores deal with the high degree of mismatch in diet versus tissue stoichiometry such as compensatory feeding rates, selective feeding, or element-specific AEs (Flores et al., 2014; Frainer et al., 2016; Eggert and Wallace, 2007). For example, the detritivorous shrimp, *Xiphocaris elongata*, ingests a significant amount of CPOM, yet most of its energy is derived from autochthonous C sources (March and Pringle, 2003). As a result of feeding on more recalcitrant resources than herbivores, detritivores are anticipated to excrete nutrients at lower rates and egest at higher rates in comparison to herbivores (McManamay et al., 2011), with important implications for consumer-resource dynamics (Atkinson et al., 2017).

Omnivores

Omnivory is prevalent among both stream invertebrates and vertebrates. Although the FFG classification scheme highlights the overall feeding strategy, there can be a high degree of resource mixing (e.g., Hood and Sterner, 2010). The reasons underlying omnivory are numerous and include mechanisms such as seasonally varying food availability, life cycle patterns, and key life history and growth strategies (Hood et al., 2014; Hellmann et al., 2013; Evans-White et al., 2003) that likely enhance AE. For example, omnivory can be driven by seasonal prey availability in *Hydropsyche* caddisflies and life-cycle patterns in amphipods (Hellmann et al., 2013). Additionally, some detritivorous insects primarily consume detritus in early instars, but then switch to cannibalism and intraguild predation during later instars (Wissinger et al., 1996). This suggests highly dynamic consumer-resource mismatches among omnivores, a varying role for omnivores in CND over their lifetime and within and across seasons.

Predators

Predators are more balanced with their food resources than are primary consumers, as they feed on resources that have a similar stoichiometry to their own body tissues (Fig. 2). As a result, predator AEs tend to be higher (Wallace et al., 1987; Benke and Wallace, 1997). Among predators, egestion rates may be lower than excretion rates due to greater assimilation efficiency of nutrient-rich animal tissues in comparison to primary consumers (Atkinson et al., 2017). Not only do predators have consumptive top-down effects (Woodward and Warren, 2007), but they can also induce indirect top-down effects on prey behaviors and stoichiometry (Rinehart and Hawlena, 2020; Hawlena and Schmitz, 2010). Predators can reduce biomass or alter the movements of primary consumers, potentially modulating the intensity and spatial pattern of primary consumer feeding (Power, 1990; Lundvall et al., 1999). For example, predator chemical cues can influence patterns of algal heterogeneity (McIntosh et al., 2004) and predator-avoidance behaviors may reduce consumer foraging time (Cowan and Peckarsky, 1994; McIntosh et al., 2004). Predation risk can also affect prey nutrient cycling by increasing prey respiration (Bell et al., 2019), therefore increasing C uptake and N and P excretion (Leroux et al., 2012), while other studies have shown predators enhance prey N and P sequestration (Costello and Michel, 2013). These effects have cascading effects on how consumers impact the abundance, species composition, and location of basal resources and how consumers recycle nutrients via their excretion and egestion.

Scaling to the community and ecosystem level

In most streams, ecosystem production is limited by N and/or P, thus the rates and ratios at which organisms store these nutrients and release them in their wastes can alter nutrient dynamics (Fig. 3; Atkinson et al., 2017). For example, animals can directly regulate stream nutrient spiraling by sequestering elements in their body tissues (nutrient storage), releasing them via excretion and

egestion, and translocating them through their movements having direct and indirect impacts to stream ecosystems. ES mass-balance principles allow researchers to scale organismal processes that mediate elemental flux and storage within and among ecosystems—below, we focus on how ES connects animals to community and ecosystem-level processes.

Nutrient storage

Within streams, animals are often a dominant pool of biomass (McIntyre et al., 2008, Atkinson and Vaughn, 2015) and can represent an important ecosystem reservoir of nutrients. ES predicts that animals with a high N (i.e., high body N:P, low body C:N) or P demand (i.e., low body N:P and C:P) for growth and production can retain the high-demand element more efficiently in their tissues. This storage can even result in a shift of nutrient limitation of primary production to the element stored in animal biomass (Knoll et al., 2009). For example, grazing snails can store more N and excrete more P than grazing crayfish (Evans-White et al., 2005), and periphyton in experimental streams stocked with crayfish had greater periphyton C:P and alkaline phosphatase activity, suggesting greater P-limitation than periphyton in streams stocked with snails (Evans-White and Lamberti, 2006). Elements stored in animal biomass can be sequestered until death, when scavengers or microbial decomposition mineralize the stored nutrients. However, high animal biomass does not necessarily mean that animals are a sink for nutrients; rather, whether they are sources or sinks for autotrophs depends on where animals feed vs. release wastes, how their biomass changes over time, and the fate of their stored nutrients after death (Vanni et al., 2013).

Nutrient release

Animal excretion can represent a major source of labile nutrients that alleviates nutrient limitation, but this is context dependent. Several factors influence the supply of nutrients by individual animals, including biomass, temperature, diet, and body stoichiometry (McIntyre et al., 2008; Hopper et al., 2018). At the ecosystem level, animals will be most important when they supply a substantial mass of nutrients relative to other sources, or relative to ecosystem nutrient demand. In particular, aggregated animal biomass is often important at the ecosystem level by generating "hotspots" of nutrient cycling. Many factors also regulate ecosystem-wide nutrient demand such as external supply (e.g., surface or groundwater inputs) and internal recycling pathways (e.g., nutrient remineralization by microbes). Biomass, metabolic rates and the nutrient limitation status of organisms (e.g., primary producers and microbes) can influence ecosystem nutrient demand. Studies relating animal nutrient supply to ecosystem demand allow for broad comparisons of animal-mediated nutrient cycling across ecosystems. Among studies, animals meet a variable proportion of ecosystem nutrient demand; for example, excretion by fish supports anywhere from 5% to over 90% of nutrient demand (McIntyre et al., 2008; Small et al., 2011; Wilson and Xenopoulos, 2011). Mortality also results in nutrient releases (Fig. 3, Flow 5). Nutrient release from carcasses occurs in stages defined by high rates of elemental release from soft tissues occurring within days to weeks (DuBose et al., 2019; Novais et al., 2017; Childress et al., 2014), followed by mechanical breakdown and chemical dissolution of bones and shells (Strayer, 2014; Strayer and Malcom, 2007) that may persist for decades to millennia. Historical accounting of previously abundant animals showed that Alligator Snapping Turtle (*Macrochelys temminckii*) carcasses and spent mussel shells could act as continuous slow-release P sources that contributed nearly 1% to total P in rivers annually from typical mortality (Wenger et al., 2019).

Nutrient subsidies

Animals can move nutrients against potential energy gradients (e.g., upstream, uphill) resulting in subsidies from one aquatic ecosystem type to another (suckers that move nutrients from lakes to streams; Childress et al., 2014). Stream animals move nutrients from aquatic to terrestrial ecosystems during ontogenetic changes, such as insect emergence (Fig. 3, Flow 8; Small et al., 2013) and amphibian metamorphosis (Tiegs et al., 2016; Capps et al., 2015b), and excretion by stream invertebrates such as mussels, which can support riparian macrophyte production (Fig. 4; Lopez et al., 2020). Terrestrial animals also contribute nutrient subsidies through movement into and defecation in streams and carcass decomposition (Subalusky et al., 2015, 2018). Subsidy importance is determined by its quality, quantity, timing, and duration, and the characteristics of the recipient ecosystem (Subalusky and Post, 2019).

Indirect effects of animals

In addition to their direct effects, animals can indirectly affect microbially-mediated nutrient transformations such as primary production, decomposition, and redox conditions (Rugenski et al., 2012; Trentman et al., 2019; Nickerson et al., 2019). For example, herbivores can reduce periphyton C:nutrient and increase nutrient turnover rates by reducing periphyton mat thickness and nutrient diffusion limitation (Evans-White et al., 2005; Hillebrand and Kahlert, 2001). Animals can also indirectly facilitate microbially-controlled nutrient transformations through the release of nutrients and by physically modifying the environment (Moore, 2006; Atkinson et al., 2018). For example, freshwater mussels supply limiting nutrients through their excretion and bioturbation of sediments, resulting in enhanced denitrification rates (Trentman et al., 2019; Hoellein et al., 2017; Nickerson et al., 2019). The indirect roles of organisms on ES in streams merit more attention.

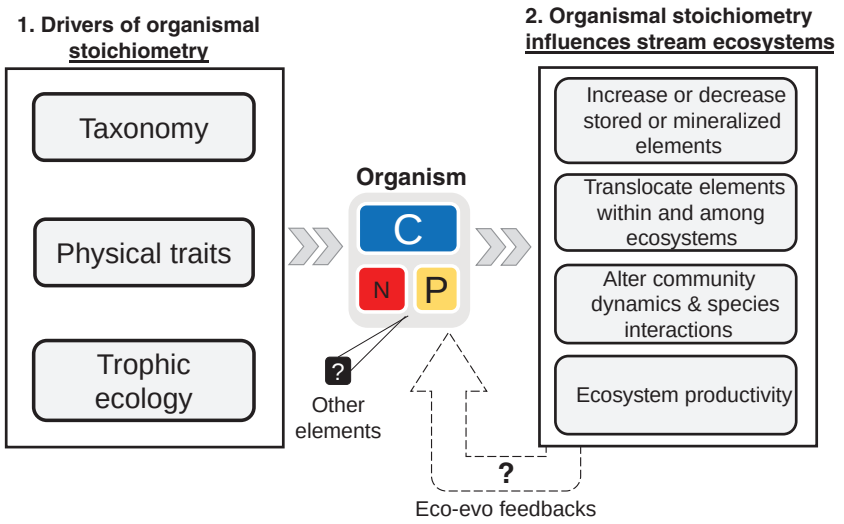

Fig. 4 Conceptual figure illustrating drivers of organismal stoichiometry and the influence of organismal stoichiometry in stream ecosystems. (1) Taxonomy, physical traits, and trophic ecology of an organism interact to govern its stoichiometric composition. (2) Variable stoichiometry of stream organism can increase or decrease local elemental availability, subsidize ecosystems via elemental translocation, alter species interactions that affect community dynamics, and ecosystem productivity through control of elemental availability, and ecosystem productivity. Whether elements beyond C, N, and P in organisms are under the same controls or influence ecosystems and eco-evolution studies in the context of organismal stoichiometry are research areas warranting attention.

Conclusions and moving forward

While we have learned much about ES in streams as reviewed here, there are still many unknowns. Here we conclude by highlighting multiple avenues for future research directions within this topic.

Trait- and organismal-based stoichiometry

Phylogenetic patterns

Broadly, phylogeny explains variance in elemental composition among animals, often indicating important variation at the family level (Allgeier et al., 2020; Vanni et al., 2002; Hendrixson et al., 2007; González et al., 2018). A recent meta-analysis by Andrieux et al. (2020) found a significant phylogenetic signal among taxa across three nested taxonomic levels (classes, orders, and families). This is consistent with the idea that structural and life-history (e.g., development and growth) characteristics are evolutionarily constrained (Fig. 4). However, within-family level analyzes have also found that phylogenetic distance dictates patterns in stoichiometric ratios which may be related to differences in life history strategy (Atkinson et al., 2020). Considering how phylogenetic signal relates to stoichiometry across a broad spatial extent and taxonomic groups warrants future study, as it may help to predict ecosystem-level importance based on taxonomic composition.

Eco-evolutionary dynamics

Stoichiometric traits have been useful for linking organisms to ecosystem processes (Atkinson et al., 2017), but more work is needed to identify consequences of stoichiometric trait variation in eco-evolutionary dynamics (Yamamichi et al., 2015; Leal et al., 2017b). For example, differential nutrient supply may influence gene-expression and life-history trait evolution by altering allocation trade-offs (Elser et al., 2000, 2003). Directional selection on stoichiometric traits may reduce elemental imbalances between a population and its resources or fluctuating selection may maintain stoichiometric trait variation within populations when there is variation in resource quality (Tsoi et al., 2011; Prater et al., 2017). Relating stoichiometric traits to fitness variation (Kay et al., 2005; Frost et al., 2006), organismal adaptation to diet elemental imbalances (El-Sabaawi et al., 2012), and selection pressures to direct or indirect effects in ecosystems (Leitch et al., 2014; Rudman et al., 2019) will be important to understanding the origins of biodiversity and eco-evolutionary consequences of global change, as stoichiometric traits may be useful for studying feedbacks between phenotypic evolution and ecosystem processes (Fig. 4).

Ontogenetic changes

Some organisms undergo substantial changes during development, potentially affecting nutrient fluxes through ontogenetic elemental allocation (Fig. 4). Ontogenetic changes in body content are most evident in vertebrates, where the development of P-rich skeletons results in a substantial increase in whole-body P content (e.g., fishes, reptiles, and amphibians; Tiegs et al., 2016, Sterrett et al., 2015, Pilati and Vanni, 2007). Other elements also can vary ontogenetically. In some species, eggs are rich in lipids and hence C, so whole-body C declines during early stages of development as lipids are metabolized. However, body C may then

increase during subsequent development as individuals store fat (Pilati and Vanni, 2007; Boros et al., 2015). In fishes, body N often declines with age (Boros et al., 2015; Pilati and Vanni, 2007), whereas trends in body N seem more variable across other taxa (e.g., invertebrates: Back and King, 2013; amphibians: Capps et al., 2015b). Ontogenetic changes must be viewed within the context of other drivers affecting body stoichiometry because genotype and environmental factors (especially diet) can interact with ontogeny to drive variation in body stoichiometry (Leal et al., 2017a). Few studies have isolated ontogenetic effects from other factors using controlled experiments.

Elements beyond C, N, and P

While ES has revealed substantial diversity among taxonomic groups and within populations by characterizing C, N and P, ES should encompass other elements (Merchant and Helmann, 2012). Ionomics is a relatively new field that has been used widely to study the complete elemental composition (i.e., ionome) of plants (Lahner et al., 2003; Huang and Salt, 2016) and microbial communities (Merchant and Helmann, 2012), but its utility in aquatic systems has only recently been demonstrated. Recent research highlights both intra-and interspecific ionomic responses of invertebrates and vertebrates to life-history (Goos et al., 2017; Hopper et al., 2021a) and resource stoichiometry gradients (Prater et al., 2020). A recent study of salmon carcass subsidies demonstrated that seasonal spawning runs are sources of micronutrients that may be essential to some freshwater streams (Currier et al., 2020). Because ionomics recognizes the coupling of multiple elements in biological systems, a nutrient balance concept that extends traditional stoichiometric ratios can be useful in generating hierarchical sets of relationships between elements based on prior knowledge (Parent et al., 2013).

Linking diet to nutrient cycling

Because consumer diet stoichiometry can affect consumer nutrient acquisition and growth rates, diet also affects the rates and ratios at which organisms release nutrient wastes into their environment (Elser and Urabe, 1999). Although models predict causal relationships between diet stoichiometry and waste stoichiometry, these models are based on assumptions including strict consumer homeostasis and fixed resource stoichiometry (e.g., no selective feeding). A recent model combines the nutrient requirements and energetic needs of fishes and provides predictions of their ingestion, respiration, excretion and egestion rates (Schiettekatte et al., 2020), and could serve as a means to make predictions for different animal taxa. Controlled feeding studies have generally supported predictions of theoretical models, empirically showing that higher-nutrient diets result in greater nutrient excretion and egestion rates across invertebrate taxa (Evans-White and Halvorson, 2017), and higher N:P diets are associated with higher N:P excretion rates across many fish taxa (Moody et al., 2015). Still, the link between diet and nutrient recycling is less clear from field data, which show mixed relationships between diet and consumer waste stoichiometry (McManamay et al., 2011; Vanni and McIntyre, 2016). To provide more realistic links between diet stoichiometry and nutrient cycling, particularly in the field, future studies must address the role of selective feeding, consumption rates, predation stress, and deviation from strict homeostasis to link diet to consumer waste stoichiometry (Halvorson et al., 2019).

Community and ecosystem level effects

CND relative to demand

The importance of animal-mediated nutrient cycling varies tremendously across systems, and we currently lack the ability to predict when and where animals will be important contributors to nutrient availability. For example, increased external nutrient loading should increase ecosystem nutrient demand and decrease the importance of animals in the short-term. However, depending on if and when animal biomass increases, their increase may render their role more important than in systems with low nutrient inputs. Studies in streams (Wilson and Xenopoulos, 2011) and lakes (Vanni et al., 2006) showed that fish were more important in systems impacted by agriculture than in less impacted systems. This may seem surprising given that agriculturally impacted systems receive more nutrients, but this was driven by higher fish biomass in the watersheds with more agriculture. In contrast, Spooner et al. (2013) found that the importance of excretion by freshwater mussels decreased in watersheds with high agriculture. These conflicting findings could be driven by differences in the population dynamics of the animals being considered. Freshwater unionid mussels are long-lived and their biomass may not increase with nutrient loading as rapidly as fish with much shorter generation times, suggesting that mussel biomass may not yet be in equilibrium with landscape nutrient inputs. In contrast, where animal species with short generation times and/or high reproductive rates dominate, animal biomass may respond more strongly to short-term variation in external nutrient supply. For example, Sharitt et al. (2021) found that excretion by gizzard shad, a dominant fish, supported anywhere from 9% to 53% (mean 31%) of summer phytoplankton P demand over a 15-year period, and most of that variation was driven by fluctuations in young-of-year biomass. Given the difficulties associated with understanding animal population dynamics and the many potential feedbacks (operating on different temporal scales), understanding where and when animals are important in ecosystem-wide nutrient cycling remains a challenging endeavor.

Importance of egestion

Many of the classic studies of CND focused on excretion of dissolved nutrient wastes in terms of the balance of C, N, and P in consumers (Vanni, 2002; McIntyre et al., 2008). Yet, consumers can also produce particulate nutrient wastes (i.e., egestion; Wotton and Malmqvist, 2001). The magnitude and fate of egestion as a nutrient flux remains understudied among many taxa, especially under in situ conditions and within whole-stream nutrient budgets (Halvorson and Atkinson, 2019), because study is still limited

by a lack of standard methods and the extended timeframe required to understand long-term fates compared to excretion (Halvorson et al., 2017). Compared to dissolved wastes, particulate wastes are transported and processed differently, and also vary widely in flux rates and C:N:P ratios (Halvorson et al., 2017; Masese et al., 2020). Further work must address the role of egestion as a cross-ecosystem nutrient flux, such as between terrestrial and aquatic systems (Subalusky et al., 2015; Dutton et al., 2018) and consider the role of animal traits, including phylogeny and feeding mode, in driving variation of the magnitude and fate of egestion (Ramamonjisoa and Natuhara, 2018).

DOM excretion and composition

Much research has highlighted the importance of animals in mediating inorganic N and P cycling; however, limited work has sought to understand animals as sources of dissolved organic matter (DOM) that can support microbial production in the brown food web (Meyer and O'Hop, 1983; Parr et al., 2020). Stream consumers span a continuum of feeding traits (i.e., FFGs) and body elemental compositions, which together dictate the composition of DOM released. For example, DOM fluorescent signatures highlighted differences among FFG in organic matter transformations, showing that predatory insects had distinct labile DOM fluorescent signatures compared with insects feeding at lower trophic positions, which excreted more recalcitrant DOM (Parr et al., 2019). Other work has indicated that DOM release within a single FFG can also vary as shown with filter-feeding bivalves (Hopper et al., 2021b). Further work is needed to fully understand how animal biomass distribution, taxonomic identity, and functional trait composition influence DOM cycling that may link green and brown food webs.

Role of CND in mediating other ecosystem processes

Consumer wastes can likely affect all ecosystem processes which are limited by nutrient availability. However, many processes associated with microbial heterotrophy, such as organic matter decomposition and community respiration, are still poorly understood particularly at the ecosystem level (Atkinson et al., 2017). Consumer wastes stimulate microbial heterotrophs such as bacteria and fungi, facilitating greater microbial respiration and breakdown rates during leaf litter decomposition (Atkinson et al., 2021; Ramamonjisoa and Natuhara, 2018; Rugenski et al., 2012). However, it is still poorly understood whether consumers can shift heterotrophic microbial communities by altering bacterial versus fungal dominance or microbial community structure, both of which are sensitive to background N and P availability (Juvigny-Khenafou et al., 2020; Gulis and Suberkropp, 2003). The stimulatory roles of CND on heterotrophic microbes are also likely counter-balanced by consumer selective feeding on nutrient-rich heterotrophic biomass, particularly consumers feeding on high C:N and C:P detritus such as wood and leaf litter (Chung and Suberkropp, 2008). These CND effects on heterotrophy may scale up to whole-ecosystem heterotrophy, affecting C storage versus mineralization at reach scales, a topic which remains open for further inquiry.

Responses to environmental stressors

Species introductions and species loss

Species introductions and losses can have profound effects on ecosystem structure and function (e.g., Strayer, 2010; Hooper et al., 2012). Declines in native biodiversity in freshwater ecosystems far exceed those in most terrestrial ecosystems, and projections indicate the rate of species decline will increase due to a variety of threats (Strayer and Dudgeon, 2010; Vaughn, 2010). The loss of formerly abundant taxa or a shift in species dominance can alter elemental balances and fluxes (Atkinson et al., 2014; Hopper et al., 2020). For example, a disease-mediated decline of 98% of tadpole biomass in a Neotropical stream resulted in higher algal and detrital biomass and a 50% reduction in N turnover rates (Whiles et al., 2013). Freshwater systems also are plagued by increasing introductions of invasive species that often possess unique structural traits (Capps and Flecker, 2013) or have high processing rates (Strayer, 2009) that can strongly modify the storage and flux of elements (Capps and Flecker, 2013). Collectively, major changes in biomass of stoichiometrically distinct organisms can lead to subsequent changes in the flux and storage of elements in ecosystems (Capps et al., 2015a).

Land use and land cover change

Humans have dramatically altered ecosystems through urbanization and agricultural land uses, which have dramatically impacted loading into streams by enhancing nutrient runoff through the application of fertilizers to lands and by reducing infiltration into soils (Galloway et al., 2003; Steffen et al., 2015; Dodds and Smith, 2016). Stream autotroph biomass generally increases with nutrient enrichment, but detrital resource quantity often decreases due to stimulated decomposition resulting in greater export of fine particles out of the ecosystem (Rosemond et al., 2015; Manning et al., 2016). Algal and detrital C:nutrient ratios tend to decrease with rising nutrient concentrations (Stelzer and Lamberti, 2001; Cross et al., 2005), improving their quality as a food resource. Nutrient enrichment of basal food resources can drive increases in consumption and growth (Evans-White and Halvorson, 2017; Halvorson et al., 2018), body size (Davis et al., 2010), biomass and secondary production (Cross et al., 2006; Demi et al., 2020), and a shift in community stoichiometry to species with lower body C:P, which likely increases nutrient demands (Evans-White et al., 2009; Tsoi et al., 2011; Prater et al., 2015).

Climate change

The reverberations of climate change are resulting in altered ecosystem structure and functioning in freshwaters worldwide (Woodward et al., 2010; Grimm et al., 2013). Aquatic organisms are especially vulnerable to climate-mediated changes because they are ectothermic and confined to aquatic habitats. Current projections suggest changes in species distributions (Heino, 2010;

Markovic et al., 2014) and enhanced metabolic demands (Seebacher et al., 2015) due to rising temperatures. Additionally, rising temperatures in aquatic ecosystems have not only led to general physiological stress (Spooner and Vaughn, 2008; Frenette et al., 2019), but also changes in resource consumption patterns. A recent literature survey found that increased temperatures increased herbivory by multiple freshwater taxa (Zhang et al., 2020). Additionally, enhanced atmospheric CO_2 is predicted to alter C:N:P ratios of basal resources, which could lead to profound shifts in the stoichiometry of elemental fluxes between consumers and resources at the base of the food web (Woodward et al., 2010). For example, leaf litter from trees grown under elevated CO_2 concentrations are of lower quality and support lower production of decomposing bacteria and fungi (Ferreira and Chauvet, 2011) and growth of a detritivorous cranefly in streams (Tuchman et al., 2002). Understanding how stoichiometric relationships in streams may change as a result of these interacting factors resulting from climate change remains a challenge.

Aquatic Food Webs In Rivers

Ross M Thompson, Centre for Applied Water Science and Institute for Applied Ecology, University of Canberra, Canberra, ACT, Australia

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Attributes Numerical properties of food webs that describe aspects of structure. Examples include food web size (number of species or nodes), connectance (proportion of possible links that occur) and average and maximum food chain lengths.
Environmental flows Managed flows within a river or wetland targeted to producing ecological benefits (Watts et al., 2020).
Food chain A series of trophic linkages which connect consumers and resources.
Food web A representation of trophic linkages between organisms as a compilation of food chains. These may be represented as presence/absence (binary food web) or weighted links (flux food web). Food webs can also be described as trophic networks. Some food web studies also incorporate non-trophic interactions such as competition.
Network A group of points or nodes connected by links or edges. In food web ecology the nodes are generally species or groups of species and the links are trophic connections. Networks can include a diversity of different types of interactions.
Topology The structure of a food web as described using a range of attributes.

Part one: An introduction to riverine food webs

A food web is a representation of interactions between organisms. Elton (1927) (reprinted 2001) coined the term food chain, and termed all the food chains in a community as a food cycle, which we now call a food web. Lindeman (1942) described the food web structure of Cedar Bog Lake in central Minnesota as a representation of flows of energy and nutrients. In so doing he defined the underpinnings of much of modern food web ecology, particularly within the tradition of ecosystem ecology. Originally specifically describing trophic interactions and fluxes of energy, modern food webs can encapsulate a wide range of trophic and non-trophic interactions (Dunne, 2006; Ings et al., 2009; Thompson et al., 2012). More correctly, this new generation of food webs, called 'interaction networks, often include non-trophic interactions including competition, plant-pollinator interactions behavioral interactions among others (see Ings et al., 2009 and references therein).

Food webs allow the visualization of interactions between groups of organisms in order to describe direct and indirect effects and how they may propagate through ecosystems (Fig. 1). Individual species, aggregations of species, or life-stages of species form the

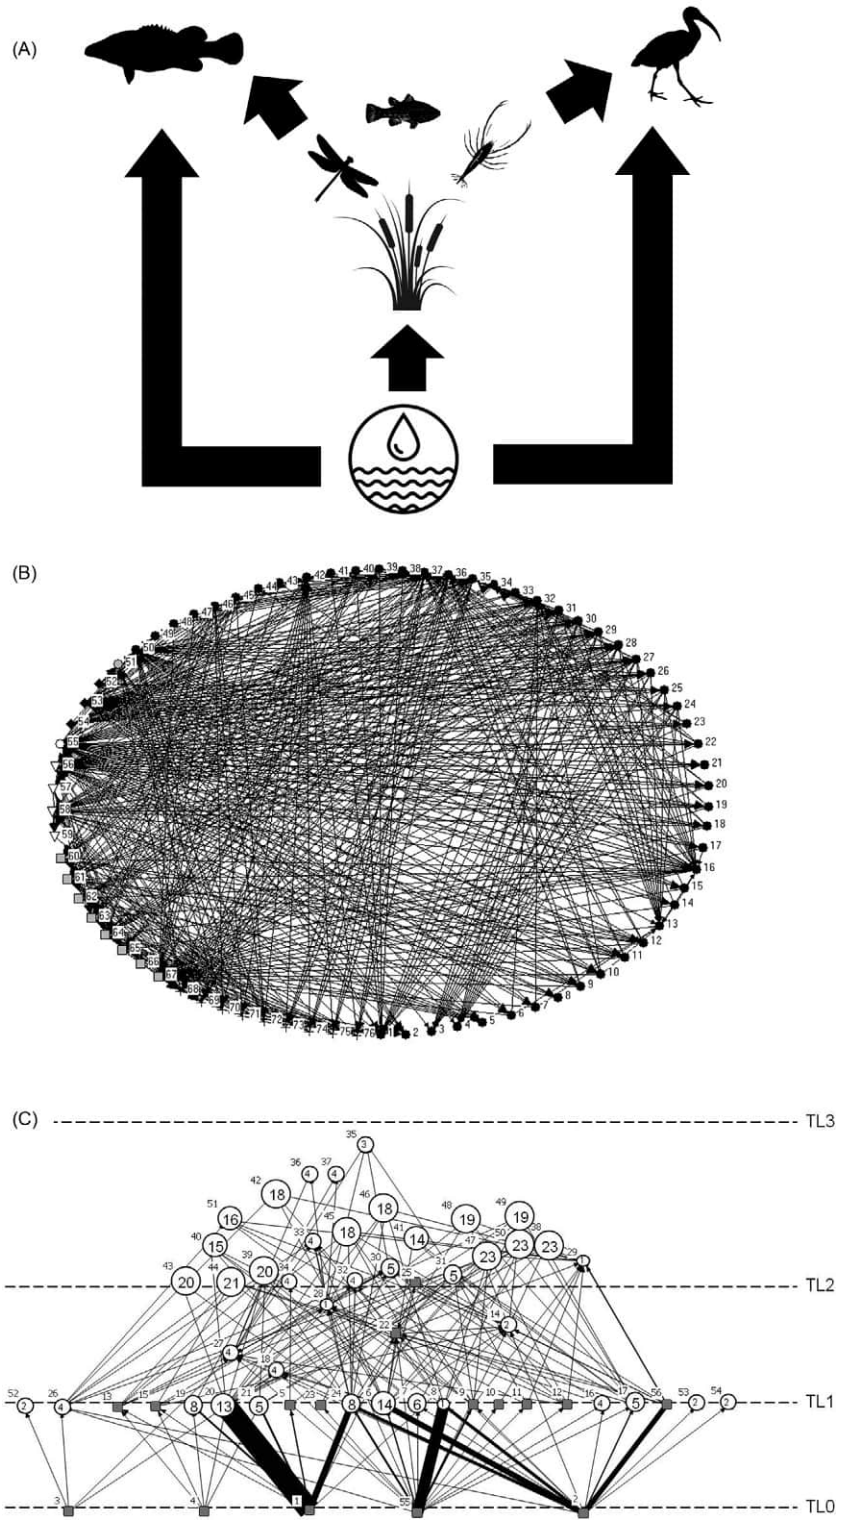

Fig. 1 Different approaches to describing food webs. (A) Simple conceptualization of links between major groups (Pollino et al., 2020). Representations of trophic interactions as (B) binary links and (C) weighted networks of energy flows (Thompson et al., 2005). components (nodes) within the food web and the flows of energy via transfers of live or dead biomass between nodes form the trophic links (edges). At their simplest, food webs allow a conceptualization of the complexity of a real ecosystem and allow development of hypotheses concerning direct and indirect effects of changes on ecosystems (Fig. 1A). Conversion of food webs into binary matrices allows calculation of a range of numeric attributes and application of a range of modelling approaches without the need for exhaustive information on biomass and energy flow (Fig. 1B; see Thompson et al., 2012 for a review). Non-binary energetic food webs include information on the biomass of each node and the magnitude of energy fluxes along trophic links, but they require detailed information and often grouping species into functional groups to make their description tractable (Fig. 1C). Weighted networks can be powerfully applied to generate estimates of biomass yields using simple mass-balance models (see Ings et al., 2009 for a review). These type of energetic food webs can incorporate the data that emerge from stable isotope analyses of diet (e.g., Peterson, 1999) and stoichiometric studies (e.g., Evans-White and Halvorson, 2017).

The analysis and interpretation of the attributes of food webs has been carried out for several decades. The nature and application of food web attributes is beyond the scope of this chapter, but it has been reviewed in detail in recent years (Dunne, 2006; Ings et al., 2009; Thompson et al., 2012). Over time the focus has shifted from seeking generalities in food web structure towards using food web attributes as indicators of ecological condition, as results of evolutionary processes and as predictors of ecosystem dynamics. Development of empirical models has allowed the exploration of a range of predictors of ecosystem dynamics, including niche segregation (Williams et al., 2010), effects of changes in consumer behavior (Kondoh, 2003) and the role of body-size distributions (Brose et al., 2006a,b). Most recently food web approaches have been directed towards understanding applied management issues such as the effects of land-use change (e.g., Thompson and Townsend, 2003), the impacts of invasion (see David et al., 2017 for a review) and management of flows (see Robson et al., 2017).

In rivers, food web studies have taken the full spectrum of approaches. Some of the earliest work on food web energetics was carried out by Allen (1951) who sought the basis for salmonid productivity in streams. Benke and Wallace (1997) played a critical role in revitalizing the energetic perspective on riverine food webs through their secondary productivity work. Long term investigations of food webs in single catchments have provided profound insights into community ecology, particularly with respect to the impacts of disturbance, seasonal variability and consumer impacts (e.g., Power et al., 2008; Cross et al., 2013). Ecosystem ecology has also benefited from the understanding generated by long-term studies of single river systems, particularly work at Hubbard Brook (e.g., Likens and Bormann, 1974) and other US Long Term Ecology Research sites (Kratz et al., 2003). Comparative studies across river systems have been applied to achieve a general understanding of the effects of ecological drivers such as disturbance (e.g., Townsend et al., 1998), changes in top predators (e.g., Romanuk et al., 2006), habitat size (e.g., Sabo et al., 2010; McHugh et al., 2015), and water quality (e.g., Layer et al., 2010). Experimental studies including whole-stream manipulations have been a critical part of understanding the role of cross-ecosystem fluxes of energy and materials (e.g., Wallace et al., 1997). The purpose of this review is to consider the key concepts which form the basis of riverine food web ecology and to extract some of the main insights that have emerged from the field in both a fundamental and an applied sense.

Part two: The conceptual basis for riverine food web research

Freshwater ecology has been characterized as focusing on testing general ecological theory rather than developing novel theory (Thompson and Lake, 2010). Certainly, the way in which the study of riverine food webs has been approached has drawn heavily on existing ecological theory. In part this is because rivers lend themselves to testing some areas of theory due to the nature of the ecosystem. Riverine food web ecology developed in parallel with ecological theory being developed in inter-tidal ecosystems, which share many characteristics including a focus on benthic processes, broadly similar food chain structure (algae-invertebrates-vertebrate consumers), an over-arching effect of physical disturbance and relative openness to fluxes of materials. Early marine community ecology research on keystone species, trophic cascades and disturbance (e.g., Paine, 1966) was particularly influential in guiding food web investigations in freshwater ecology.

Through the 1960s and 1970s studies of riverine food webs occurred in two loose groupings. Studies focusing on fish and fisheries tended to draw heavily on concepts from population biology and ecosystem ecology. This included the development of population models and the later extension of those into bioenergetic and population genetic models (e.g., Frank et al., 2011). Habitat work tended to focus on the requirements for a single species or small groups of species. This line of inquiry developed sets of physical habitat models aimed at optimizing management for fish habitat which ultimately linked to work on bioenergetic costs of habitat occupancy (and to environmental management (e.g., Dunbar et al., 2012; Naiman et al., 2019). Key concepts that have underpinned fisheries-oriented riverine food web studies have been based on bottom-up processes and habitat control of biomass, principles of meta-populations and connectivity, and managing for relative habitat stability.

The second major grouping of riverine food web studies have focused primarily on the invertebrate components. This work has been more heavily based in community ecology, with an initial focus on community composition and functional feeding groups evolving into a more dynamic view of trophic interactions including trophic cascades (Minshall et al., 1985). Habitat work had as a major driver the area of bioassessment, which sought to use primarily invertebrate communities to assess environmental condition and responses to a diverse range of stressors including water quality and channel modification (see Clarke et al., 2003 and references therein). The recognition of disturbance as a key driver in river ecosystems drove a focus on disturbance and succession processes, later extended to larger spatial scales (e.g., Feminella and Resh, 1990). Much less prominent, in part because of the logistic

challenges of such work, were ground-breaking studies of energy flows within river food webs (e.g., Benke and Wallace, 1997). Integrating studies of energetics and community structure became more tractable through the use of stable isotope analysis (e.g., Finlay, 2001; Jepsen and Winemiller, 2002).

Concepts from population biology

Size structure

The analysis of individual traits and population trait-distributions has been a significant part of ecology for decades. The inclusion of species traits as attributes in food webs has emerged as an important advance over the last 20 years, with studies incorporating behavioral traits (e.g., Moran et al., 2017) and trait diversity (Gravel et al., 2016). Among traits, body size has a pivotal position as a fundamental ecological characteristic with implications for trophic role, competitive ability, fitness and habitat occupancy (see Woodward et al., 2005a,b,c; Ings et al., 2009; Brose, 2010 for reviews). In aquatic communities size structure is influenced by a range of ecological drivers including physical and chemical disturbance regimes (e.g., Townsend et al., 1997a,b) and predation regimes (e.g., Layman and Winemiller, 2004). Incorporating body size into descriptions of riverine food webs has provided an increased understanding of the processes that operate to maintain diversity by preventing competitive exclusion and predator-prey interactions leading to the local extinction of prey (e.g., Layman et al., 2005; Woodward et al., 2005a,b,c). There is now clear evidence from river food webs that body size distributions are sensitive to effects of disturbance. For example, resilient species are characterized by short life cycles, rapid growth and high reproductive rates, and are also usually small. Thus altered disturbance regimes can directly influence size distributions (e.g., urbanization; Walsh et al., 2005).

Beyond considerations of body size distributions within populations, ratios between predator size and the average size of their prey (hereafter: body-mass ratios) have been the focus of considerable attention in general ecological theory (e.g., Warren, 2005; Brose et al., 2006a,b). These relationships have been suggested as being important predictors of food web structure, dynamics and stability (Otto et al., 2007). In riverine food webs, allometric scaling relationships have been shown to be altered by the over-arching effects of physical flow, which constrains the form of large consumers (Riede et al., 2011).

Meta-populations and dispersal

Perspectives from population biology provide opportunities to achieve better understanding of food webs. Predator-prey population dynamics can be extended into a food web framework and have been shown to affect food web structure and dynamics (Brose et al., 2006a; Otto et al., 2007). Within populations, differences in the trophic role of reproductive and non-reproductive individuals and differently sized individuals can influence food web structure (e.g., Woodward et al., 2005a,b,c). Population models are widely applied to the management of fish in river ecosystems, particularly for endangered large-bodied, and commercially significant, fish species (e.g., Gouraud et al., 2001). Although fisheries biology began as a science based on relatively simple population models with little consideration of movement between populations, the study of fish movement across riverscapes emerged as a core line of enquiry in riverine food webs through the 1980s and 1990s (e.g., Winemiller and Jepsen, 1998; Humphries et al., 2020). The critical role of connectivity across river networks became integrated into studies of fish population biology and community structure (e.g., Romanuk et al., 2006; Yeakel et al., 2014). Exploring these questions was enabled by the application of tools from remote sensing, population genetics and isotope science (see Lucas and Baras, 2000 for a review). What these studies have revealed is the critical importance of maintaining connectivity across river networks to support populations and riverine food webs (Winemiller and Jepsen, 2004; Liao et al., 2017). A key part of applying this insight to river management has been the development of meta-population models for riverine fisheries that include quantitative assessments of dispersal (e.g., Bellard and Hugueny, 2020). The application of population genetic tools has allowed not only a greater understanding of the role of dispersal in determining food web structure in rivers but also the importance of managing rivers as networks of interacting populations linked by dispersal (e.g., Morán-Ordóñez et al., 2015).

Concepts from community ecology

The habitat templet

Perhaps because of clear sub-habitat divisions (pools, riffles, runs, differences in substrate and flow velocity), riverine ecology through the 1960s and 70s drew heavily on ideas which linked physical habitat to community and food web structure. Southwood (1977) described the concept of the habitat templet, which acts on taxa over evolutionary time to select for traits closely matched to habitat axes. This was formalized for river systems by Townsend and Hildrew (1994). From an initial focus on physical habitat, habitat templets in river systems were expanded to incorporate differences in resources and functional feeding traits (e.g., Compin and Céréghino, 2007) and the effects of disturbance regime and associated traits (e.g., Huryn et al., 2005).

The focus of early riverine ecology on smaller 'wadeable' systems has a legacy which is evident in riverine ecology to this day. There tends to be a focus on patches of habitat and matching between local conditions and local communities. Numerous studies have related community composition and trait distributions to substrate characteristics and hydraulic variables (e.g., Gayraud and Philippe, 2001). Fewer studies have investigated the impacts of these patch-scale differences on food web structure. Power (1992a) showed that patch scale habitat heterogeneity affected food web structure by reducing the feeding efficiency of fish. Power and Dietrich (2002) emphasized the likely importance of connections between patch scale food webs within river systems. Thompson and Townsend (2005) illustrated this with a study of riverine food webs that showed a diversity of patch-scale food webs were

linked by the movements of predators at larger spatial scales. The recognition that movement between patches is a critical process influencing riverine food webs has reduced the emphasis on local habitat associations and led to studies which incorporate much larger scales within a nested and hierarchical understanding of the drivers of local food web structure (Woodward and Hildrew, 2002; Woodward et al., 2005a,b,c).

Trophic cascades and top-down vs bottom-up dynamics

The potential importance of predators in driving patch-scale food web structure brings together concepts of patch dynamics and trophic dynamics in river food webs. Debate over the relative importance of top-down (consumer-controlled) and bottom-up (resource-controlled) processes raged in ecology from the 1970s onward (see Power, 1992b; Matson and Hunter, 1992 for reviews). The most extreme examples of top-down influences, where consumer effects result in alternating positive and negative impacts along food chains have been observed in river food webs as a consequence of fish predation and appear particularly strong and prevalent in freshwater ecosystems (e.g., Brett and Goldman, 1996; Woodward et al., 2008). This may be because riverine food webs are dominated by invertebrate herbivores (Borer et al., 2005) and tend to have a lower proportion of omnivores (Thompson et al., 2007) than other ecosystems.

Studies of top-down and bottom-up influences in river food webs have revealed genuine complexity in these processes through space and time. Fish exclusion experiments in the South Fork Eel River in California, United States showed that the strength and direction of trophic influences varied with substrate type, time since disturbance and inter-annual variability in discharge (Power et al., 2008). Other studies have suggested that nutrient status, water temperature (Su et al., 2021), local hydrology (Strayer et al., 2008) and body size distributions of predators and prey (Detmer and Wahl, 2019) may also affect the strength and duration of trophic cascades in rivers. The modern synthesis suggests that strong top-down and bottom-up influences may be particularly common in rivers, but that those effects are transient in space and time and strongly influenced by a wide range of interacting drivers (Su et al., 2021).

Disturbance

A fundamental feature of riverine ecosystems is flow, flow variability and flow-elated disturbance regimes. Highly variable and/or unpredictable patterns of discharge in rivers act as disturbances with various frequencies and intensities (Poff and Ward, 1989). These disturbances can modify population and community processes and through evolutionary time have selected for traits hat confer resilience (adult mobility, habitat generalism, rapid population rowth) or resistance (clinging behavior, streamlined/ flattened morphology, several terrestrial life stages) (Townsend et al., 1997a). In recent years it has become clear that the effect of river flow on body form has implications for riverine food webs. Riverine ecosystems deviate from general scaling models for body mass and trophic levels, seemingly because flow selects for elongate rather than globular body forms (Riede et al., 2011; Brose et al., 2019). This morphological constraint may contribute to shorter food chains in rivers than in other ecosystems (Brose et al., 2019).

Disturbance is also an important driver of community dynamics in rivers. Studies of river food webs have shown that disturbance may have a role in affecting the outcomes of competitive interactions between species (Wootton et al., 1996; Townsend et al., 1997a,b). Moderate levels of disturbance appear to result in more diverse food webs with longer food chains (Townsend et al., 1997a,b; McHugh et al., 2015; Sabo et al., 2010), consistent with Connell's (1978) Intermediate Disturbance Hypothesis. However, this relationship appears to have complex relationships with other drivers including productivity (Townsend et al., 1998), trophic structure (Wootton, 1998) and the presence of refugia in the landscape (Harvey et al., 2018). Refugia from disturbance can occur at multiple spatial scales ranging from stable patches of substratum to adjacent undisturbed reaches (Sedell et al., 1990; Rempel et al., 1999). Improved understanding of the complex interplay of disturbance with food web dynamics in rivers has led to the concept of the 'Natural Flow Paradigm' (Poff et al., 1997) as a focus of restoration. This has the objective of restoring not only volumes of flow but also the timing and relative magnitude of flow events.

Increasingly it has become clear that local habitat, disturbance and energy supply influence food web structure in streams, with complex interactions in space and time driving the primacy of physical or biological processes (Townsend et al., 1998; Van Looy et al., 2019). The dynamic nature of these processes in space and time creates challenges in understanding how best to restore river food webs and how to detect trend changes because of press disturbances such as land-use alteration and climate change.

Concepts from ecosystem ecology

Bioenergetics

Food webs are fundamentally maps of energy and material flows, and as such might be expected to have close associations with disciplines such as ecophysiology. Intellectually food web ecology has tended to align more with community ecology than individual or population biology, particularly in rivers. There have in recent years been attempts to bring individual and population perspectives into food web ecology. It has been suggested that individual behavior can have profound impacts on food webs via effects on factors including prey selectivity, body size and fitness (e.g., Brose, 2010; Moran et al., 2017). This provides a clear link between evolutionary processes and food web structure, although these relationships remain relatively little explored (but see Valdovinos et al., 2010; Moya-Laraño et al., 2014). Individual variation in behavior and physiology can cascade up to ecosystem processes and can be incorporated into food web models (Stouffer, 2010). There have been relatively few studies at the junction of ecophysiology and food web ecology (but see Gaye-Siessegger et al., 2004 and Chikaraishi et al., 2007 for riverine examples). The fact that both disciplines share the use of energy as a fundamental currency provides rich opportunities for integrating individual level physiological studies into a food web context (Olff et al., 2009).

In marine systems, bioenergetic food web models have been used widely to advise fisheries management (e.g., Pauly et al., 2000). Adoption of these approaches in rivers has been slower, although the EcoPath (Pauly et al., 2000) modelling tool has been applied to investigating fisheries impacts of major impoundments (e.g., Deng et al., 2015). There remains considerable opportunity to use models of this type to bring together population processes and energetics within quantitative food web models (Robson et al., 2017).

Subsidies across ecotones

Across both fisheries-focused and other riverine food web studies, awareness of the importance of connectivity laterally and longitudinally emerged beginning in the 1970s (Likens and Bormann, 1974). This concept was formalized in a number of ways including in the River Continuum Concept (Vannote et al., 1980) and the Flood Pulse Concept (Junk et al., 1989). In rivers floods are important for allowing movement of materials and biota between the channel and the floodplain (Junk et al., 1989; Høberg et al., 2002). These movements can have profound impacts on in-channel food webs in terms of subsidizing productivity, connecting refugial aquatic habitats and providing access to breeding habitat (e.g., Winemiller, 2004). Movement of large mobile predators into the floodplain acts to connect food webs spatially and can provide the stimuli and resources necessary to support fish spawning (e.g., Jiménez-Segura et al., 2010; Humphries et al., 2020). Loss of floodplain connectivity as a consequence of impoundments, water abstraction and flood management has had a significant impact on river food webs globally, including loss of top predators, simplification of local food webs and increased heterogeneity of food web structure across the landscape (e.g., Ward et al., 1999; Jiang et al., 2021).

Work on river subsidies has included quantification of fluxes of carbon from marine systems into rivers and between floodplains and rivers (e.g., Wipfli et al., 2003). Influential experimental studies in the 1990s illustrated the importance of energy flows across the ecotone between rivers and terrestrial ecosystems (e.g., Wallace et al., 1997; Fausch et al., 2002). These showed that subsidies from adjacent ecosystems could profoundly alter food webs; for example, Nakano et al. (1999) was able to show that riparian insect inputs into rivers affected the strength of trophic cascades by providing alternate resources for trout. Other studies have shown the importance of aquatic subsidies in driving the dynamics of terrestrial food webs (e.g., Baxter et al., 2005; Wipfli and Baxter, 2010). The modern perspective of food webs in rivers recognizes that movements of energy and materials laterally and longitudinally are critical drivers of local food web structure and dynamics (Marcarelli et al., 2011).

Meta-communities and landscape processes

The recognition of the importance of the flow of energy within river ecosystems coincided with the emergence of landscape ecology as a discipline. Over recent decades food web ecology and landscape ecology have increasingly merged, as it has become clear that landscape processes (movements of individuals, energy and materials) are critical to local food web structure (Polis et al., 1997; McCann et al., 2005). This perspective has brought together studies of patch dynamics, disturbance ecology, meta-populations and energy subsidies in a spatial framework that recognizes the importance of nested spatial and temporal drivers (Thorp et al., 2006).

Building on concepts from community ecology, meta-community perspectives recognize the role of movement across landscapes in determining community composition and food web structure (Polis et al., 1997). This recognizes the critical role of dispersal in linking food webs spatially. The study of dispersal traits and landscape genetics have emerged as important areas of research endeavors to understand aquatic food web dynamics (e.g., Heino et al., 2015). Connectivity has also become integrated into studies of fish population biology (e.g., Yeakel et al., 2014). Large scale analyses of freshwater communities and food webs have revealed complex interactions with different spatial scales, dispersal traits, habitat variables and landscape position (Thompson and Townsend, 2006; Heino et al., 2015). The complex, nested and hierarchical nature of the relationships between drivers of community structure and food webs in riverine systems requires the adoption of sophisticated statistical approaches to disentangle the effects of different ecological factors (e.g., Thomson et al., 2012).

Novel features of river food webs emerge from the meta-community approach. Firstly, connectivity is a critical feature linking local-scale food web dynamics but is highly directional due to the effects of flow. This creates strong dependencies in lowland rivers on processes occurring upstream (Vannote et al., 1980; Power et al., 2013). Secondly, high frequency of food webs structured by top-down effects means that movement of vertebrate predators (mainly fish, but also birds; Steinmetz et al., 2003) at large spatial scales has important effects on food web dynamics. Movements of fish have been shown to have significant effects on food web structure (e.g., Winemiller and Jepsen, 1998, 2004; Cross et al., 2013). Consequently, river food webs are particularly vulnerable to the effects of dams and dewatering of channels which disrupt both movements of energy and organisms through the river network (e.g., Power et al., 1996; Naiman et al., 2012).

Part three: Three key insights from riverine food web ecology

The importance of a landscape perspective

The artificial silos of scientific disciplines have tended to segregate food web ecologists working on terrestrial and aquatic ecosystems. However cross-ecosystem perspectives have provided important conceptualizations that have driven river science. The River Continuum Concept, developed for North American streams flowing through deciduous forest, was important in recognizing that longitudinal variation in conditions and resource available can be expected to be reflected in food web structure (Vannote et al., 1980). The Flood Pulse Concept (Junk et al., 1989) provided a similar framing for the lateral movement of materials

between floodplains and rivers. Developments of these concepts have described temporal and spatial variability in subsidies of energy from upstream and lateral sources, creating a biogeochemical landscape of 'hot spots and hot moments' (McClain et al., 2003). There is an emerging understanding of the importance of connectivity at a wide range of scales for a wide range of biota and processes in terms of supporting food web structure and function (Vinagre et al., 2011; Liao et al., 2017).

Because of these linkages between rivers and their catchments, river food webs are profoundly influenced by the effects of land use change. The effects of land use change on rivers are both multi-facetted and highly complex, incorporating changes in hydrology, geomorphology, resource supply, impacts of contaminants and impacts of invasive species (e.g., Stets et al., 2020). The proximal effects of riparian land use change on food webs have been described in numerous studies ranging from the impacts of clear-cut forestry (see Wootton, 2012 for a review) to the effects of urbanization (e.g., Calizza et al., 2012). The nature of the effects on food web structure from land use change is strongly driven by the type of physicochemical impacts. Impacts appear to be particularly profound where land use change affects disturbance regimes, sources of productivity and physical habitat. Because rivers integrate the impacts of landscape level changes in landcover, impacts on the lower reaches of large rivers are particularly significant (e.g., Stets et al., 2020).

Food web studies in the 20th Century largely focused on small spatial and temporal scales (McCann et al., 2005) but that has dramatically changed in the last decades, enabled by a range of tools from population genetics, stable isotope chemistry and the geospatial sciences. Spatial coupling of habitats at different scales due to different sizes and dispersal traits of top predators is an important process in food webs generally, but particularly in rivers (e.g., McCann et al., 2005). Species dispersal between patches affects the local and global dynamics of populations with strong effects on food web persistence (Gravel et al., 2011). These results suggest strong feedbacks between local and landscape-scale dynamics that may interactively determine food web topology, species extinctions and ecosystem functioning.

Although many general principles of landscape ecology apply in river systems, connectivity within rivers is distinguished by the effects of directional flow. Accordingly, any point in a river is more likely to be influenced by conditions x distance upstream of that point than it is by conditions the same distance downstream. Although upstream movement of organisms acts to connect food webs in the lower reaches of rivers with those upstream, *net* movement of materials is from upstream to downstream (Wubs et al., 2016) in concert with substantial lateral fluxes (Junk et al., 1989; Nakano et al., 1999). Capture of organic matter from upstream and retention of organic matter are important drivers of local food web structure in rivers (Thorp et al., 2006; Roach, 2013). Features that trap and store organic matter, for example snags and depositional areas, are often hotspots of productivity and diversity (e.g., Benke and Wallace, 1997, 2015; Sheldon and Thoms, 2006). Similarly, adaptations to capture and retain organic matter are a feature of a wide range of riverine biota (e.g., freshwater mussels, filter-feeding caddis flies and crustaceans). Dams and impoundments that disrupt these flows of energy have substantive effects on food web structure in rivers and in some cases adjacent coastal ecosystems (e.g., Sabo et al., 2018; Vinagre et al., 2019).

Disturbance is the norm

Flowing water ecosystems illustrate the critical role of disturbance in shaping food web structure and dynamics. Every part of a river system is either experiencing disturbance or recovering from disturbance all the time. The combined effects of multiple disturbances, and lag and legacy responses to previous disturbances create a spatial and temporal mosaic of successional processes in rivers that is at odds with the traditional equilibrium view of ecosystems (Leitner et al., 2021). Food webs have been proposed as the over-arching framework that generates stability as an emergent property, through generating feedback loops, providing alternate energy pathways to consumers and supporting functional redundancy. Increased food web complexity appears to buffer species from the effects of species loss (Brose et al., 2005) and invasion (Romanuk et al., 2009). Elements of empirical network structure such as niche contiguity (Martinez et al., 2006) and compartmentalization (Stouffer and Bascompte, 2011) do increase dynamic stability beyond that observed in more randomly-structured networks. Adaptive behavior within food webs is likely to be important for stability and persistence by preventing consumers driving resources extinct (Valdovinos et al., 2010). The broadly consistent patterns in body sizes distributions and ratios may also generate stabilizing forces in food web structure (Otto et al., 2007). Allometric scaling relationships are less consistent in river food webs than in other ecosystem types (Riede et al., 2011) and it might be expected that this would mean less dynamic stability.

The persistence of complex, diverse river food webs despite effects of disturbance can be explained by the combined effects of individual species' resistance and resilience traits, consequences of network structure within food webs at a location, and landscape-scale processes of dispersal (Thompson and Williams, 2017; Liao et al., 2017). Of particular concern in an applied context is that a number of stressors have been able to be shown to disrupt these mechanisms. Brose et al. (2005) have shown that nutrient enrichment can result in the loss of keystone species. Fragmentation of habitats can disrupt the landscape processes that would act to 'rescue' species undergoing local extinction events and maintain river-scale biodiversity (e.g., Ru et al., 2020; Wang et al., 2020). In degraded rivers the importance of restoring physical habitat *and* the 'natural' disturbance regimes that maintain physical and ecological processes is now well understood (Poff et al., 1997). However, there are substantive management challenges in recreating these processes in rivers which are dammed, affected by water extraction and subject to regional scale impacts of invasive species, land use change and climate change (Poff, 2018).

The importance of energy as a unifying currency

Food webs provide a framework for combining perspectives from community ecology that largely focus on biodiversity, with those from ecosystem ecology that generally focus on energy flow (Thompson et al., 2012). The literature on biodiversity/ecosystem function relationships has predominantly focused on single trophic levels rather than full food webs (Qiu and Cardinale, 2020). The majority of these studies have occurred in terrestrial ecosystems, although freshwater studies have also contributed insights (Lecerf and Richardson, 2010). More recent studies have explicitly tested relationships between food web structure and ecosystem functioning (O'Connor et al., 2009). Food web approaches emphasize that the relationship between biodiversity and ecosystem function is one of co-dependence, and that the mechanisms underpinning these relationships are crucial to maintaining functioning ecosystems (Thompson et al., 2012).

The new synthesis emerging in riverine food webs uses energy as a common currency that links the river to its catchment, headwaters to lowland reaches and species to one another. The basis for this integration emerges from the early work of Lindeman (1942) and Fisher and Likens (1973) but is now enabled by a suite of new analytical tools. These allow organic matter sources to be identified using stable isotope analysis (e.g., Pingram et al., 2012; Fig. 2) and productivity to be measured in situ using open-channel metabolism (Demars et al., 2015). These measurements can be integrated with high resolution remote sensing data (Piégay et al., 2020) and powerful modelling approaches (e.g., Robson et al., 2017). The emerging ability to tractably track the movement of carbon in all its forms (dissolved, particulate, in organisms) through rivers, across ecotones with terrestrial and marine ecosystems and into and out of the atmosphere presents the immediate potential for virtual models of river systems that allow testing of management scenarios in silico within the next decade.

Part four: Applications of food web ecology to managing rivers

For decades most food web studies were fundamental in focus, with debate as to when, and even if, food web analysis could be applied to real-world problems (e.g., Memmott, 2009). However, the advances conceptually and empirically described in this chapter illustrate that food webs are now a powerful tool to understand, predict, and manage ecosystems experiencing multiple competing demands and environmental perturbations. Conceptually, food webs provide a simple framing of ecological systems that recognizes interdependencies between ecosystem compartments and the potential for indirect effects and feedbacks (Fig. 1A). This need not require an exhaustive description of trophic links or quantification of energy flows to provide a useful tool for integrating multiple sources of data from across river ecosystems into a single framework. When used in an empirical way, food webs can be applied to trace and predict the distribution of contaminants within ecosystems, allowing a better understanding of

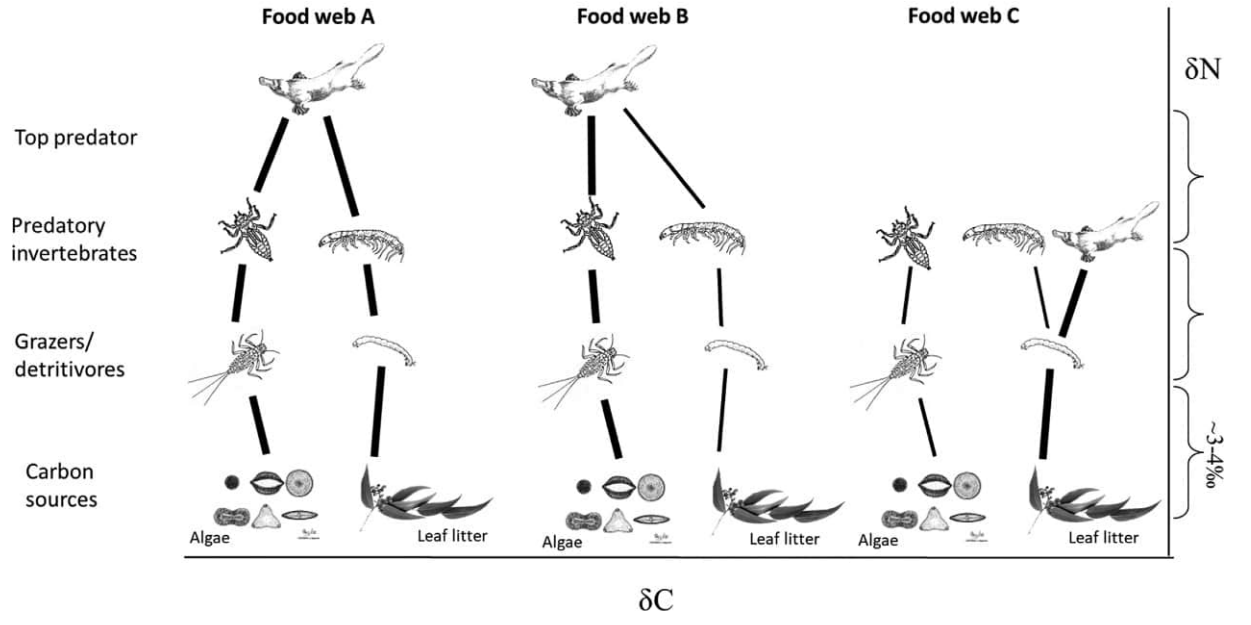

Fig. 2 Simplified representation of the use of stable isotopes to determine the trophic relationships of aquatic organisms. The x-axis shows the ratio between the two stable isotopes of carbon (δC), which differs between carbon sources. The y-axis is the ratio between two stable isotopes of nitrogen (δN). Each time a compound is consumed and excreted this ratio increases by 3–4 parts per thousand. In Food web A the top predator (platypus) has the highest δN value and therefore will be consuming predatory invertebrates. Because the platypus has a δ_C value intermediate between algae and leaf litter, energy is likely to be flowing from both carbon sources along food chains to the platypus. In Food web B the platypus has a δ_C value similar to the value for algae, so most energy is likely to be flowing along the food chain originating with algae. In Food web C the platypus has a δN value similar to that of the predatory invertebrates and a δ_C value similar to leaf litter. The platypus is likely to be directly competing with the predatory invertebrate which is sourcing its energy from the leaf litter-based food chain.

patterns of exposure across species within food webs and public health risk from consumption of fish and other taxa. Advances in dynamic modelling of food webs allow exploration of management scenarios for a range of environmental issues where species invade, go extinct or are harvested. Finally, where systems are being managed for both biodiversity and ecosystem functions, food webs provide a way to bring these perspectives together to guide whole-of-ecosystem management.

Framing a systems approach to river management

Managing small-to-large river basins incorporates a range of complex, interacting networks, including social, economic and ecological. Adopting systems thinking in natural resource management provides a suite of advantages including a refined ability to visualize interdependencies, predict indirect effects and manage for multiple outcomes (Thompson et al., 2019; Jacob et al., 2020). This not only involves treating the biological components of rivers as networks, but also linking food web networks with networks of other drivers. Food web frameworks for combining trophic networks with hydrologic metrics have been developed and applied in rivers already (e.g., Cross et al., 2013; Robson et al., 2017). However, the broader challenge is to link trophic networks into social-ecological systems treating river basins as a bio-geo-physical unit with associated social actors and institutions. Recent reviews have illustrated the ways in which this can be approached, ranging from simple conceptualizations of connections to communicate complexity through to networks of models that can be used in dynamic optimization (e.g., Dee et al., 2016). There is considerable opportunity to learn from marine fisheries management in adopting systems approaches to large river basin development (Jacob et al., 2020).

Multiple stressors and emerging contaminants

The vast majority of the world's river ecosystems are subject to anthropogenic stressors including hydro-electric development, abstraction for irrigation, urban development, water pollution and the multiple interacting impacts of climate change (e.g., Johnson and Penaluna, 2019). Understanding the effects of multiple stressors on rivers and their interactions across spatial and temporal scales is a significant challenge made more complex when those effects occur in food webs (Birk et al., 2020). However, food webs are already showing their utility in terms of predicting which taxa will be affected to what degree by a range of river pollutants (e.g., Liu et al., 2020). The need for an integration of food web ecology and ecotoxicology has been discussed before but an emerging understanding of interactions between networks of stressors and trophic networks is only now emerging (e.g., Gessner and Tlili, 2016; Nilsen et al., 2019).

Invasion and conservation management

The study of riverine food webs also provides a useful framing for understanding the effects of species' invasions and extinctions (Tylianakis et al., 2008). Unpredicted ecosystem-wide consequences of species invasions have been described from numerous systems (e.g., Rezende et al., 2007). The addition or deletion of species alters energy flows in ecosystems, and the degree to which an ecosystem changes will depend upon the network structure and the strengths of these connections. Food web models can be used to predict ecosystem impacts of species additions or deletions, and the vulnerability of food webs to invasion (Romanuk et al., 2009). Understanding the trophic role of invaders allows an assessment of whether they will substitute roles for an equivalent native species or significantly disrupt energy flow to other parts of the food web with the risk of secondary extinctions or altered ecosystem processes (Van Riel et al., 2006). Food web studies of invasions of rivers and streams appear to suggest that impacts are most profound when invaders have novel foraging strategies not present in the receiving community or physiological advantages such as more effective energy acquisition (e.g., Charlebois and Lamberti, 1996; Singh et al., 2013). Similarly, consideration of food webs during restoration activities can provide useful guidance on the order of management interventions and potential unintended consequences (Vander Zanden et al., 2006).

Impacts of flow modification—dams and water abstraction

Most large river systems globally are now heavily impacted by human activities and these pressures will be exacerbated by the effects of climate change (Hanjra and Qureshi, 2010) and increasing river development (Poff and Olden, 2017). Most often, the pace of river basin development has outstripped the ability to impose limits and develop policy to manage these pressures. Because river management involves numerous drivers and often multiple targets, food webs can provide a useful integrating framework. Cross et al. (2013) studied flow restoration in the Colorado River, by describing the full food web including energy flows. Understanding the patterns of energy flow in a food web context allowed determination of the mechanisms that led to increases in trout biomass. In a major environmental flow monitoring program in Australia (www.flow-mer.org.au) links are being sought between flows, patterns of production and respiration and in-channel food webs (Fig. 3). This advances a conceptual framing of relationships (Fig. 1A) to a process-based model that relates flow management to energy flow to top consumers (Fig. 3). Food web approaches are particularly important in studying and mitigating effects of large river impoundments because of the profound impacts that these have on energy flow (Ru et al., 2020).

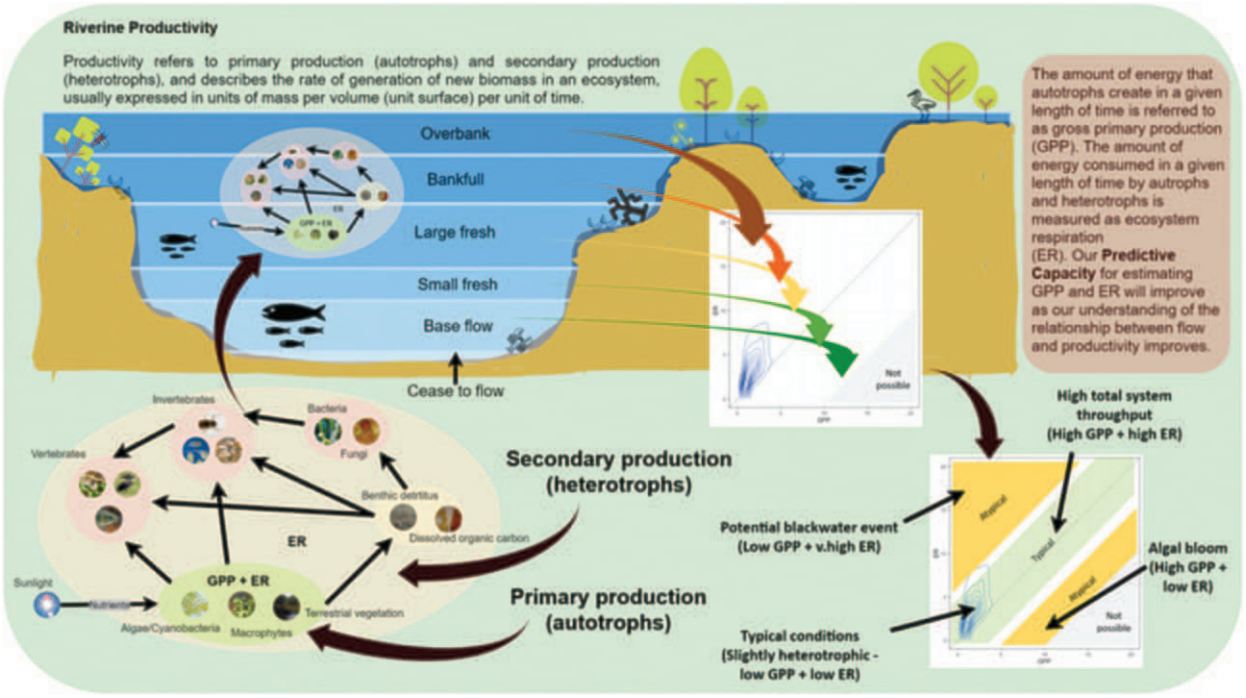

Fig. 3 Representing the effects of water level manipulation on production and respiration in a large floodplain river in southern Australia. A representation of the food web (lower left) links biodiversity to indices of ecosystem functions (bottom right). Figure: Paul McInerney, CSIRO.

Part five: Conclusion

River systems are defined by their connectivity. River food webs provide a framework for the integration of diverse sub-fields of ecology and quantification of links between biodiversity and ecosystem processes. Decades of research on river systems have elucidated drivers of food-web structure and dynamics at scales from the microscopic to the landscape. These clearly indicate the ways in which perturbations in food webs can have direct and indirect impacts that propagate throughout ecosystems. Adopting a food web approach does not necessitate exhaustive description of trophic links. At its simplest, adoption of food web thinking in rivers simply recognizes a set of inter-dependencies that allow predictions of potential knock-on effects of changes. This kind of systems thinking is important for avoiding unintended consequences of management interventions and predicting potential effects of perturbations. In a similar way, recognizing that river food webs are connected at whole-of-landscape scales provides a framework for understanding what stressors may be affecting a location in a river network. The development of food-web and network approaches is making it increasingly feasible to build systems models to test management scenarios via computer models. This scale and sophistication of food-web integration is the future of river management.

Acknowledgments

Particular thanks to the editors for their patience and to two anonymous reviewers for comments that improved the quality of the text. Colleagues in the Flow Monitoring Evaluation and Research, Environmental Watering Knowledge and Research and the Long Term Intervention Monitoring program, particularly Ben Gawne (Alluvium Consulting), Carmel Pollino and Paul McInerney (CSIRO), Fiona Dyer and Darren Giling (University of Canberra) and Darren Ryder (University of New England) greatly contributed through sharing concepts and data.

Energetics and Food Webs in Large Rivers☆

James H Thorp, Kansas Biological Survey and Center for Ecological Research, and Department of Ecology and Evolutionary Biology, University of Kansas, Lawrence, KS, United States

This is an update of J.H. Thorp, Models of Ecological Processes in Riverine Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00264-7.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Community ecology Research on the species diversity and functional relationships of multi-species populations within a specified area and time scale.

Endorheic Streams Rivers terminating in a desiccation basin or lake (freshwater or saline) and without ultimate flow to the sea; while these are the most downstream portions of some basins, assigning them a stream order number is misleading because the largest discharge component may be at the terminus or farther upstream, depending on whether the river flows into a lake or disappears by evaporation or into a sinkhole.

Floodscape That portion of a river lateral to the riverscape (main channel and slackwaters); it consists of normally dry floodplains, high elevation wetlands, and lakes/ponds that are inundated periodically by floodwaters.

Food Webs Feeding relationships within a community involving pathways for the transfer of energy and nutrients from primary producers to top carnivores.

Functional Process Zones (FPZs) Sections of all rivers characterized by one of many possible physical (hydrogeomorphic) structures, such as constricted, braided, meandering, and anastomosing channels; biotic diversity and functional processes typically vary in different FPZs.

Large River A vague term describing systems having a stream order greater than six; "great rivers" are large rivers often considered as having a stream order of 11 or greater.

Lotic Ecosystems Streams from small ephemeral headwater creeks to large or great rivers.

Riverscape The wetted portion of a river below the floodscape, including the main channel, side channels, and true backwaters (the latter with no flow-through during low to average river discharge).

Slackwaters Area where water flow rates are low in comparison to those in the middle of the main channel; includes wetted shorelines, embayments, and side channels of rivers.

Stable Isotope Analyses Analytic techniques for tracing elements passing from the abiotic to biotic environment and back; in food web studies the most common approach involves analyses of bulk tissues for the ratio of heavy-to-light carbon (13C vs 12C) and nitrogen (15 N vs 14 N) to determine food source and trophic position from producer to highest carnivore, but a more recent, precise, and expensive technique (e.g., Bowes et al., 2019) involves analyses of the presence or absence of essential amino acids in order to trace food sources (CSIA-AA).

Stream Order A hydrologic and geomorphic term providing vague information on the size of a stream based on the amount of branching occurring in a river basin; the lowest stream order equals "1" and is assigned to a relatively permanent stream that lacks upstream tributaries entering its main channel; the stream order increases by one when two equal sized stream orders join (e.g., two second-order streams produce a third-order stream but a second order plus a first order does not). Ecological process within two streams of the same stream order may vary significantly within the same or different basin.

The physical nature of large rivers and some ecological implications

This encyclopedia article is focused on "large rivers", but what does that term mean and how does the physical nature of a river influence its food web? A colloquial but surprisingly germane definition of such rivers for scientists and the public alike could be:

☆*Change History*: October 2021. James H. Thorp updated the chapter.

"One that is big enough to intimidate!" - perhaps reflecting the width, depth, physical complexity, high current velocity, and potential danger of these rivers. From a tributary junction perspective, a large river requires a stream order of at least 7 but may reach 12–14, depending on how you count the order of headwater streams (which altogether can constitute 80% of the river's total length). For example, the Mississippi has a stream order of 10–12 and the Amazon 12–14. Determining which rivers in the world are the largest depends on the metric you use and which reference you consult and for what time span, but for comparative sake the following is roughly correct: (a) the Nile (6695 km) and Amazon (6400 km) are the longest rivers (compared to the Missouri-Mississippi at 5971 km); (b) the Congo is the deepest river at its mouth (220 m); and (c) the Congo (41,000 cubic meters per second) and Amazon (209,000 cubic meters per second) and have the greatest annual discharge.

Large rivers are extremely powerful and typically deep, but their flow can be visually deceptive because of their relatively laminar flow nature when compared to the obvious turbulence of water flow in many low to mid-order streams. Their power becomes evident when something obstructs their path or you try to move upstream against the flow . . . and especially when the river breaks through a levee and sweeps away human-built structures. The proverb "still waters run deep" (apparently of Latin origin) succinctly describes the relationship between flow and depth in these massive rivers.

Generally speaking, all streams (headwaters up to the largest rivers) flood periodically. The ecological impacts of a flood are strongly related its spatial extent, duration, seasonality, and temporal predictability. Headwater streams are subject to rapid, more ephemeral, less predictable, and sometimes dangerous fluctuations in discharge, especially in confined canyons. In contrast, floods in large rivers can generally be predicted many days in advance and the rate of increase and decrease in discharge is far slower. Humans are often more cognizant of the effects of flooding in large rivers, however, because their flood waters spread farther laterally and typically cause more damage to human structures, especially those built close to levees if flood waters break through them. The seasonal timing of a river's flood, its temporal length, and the change in discharge vary greatly latitudinally (maximum in tropical latitudes) and with the primary source of flood waters (e.g., seasonal snow melt vs monsoons vs unpredictable rainfall).

The long-term temporal pattern and extent of flooding have significant influence on ecological patterns and biotic processes occurring in the riverscape and floodscape. If an annual flood occurs consistently by season and predictably lasts for long periods (e.g., in the Amazon River), then natural selection may favor species adapted in diet preferences, growth, and reproduction to an inundated floodscape. In contrast, an early spring flood in many temperate zone rivers (e.g., the Mississippi) that usually lasts for only a few weeks and occurs outside periods of maximum algal productivity and animal growth rates will likely have a minor selective effect on community composition and reproductive patterns compared to floods lasting for many months and regularly occurring during periods of maximum animal growth and reproduction.

Large rivers carry an enormous amount of sediment derived from tributaries, and thus are generally highly turbid, though exceptions occur such as the cobble-bottomed Yellowstone River in the northern USA and the Eg River in northern Mongolia. Consequently, the photic zone of these rivers is shallow; therefore, light typically does not reach the bottom of the river in the main channel of most large rivers except nearshore. As a consequence, primary production is often substantially depressed in most areas of the main channel. The downstream helical flow of the river also carries phytoplankton below the photic zone on a regular basis (see later discussion on river primary production). Another consequence of this sediment load is that the bottom substrate in the main channel of most large rivers tends to be sand or gravel (see later contrasts with side channels). From an ecological perspective, this low physical complexity results in a very limited diversity of niches for zoobenthos except near shore and in slackwaters. As a result, sediment-dwelling dipteran larvae (e.g., midges) and suspension-feeding bivalved mollusks often dominate the zoobenthos in much of the main channel (other than along the shores).

In contrast to the low habitat diversity in most of the main channel, the slow moving slackwaters of the main and side channels of the riverscape may contain a substrate diversity comparable in many ways to that present farther upstream. In particular, wood snags often dominate these areas in the form of whole tree trunks (especially after floods), branches, and roots from the riparian trees. Such areas provide vital hard substrates for invertebrates and hiding places for small through large fishes and other vertebrates. In addition to tree snags in these lateral areas, large rivers also may be characterized by extensive growths of macrophytes near shore, such as wild celery (*Vallisneria americana*), which provide protective habitat for small fish and invertebrates while also slowing the water currents. In navigable rivers of many countries in Europe and North America, these vital wood snags have been largely eliminated, at least from the main channel (initially for passage of paddlewheel steamboats in the mid-1800s), while at the same time access by fish to side channels and inundated floodplain habitat have been impeded by weirs and/or levees. The result of these government policies that were designed to support boat/barge navigation and flood control was a major reduction in habitat diversity of large river systems with subsequent severe ecological alteration. This can be seen from a century of changes in the Upper Mississippi River, as shown in Fig. 1.

From a more macro-perspective, the channels of rivers are not characterized by a simple increase in width from upstream to downstream, as often portrayed in classical theories from the last century and even today in many general ecology textbooks. Instead, they are often a mosaic formed by different hydrogeomorphic reaches that may vary throughout their length from a constrained or meandering channel all the way to multi-channel sections characterized by braiding, anastomosing, or even more permanent anabranching channels (Fig. 1). The different hydrogeomorphic areas ecologically form functional process zones (FPZs), which can support major differences in fauna and ecological processes. The most terminal point of a river that enters the often consists of multiple channels, but may instead be represented by other hydrogeomorphic forms, including by a constrained channel in more mountainous regions. Although floodplains may be more common downstream with a decline in a river's gradient, they can also be found in other low gradient sections of a river including within headwater regions.

Potential knowledge of large river ecology in the absence of anthropogenic disturbances is substantially limited by the extensive physical modifications of most large, temperate-zone rivers where the majority of river ecologists conduct their research (principally

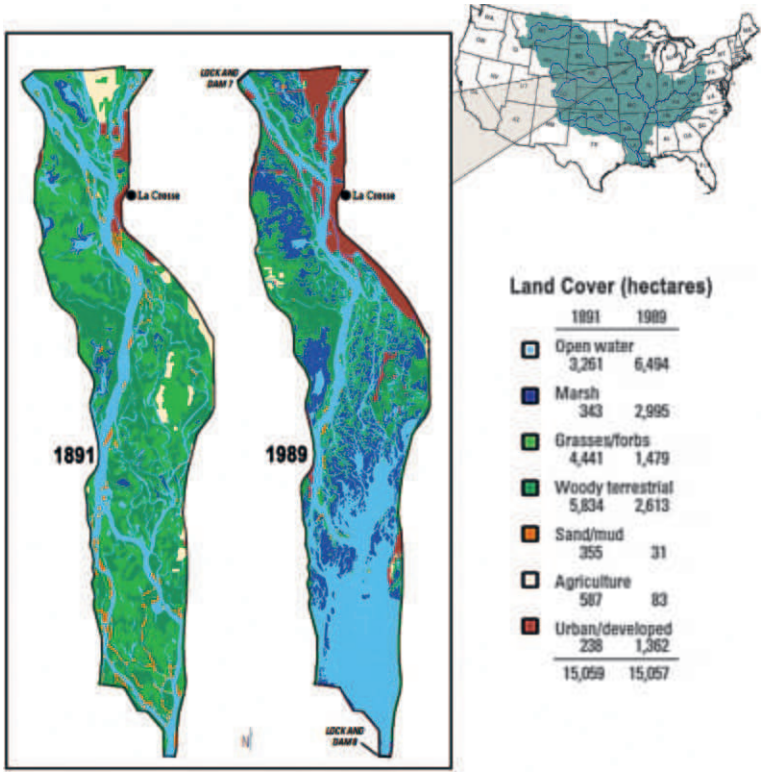

Fig. 1 Shown here are land cover and land use maps of the Mississippi River at Pool 8, located near La Crosse, Wisconsin, USA (GIS data from USGS.gov) showing the extensive decrease in slackwaters of this large river over time. The 1891 map provides a look at the river prior to the development of the lock and dam system in the 1930s. The 1989 map displays the significant changes impoundment of the river introduced into the system. This figure was copied verbatim from Bowes et al. (2019), and all data were obtained from: https://www2.usgs.gov/science/cite-view.php?cite=1587, and https://www.umesc.usgs.gov/data_library/land_cover_use/land_cover_use_data.html.

in Australia, Europe, and North America). Less modified rivers typically occur in tropical to sub-tropical regions of Africa, Asia, and South America. The presence of impoundments and levees has sometimes inadvertently led to misunderstanding about the importance of a river's hydrogeomorphic structure on ecological patterns and processes (see the next section). In particular, the relatively few studies of the importance of hydrologic connectivity and interactions laterally from the main channel to both slackwater areas of the riverscape and the floodscape have contributed most extensively to misunderstandings about large river ecology.

Energetics and food webs

To understand the nature of energetics and food webs in large rivers, at least five basic components of the system must be understood: (1) the physical structure of rivers as it may influence the metabolism, biomass, and growth rates of producers and consumers; (2) the types and proportions of functional feeding groups (consumer feeding guilds) in various habitats; (3) the composition and relative concentrations of organic materials derived from allochthonous (terrestrial in this case) and autochthonous (local and upstream aquatic) sources; (4) environmental and enzymatic limitations to the production, uptake, and transformation of these materials; and (5) seasonality of food web processes. For the sake of space in this article, the following discussion will partially focus on food webs located in one of the most physically complex, functional process zones, i.e., those with anastomosing channels.

Complex FPZs: An anastomosing FPZ (e.g., Williams et al., 2013) has a riverscape consisting of the main channel (the area with the highest flow rates, except for its low flow areas near shore) along with one or often more side channels, and sometimes one or more true backwaters (strictly speaking, those areas where through-flow occurs only during higher river stages). In comparison to main channel habitats, these lateral slackwater areas as a group are characterized by more substantial interactions of organisms with the riparian zone and significantly higher aquatic primary production as a result of slower current velocities, shallower depths, and generally low turbidity, thereby allowing a greater depth of sunlight penetration. All other FPZs - with the possible exception of

those with temporarily disconnected, anabranching channels - are likely to have lower densities and diversities of vertebrates and invertebrates as well as less complex food webs with a lower maximum trophic position (food chain length).

Aquatic Organisms: The freshwater faunas in slackwater areas of the riverscape (main channel border and side channels) - in contrast to high flow areas of the riverscape - are more likely to resemble those present in mid-sized rivers (orders 4–6) than they will to fauna in the higher flow areas of the main channel. This almost certainly reflects the combined effects of diversity in current velocities, turbidities, available benthic substrates, and food resource abundance and composition. This is true for bony fishes (and cartilaginous species in some parts of the world), other vertebrates (amphibians, reptiles, and a few mammals), aquatic insects, other benthic invertebrates, and zooplankton. While the dominant zoobenthos in higher flow areas of the main channel of large rivers primarily consists of animals that burrow into the soft substrate (e.g., Diptera such as chironomid midges along with patches of native unionid mussels and the invasive Asian clam *Corbicula* in some continents), one can find snails, small crustaceans, insects and other invertebrates along the shoreline of the main channel (especially in areas with abundant wood snags), though not in as great abundance or diversity as in lateral channels of the riverscape.

Among the most significant differences between fauna in main channel habitats (headwaters to large rivers) and lateral slackwaters (in mostly mid-order to large rivers) are the abundance and diversity of zooplankton. One common misconception among some aquatic ecologists is that freshwater zooplankton are not native to rivers and instead are merely recent and continuous immigrants from human-constructed reservoirs. From a conceptual perspective, this ignores the fact that rivers on many continents are typically more ancient than lakes (many natural lakes in Europe and North America are derived from relatively recent glacial scouring and lake formation). Moreover, one of the most ancient and signature species in large rivers of the Mississippi River Basin is the large paddlefish, *Polyodon spatula*, which as adults feeds primarily on river zooplankton (a related zooplanktivorous species, *Psephurus gladius*, may still survive in some areas of the Yangtze River of China)! The greatest diversity and abundance by far of lotic crustacean and rotifer zooplankton species occur in the lateral channels of anastomosing rivers where they primarily consume phytoplankton, some bacteria, and other zooplankton. Consequently, these zooplankton play important roles in secondary production of fishes, nutrient cycling, and funneling nutrients from the plankton to the benthos and transfer of some nutrients from slackwaters to the main channel.

Food Sources: Five potential sources of organic carbon contribute in varying degrees to food webs in lotic systems (as listed in random order): (1) mostly recalcitrant carbon derived from upstream organic processing; (2) allochthonous, terrestrially-derived carbon from the local riparian zone; (3) methane-derived carbon from the anaerobic riverscape bottom; (4) autochthonous carbon from benthic algae, phytoplankton, and some macrophyes in mostly slackwater and true backwater habitats of the riverscape; and (5) allochthonous carbon from the floodscape during flood events. These sources vary substantially in their seasonal abundance potential nutritive value, and how easily they can be obtained, chemically transformed - and most especially - assimilated into consumer tissues. Carbon derived from terrestrial habitats (floodscape and the upstream and local riparian zones) is usually far more structurally recalcitrant and thus more difficult to digest efficiently than are the chemically simple, labile organic compounds produced locally by eukaryotic algae. Consequently, in per unit carbon consumed, recalcitrant carbon does not lead to equivalent growth rates by consumers unless it has been colonized and transformed by prokaryotes into more labile and nutritious forms. Methane derived carbon must be transformed from a gas by specialized methanotrophs (e.g., methane-oxidizing bacteria) into a usable biochemical form before it enters metazoan food pathways. While the study of methane in lotic food webs is in its infancy, its overall contribution to eukaryotic food webs is probably minimal in most lotic habitats because it usually requires anoxic conditions. Its greatest importance is likely restricted to slow moving side channels and especially true backwaters where dissolved oxygen is depleted from bottom water and sediments for much of the year.

In contrast, stable isotope studies using either bulk-tissue analysis or compound specific stable isotope analysis with amino acids (CSIA-AA) (see description of both techniques in Arsenault et al., 2021a) have overwhelmingly demonstrated the primary importance of algae as the primary base of the food webs in most rivers with quasi-natural flow (i.e., without high dams or levees that eliminate access to slackwaters or other off-channel aquatic habitats). This has been recently demonstrated for both headwater (Fig. 2; Arsenault et al., 2021b) and large river food webs (e.g., Thorp and Bowes, 2017).

One caveat to this conclusion is related to potential contributions of allochthonous organic matter from the floodscape to the river metazoan foodweb. A prominent conceptual model (Junk et al., 1989) argued for the importance of terrestrially derived carbon from floodplains of the Amazon River as a subsidy to the main channel food web. Conclusions from that theoretical study, however, are questionable even for the Amazon because the role of floodplain algae (phytoplankton and attached algae) as a food source was not considered (nor were potentially crucial isotope data collected in that early study). In tropical floodplain rivers, the length of inundation of the floodscape is often long (months), the seasonal timing and flood length are relatively predictable, and the floods coincide with periods of high secondary productivity and reproduction of aquatic animals. In contrast, floods in temperate zone rivers, even if seasonally predictable (often during spring snow-melt), are typically short-lived (on the order of weeks rather than many months) and often not aligned with periods of maximum secondary production. Consequently, the contribution of floodscape carbon to metazoan production in temperate zone rivers is almost certainly significantly reduced in comparison to tropical floodplain rivers, although it may be important in sustaining populations through non-reproductive and largely growth-neutral periods. Note, however, that the largely recalcitrant carbon from the floodscape probably contributes substantially to carbon flow and system metabolism via the microbial-viral loop. This organic energy probably also enters the metazoan food web in both the inundated floodplains and the usually flooded riverscape via uptake first by heterotrophic microorganisms like protozoa and rotifers which are then consumed by crustacean zooplankton as part of a microbial-viral component of aquatic food webs.

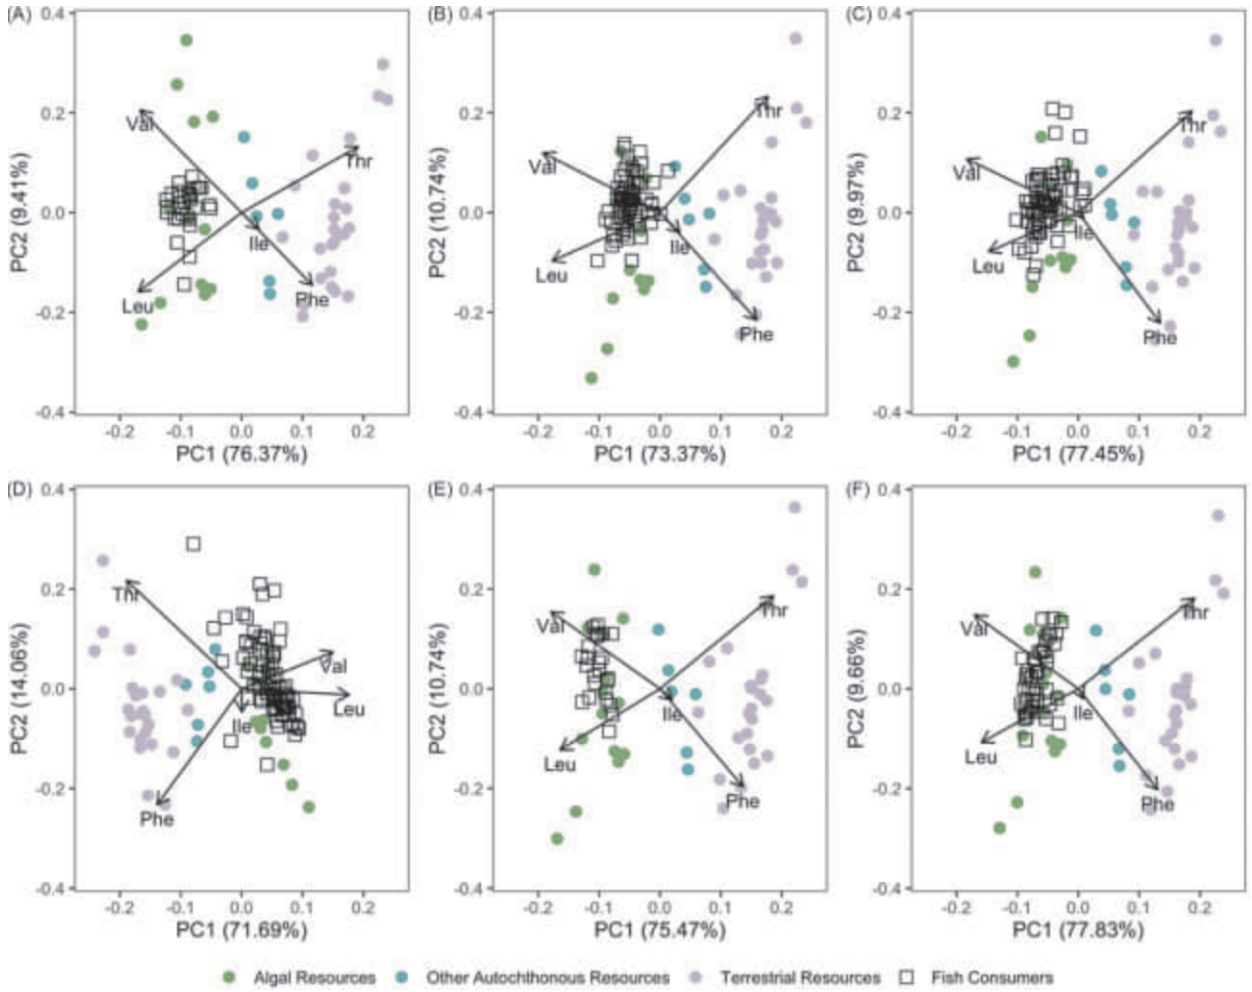

Fig. 2 Original graph from Arsenault et al., (in review): Principal component analysis showing normalized δ13CAA profiles of essential amino acids isoleucine (Ile), leucine (Leu), phenylalanine (Phe), threonine (Thr), and valine (Val) for six ecoregional types in two countries (A = United States grassland, B = United States mountain steppe, C = United States semi-arid terminal basin, D = Mongolia grassland, E = Mongolia mountain steppe, and F = Mongolia semi-arid terminal basin). Solid points represent potential basal carbon resources for freshwater systems, categorized as algal, other autochthonous, and terrestrial, and fish consumers collected in each ecoregion are represented by open boxes. Overlap between sources and consumers indicates likely basal dietary contribution.

Conclusion/synthesis

The physical structure of large rivers (stream orders seven and above) varies from single constricted channels to multiple anastomosing and anabranching channels, and these hydrogeomorphic structures have substantial effects on the abundance and diversity of metazoan organisms and food web processes in natural rivers (those where levees have not eliminated vital lateral channels). Rivers with abundant side channels typically have a higher overall species diversity and secondary productivity than other types of rivers present in similar ecoregions. The vertebrate, benthic invertebrate, and planktonic fauna present in slackwaters of anastomosing rivers are often more typical of mid-order rivers than they are of the main channel fauna of the contiguous large river.

A common misconception about large rivers is that zooplankton are naturally rare and perhaps even refugees from reservoirs, when in fact they are naturally abundant in side channels and backwaters where they provide food for both aquatic fauna and migrating waterfowl; and in some rivers, they energetically support large, ancient planktivorous vertebrates like riverine paddlefish.

The metazoan fauna of large rivers are principally supported energetically at the base of the food web by autochthonous sources (primarily algae), but overall carbon metabolism in rivers is heavily fueled by recalcitrant carbon processed in the microbial-viral loop. Terrestrially derived carbon from immersed floodplains can be important along with algae when the flood period is long, predictable in length, and coincident with periods of maximum secondary production and reproduction of resident aquatic animals.

Knowledge gaps

- What is the relationship between the timing (vis-a-vis growth and reproduction) and length of annual floods to the relative importance of autochthonous and allochthonous carbon sources for secondary production and species diversity in large rivers?
- How significant is the role of methane in carbon cycling and food webs in rivers and what factors influence its role?
- To what degree are latitudinal and ecoregional differences in the location of rivers critical for food web processes?
- How are energetics, food web structure, and community composition influenced by the hydrogeomorphic structure of rivers?
- What role does the hydrogeomorphic structure of rivers play in the transformation of recalcitrant to labile carbon and its subsequent incorporation into metazoan food webs?
- How important are energy subsidies from adjacent terrestrial zone to riverine food webs?
- What is the relative importance of autochthonous and allochthonous carbon to rivers through two metabolic food web pathways, one founded primarily on algae and a large metazoan component and the other based mostly on terrestrial carbon and a bacteria-dominated, microbial-viral loop?

Acknowledgments

The author appreciates insightful critiques of an earlier draft of this manuscript by Drs. F. Andrew Casper and Clifford A. Ochs. Production of this manuscript was aided by NSF research grants to study lotic and lentic systems in the USA and Mongolia (NSF 1442595 and 1926596).

Ecological and Evolutionary Consequences of Disturbance in Freshwater Ecosystems

Angus R McIntosh and Isabelle C Barrett, School of Biological Sciences, University of Canterbury, Christchurch, New Zealand

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Alpha and beta diversity Alpha diversity describes local richness (e.g., of macroinvertebrates) while beta diversity describes the turnover in species between locations.

Disturbance driver versus disturbance impact A *disturbance driver* is a 'force, either biotic or abiotic, that generates a deviation from the local, prevailing background conditions', whereas a *disturbance impact* 'represents the social-ecological consequences of a driver relative to a scale-dependent baseline state' (sensu Graham et al., 2021).

Life history Evolutionary adaptations relating to survival and reproduction that determine persistence in an environment, including traits associated with timing of reproduction, number of offspring, or lifespan.

Metacommunity Local communities linked at landscape scales by dispersal of potentially interacting species.

Pulse, ramp and press disturbances In *pulse* disturbances the driver is typically shorter and intense, whereas in a *press* disturbance, the driver may start suddenly but a consistent level is maintained over a longer period (Lake, 2000).

Refuges versus refugia Both terms are used to refer to habitats that convey spatial and temporal resistance and/or resilience to populations affected by disturbances, however 'refuges' operate on shorter timescales of minutes to decades, so reflect ecological processes, whereas 'refugium' (plural: 'refugia') are based on longer evolutionary timescales (i.e., millennia) (Davis et al., 2013).

Resilience The capacity to recover from the disturbance even though the biota and ecological processes have been diminished (sensu Lake, 2013).

Resistance The capacity of ecological entities to withstand the disturbance (sensu Lake, 2013).

Introduction

Disturbances have far-reaching and pervasive influences on rivers, where floods have been regarded as principal structuring forces on populations and communities (Death, 2010). However, more recently, the roles of drought and drying-related disturbances on rivers have been brought into focus, with very large amounts of stream length world-wide thought to be intermittent and with similarly far-reaching consequences for stream inhabitants (Leigh and Datry, 2017). Many human influences have also come to be regarded as disturbances, with similarly profound consequences for river ecosystems. In understanding the breadth of ecological and evolutionary consequences of the broad range of disturbances affecting freshwater ecosystems, appreciating the characteristics of the disturbance drivers helps explain their subsequent impacts on biota. Thus, we first describe and define disturbance in freshwater ecosystems, before outlining the types of ecological and evolutionary consequences.

Even though knowledge of disturbance underpins our fundamental understanding of freshwater ecosystems, ecologists have not always agreed about how to define it. To meet global-change challenges an interoperable understanding of disturbance in freshwaters is useful (Graham et al., 2021), so we introduce a generally-based framework for understanding both disturbance *drivers* and disturbance *impacts*, and highlight the dimensions they can take. We include human-driven as well as natural influences.

The impacts of disturbance are pervasive across levels of biological organization in freshwaters, so we organize our summary across those levels, from organismal traits, to population responses, to community-level effects, and finally to food webs. These consequences have high relevance for freshwater futures because disturbance drivers linked to global change processes are set to become more influential as climate warming takes hold. This is because the disturbance regimes freshwater systems experience now will likely not be what they experience in the future (Tonkin et al., 2019). Thus, we conclude by framing the challenges of predicting and managing the influences of disturbance in response to the large range of global changes affecting freshwaters, but especially those driven by climate change. All river taxa are impacted by disturbance (algae, insects, fish, plants), but we will focus mostly on insect examples here.

The dimensions of freshwater disturbance

A definition of disturbance

Even though disturbances are fundamentally important for understanding virtually any aspect of freshwater systems, our grasp of them has been hampered by inconsistent terminology. That 'disturbance' can refer to both the physical alterations that change ecosystems and the consequences of those events is particularly confusing (Graham et al., 2021). Thus, separating biological or other responses, from their drivers is critical for defining aspects of disturbance (Death, 2010).

Following emphasis on physical removal processes, early definitions sought to characterize disturbance in terms of the removal of organisms associated with specific physical events. For example, a disturbance in a stream could be 'any relatively discrete event in time that removes organisms and opens up space which can be colonized by individuals of the same or different species' (Townsend, 1989). Around this time, Resh et al. (1988) suggested that predictable events, like high discharges due to spring snowmelt runoff, might not be disturbances since organismal life histories were geared to cope, and communities showed relatively little change in response. On the other hand, Poff (1992) argued focus should be on when habitat was disrupted and any tautological linking of disturbance occurrence with impact should be avoided. These debates certainly fueled awareness of the multiple dimensions of freshwater disturbances, and the need to separate disturbance drivers from their impacts, but they did not regard human influences as disturbances.

More recently, human influences on freshwater systems have also been characterized as disturbances. For example, Collier and Quinn (2003) describe deforestation and conversion to pasture, which alters wood and leaf-litter inputs, channel shapes, temperatures, nutrient inputs and flow regimes, as a disturbance. Similarly, a synthesis of the urban stream syndrome describes urban streams as disturbed because their physical conditions are degraded relative to those not affected by urbanization (Booth et al., 2016). Managers have embraced this view as a way to frame and communicate human impacts on freshwater systems, even though it does not fit with Townsend's (1989) definition above. Many would see human influences as stressors and would prefer to label more discrete events as disturbances. Moreover, because disturbance is an integral part of maintaining freshwater biodiversity (Bunn and Arthington, 2002), it's important that we do not necessarily associate a disturbed system as being in any way generally unhealthy. Nevertheless, the many uses across freshwater science, and the clear human influence on most disturbances regarded as natural, mean a definition reflecting the diversity of use is essential.

Recognizing that many scientists, and those implementing disturbance ecology, hold a wide range of views, we prefer the Graham et al. (2021) framework that broadly defines disturbance while also clearly distinguishing the disturbance driver from the disturbance impact. Thus, a *disturbance driver* is a 'force, either biotic or abiotic, that generates a deviation from the local, prevailing background conditions', and a *disturbance impact* 'represents the social-ecological consequences of a driver relative to a scale-dependent baseline state'. Of course, impacts will be relative to the scale and context, but as long as we seek to clearly distinguish *drivers* and *impacts*, this definition can be used.

Types of disturbance drivers

A great array of disturbance drivers has been characterized from freshwater systems and measured using a variety of techniques (Table 1). In addition to the flooding and drying of aquatic habitats, these include physical alterations associated with forest fires that affect floodplains, channel characteristics and resource inputs (Malison and Baxter, 2010), and cause pulses of sediment know as 'sand slugs' (Lyon and O'Connor, 2008). In winter, stream channels can freeze and be enclosed in ice, with the entire channel freezing solid in some cases also creating a disturbance (Parker and Huryn, 2013). Natural processes are often involved in these disturbance drivers, but event magnitude is most important. For example, blackwater events, where large amounts of dark-colored deoxygenated (i.e., hypoxic) water are released downstream (e.g., ~2000 km of the Murray Darling in Australia; Whitworth et al., 2012), are associated with decomposing plant litter that releases dissolved organic carbon (DOC). It is the scale and extent of the DOC released in blackwater events that fuels aerobic bacteria, potentially depleting oxygen for kilometers downstream. The poisoning of aquatic animals through discharge of human-associated contaminants like heavy metals in urban stormwater is also unfortunately common (Booth et al., 2016).

Freshwater disturbance drivers can be characterized in terms of their magnitude, frequency, timing, predictability, duration, rate of change and extent, similar to flow regimes, but three general types of disturbance driver are generally recognized based on their temporal characteristics (Fig. 1). Firstly, in 'pulse' disturbances the driver is typically shorter and intense like a flood (Lake, 2000). Although the driver may have a sudden onset in a 'press' disturbance, a consistent level is maintained over a longer period (Lake, 2000). Many human-associated disturbance drivers, such as the presence of a dam or acidity associated with mining, are press disturbances, because they continue over long periods. Regular or 'seasonal' drying could also be a press disturbance (Lake, 2003). Finally, in 'ramp' disturbances the strength of the driver changes steadily over time. Ramp disturbances may include increasingly severe drought conditions, such as a multi-year (or supra-seasonal) drought (Lake, 2003), or decreasing disturbance such as stream restoration that slowly alleviates degradation.

Connections to ecological stability and the roles of resistance and resilience

Another important aspect of the temporal dimensions of disturbance is the connection to ecological stability, especially resistance and resilience. Ecological stability has multiple dimensions, but most simply, stable communities either maintain, or return to, their previous state after a disturbance, so disturbance impacts are closely related to the resistance and resilience of communities (Donohue et al., 2016). *Resistance* is 'the capacity of ecological entities to withstand the disturbance,' whereas *resilience* is 'the capacity to recover from the disturbance even though the biota and ecological processes have been diminished' (sensu Lake, 2013). Resistance and resilience can be assessed by measuring changes over time relative to a baseline. For example, applying a disturbance assay that involved water-blasting stream beds followed by comparison of community recovery relative to control reaches revealed that the communities of small streams were much less resistant to disturbance than those of large streams (Greig et al., 2021). A full evaluation of factors affecting the stability of river communities is beyond the scope of this chapter, but in general recovery is closely related to the availability of resources, recruits and refuges (Van Looy et al., 2019).

Influences on individuals, life histories and populations

Disturbance avoidance strategies

Since disturbances can cause widespread mortality among organisms, they have been a powerful force shaping the behavior of individuals, their life histories, population dynamics and ultimately distributions. Not surprisingly, river organisms try to avoid their consequences! Tactics vary according to waterway type, but these generally include life history, behavioral and morphological adaptations that provide benefits by enhancing survival or recolonization (Lytle and Poff, 2004).

Table 1 Examples of disturbance drivers and their measurement in freshwater systems.

Disturbance driver	*Measurement approach*	*References*
Flooding	Insertion of marked tracer particles in the stream bed	Townsend et al. (1997a,b)
Flooding	Multivariate disturbance index incorporating the Pfankuch bed stability score	Death and Winterbourn (1995)
Floods and stream drying	Spectral analysis and extreme event analysis	Sabo et al. (2010)
Freezing	Temperature loggers	Parker and Huryn (2013)
Stream drying	Range of flow-related statistics associated with magnitude, timing/predictability, frequency and duration of long-term and antecedent (immediately prior) flows.	Leigh and Datry (2017)
Flood-disturbed patches	'Scour chains' to measures patterns of bed filling and scouring	Matthaei et al. (1999)
Sedimentation (sand slugs)	Sediment depth transects over time	Lyon and O'Connor (2008)
Wildfire	Periphyton chlorophyll *a* or ash-free dry mass	Malison and Baxter (2010)

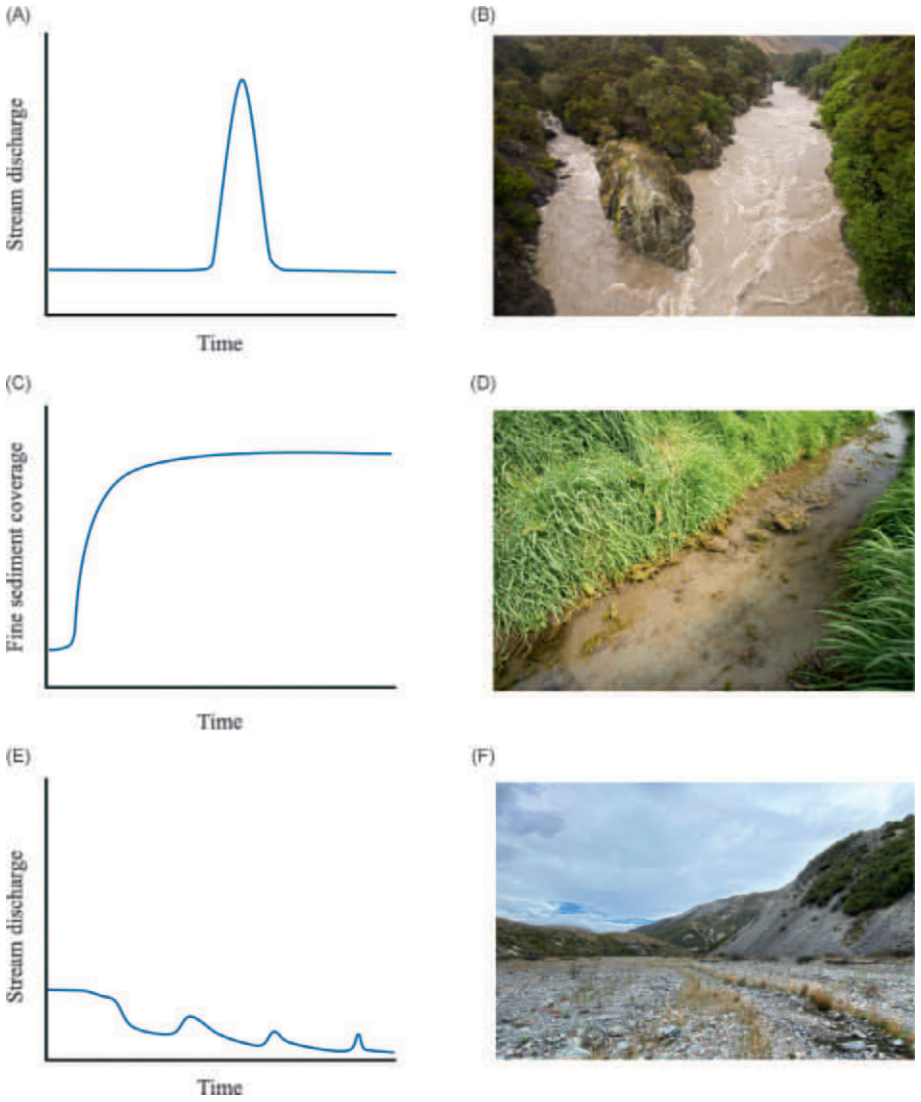

Fig. 1 Three general types of disturbance drivers in freshwater ecosystems indicated by change in important driver-related measures over time: pulse (A and B), press (C and D) and ramp (E and F). Pulse disturbances are usually short and intense like the flood in this New Zealand river (B), whereas press disturbances maintain a more constant level over time as in the case of fine sediment inputs to a stream following land use change from forest to pasture (D). Finally, during ramp disturbances the strength of the driver changes over time, such as the in the river shown (F) where a drought initially exposed part of the river bed, but then progressed to full drying downstream.

The trade-off between growth and development versus disturbance mortality risk

Although animals employ the strategies described above, they still have to balance growth and development with the risk of disturbance-driven mortality. For example, the disturbance avoidance strategies described above almost always come at some cost like the loss of biomass, smaller body size or reduced competitiveness (Lytle and Poff, 2004). This trade-off is especially important for those completing most of their growth in aquatic environments like many stream insects. Research in the arid Southwest of the United States, where flash flooding caused by localized thunderstorms can cause widespread mortality of stream faunas, has been particularly helpful in understanding these trade-offs. For example, 86% of *Phylloicus aeneus* caddisflies emerged from montane streams in the Chihuanhuan Desert before the long-term average arrival date of seasonal flooding (Lytle, 2002). The life history of these caddis also reflects the growth versus survivorship trade-off because they adjust their body size according to the likelihood of flooding, speeding up development and emerging smaller as the risk of flooding approaches (Lytle, 2002).

One of the most interesting examples of adaptation to flash floods is the behavior of a flightless giant waterbug, *Abedus herberti* (Order Hemiptera), in streams of the Madrean Sky Islands, again in the Southwest United States. The waterbugs' use persistent rainfall on the stream surface as a cue for an impending flash flood, and they walk out of streams to avoid the wall of water and almost certain death (Lytle et al., 2008). The behavior is even able to be triggered by simulating rainfall with a pump and firehose (see video in https://lytlelab.science.oregonstate.edu/floodescape).

Disturbance predictability and life history evolution

The effectiveness of the strategies for avoiding drying described above strongly depends on the characteristics of the disturbances. Theory explaining the evolution of life-history responses to freshwater disturbances suggests the strength of selection pressure for such strategies will only be strong when both disturbance magnitude and predictability are high (Lytle and Poff, 2004). This is because the consequences of lost foraging opportunities linked to false alarms are also important. Giant waterbug behaviors in the Madrean Sky Islands also illustrate this. The waterbugs are much less responsive to local rainfall cues in small catchments because floods seldom occur there, whereas local rainfall in medium-sized catchments is a reliable indicator of immanent flash flooding, and that is where the waterbugs are most responsive to the rainfall cues (Lytle et al., 2008).

If predictable disturbances are required for finely tuned disturbance responses, what do organisms do when presented with quite unpredictable or non-seasonal disturbances? In an analysis of the seasonality and predictability of 30-year rainfall records from around the world, Tonkin et al. (2017) showed this is exactly the sort of flooding regime that occurs in places affected by a strongly oceanic climate like New Zealand. Winterbourn et al. (1981) explained that, 'New Zealand stream invertebrates possess flexible, poorly synchronized life-histories with non-seasonal or weakly seasonal patterns of development, and extended flight and egg-hatching periods' and linked these characteristics to the unpredictability of New Zealand's floods. These life history traits contrast those from locations with predictable flooding like Colorado's Rocky Mountains, where development is synchronous and tightly linked to seasonal snow-melt (Peckarsky et al., 2000) (Fig. 2). Thus, unpredictable disturbance is associated with flexible life histories and generalist traits.

The flexible life histories and generalist traits involved in responses to unpredictable disturbance regimes are exactly what life history theory predicts (Lytle and Poff, 2004). Unpredictable disturbances are difficult for organisms to forecast and pose risks, but such habitats can also offer large benefits if organisms can exploit windows of opportunity in them.

Effects of disturbances on genomic diversity

Understanding how disturbance ultimately affects populations, including how the various strategies described above evolve, will be aided by genetic studies. Understanding at this level is still developing, but recently Poff et al. (2018) demonstrated extreme flooding across 14 streams had a variety of effects on genomic diversity (allelic richness). Among six stream invertebrate species studied, two declined in allelic richness and one increased following the flooding. The one increasing, the common mayfly *Baetis tricaudatus*, probably recolonized from upstream populations, presumably adding new alleles to local populations. The variety of genetic responses observed suggested that making generalizations about the evolutionary processes involved would be difficult, but this study did highlight the potentially important role for refuges (upstream reaches in this case).

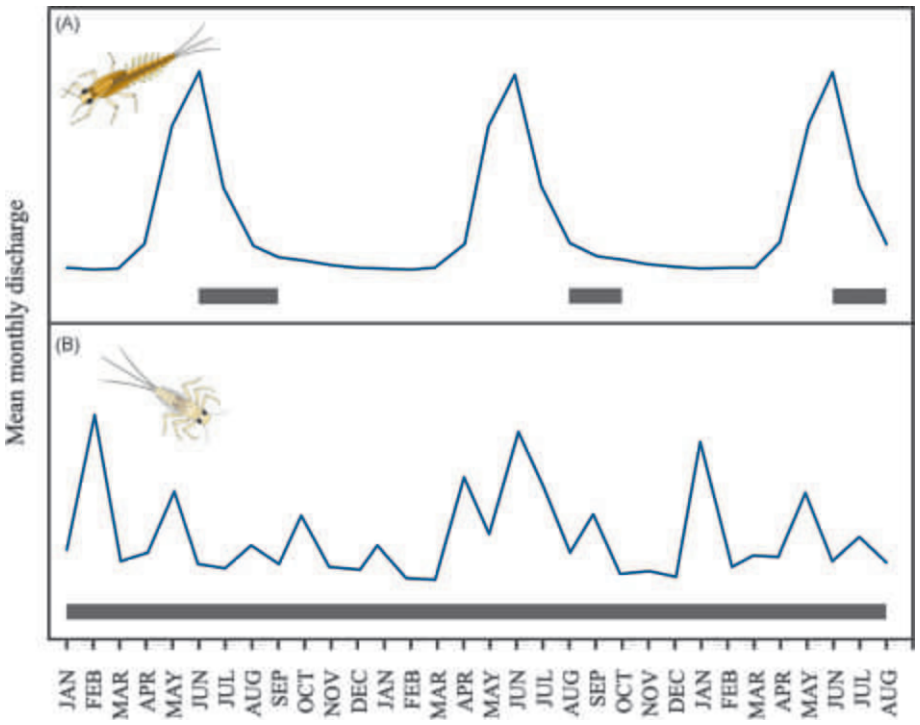

Fig. 2 Examples of synchrony and lack of synchrony in invertebrate life cycles associated with predictable and unpredictable disturbance drivers, respectively, indicated by emergence (gray bars) of *Baetis* mayflies in Colorado, United States, in line with seasonally predictable flooding (blue line; A), and asynchronous emergence of *Deleatidium* mayflies in New Zealand where the flooding regime is highly unpredictable (B).

Ecological 'refuges' versus evolutionary 'refugia'

As the genomic information implies, the resilience of populations in response to disturbances is closely related to the availability of individuals from elsewhere to repopulate disturbed areas. The terms 'refuges' and 'refugia' are both used to refer to habitats that convey temporal resilience to populations affected by disturbances, but the key difference is the timescale that these operate on (Davis et al., 2013). 'Refuges' operate on shorter timescales of minutes to decades, so reflect ecological processes, whereas 'refugium' (plural: 'refugia') are based on longer evolutionary timescales (i.e., millennia) (Davis et al., 2013). Distinguishing between refuges and refugia in aquatic systems is integral to understanding the processes that maintain them in aquatic landscapes (Davis et al., 2013).

Perennially-flowing reaches to which aquatic organisms can retreat to, and recolonize from are important refuges in drying rivers. For example, in rivers with seasonally-drying reaches associated with Mediterranean climates, the recovery of populations of stream invertebrates following dry periods depends on connectivity to perennially flowing reaches (Robson et al., 2013). For many flood-prone rivers, less impacted tributaries upstream can act as refuges, as the Colorado study above demonstrated (Poff et al., 2018). Similarly, stable portions of the stream bed (Matthaei et al., 1999) or even deep stream-bed sediments, an area known as the hyporheic zone, can act as refuges in flood-prone rivers (Stubbington, 2012). In all cases, dispersal, recolonization and recruitment facilitated by connectivity with the refuge are important for population recovery (Van Looy et al., 2019). The identification of refugia has been more difficult, because of the much longer time scales involved, but Davis et al. (2013) have identified evolutionary refugia in the arid zone aquatic habitats of Australia. These are groundwater-dependent habitats like subterranean aquifers and springs that supported relict or poor-dispersing fauna. Thus, both refuges and refugia are important in recovery from disturbance, but the refugia are much less well known and may be crucial given ongoing climate change.

Disturbance impacts on aquatic community composition and diversity

Many of the stream disturbance impacts described as profound in the literature are linked to substantial effects on the composition, richness, diversity and traits of organisms in affected communities.

Mostly, disturbance reduces taxonomic richness in communities

Both linear and non-linear relationships between local diversity components and river disturbance have been identified across disturbance gradients. The intermediate disturbance hypothesis, whereby a trade-off between competitive and disturbance-tolerance drives richness, has been invoked in stream disturbance studies, but empirical support for this hump-shaped relationship is low (Lepori and Hjerdt, 2006). A diversity peak in stream community richness at intermediate levels of flooding disturbance has been found (Townsend et al., 1997a), but most studies typically reveal that species are removed from communities as the harshness of the flooding regime increases so richness declines with flood disturbance (Death and Winterbourn, 1995). Gradients of human-driven stream disturbance usually show similar patterns whereby both richness and measures of diversity decline with disturbance drivers that increase the harshness of stream environments (Booth et al., 2016). Patterns conforming to the IDH may be uncommon in streams because competition is less likely in movement-dominated open systems (Death, 2010). However, comparisons could also be confounded because stable streams could also have more habitat heterogeneity (e.g., through more aquatic plants which add additional habitats), thereby making exclusion less likely. Overall, richness usually declines at the harsh end of disturbance gradients, but the drivers of richness at the stable end of disturbance gradients involve a range of different drivers and resulting patterns.

Relationships with time since disturbance and productivity

Relationships with time since disturbance and productivity shed further light on these patterns in richness. Time since disturbance tends to show strong relationships with diversity and abundance. For example, insect abundance in flood-prone streams of the Venezuelan Andes is closely related to days since the last storm reflecting the time taken for recolonization and recruitment from refuges (Flecker and Feifarek, 1994). More frequent, less intense disturbance events may also have a more severe impact on long-term community composition than fewer, more intense disturbances, because high disturbance frequency more severely disrupts those recolonization and succession processes (Hemphill and Cooper, 1983).

An important mechanism behind the effects of disturbance on community richness are influences on resource availability (Parker and Huryn, 2013). This is particularly important with flooding, where bed movement and scour remove attached algae from stone surfaces and washes away detrital accumulations. For example, the direct effects of flood-driven bed movement on fish whereby fish are washed away are of similar magnitude to the indirect effects via influences on their invertebrate food supplies (Jellyman et al., 2013). Overall, it is likely that both productivity and disturbance interact additively to strongly influence diversity, whereby productivity sets an upper limit to richness that can be achieved by colonization, and disturbance acts to remove taxa below that level (Death, 2010).

The importance of traits that confer resistance and resilience

Delving beyond species identities and investigating their traits (i.e., biological attributes such as body shape, feeding method, movement type, etc.) provides further insights into the influences of disturbances on communities. As described above, disturbances impact taxa differently depending on their capacity to withstand and recover from disturbance. Persistent species have disturbance-resistant traits. For example, mobile invertebrates can better survive floods than more sessile taxa (Wootton et al., 1996; Jellyman and McIntosh, 2020), and detritovores can better survive fine sediment deposition in gravel beds than scrapers which require clean gravels to feed (Burdon et al., 2020). Analyses of whole communities also show the frequency of traits which confer resistance and resilience to disturbance increase with disturbance magnitude (Townsend et al., 1997b). Thus, disturbance likely shapes communities by invoking an environmental filter that selects for species with characteristics that confer resistance and resilience.

A particularly important trait conferring resilience is dispersal. During recovery from disturbance, freshwater communities are often dominated by organisms with strong dispersal (Vieira et al., 2004). These species usually have a terrestrial adult stage, and therefore ability to recolonize after unfavorable conditions. For example, after the extreme Colorado flooding mentioned earlier, 84% of taxa present had mobile larvae or terrestrial adult stages (Poff et al., 2018). In the aftermath of a large flood in Ireland, it was species with shorter life cycles (i.e., more r-selected traits) that colonized fastest, whereas longer lived mayflies or stoneflies took much longer (Woodward et al., 2016). Overall, trait-based information can give important mechanistic insights into how disturbance affects community structure that diversity metrics alone do not resolve.

Disturbance-driven community assembly processes

Given that disturbances are widespread in freshwater ecosystems, it is not surprising that they have a strong influence on community assembly. Studying those communities at various stages during and after disturbance has provided insights into the processes involved.

Community disassembly and then re-assembly following disturbance

Streams undergoing wet-dry cycles illustrate community disassembly during drying and then re-assembly following re-wetting. Although drought is a ramp disturbance with conditions getting progressively worse over time, the magnitude of the effect on fauna is also connected to key thresholds being surpassed (Boulton, 2003). One of the best descriptions of this comes again from the Madrean Sky Island streams (Fig. 3). The drying process starts with loss of lateral flow connectivity, progresses to loss of longitudinal connectivity especially riffle habitat and formation of remnant pools, and then if drying is particularly harsh (e.g., during a drought lasting a long time), loss of all surface water followed by loss of the refuges in the hyporheic zone (Bogan et al., 2015). Most flowing water (i.e., lotic) species disappear with loss of longitudinal connectivity leaving only still water (i.e. lentic) species. This has been described as a stepped response, with the gradual change punctuated by swift transitions in community structure as particular types of habitat are lost (Boulton, 2003). Recovery then depends on the extent of water loss in the initial drying as well as the isolation from colonization sources (Boulton, 2003; Bogan et al., 2015). Upstream perennially-flowing reaches provide particularly important sources of colonists (as described in Section "Ecological 'refuges' versus evolutionary 'refugia' above), but if all local refuges including the hyporheic zone have dried and taxa lack desiccation-resistant stages, then recovery will depend on recolonization from distant sources and will be affected by taxon mobility.

After disturbance, community succession starts. A classic example of this is the changes in algal community composition and benthic macroinvertebrates described from Sycamore Creek, a desert stream in Arizona that experiences flash floods. Detailed sampling over 60 days after such a flood revealed substantial changes in algal communities over time with diatoms initially dominating and then being joined by cyanobacteria and the filamentous green alga, *Cladophora* (Fisher et al., 1982). Much of the work in streams indicates these sorts of successional processes are controlled by the environmental tolerance of the organisms. One of the most complete records of succession following the removal of disturbance illustrating this comes from the streams revealed after glacial retreat in Glacier Bay, Alaska. Milner et al. (this volume) sampling over 28 years revealed that most species colonizing, except cold-tolerant early successional midges, persisted over time, with more species being added as conditions became less harsh. The development of riparian vegetation and the addition of the associated leaf-litter resources were particularly important stages in the succession of these glacial stream, and by providing food resources, reduced environmental harshness.

Using a metacommunity framework to investigate community recovery following disturbance

Recently, investigations of controls on recovery from disturbance have broadened to include a range dispersal-related process as alluded to above. This involves increasing emphasis on processes driven at large spatial scales, including isolation from colonist sources and the role of chance (i.e., stochastic) events. The approach reflects that local stream communities are part of metacommunities linked at landscape scales by dispersal of potentially interacting species (Tonkin et al., 2018). At one extreme, limited dispersal ability and chance events could restrict recolonization regardless of environmental tolerances to local conditions, whereas at the other extreme high dispersal rates may override local habitat controls on assembly. The configuration of a river network will

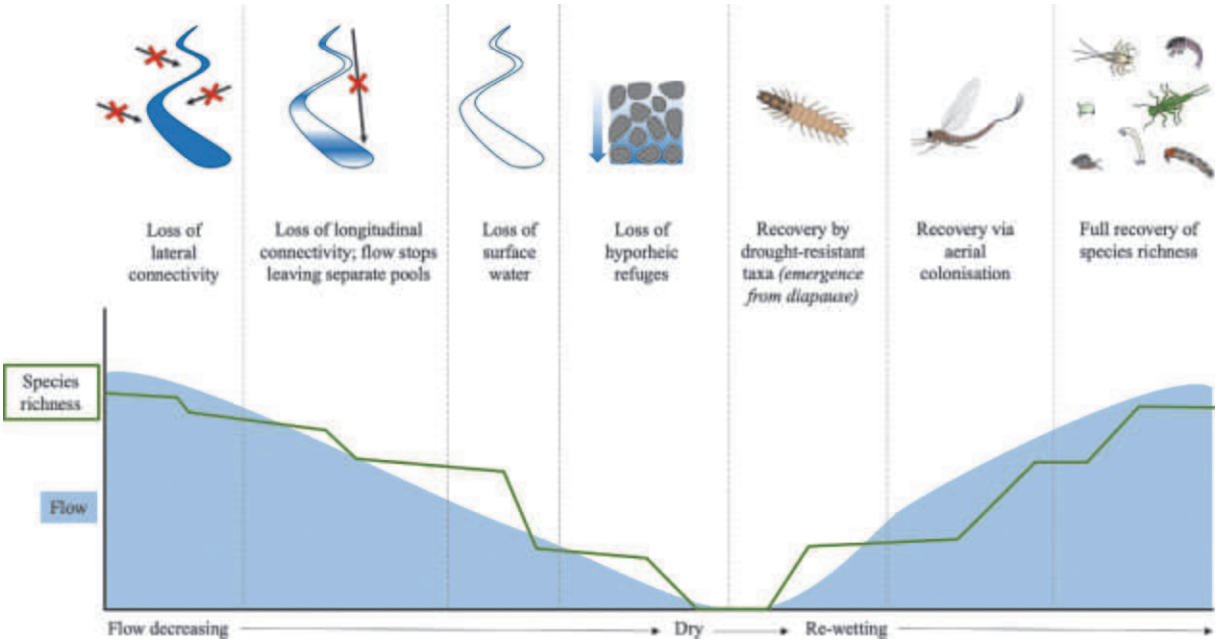

Fig. 3 Stages of community disassembly and re-assembly associated with stream drying and subsequent re-wetting. Adapted from Bogan MT, Boersma KS and Lytle DA (2015) Resistance and resilience of invertebrate communities to seasonal and supraseasonal drought in arid-land headwater streams. *Freshwater Biology* **60**: 2547–2558.

also be important here, having more influence on organisms restricted to aquatic habitats (like fish) compared to those with aerial dispersal stages like aquatic insects (Tonkin et al., 2018). Investigation of these effects has really just begun, but a study of 21 rivers undergoing restoration in Germany indicated that factors related to the regional pool of taxa and the proximity of colonist sources had an overriding effect on local recolonization outcomes (Tonkin et al., 2014). Similarly, a review of processes affecting reassembly in intermittent rivers suggests that dispersal and stochastic processes were important immediately after the drying disturbance, but local factors such as biotic interactions and species habitat requirements become more important as more speciose communities establish (Datry et al., 2016).

Disturbance effects on both alpha and beta diversity

Given that stochastic dispersal is likely to be particularly influential on recovery from disturbance, one would expect that to be reflected in between-site differences in measures of biological diversity. A broad-scale analysis of rivers ranging from intermittent to permanent in Australia and Europe revealed that flow loss acted as a strong environmental filter, eliminating species lacking traits to resist drying and thereby decreasing local macroinvertebrate richness (alpha diversity) (Leigh and Datry, 2017). This is consistent with other studies reporting disturbance effects on local richness described in Section "Disturbance impacts on aquatic community composition and diversity" above. However, the effects of disturbance on beta diversity, or the turnover in species between locations, suggested the full range of community assembly processes was involved. Firstly, drying disturbance appeared to both increase beta diversity by enhancing the sorting of taxa along an environmental gradient, thereby increasing differences in species identity between localities, and also decreased beta diversity by increasing selection for a common core of disturbance-tolerant taxa (Leigh and Datry, 2017). Secondly, strong flight-driven dispersal decreased beta-diversity effects (Leigh and Datry, 2017). This combination of positive and negative influences on the turnover of species between sites reflects the mix of local conditions affecting who can occupy a site, the differences in those conditions between sites and the influence of dispersal on the resulting diversity patterns.

Just as the predictability of the environment is associated with the evolution of responses to disturbance, it is also involved in these diversity patterns. For example, communities living in highly seasonal climates with predictable disturbance regimes tend to have complete turnover of species between seasons and thus high beta diversity (Tonkin et al., 2017). However, communities experiencing unpredictable and non-seasonal fluctuations in assembly show more random (i.e., stochastic) patterns of community assembly and hence lower temporal beta diversity (Tonkin et al., 2017). Overall, these studies of disturbance-driven community assembly point to strong roles for both species sorting based on local environmental conditions and dispersal-related stochastic processes influencing community assembly, with the combination depending on particular local disturbance regimes and the configuration of the stream network (Tonkin et al., 2018).

Disturbance influences on food webs

Disturbance has particularly important ramifications for energy flow through freshwater ecosystems, especially via effects on the strengths of interactions between organisms, including the relative importance of top-down and bottom-up influences.

Alterations to top-down and bottom-up effects in food webs driven by flood-influences on consumer traits

Because of the strong influences of floods on the composition of invertebrate consumers in river food webs, flood disturbance alters energy flow to higher trophic level consumers like fish in rivers. This is nicely demonstrated in northern Californian river. These rivers typically experience harsh winter flooding, with consumer assemblages consequently dominated by mobile invertebrates like midges and mayflies that are good at escaping floods (Wootton et al., 1996). However, when flood-disturbance is removed via dams (which moderate flows), or in benign years with few floods, invertebrates with protective cases like cased-caddisflies, especially *Dicosmoecus*, are able to dominate. These disturbance-driven changes in consumer composition strongly affect energy flow because mobile invertebrates, like the midges and mayflies, are easy for drift-feeding fish like trout to catch, whereas the cased-caddisflies, which are protected by their case, are much more difficult for trout to capture. As a result, either dams or benign years can lead to reductions in fish populations because the prevalent invertebrates, cased-caddis, are so well protected from predators, an effect called bottom-up limitation (Wootton et al., 1996). Overall, this switch in invertebrate consumer types is driven by a trade-off between vulnerability to disturbance and vulnerability to predatory fish that affects invertebrate traits. Mobile invertebrates lacking cases or shells can escape floods but are more easily consumed by fish, whereas those with cases or shells are relatively protected from predation but are much more vulnerable to being crushed in floods (Wootton et al., 1996). The disturbance-driven changes in consumer traits also affect interaction strengths; in flood-free conditions there is more competition meaning caddis dominate, but predatory interactions between mayflies and trout strengthen after flooding (i.e., top-down effects increase).

Similar flood-driven changes in invertebrate composition also control the energy flow and strength of interactions in streams of New Zealand's South Island high country, but the effects extend to altering the composition of fish assemblages. In these New Zealand streams, the top-down predatory effects of the fish on invertebrates are much weaker on consumers protected by a case or shell (e.g., cased caddisflies or snails) compared to those lacking such protection (e.g., mayflies) similar to the Northern California situation (Jellyman and McIntosh, 2020). However, since particular types of fish have feeding niches connected to different invertebrate traits, the most common type of predatory fish also changes along the disturbance gradient due to bottom-up effects (Jellyman and McIntosh, 2020). In this case, eels dominate spring-fed habitats lacking floods because their benthic-foraging habitats are better suited to eating cased invertebrates, whereas trout dominate intermediately disturbed habitats where mobile invertebrates like mayflies are common. Finally, and involving another influence of disturbance on organism traits, native galaxiids occupy the most flood-prone streams because they are more tolerant of the flooding influences than the non-native trout. Thus, in both California and New Zealand, through a combination of both top-down and bottom-up effects mediated by the differential effects of disturbance on invertebrate and fish traits, disturbance influences how and to who energy flows in river food webs.

These flood-driven effects on organism composition and energy flow also have one other major influence via limiting the development of long food chains in rivers. There are two major mechanisms involved here. Firstly, reductions in prey availability associated with periodic flooding mean that there is less energy available and availability fluctuates depending on the time since the last flood, leading to so called dynamic constraints on energy availability. Secondly, there are fewer taxa like predatory invertebrates and small fish at intermediate trophic levels in flood-prone streams, forcing bigger fish, which are usually the top predators, to gain a greater proportion of their energy from primary consumers thereby causing a change in their trophic omnivory. Together, both the dynamic constraints on energy flow to top predators and the changes in top-predator trophic omnivory, mean that food chains are shorter in flood-prone streams compared to more stable streams because top predators are generally gaining a greater proportion of their energy at lower trophic levels (McHugh et al., 2010).

Food-web collapse associated with predator loss in drought-affected streams

River drying disturbances also cause dramatic effects on energy flow in river food webs, but in this case the reduction in habitat size and stress associated with water loss generally leads to food-web collapse associated with species loss. This has been well studied using stream channels in southern England where water flow was controlled such that channel dewatering occurred for 6 days every 33 or 99 days (Ledger et al., 2013). In comparison to controls, basal species (e.g., algae) in dewatered channels weren't greatly affected, but dewatered channels experienced substantial loss of primary consumer species and biomass; 37% of invertebrate primary consumer taxa were eliminated and their biomass was reduced by 64%. The effects were greatest on large-bodied species (78% loss of taxa), and because most of those larger species were predatory, this led to partial food-web collapse associated with big reductions in the amount of energy flowing to predators. Thus, these food webs subjected to experimental drying were simplified and contained many fewer predatory taxa.

This loss of predatory taxa associated with stream drying also affects the length of river food chains. Gradual longitudinal water loss in rivers flowing across a bed of porous alluvial gravels revealed a corresponding loss of predatory taxa that was in turn associated with reductions in food chain lengths that eventually ended in food-web collapse (McHugh et al., 2014). In these real streams, the reduced number of trophic levels present was closely associated with reductions in the maximum body size of the top predators. Thus, as the drying disturbance strengthened and habitats became smaller downstream, the food-web collapse measured

by food chain lengths was driven by the inability of large predators to survive in the increasingly small and harsh conditions. Overall, the most dramatic reductions in food chains are caused by the loss of whole trophic groups in drying streams (e.g., predatory fish), compared to the dynamic constraints and alterations in trophic omnivory of predatory fish that typically shorten food chain length in flood-prone streams (Sabo et al., 2010).

Conclusions and synthesis

Disturbance drivers in rivers have far-reaching influences starting with organismal traits and population responses, that then lead to community-level effects, and finally to important changes in stream food-webs. These influences will only increase as climate change continues. Since most so-called natural disturbances are being altered by humans, having a widely applicable and general definition of disturbance that doesn't split human-driven and natural-driven disturbances will aid disturbance ecology assist river management. Moreover, the many dimensions of river disturbance described above, and the prospect that many future disturbances regimes are likely to be characterized by changing intensity and timing of extreme events suggest that disturbance ecology will be particularly important for future management. We conclude by highlighting these important connections.

Climate change will alter the predictability, magnitude and other disturbance dimensions, necessitating predictive approaches

Firstly, of the influences of climate change on freshwaters, alterations to the predictability, magnitude and other dimensions of hydrology-related disturbance regimes (i.e., floods, drought and habitat drying) will be some of the most important (Woodward et al., 2016). The non-stationarity (i.e., continual alteration) of hydrological influences means the future dimensions of disturbance drivers will be different to those experienced in the past, requiring more sophisticated predictive approaches to help prepare freshwater ecosystems for those impacts (Tonkin et al., 2019).

Places where disturbance drivers are changing the most will be worst affected, so maintaining evolutionary refugia will be critical

Rivers experiencing the largest changes in disturbance drivers will be disproportionately affected by climate change. Some of these include high latitude, high altitude or very dry areas where organisms and system dynamics are highly attuned to the current predictable disturbance regimes (Davis et al., 2013; Parker and Huryn, 2013; Peckarsky et al., 2000). In extreme cases, identifying evolutionary refugia critical for maintaining biodiversity will be particularly important (Davis et al., 2021).

Altered disturbance regimes will affect invasion

Another particularly important aspect of changing disturbance regimes will be the consequences for invasion and invaders. In some cases, natural disturbance regimes keep invaders at bay, effectively creating natural invader-free space (Boddy and McIntosh, 2021), whilst in others, disturbances, especially human driven ones, facilitate invasion (Marchetti et al., 2004). Thus, changes in the disturbance regimes experienced by freshwater systems are very likely to influence invasion and associated consequences, indicating that better understanding of these controls is needed. Here, it may not be just maintaining one disturbance regime in a river network that is important, but the variety of disturbance types in a location may also be critical for maintain biodiversity in the face of invasion (Boddy and McIntosh, 2021).

Insights from disturbance ecology will be important for improving restoration success

Given the widespread impacts of invaders, the influences of human-driven disturbances such as land-use change, and the pervasive effects of climate change, the importance of freshwater ecosystem restoration will only increase. Restoration effectively involves disrupting the current, degraded, state of an ecosystem to move it to a more desired state, so understanding the controls on the resistance and resilience of ecosystems to disturbance will be integral to restoration (Lake, 2013). Degraded freshwater ecosystems are often highly resistant and resilient, possibly due to the traits of the organisms that constitute those communities (Barrett et al., 2021), and failure to account for this in restoration may underlie a lack of restoration success in freshwater ecosystems (Lake, 2013). Better understanding of how disturbance drivers might affect restoration-resistant communities could help improve restoration success (Barrett et al., 2021).

Disturbance drivers have cross-ecosystem consequences

Finally, we have concentrated on the consequences of freshwater disturbance drivers for aquatic ecosystems, but those disturbance drivers often have important cross-ecosystem effects. Disruptions or alterations to cross-ecosystem energy subsidies from aquatic to terrestrial ecosystems associated with freshwater disturbances can alter riparian populations and communities (Greenwood and McIntosh, 2008). Likewise, terrestrial subsidies to aquatic ecosystems may also be important for the resistance of freshwater ecosystems to freshwater disturbances, so will be important in management. Thus, the relevance of freshwater disturbance-drivers is certainly not restricted to just aquatic ecosystems.

Knowledge gaps

- The non-stationarity (or continual alteration) of hydrological influences means the future dimensions of disturbance drivers will be different to those experienced in the past, requiring more sophisticated predictive approaches to help prepare freshwater ecosystems for those disturbance impacts.
- Future changes in disturbance regimes imply that evolutionary refugia will be critical for maintaining biodiversity, so identifying refugia in landscapes will be critically important.
- Understanding how climate change influences on the dimensions of disturbance, especially their predictability and magnitude, will affect a myriad of other processes such as invasion and the flow of energy through food webs, but we currently lack an adequate understanding to predict and manage those consequences.
- Disturbance is closely associated with restoration because it involves altering community resistance and resilience, but understanding of those process in aquatic restoration is still poorly developed.
- Disturbances in aquatic ecosystems have cross-ecosystem consequences for terrestrial ecosystems and vice-versa, but knowledge of controls on those influences is also poor.

Glossary

Allogenic succession Succession is a result of abiotic or physical processes.
Autogenic succession Succession occurs as a result of biotic interactions.
Deterministic The successional trajectory occurs in a predictable way for a given region.
Facilitation Early colonizers make the habitat more suitable for later colonizers.
Inhibition Early colonizers prevent later colonizers from establishing, either by modifying the environment or through direct competition/predation until they are eliminated by a disturbance.
Press disturbance Abrupt and reaches a disturbance level that is then continual.
Primary succession Process of succession in which no remnants of the previous biotic community are present following a disturbance.
Pulse disturbance Short term and time delineated, i.e., transient.
Ramp disturbance Increases in severity over time.
Secondary succession Elements of the biotic community persist after a disturbance.
Stochastic The successional trajectory is influenced strongly by chance events, depending on the traits of the colonizers or extreme disturbances.
Tolerance Taxa that colonize co-exist.

Introduction

Succession is defined as change in community composition following a disturbance (Fisher, 1983, 1990). Succession may be primary (no remnants of previous biotic community exist) or secondary (species remain after disturbance). Potentially we could consider a tertiary succession where, linked to human modifications, species are able to colonize where they would not naturally establish. The process and pattern of succession depends upon traits and life histories of the individual species. Succession may be allogenic where changes in the community are modified by the abiotic environment, or autogenic where biotic processes influence community change. Conceptually, community changes during successional processes end in the climax community—the final community for that specific region and climate.

The concept of succession has been around since the early 20th century when it was developed initially for terrestrial plant communities. Clements (1916) proposed a deterministic model where the vegetation progresses through a series of successional stages towards a predetermined climax community for a given area, whereas Gleason (1926) suggested an individualistic, more

stochastic model depending upon the attributes of the colonizers. Connell and Slatyer (1977) proposed three models for considering succession in different ecosystems: (1) facilitation where early colonizers make the habitat more suitable for later colonizers, (2) inhibition where early colonizers inhibit later colonizers until they themselves are eliminated and (3) tolerance where all the taxa are present initially or colonize later but biotic interactions are negligible. Fisher (1990) considered that any theory of succession relevant to lotic ecosystems should potentially be developed directly from the study of streams, rather than use ideas developed for other ecosystems.

Nevertheless, the concept has elicited much discussion and debate. One aspect is whether changes in species composition are directional or whether they are non- directional, but in either case succession represents any change over time in species composition (Platt and Connell, 2003). Because succession has suffered from confusion over time, Fisher (1990) even suggested that the term should be abandoned for streams, in favor of the broader view provided by stability theory. However, these two concepts are linked. In this chapter, we view succession as the progressive change over time as the ecosystem progresses to a mature community, whereas stability relates to the extent to which disturbances or internal dynamics reset or shift the trajectory of that successional movement.

Biological traits related to feeding specialization, dispersal ability, and habitat specialization, along with taxonomic and phylogenetic identity, mediate organism responses to disturbance (Van Looy et al., 2019). A directional view of succession assumes that community assembly is deterministic whereas a non-directional view infers that assembly and associated succession is stochastic. This has created a great deal of debate in the literature and Fisher (1983) considered stream succession to be stochastic with deterministic evidence lacking. Although often considered opposing, stochastic and deterministic processes undoubtedly interact with their relative contributions to community assembly being determined by the strength of the disturbance. Potentially a successional sequence could be determined initially by deterministic controls depending on the severity of the disturbance and then by stochastic processes. In terrestrial ecosystem theory, the community potentially reaches a stable state (Olito and Fukami, 2009), but this is often not the case with streams.

In this chapter we will not consider seasonal succession as this relates to changes in abundance due to the seasonality of the organisms, particularly insects, and thus it is not true succession as defined above. In addition, this chapter does not examine longitudinal succession in any detail; which Fisher (1983) stated was unique to streams. This is more appropriately termed 'longitudinal zonation' according to distance from water source, and detailed synthesis articles are available elsewhere (Doretto et al., 2020). Initially this chapter considers the disturbance regime that may initiate stream succession (see McIntosh and Barrett this volume) and the ways in which successional process knowledge can be applied to enhance the potential success of river restoration. We then examine the temporal dynamics of different groups of organisms from microbes to fish and consider how stream succession may be influenced by links to other ecosystems, such as the terrestrial riparian zone, or the underlying hyporheic and groundwater systems. The chapter subsequently examines anthropogenic and climate change effects on stream succession and concludes by synthesizing key evidence for successional pathways that are evident in streams and and compares stream succession with terrestrial and nearshore marine ecosystem succession.

Disturbance regime and succession

Compared to other ecosystems, streams are subjected to frequent natural disturbances (mainly floods and droughts) that typically restructure the physical habitat and the distribution of resources, thereby causing extensive loss of biota. Thus, disturbance is the dominant organizing factor in stream ecosystems (Resh et al., 1988). Given the importance of disturbance many authors have strived to create a systematic framework for classification of disturbance e.g., (Poff et al., 2006). In any review of stream succession then, the characterization of the disturbance regime is important to facilitate interpretation of the subsequent successional processes. Lake (2000) suggested three levels of classification based on the temporal pattern and structure of a disturbance (Fig. 1). Pulses are short term and time delineated (e.g., intermittent drying or floods, sediment pulses), presses are abrupt and

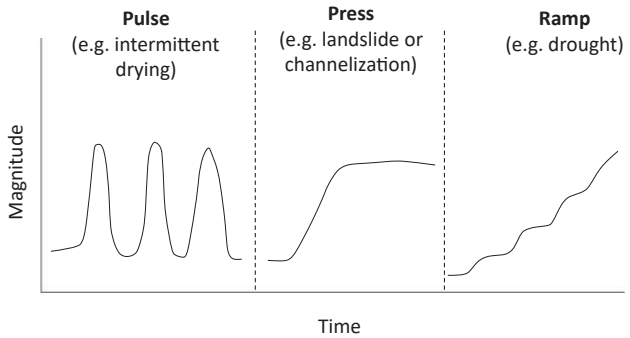

Fig. 1 Three disturbance types. After Lake PS (2000) Disturbance, patchiness, and diversity in streams. *Journal of the North American Benthological Society* **19**: 573–592.

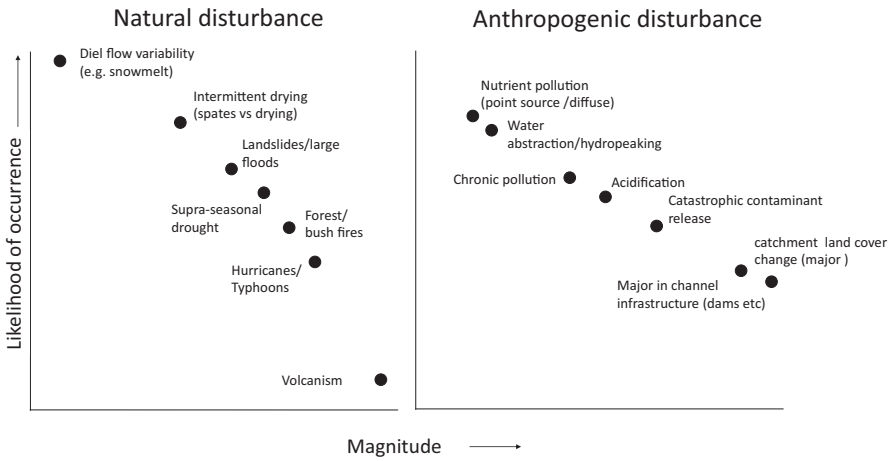

Fig. 2 The relationship between predictability and magnitude of disturbances in streams for natural streams and anthropogenically modified streams. Adapted from Jentsch A and White P (2019) A theory of pulse dynamics and disturbance in ecology. *Ecology* **100**: e02734.

reach a disturbance level that is then maintained (e.g., channelization, continual sediment pulses) and ramps increase in severity over time (e.g., drought). Typically anthropogenic modification such as pollutant inputs, flow modification or land use changes lead to press or ramp disturbances (Van Looy et al., 2019). Although some authors (Reice et al., 1990; Resh et al., 1988) do not consider predictable events (e.g., seasonal drying that occurs every year at the same time) as a disturbance, in this chapter such events are considered disturbances sensu Poff (1992), as successional sequences are initiated.

The magnitude of the disturbance is also a highly important variable in influencing successional trajectories for all biotic communities. For example, recovery trajectories of lotic diatom assemblages following a major landscape-scale disturbance due to wildfire were a function of disturbance magnitude resulting from differences in catchment characteristics (Robinson et al., 1994). In addition, the link between magnitude and likelihood of occurrence is noteworthy (Fig. 2; Jentsch and White, 2019). For natural disturbances there are highly predictable disturbances of low magnitude that occur very frequently (e.g., diel flow variability associated with snowmelt), whereas natural disturbances of very high magnitude (e.g., a volcano or violent hurricane) are extremely rare. The relationship between anthropogenic disturbance magnitude and likelihood of occurrence is less pronounced, with high magnitude disturbances such as land cover change or construction of in channel infrastructure (e.g., dam construction) being comparatively more frequent than volcanoes or hurricanes (Fig. 2). Potentially, anthropogenic disturbances are more likely to be press than pulse.

Linking successional theory to stream restoration

Stream restoration projects offer a unique opportunity to study successional processes. While restoration projects often define goals and endpoints, the successional pathways and mechanisms by which these may be achieved are rarely considered, despite the large of body of theory (Lake et al., 2007) as outlined in this chapter. Successional theory informs us that the distance to colonizer source pools and dispersal pathways (i.e., metacommunity processes) must be considered in any stream restoration planning and in this respect connectivity is a major issue (Westveer et al., 2018). Indeed, Li et al. (2016) developed a new metric reflecting temporal succession of benthic invertebrates in the restored reaches based on their dispersal abilities. Strong dispersers will colonize early in the sequence and weaker dispersers will appear later and the authors believe their approach could also be used for recovery from extreme events like floods, droughts and major pollutant episodes. In addition, seasonality is an important considerations for the timing of the stream restoration projects, particularly new channels, to ensure rapid colonization when colonizers are available and shorter successional sequences (Westveer et al., 2018).

With restoration there is often the Field of Dreams adage "build it and they will come" and in certain instances this works for stream communities (Bogan et al., 2020) where there is high connectivity to systems that are not degraded. However, sometimes resilient degraded communities inhibit the colonization by other taxa (e.g., NZ mudsnail https://bioheritage.nz/if-you-build-it-will-they-come/) or seeding is required to overcome dispersal limitations and initiate/modify the successional process.

Space-time considerations

The impact that a disturbance has on a community and successional trajectories that follow may differ depending on the spatial scale at which succession is assessed, for example on a boulder vs a stream reach vs a whole catchment as seen for temporary streams (Godoy et al., 2016). Townsend (1989) proposed the patch dynamics concept in streams, where disturbances create different size patches in stream reaches which can then be in different successional stages, thereby contributing to community heterogeneity.

The timing of disturbance is also important as exemplified by an atypical winter flood in Ireland where the successional recovery pattern was different when compared to a summer flood (Jackson, 1988). Similarly, Boulton et al. (1992) showed that when floods occurred in summer, succession occurred more rapidly, possibly due to higher water temperature when compared to spring floods. At the finer scale, use of refugia may differ as function of the life history stage of a given taxon, with implications for the pioneer species that can quickly re-colonize a habitat following a disturbance (Van Looy et al., 2019). Field experiments have highlighted the role that differing macroinvertebrate pioneer species can have on community succession (e.g., facilitative vs inhibitory—see autogenic effects below). Furthermore, disturbance timing can have important implications for structural abiotic legacies, such as micro-habitat availability, or resource legacies, such as nutrient or detritus availability (Johnstone et al., 2016). Newman et al. (2015) showed that the timing of leaf litter input influenced microbial succession. Even time of day can shape patterns of succession after flooding as diel emergence, mating and oviposition behavior varies among insect species (Woodward et al., 2015).

Biological community succession

Groups of organisms have different traits that facilitate colonization, use of refugia and resources—see Table 1. Hence, groups may display different responses and recovery to a particular disturbance as outlined below.

Microbial communities

Succession among stream microbial communities (fungi, bacteria) has received less attention than the macrofauna, although understanding of biofilm (a collection of microorganisms on the substrate surface) succession has developed in recent years with advances in molecular biology. Similar to other types of ecosystems and organismal groups, microbial communities shift over time from those that are predominantly influenced by physical properties of the environment to ones in which coupled biophysical controls become important (Besemer et al., 2007).

Bacteria and fungi rapidly colonize surfaces in running water, such as mineral particles, plants and other organisms and modify the habitat to facilitate later colonizers arriving via the water column with rapid increases in species richness (Jackson et al., 2001). Richness may then decline, as some species are out-competed; later colonizers become more dependent on autotrophic production within the biofilm matrix, leading to enhanced niche availability and further increases in richness (Besemer et al., 2007). These successional dynamics, however, have been monitored over very short timescales (week-months) compared to 'traditional' ecological studies of succession, which span years-decades or even centuries when using a chronosequence approach. In periods of stable environmental conditions in rivers, successional pathways within biofilms can proceed to a point at which a 'climax' community is established (Lyautey et al., 2005).

Table 1 Comparison of different biotic groups for some key elements of stream succession.

Group	*Successional Mechanisms*	*Deterministic v Stochastic*	*Time Frame*	*Traits/main drivers (Van Looy et al., 2019)*	*Role of refugia/ legacies*
Bacteria	Both facilitation and inhibition (Besemer et al., 2007)	Initially stochastic then deterministic (Jackson et al., 2001; Lyautey et al., 2005)	Rapid (Veach et al., 2016)	High fecundity, easily dispersed.	Less important
Algae	Potentially all three mechanisms at play.	Stochastic	Relatively rapid unless after major disturbance e.g., Mt. St Helens (Steinman and Lamberti, 1988)	Strong Dispersal, reproductive potential and nutrients (McCormick and Stevenson, 1991; Stevenson et al., 1991)	Less important except maybe phytoplankton in slow flowing areas
Invertebrates	Tolerance (Milner et al., 2011) although facilitation does occur (Cardinale et al., 2001; Tumolo et al., 2019; Hammock and Bogan, 2014)	Deterministic initially where water temp/ channel stability low but then stochastic	<1 year typically unless following press disturbances or new streams after glacial recession/channel relocation	High fecundity, drift. Differences in colonizing abilities drives community, particularly in primary succession (Miyake et al., 2003)	Major role in successional trajectories (Ledger et al., 2006; Dodds et al., 1996)
Fish	Mostly tolerance but some examples of facilitation (Schlosser and Kallemeyn, 2000)	Stochastic	Longer than the other groups	Strong disperser with migration ability and high fecundity.	Some habitat specialists can enter substrate but less important with anadromous fish

Besemer et al. (2007) showed experimentally that successional pathways could diverge due to flow variations, with filamentous bacteria and cyanobacteria developing more strongly in experiments where flows were laminar. However, over longer time scales the differences were lost and all biofilms developed similar compositions. During the early stages of succession, benthic microbial biofilms are influenced by stochastic processes linked to dispersal and colonization success from the water column (Jackson et al., 2001; Lyautey et al., 2005). As succession proceeds, control from biological interactions increase and can be attributed to algal community development (Besemer et al., 2007) implying facilitation was also a key process influencing the development of these communities. Fungi play a role in the major river ecosystem function of organic matter decomposition, and communities differ in streams as glaciers recede in alpine areas (Fell et al., 2021).

Algal communities

Benthic algal succession occurs in lotic environments following a disturbance. Within a primary successional framework of 6 years following the eruption of Mount St. Helens, increased richness of cyanobacteria (blue-green algae) and chlorophyte green algae taxa occurred (Steinman and Lamberti, 1988), dominated by *Achnanthidium minutissimum* (Rushforth et al., 1986). In a desert stream following flash flooding, diatoms were the first colonizers dominating the community followed by filamentous greens and blue-green algae in the successional pattern (Fisher et al., 1982). Colonization was rapid within about 2 weeks. This sequence was also observed following experimental flow releases from dams, with the first colonizers including the diatoms *Cocconeis*, *Synedra* and *Fragilaria*, followed by a proliferation of the filamentous green *Stigeoclonium* in the later successional community (Davie et al., 2012). Diatom succession was also evident in a tropical rainforest stream over a 60-day period involving a total of 127 taxa falling into four distinct groups (Rondon and Aragon, 2018). Early successional dominance of diatom taxa in streams is a result of colonizing abilities through their small size and large population sizes enabling rapid dispersal such as via downstream drift or by terrestrial vectors such as birds (Manning et al., 2021), and the high reproductive potential of the algal assemblages overall plays a major role in the outcome of the successional pathway. Patchy dewatering of habitat patches during periods of low flows influences the successional dynamics of algae, thereby creating distinct mosaics of algal species on the stream bed (Ledger et al., 2008). Riparian vegetation on small streams and afforestation practices can reduce successional patterns and community complexity by reducing light availability, thus favoring dominance by low-profile species tolerant of low light conditions (Cibils-Martina et al., 2017).

Acid mine drainage can seriously impair stream water quality reducing pH, and has been shown to affect diatom succession in streams and consequently may play a role in bioassessment where diatoms are used to assess water quality (Smucker and Vis, 2013). Diatom succession was more simplified with less turnover at sites severely impacted by acid mine drainage than at less impacted sites and control sites.

Invertebrate communities

It is a rare flood that initiates a primary successional sequence in invertebrate community recovery. However, new river channels created either through stream restoration or glacial retreat offer an opportunity to examine successional sequences under primary successional processes. Meiofauna (invertebrates <500 μm <45 μm) colonization of a newly constructed tributary of the Thames showed that the colonization and successional trajectory was rapid, potentially because of the close proximity of the colonizers, but the community that established was significantly different than the colonizing source (Robertson et al., 2014).

Malmqvist et al. (1991) examined invertebrate colonization of a new stream channel in Sweden and found blackflies (Diptera) were the pioneer colonizers in high densities but their abundance decreased after a year when hydropsychid caddisflies (Trichoptera) became numerically dominant. Coleoptera, Odonata, and some Trichoptera were generally slower to colonize than Ephemeroptera and Plecoptera. Invertebrate colonization of former sewage channels restored as streams (Winking et al., 2016) followed a primary successional sequence from pioneer assemblages to mature communities, which resembled that of proximal unpolluted sites. For restored channels that were connected to an upstream colonizing source, the successional timeframe was up to 19 years to reach a mature community but longer where no connection existed.

One rare and very high magnitude disturbance was the eruption of Mount St. Helens in Oregon in 1980, where community assembly in newly formed streams was under primary succession. Chironomids, baetid mayflies and capniid stoneflies were initial colonizers, and subsequently richness increased to between 38 and 58 taxa after 36 years. However, the combination of disturbance magnitude and hydrologic source variation of the Mount St. Helens streams has driven divergent successional trajectories in streams of similar age, geology and the macroinvertebrate colonizing pool (Claeson et al., 2021).

Glacial recession affords unique opportunities to examine community assembly in the new streams subsequently created under a primary successional framework. One such example is Glacier Bay National Park in southeast Alaska, where glaciers have retreated from a Neoglacial maximum in 1750, thereby creating a chronosequence time gradient of 270 years across a spatial gradient of 70 km. Typically these streams are initially fed by remnant ice with a pro-glacial lake creating a stable channel until the lake is no longer connected to the stream. In addition, Milner and co-workers (Milner et al., 2008, 2018) have assembled the longest single record of site-specific temporal primary successional sequence at one stream Wolf Point Creek (WPC) that extends to 40 years.

Initially, WPC was fed by ice and was cold (about 2 °C) and turbid (approximately 150 NTU) and the first macroinvertebrate colonizers were chironomids (*Diamesa* and *Paratrichocladius*) adapted to the inhospitable conditions. In particular *D. davisi* was found in large densities (>5000 m^{-2}) with no predators or competitors. At WPC these pioneer taxa were followed by mayflies

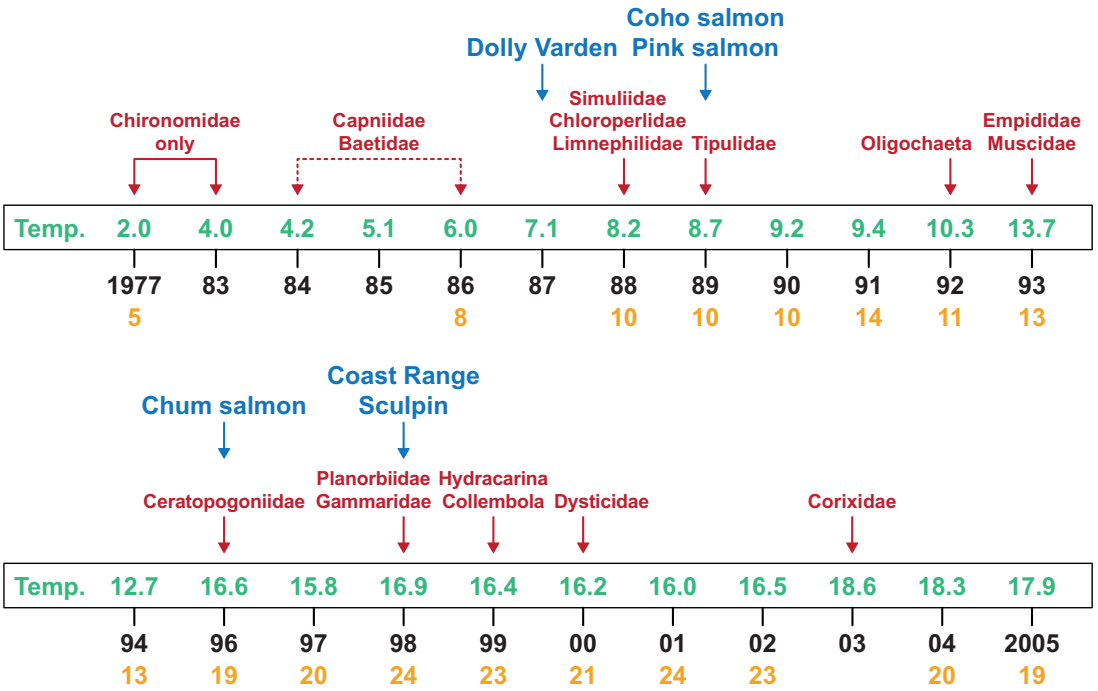

Fig. 3 Year of appearance from 1977 to 2005 of specific macroinvertebrate families and fish species in Wolf Point Creek, SE Alaska with the water temperature in green and the number of taxa orange below the year in black. After Milner AM, Robertson AL, McDermott MJ, Klaar MJ and Brown LE (2013) Major flood disturbance alters river ecosystem evolution. *Nature Climate Change* **3**: 137–141.

(Baetidae) and stoneflies (Capniidae) between 1984 and 1986, when maximum water temperature reached 6.0 °C. Blackflies (Simuliidae) and chloroperlid stoneflies were first collected in 1988. The first macroinvertebrate non-insects to colonize WPC were Oligochaeta in 1992, followed by snails (Planorbidae) and freshwater amphipods (Gammaridae) in 1998. Water beetles (Dytiscidae) colonized in 2000 and water boatmen (Corixidae) in 2003 as more pool habitat was formed in the stream (see Fig. 3). In alpine glacier-fed streams, new sites that open up as ice recedes are initially dominated by Diamesinae, but over time this group can decrease in abundance by up to 40% as stoneflies and mayflies colonize from downstream areas (Robinson et al., 2014).

Some of the early colonizing *Diamesa* species in WPC became extinct when water temperature increased, notably *D. davisi* which was not collected in August after 1992 when water temperature reached 10 °C. *Pagastia partica*, which first colonized WPC in 1986, was numerically dominant from 1990 through 1998. Initially it was considered that *D. davisi* became extinct due to being a cold stenothermal, but later experiments showed that this species was eliminated due to competition by *P. partica* and not water temperature (Flory and Milner, 1995). The chironomids *Orthocladius mallochi* and *Eukiefferiella gracei*, which colonized in 1988 and 1991, respectively, were both relatively abundant in the mid-1990s, but numbers subsequently declined. *Eukiefferiella claripennis*, first collected in 1986, was co-dominant in 2001 with *Cricotopus tremulus*, which first colonized in 1996. *Tanytarsus*, a genus that typically inhabits stable habitats, was dominant in 2004. *Paratrichocladius* was the only chironomid that has been collected throughout the entire record (1977–2018) (Milner et al., 2008).

Macroinvertebrate community assembly appears to have been initially strongly deterministic in the early successional sequence owing to low water temperature associated with remnant ice masses, in that similar patterns of macroinvertebrate succession were found in another new stream (Stonefly Creek) that emerged from ice recession later than WPC (Milner et al., 2011). However, as stream age and water temperature increased, macroinvertebrate colonization was also more stochastic, and taxonomic similarity between Stonefly Creek and Wolf Point Creek at the same stage of development was <50%. Dispersal constraints have also influenced the succession, as non-insect taxa required at least 20 years to colonize these new streams. Tolerance was suggested as the major mechanism of macroinvertebrate community assembly. Most taxa, with the exception of the cold-tolerant first colonizers, have persisted within the community following colonization, although relative abundance has changed markedly with time (Milner et al., 2011). Similar initial deterministic trends and the tolerance model were proposed for invertebrate community succession in streams affected by the Mount St Helens eruption in 1980 (Claeson et al., 2021).

Interestingly, WPC experienced two major floods in November of 2005 and during the summer of 2014 prior to sampling that year. These floods markedly reset the successional sequence causing the elimination of some of the later colonizing taxa. The November 2005 flood reset the community to approximately 15 years earlier based on taxa composition, and the summer 2014 floods reset an additional 5 years (see Fig. 4). Amazingly *D. davisi*, which became locally extinct in 1992, re-colonized after both flood events due to less competition and persisted for 2 years before becoming extinct from the community as numbers of other taxa increased (Milner et al., 2013, 2018). Slow flowing habitat did not recover after both flood events and pool-dwelling taxa (e.g., Gammaridae, Planorbidae, and Dytiscidae) have never recolonized to date.

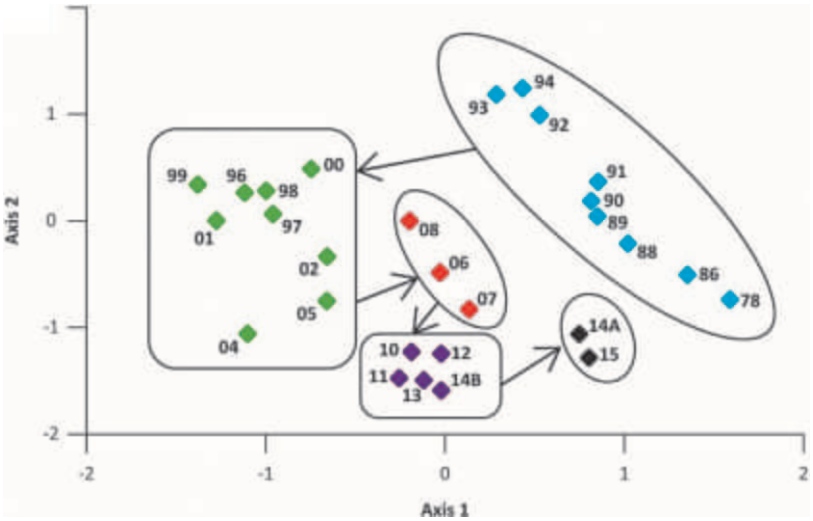

Fig. 4 Non Multi-Dimensional Scaling (NMDS) plot for macroinvertebrates from 1978 to 2015 using mean abundance data from 10 replicates collected in August/early September. 1978 to 1994 in blue represents early successional stages while 1996 to 2004 shows a later more mature successional stage in green. 2006 to 2008 in red shows a reset of successional trajectories after a major flood in November 2005 which shows some recovery 2010–2013 in purple. 2014 to 2015 in black shows a further reset after a second summer flood prior to sampling in 2014. Increased community diversity appears to the left of Axis 1. After Milner AM, Picken JL, Klaar MJ, Robertson AL, Clitherow LR, Eagle L and Brown LE (2018) River ecosystem resilience to extreme flood events. *Ecology and Evolution* **8**: 8354–8363.

Fish communities

Of the biotic communities, fish succession has been the least studied. One study of fish diversity of a restored large floodplain after connection to the upper Danube River showed that 46% of the species pool rapidly colonized after only 2 months (Pander et al., 2015). Colonization by fish of newly constructed habitats and channels is highly dependent on lateral and longitudinal connectivity and distance from colonizing source as evidenced in Glacier Bay (Milner et al., 2008, 2011). Anadromous fish have the advantage for colonization with glacial recession, but greater species richness was associated with older streams, with more habitat complexity and aquatic vegetation and algae, as observed in the Bering Glacier region of Alaska (Weigner and Von Hippel, 2010). Although the ever-changing aquatic landscape has been colonized by fish species typical of the region, some have evolved in atypical ways including populations of dwarf Dolly Varden (*Salvelinus malma*) and sympatric pairs of sticklebacks (*Gasterosteus aculeatus*) (Weigner and Von Hippel, 2010).

Autogenic effects on successional trajectories in streams

The role of autogenic (biotic or within community) effects on successional processes in streams have not been widely documented, particularly with relation to Connell and Slatyer (1977) models of facilitation and tolerance. A fascinating experimental study by Hammock and Bogan (2014) demonstrated that blackfly larvae facilitate diatom colonization through their production of silk as a substratum for diatoms that can then enhance later invertebrate colonizers. The authors compared this occurrence in streams to facilitation by nitrogen-fixing alder trees following glacial retreat enhancing later successional plant species. Additionally, experimental approaches showed that the net-spinning caddisfly, *Ceratopsyche bronta*, facilitated recruitment of later species by constructing their retreats and catch nets that increased microhabitat complexity (Cardinale et al., 2001). Similarly, Tumolo et al. (2019) showed that modification of the habitat by net-spinning Hydropsychidae caddis flies facilitated changes in the stream community.

Successional sequences in stream biofilms is driven primarily by algae, which modulate the microenvironment by reducing the physical effects of flow and by influencing community biofilm succession (Besemer et al., 2007). Colonization of river ecosystems by invertebrate grazers can be expected to lead to continual removal of biomass, thus limiting microbial biofilms and inducing continual turnover and successional sequences (Veach et al., 2016). Likewise invertebrate can graze on selected species and thereby influence algal communities and taxa abundance (Wellnitz and Rader, 2003).

Colonization by predators could initiate succession in streams. For example, climate change could facilitate predators being able to colonize further up-valley in alpine streams and thereby influence prey community composition and taxa abundance. Experiments have shown that when the predatory stonefly *Perla grandis* colonizes more upstream reaches in alpine streams, the abundance of *Baetis* spp. was depressed through direct consumption or predator avoidance and that their body size generally decreased (Khamis et al., 2015).

Legacies of the biota that survive a disturbance may influence the successional sequence that follows. Ledger et al. (2006) found in post-disturbance channels that the snail, *Radix peregra*, facilitated the settlement of filter feeders by removing algal growth and that the freshwater shrimp, *Gammarus pulex*, excluded or reduced abundance of subsequent invertebrate colonizers. There are also potential abiotic legacies like coarse woody debris that may influence successional recovery in streams after a disturbance.

The amphipod, *Dikerogammarus villosus* (known as 'the killer shrimp'), invaded western Europe via the Danube-Main-Rhine canal (van Riel et al., 2006). In some habitats, there is evidence that the beds of a previous invasive species (akin to a press disturbance), the zebra mussel, *Dreissena polymorpha*, facilitated the shrimp's invasion by providing habitat and food. The case of *D. villosus* provides a good example of how alterations to trophic interactions may lead to successional change in community structure and functioning and could be considered an example of "tertiary" succession. Stable isotope studies have shown that this small-bodied shrimp can actually occupy the same trophic level as predatory fish (van Riel et al., 2006). In addition, oligochaete worms, caenid mayflies, chironomids and tipulids are also particularly vulnerable to *D. villosus* predation (MacNeil et al., 2013), leading to successional changes in the benthic community.

Interactions with other ecosystems influencing stream succession

Stream systems do not exist in isolation from other ecosystems, particularly the terrestrial ecosystem, which can potentially influence succession in streams. Following glacial recession in Glacier Bay southeast Alaska, new watersheds are formed with vegetative succession occurring on the landscape. The development of riparian vegetation in a new stream in Glacier Bay with a stable channel due to an upstream lake markedly influenced colonization of the stream by certain invertebrate taxa, thereby playing an important role in the successional sequence of macroinvertebrates and overall assemblage development (Flory and Milner, 1999). Several features of riparian interaction were documented, including invertebrate use of willow catkins entering streams in summer and of submerged alder roots as a substrate for attachment and as a source of building material for caddisfly cases (Milner and Gloyne-Phillips, 2005). In a study of restored channels, woody riparian vegetation supported the development of the invertebrate assemblage by providing habitat (sites for oviposition and leaves for case building) and food sources (leaves for shredders; Winking et al., 2014). Riparian vegetation requires time for development before interacting strongly with the stream, so this can delay the successional pathway to the mature invertebrate community.

When Pacific salmon and other anadromous fish from the marine ecosystem enter freshwaters and construct redds on the streambed to lay their eggs during the summer/fall, substantial disturbance of the bed occurs that can alter invertebrate community structure and thus potentially initiate secondary succession in the disturbed patches (Moore and Schindler, 2008). Monaghan and Miner (2009) found that pink salmon (*Oncorhynchus gorbuscha*) redd construction caused $\sim 10\times$ reduction in overall invertebrate abundance and reduced invertebrate taxa richness from 18 to 10 in a 10 m reach. However, certain taxa, like simuliids, increased in abundance, suggesting that redd construction potentially facilitates the persistence of these fugitive taxa in the community. This biotic effect on succession is not true facilitation, because it does not improve the habitat for a later colonizer, but it is evidence of biotic effects on succession processes.

Refugia in streams influencing succession after recovery from disturbance

Rapid recovery from disturbances, like floods, may be enhanced by the close proximity of colonizers in refugia, from which taxa may re-colonize disturbed patches and influence the successional sequence of recovery. Most refugia in streams are characterized by extensive coupling of the main channel at a variety of spatial scales with streamside forests, floodplain features and groundwater like the hyporheic zone (Sedell et al., 1990). The hyporheic zone also affords invertebrates a refugia from floods and droughts allowing taxa to recolonize rapidly after subsidence of the event.

Anthropogenic allogenic (abiotic) effects on successional pathways

Humans can directly influence succession in streams via direct engineering activities in or adjacent to the stream channel (e.g., dam construction, culverting or channelization), major alteration of the land cover in the catchment (e.g., logging or urbanization) or diffuse/point source release of contaminants (Wallace, 1990). The impacts of such activities vary from months/several years for discrete events to decades for chronic contamination or physical habitat change. However, clear examples in the literature highlight the impact humans have on successional pathways in streams.

Cibils Martina et al. (2013) found that downstream of a dam, the successional sequence of epilithic algal communities was advanced by reduced current velocity and flow variation. However, upstream of the dam, frequent flow fluctuations caused sloughing of the biofilm thereby resetting the algal community to an early successional stage. By acting as barriers to dispersal, dams can alter successional trajectories following low and high flow disturbances (Liu et al., 2013). This is unsurprising, as differences in colonizing ability among taxa are major factors governing succession in stream invertebrate communities.

Clear cutting of forests can have immediate and long-term effects on macroinvertebrate succession in stream by changes in the energy base of the stream food web with increased autochthonous production enhancing scraper species with loss of shredders

(Haefner and Wallace, 1981). Conversely, afforestation of riparian zones can influence succession of periphyton communities with lower biomass, and diversity and increased small, low-profile, unicellular and stalked algal species when compared to streams flowing through regions with limited riparian tree cover.

Pesticide contamination can have significant implications for riverine macroinvertebrate communities with loss of sensitive species from impacted sites (Thompson et al., 2016). Pesticide impacted streams with forested headwaters can display enhanced recovery of invertebrate communities compared to streams in uniform agricultural landscapes that are more prone to local extinction and long-term shifts in climax community diversity and structure (Orlinskiy et al., 2015).

Summary

In this overview we have reviewed and synthesized publications since Fisher's classic chapter on stream succession (Fisher, 1983). Successional processes in streams have been compared with terrestrial and nearshore marine ecosystems (Table 2), highlighting that stream systems have some unique attributes. Specifically, successional process for most biotic groups in streams are more rapid than in other ecosystems, and in addition the role of refugia, legacy effects and linkage to other ecosystems is more important in stream ecosystems.

A matter of great debate in the literature is whether successional pathways in streams are deterministic or stochastic. Fisher (1983) thought that the dominant mechanism for macroinvertebrate succession was stochastic. However, from a review of colonization by lotic invertebrates, Mackay (1992) concluded that recovery from disturbance was not stochastic, as recurring ecological patterns among early colonizers occurred. For macroinvertebrate primary successional sequences with long temporal records, it is probable that both mechanisms occur. Initially deterministic control will occur when channels have low water temperature and unstable habitats that are suitable for a limited number of taxa. But as conditions become more generally favorable, there is a switch to stochastic control, as seen a few years after glacial recession or volcanic eruptions. Microbes exhibit successional dynamics highly influenced by deterministic processes such as physical conditions, but may also be controlled by stochasticity i.e., random speciation or extinction events, dispersal or drift during certain stages of succession.

Traits of the different biotic groups are important in terms of successional strategies. For example, macroInvertebrate succession of new stream habitat is shaped by a number of factors including distance from the regional species pool, dispersal capacity and life history traits (e.g., number of generations per year) of colonizing taxa, suitable habitat for colonization, and timing of dispersal. Differences in colonizing ability among taxa is one of the major factors that creates succession in stream invertebrate communities.

An appreciation of successional patterns in streams is critical, as this understanding will lead to greater understanding of the management of biodiversity and thus ecosystem processes in these dynamic and changing ecosystems. Understanding successional processes also has important management implications in terms of planning and implementing appropriate restoration approaches in the face of both natural and anthropogenic disturbances.

Table 2 Comparison of the main elements successional processes for stream, terrestrial and nearshore marine ecosystems.

Process	*Streams*	*Terrestrial*	*Nearshore Marine*
Dominant Mechanism of succession	Tolerance dominant. Many cases of inhibition (Hammock and Bogan, 2014; Cardinale et al., 2001)	Facilitation and Inhibition	Mostly inhibition (Sousa, 1979)
Autogenic/ Allogenic	Mostly Allogenic	Autogenic	Both autogenic/allogenic
Relative Time Frame	Rapid for microbes, algae and invertebrates, longer for fish (<3 years)	Long term (often >50 years)	Medium term
Deterministic v Stochastic	Both - often deterministic where abiotic variables dominate early in successional sequence	Invertebrates mostly deterministic (Kaufmann, 2001) Plants deterministic/stochastic	Mostly stochastic
Climax Community?	Possible, but highly disturbed relatively to other ecosystems so resets to earlier stage	Yes, except where disturbances occur	Relates to disturbance sheltered shores more likely to have a climax community
Disturbance regimes over time	Highly disturbed over large areas occurring frequently, except for groundwater streams.	Only small percentage disturbed large areas not disturbed relatively over time.	Relates to shore exposure—exposed high disturbance frequently, sheltered shores less so
Use of refugia	For certain disturbances like floods and droughts extensive particularly the hyporheic zone	Potentially for invertebrates	Not widespread
Legacy Effects	Evident—both biotic and abiotic	Low	Low
Links to other ecosystems	Succession affected by the riparian zone and spawning salmon from the marine ecosystem.	Riparian zone succession linked to stream flooding.	Negligible link

Dispersal in Stream Networks: Meta-populations and Meta-communities

Sara Cathey and Bryan L Brown, Department of Biological Sciences, Virginia Tech, Blacksburg, VA, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Dendritic network The landscape of stream networks are dendritic, mimicking the dendrites of animal nervous systems. In a dendritic network, there are no discrete nodes or patches; habitat is contiguous throughout the network. The branching nature of dendritic networks affects how materials and information move along the network between sites. In a similar fashion, the dendritic nature of stream networks affects how organisms move between locations within the network.

Dispersal Dispersal is the movement of organisms between populations and communities. Dispersal may be an active behavior or a passive process.

Drift dispersal The active or passive dispersal by aquatic organisms as they become entrained in the water column and carried downstream.

Drift Paradox Due to the downstream drift of aquatic insects and the lack of upstream sources of recolonization, logic suggests that upstream reaches could be left devoid of individuals. Experimental work has demonstrated that aerial upstream flight by adult life stages allows for recolonization of upstream areas.

Graph-based dispersal proxy A proxy based on the distance between populations and communities within the stream network. There are numerous ways to measure this distance, including overland dispersal between sites as well as stream network distance between sites.

In-network dispersal (IND) This dispersal is limited to the confines of the aquatic habitat of the stream network. The dispersal of obligate aquatic taxa, such as fish and some macroinvertebrates, is restricted to the aquatic habitat of streams.

Meta-community An extension of meta-populations, a meta-community is a network of communities connected by the dispersal of organisms between communities.

Meta-population A network of populations on a landscape connected by dispersal.

Network Position Hypothesis Suggests that the position within a stream network affects patterns of biodiversity and community assembly. As you move across a stream network, levels of dispersal, habitat conditions, and species interactions may vary, and this variation may produce predictable patterns based on network location.

Organismal-based dispersal proxy A proxy based on an organismal attribute or trait. These traits may be directly measured, such as body size, or categorical, such as dispersal ability (weak versus strong).

Out-of-network dispersal (OND) Dispersal that occurs outside the aquatic habitat of the stream network. For instance, salamanders and crayfish may disperse overland between headwater streams and adult aquatic insects may fly between adjacent streams and networks.

Radio telemetry A technique to monitor dispersal that relies on the generation and detection of radio waves to identify the location of aquatic organisms. Common methods utilize PIT tags (passive integrated transponder tags).

Introduction

Meta-approaches in ecology

The substantial variation in dispersal that exists between organisms contributes to the structuring of ecological populations and communities in space and time. Most organisms find a way to get around on a landscape, including sessile organisms like plants and corals that use their reproductive stages as a major vehicle for dispersal. The influences of dispersal were included in a number of approaches aimed at understanding the distributions and diversity of species, including the Island Theory of Biogeography (MacArthur and Wilson, 1967), and Supply Side Ecology (Sale, 1977), but these approaches addressed the influence of dispersal at very large and very small scales, respectively. However, the influence of dispersal at a landscape or meso-scale has historically been one of the underappreciated aspects of the ecology of organisms, populations, and communities.

Two bodies of theory, meta-population ecology and meta-community ecology, emphasized the incorporation of meso-scale dispersal of organisms into the study of the distributions and abundances of species. A meta-population is a spatially separated group of populations connected on a landscape by the dispersal of individuals (Hanski and Gilpin, 1997). The multi-species extension of this idea, a meta-community, is a group of multi-species communities connected on a landscape by the dispersal of one or more species (Leibold et al., 2004). These ideas are conceptually linked in that they (1) emphasize the importance of dispersal in structuring populations and communities and (2) necessitate a multi-scale approach in their investigation. Local scales are defined by the structure and dynamics of a single population or a single community on a landscape, while regional scales are the aggregate properties of all local populations or local communities on a landscape.

Both meta-population and meta-community theory have had profound impacts on the field of ecology, by presenting testable predictions for empiricists and catalyzing research that includes mathematical theory, simulation studies, survey approaches, and experimental manipulations. Virtually every subfield of ecology has benefitted from the insight of meta-approaches, including the study of diversity in stream and river networks. However, the study of meta-patterns in riverine ecosystems presents challenges and opportunities that are quite unique.

Meta-approaches in stream networks

By their very nature, stream networks present challenges to meta-scale approaches. Prototype meta-populations and meta-communities were defined as distinct populations or communities on a landscape that are connected by dispersal (Fig. 1). The populations and communities within these networks exist in habitat patches with discrete boundaries, such as a forest patch in a grassland. In contrast, riverine systems are constructed dendritically (Fagan, 2002; Grant et al., 2007). Dendritic systems—so named because of their structural similarity to the dendrites of animal nervous systems—are linear, hierarchically-branching continuous habitat (Fig. 1); thus there are no discrete patches in dendritic systems (Fagan, 2002; Grant et al., 2007). The lack of distinct patches also leads to the lack of distinct boundaries by which to define the populations and communities that are members of a meta-population or meta-community. A second challenge is that, while much of the theory constructed from meta-approaches assumes that organisms disperse randomly, dispersal in river networks is often strongly directionally oriented. Fish, amphibians, and both the larval and adult stages of aquatic insects have been found to move in fairly specific and repeatable directions relative to the downstream flow of water (Mackay, 1992; Hershey et al., 1993; Skalski and Gilliam, 2000; Lowe, 2003; Petersen et al., 2004;

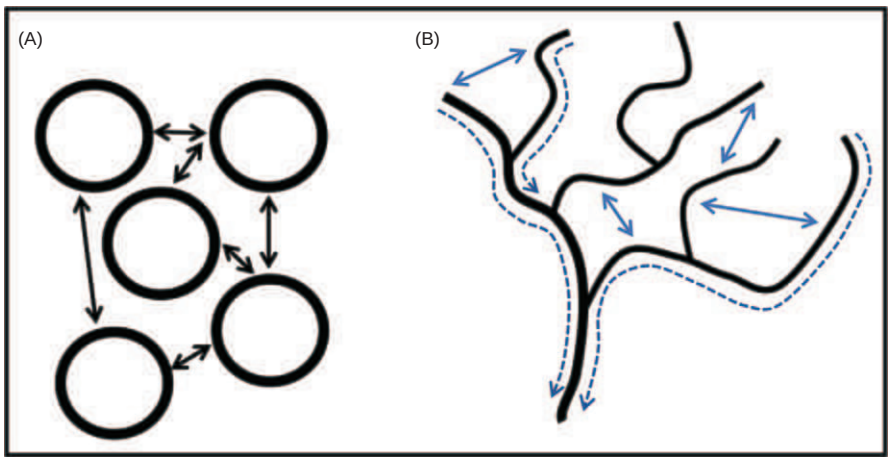

Fig. 1 Schematic examples of aquatic networks. (A) A "classic" aquatic meta-community in which habitat patches are fairly discrete entities like ponds, and dispersal of species occurs among those patches. (B) A stream dendritic network in which there are two modes of dispersal: In Network Dispersal (IND), represented by dotted arrows, is dispersal via waterway within the network and that often has a distinct downstream bias, and Out of Network Dispersal (OND) represented by solid arrows occurs when organisms walk, crawl, or fly overland to other points in the aquatic network.

Finn et al., 2006). However, while these two properties of river networks initially challenged the utility of meta-population and meta-community approaches in riverine systems, both sets of theory have proven to be adaptable and broadly applicable for understanding the diversity, distribution, and abundances of species in river networks.

Even though meta-populations and meta-communities are often conceived and visualized as sets of discrete patches (Fig. 1), this particular depiction does not reflect an actual requirement of meta-approaches. Delineating "patches," even in continuous habitat, allows the application of the same theory and approaches that are applied in landscapes with spatially distinct patches. This tactic is particularly effective in networks where habitat characteristics are expected to differ depending on location in the network. Although stream networks are continuous dendritic habitat, that habitat is not uniform throughout. This foundational principle was codified by the River Continuum Concept which details how a large number of environmental parameters predictably change from the smallest headwater streams to progressively larger streams and rivers (Vannote et al., 1980). Along this gradient, stream size and discharge increase, while stream gradient and average substrate particle size decrease. The base of the stream food web also shifts progressively from leaf-litter decomposition to increasing amounts of algal primary production (Vannote et al., 1980). While these changes in stream environmental characteristics occur gradually down the length of a stream network, delineating spatially separated "patches" within this network allows an investigator to not only apply meta-approaches to river networks, but is also likely capture the environmental heterogeneity that creates unique conditions in different parts of river networks. Additionally, environmental conditions are not the only predictable differences between sections of stream networks; dispersal abilities and propensities vary predictably with network location.

Dispersal in stream networks

The dispersal of stream organisms is highly variable among taxa, and one major difference among taxa is whether or not their dispersal is restricted to inundated sections of the stream network. Fish and snails, for example, are strictly limited to in-stream dispersal, while a number of aquatic taxa including crayfish, amphibians, and some aquatic insect larvae have the ability to make limited journeys across land. Thus, in stream networks, there are two major dispersal modes: in-network dispersal (IND), and out-of-network dispersal (OND) (Fig. 1). Aquatic insects, the most commonly studied organisms in streams, actually use both IND and OND during their life cycles. In their larval forms, most aquatic insects are limited to IND by either crawling or allowing themselves to be swept along in stream current, a process termed "drift." Initially, drifting by macroinvertebrates was thought to be accidental or passive and that entry into the drift was the product of organisms losing purchase on benthic substrate and being swept away by current. While such passive drift entry certainly occurs, especially in high flow conditions, subsequent investigations have revealed that drift entry is most often an active process used to change foraging locations or escape predation (e.g., Kohler and McPeek, 1989). However, as stream insects meta-morphose into reproductive adults, most aquatic insects possess wings that allow them considerable freedom for OND. The typical life cycle of an aquatic insect is a prolonged larval stage, followed by a short-lived winged adult stage that quickly reproduces and then deposits eggs in or near a stream. These winged flying stages not only allow OND, but may be a primary mechanism for recolonizing upstream sites, especially headwaters, whose populations have been denuded by constant downstream drift (Hershey et al., 1993, but see Anholt (1995) for alternative resolution to the so-called Drift Paradox).

As with environmental conditions, dispersal dynamics of organisms may change with network position. With highly mobile organisms like fish, dispersal is rarely limited by the physical ability of a species to move between stream networks and river basins. However, a number of abiotic factors limit the ranges of fish in stream systems. For example, fish are often excluded from upstream sections of stream networks because of perennial drying or lack of adequate depth, or they may be excluded from some sections of stream networks because the stream thermal regime lies outside of a species' tolerance range. The effect of network location on benthic invertebrates may be even more profound. The major IND mode of benthic macroinvertebrates is drifting, which has been measured to occur over two kilometers (Hershey et al., 1993), and drift dispersal is unidirectional because water flows downhill. Additionally, drift propensity and distance are related to discharge, stream substrate, and local densities of similar species (James et al., 2009). Taken together, these factors suggest that dispersal has a considerably stronger influence on macroinvertebrate diversity and distributions in larger streams when compared to smaller, headwater streams (Brown and Swan, 2010). This conclusion has profound implications for the factors that dictate diversity and distributions of species in river networks.

The Network Position Hypothesis (NPH; from Schmera et al., 2018, based on hypotheses presented in Brown and Swan, 2010) suggests that the factors that control diversity and distributions of organisms in stream networks depend on the position of a population or community within a river network. Based on the NPH, the influence of IND is expected to increase from smaller to larger streams within a river network, thus the structuring forces on a population or community are predicted to shift from more local factors like environment and species interactions, to more regional controls driven by the movement of organisms. The NPH has been evaluated in a large number of studies primarily focusing on benthic invertebrates and fish. The results of these investigations have been mixed, with some studies strongly supporting the NPH (e.g., Wilson and McTammany, 2014; Tornwall et al., 2017; Brown et al., 2018), some studies producing results counter the NPH (e.g., He et al., 2020), and some studies showing mixed or equivocal results (e.g., Schmera et al., 2018; Henriques-Silva et al., 2019). Taken together, these studies suggest that the NPH does capture a fundamental pattern in river network systems, but that the overall model may be strongly modified by context. Those contexts include the life histories and dispersal abilities of organisms involved, the spatial heterogeneity captured in a river network, and human modifications to stream networks.

Meta-approaches have had a strong influence on the study of stream biodiversity. Not only have they provided new theoretical foundations for understanding the biodiversity of organisms in running waters (e.g., Brown and Swan, 2010; Holt and Chesson, 2018), but they have also provided empirical tests of these theories (e.g., Swan and Brown, 2017; Tornwall et al., 2017) and described new patterns of biodiversity in river networks. Additionally, they have informed management of threatened native species (e.g. White and Wagner, 2021). Foundational to applying meta-approaches is the study of organismal dispersal in river networks.

Studying organism dispersal in streams

Challenges to studying dispersal in streams

Studying dispersal in a meaningful way is difficult for many organisms (Heino et al., 2017). Some organisms like fish and amphibians can be marked, tagged, or tracked using various individual marking techniques, radio transponders, or passive integrated transponder (PIT) tags, and there are numerous examples of studies that use such techniques to infer dispersal behavior (e.g., Bubb et al., 2002; Hedden and Gido, 2020). However, invertebrates are the most commonly studied organisms in stream and river networks (Tornwall et al., 2015), and to date, no practical method has been developed to directly monitor the movement of benthic invertebrates with the possible exception of PIT tagging in large macroinvertebrates like crayfish (Bubb et al., 2002). For smaller benthic invertebrates like aquatic insects that make up the vast majority of benthic biomass and diversity, such marking or tagging is either methodologically impossible or impractical for three reasons. The first is the limitation imposed by the small size of most benthic macroinvertebrates, many of which are <1 mm in length and which rarely exceed 2 cm in length, a size that prohibits the use of radio or PIT tagging. Secondly, there is a low probability of recapture of marked organisms. Smaller invertebrates could conceivably be marked using a surficial marking like latex paint. However, due to the small size and high densities of these organisms, the probability of recapturing organisms marked in such a manner would be quite low. Additionally, great care would be necessary when marking these small organisms to prevent the marking compound from hindering organism function by coating gills or sensory structures. Third, insects molt, and some taxa molt frequently. Each molt would shed the exoskeleton and thus any superficial marks on the organism.

Given these limitations, there has been a considerable amount of creative science devoted to inferring the dispersal behavior of stream organisms. For larger organisms, the methods are often more direct. However, for smaller organisms like stream insects, investigators rely on inferential methods that include estimating species dispersal pattern by their abundances in drift samples, isotopic tracing of labeled populations, scaling-up based on the results of small-scale controlled studies, and modeling studies that predict dispersal based on known organism traits. Below we categorize and describe the major ways that the dispersal of aquatic organisms is either directly studied or indirectly inferred.

Approaches for studying the influence of dispersal in river networks

Movement monitored

Capture-mark-recapture work in stream meta-populations has mainly relied on radio telemetry. These approaches have been used to study the dispersal of larger stream organisms, predominantly fish, but also crayfish and salamanders, and even river otters. After stream organisms are captured and radiotagged, radio transponders may be placed along the stream bank to detect organisms as they move, or organisms may be detected within the stream itself by more active recapture or tracking techniques. For example, Hedden and Gido (2020) used mark-recapture methods to investigate the effects of stream drying on fish communities in stream networks. Deploying PIT antennas upstream and downstream of a perennial stream, the researchers found that stream fishes recolonized rewetted reaches. White and Wagner (2021) also used radio telemetry to monitor the dispersal of wild brook trout (*Salvelinus fontinalis*) in a small network in Pennsylvania (United States). They tracked the movement of the trout by actively monitoring them through the stream network to find that half of the tagged fish were sedentary. The mobile fish that dispersed moved over a short duration of time, and this behavior may be important for maintaining connectivity within the stream network.

For smaller organisms, tagging with radiotags is not currently possible. For stream insects, researchers have marked aquatic larvae by enriching the stream benthos with stable isotopes. As aquatic insect larvae feed on stream periphyton (i.e., algae and attached organic detritus), they too are marked with the stable isotope. The insect larvae can then be caught in stream drift nets. To understand the drift dynamics of stream insects, Hershey et al. (1993) captured drifting *Baetis* may fly larvae along the Kuparuk River in Alaska, determining that the larvae drifted at least 2.1 km downstream over the course of the Arctic summer.

Stable isotope enrichment has also been used to understand the aerial flight dynamics of adult stream insects. After enriching the stream benthos, researchers have set up nets at locations within and across stream networks to capture the marked insects. Briers et al. (2003) used this approach to understand the dispersal dynamics of stonefly populations (*Leuctra inermis*) in Wales, becoming the first to show insect dispersal between streams. Macneale et al. (2005) used a similar approach at Hubbard Brook Experimental Forest, New Hampshire (United States), where they added enriched nitrogen to streams before capturing adult stoneflies (*Leuctra ferruginea*) to identify their dispersal patterns. Their work demonstrated that stonefly populations can be connected across catchments within one generation via aerial dispersal.

To detect trends in species movement, there are a variety of traps and nets that may be used to capture stream organisms as they move within and across networks. Researchers often use Malaise traps to capture adult insects, drift nets for larval stream insects, and various traps, such as minnow traps, for fishes (Baxter et al., 2017). Malaise traps are set up along stream corridors and various distances from streams to capture flying adults as they move around stream networks. Petersen et al. (2004) trapped adult insects in malaise traps within a stream network and identified the crucial role that the stream corridor can play in the dispersal of adult aquatic insects. Likewise, traps have also been used to extensively estimate the movement of flying adult insects in urban stream corridors (Smith et al., 2015a, 2015b). Drift nets are deployed to catch the larval stages of aquatic insects as they drift in the current downstream, and they have been used in a large number of studies to produce estimates of dispersing aquatic insects and to infer how this dispersal behavior influences meta-population and meta-community patterns (e.g., Lancaster and Downes, 2017a, 2017b). Similar techniques can also be used for fish, including weir traps. For example, Schlosser (1998) used weir traps to demonstrate that the creation of beaver ponds was the primary factor driving the dispersal of fish to upstream reaches.

However, the measures of organism movement derived from the use of nets and traps have to be interpreted with extreme caution for two reasons. First, temporal variability in movement patterns can be profound. For example, aquatic insect drift density changes on a diel cycle, with the majority of drift occurring at night (Waters, 1965), so studies need to integrate both diel and diurnal movements. The second concern is that some organisms may actively avoid traps, so trapping may be an underestimate of actual dispersal behavior.

Organismal-based proxies

Due to the limitations of directly monitoring the dispersal of stream organisms within and between stream networks, researchers often turn to organismal-based proxies to infer dispersal. These proxies may include traits-based approaches that utilize organismal attributes relating to size, dispersal ability, and dispersal mode, as well as approaches that examine the population genetic structure and the natural isotope abundance of stream organisms. For symbiotic stream organisms, the dispersal of the host may also be used to understand symbiont dispersal.

Traits relating to size, such as body size, wing size, or fin size, are commonly used as proxies for dispersal ability. Wing morphology is also used as a proxy to understand dispersal dynamics in stream networks. Over the course of 3 years, Lancaster and Downes (2017a, 2017b) measured the size and shape of the wings of *Ecnomus* caddisflies. Pairing this information with data from benthic samples that allowed them to categorize individuals as residents or immigrants, they were able to determine that wing morphology may serve as a proxy for dispersal ability.

For aquatic insects, researchers often rely on the dispersal traits available in published trait databases to examine the role of dispersal in community assembly. Brown and Swan (2010) used a traits-based approach to examine how the dispersal ability and mode of stream macroinvertebrates affected patterns of community assembly across three Maryland (United States) stream meta-communities. Using traits for both adult and larval dispersal, they determined that dispersal-driven dynamics were more important in well-connected mainstem sites within the river network, while more isolated headwater sites were driven by local conditions.

Grönroos et al. (2013) applied a similar approach to investigate how the dispersal mode of aquatic insects affected community assembly of stream macroinvertebrates. They grouped the macroinvertebrates based on whether the larval stages of the organisms were active or passive dispersers and whether the adult stage was aquatic or terrestrial. They found that macroinvertebrates with an active larval dispersal stage and a terrestrial flying adult stage were more likely to be affected by the environmental conditions of the stream network (such as sediment size and flow conditions), suggesting that those organisms may be better able to track environmental conditions.

Examining the population genetic structure of stream organisms can be used as a proxy for dispersal as it may provide insight into gene flow between stream populations. Alp et al. (2012) examined the population genetics of two aquatic species with different dispersal strategies, a baetid mayfly (*Baetis rhodani*) and an amphipod (*Gammarus fossarum*). This work revealed that the mayfly, with its overland dispersal capabilities and its generalist niche, had little genetic structure across the river network. The population genetic structure of the amphipod, on the other hand, was impacted by its dispersal limitation within the stream network.

Historically, population genetics work has examined processes that occur over larger spatiotemporal scales. Recently, including within the freshwater ecology literature, researchers have been using population genetics studies to understand community assembly and processes at finer spatial scales. Yaegashi et al. (2014) used a population genetics approach to investigate the population genetic structure of the caddisfly *Stenopsyche marmorata* across four stream networks. Through this approach, the researchers found that the dispersal distances inferred from genetic work were similar to those distances measured for one generation in the field. Kelson et al. (2015) also used a fine-scale genetics approach to examine the genetic structure of brook trout (*S. fontinalis*) within a New Hampshire stream network. This study revealed the effects of isolation due to waterfalls on the genetic structure of the meta-population as well as the dispersal of highly migratory individuals across the network. As demonstrated by Kelson et al., population genetics studies at fine scales within river networks can reveal insights that may improve conservation and management strategies.

The stable isotopic signatures of species may provide clues to their dispersal in stream networks. Cook et al. (2007) analyzed isotopic data alongside the population genetics of the southern pygmy perch (*Nannoperca australis*) to examine dispersal across a stream network. This approach allowed them to determine that at least half of the fish sampled were residents of the stream where they were captured, suggesting little population connectivity within the network.

For freshwater species that participate in symbioses, one way to understand the dispersal of the symbiont is to determine the dispersal of its host. Terui and Miyazaki (2015) studied the dispersal of the freshwater mussel *Margaritifera laevis* based on the dispersal of its host fish, *Oncorhynchus masou masou*. After identifying the location of mussel beds within the river network, the researchers conducted fish sampling during the seasons of symbiont larval attachment and detachment periods. With this approach, they found that fish that were "tagged" with mussel larvae dispersed over four kilometers, demonstrating the importance of the host for symbiont dispersal across the river network.

Graph-based proxies

To understand the role of dispersal in stream networks, researchers often use graph-based proxies to infer dispersal based on the distance between populations and communities (Heino et al., 2017). These proxies differ based on which metric is used to quantify distances between sites in the network (Fig. 2). Often, ecologists will utilize more than one graph-based proxy in their study and compare how the various distance methods better describe dispersal within and between networks. In addition, certain proxies may be better suited for certain taxa or life stages. For instance, Euclidean distance, or the overland, straight-line distance between sites, may be a more appropriate proxy for taxa with both aquatic and terrestrial life stages or for the adult life stages of aquatic insects. On the other hand, for taxa that passively disperse with the current, dispersal distance may be better described with network distance, a graph-based proxy that relies on the contours of the stream network and/or flow distance, which accounts for the direction of dispersal based on streamflow (upstream versus downstream). To study community assembly dynamics in a Swedish stream meta-community, Göthe et al. (2013) employed all three of these graph-based proxies: overland (Euclidean) dispersal, network (along-stream) dispersal, and flow (directional downstream) dispersal. This approach, coupled with their traits-based analysis, allowed them to identify the role of these different dispersal strategies in structuring stream communities and how this role changed with taxa, season, and spatial scale.

In addition to relying on linear distances for graph-based proxies, stream ecologists have developed proxies that utilize circuit theory to study dispersal (Cañedo-Argüelles et al., 2015). For instance, the topographical distance between study sites can be used to account for the effect of landscape features on dispersal, with species traveling downhill facing lower resistance to movement between sites. Stream organisms also have to contend with the intermittency of aquatic habitats in stream networks. This circuit theory-based approach can also be extended to intermittent networks. Here, species traveling between sites that are separated by perennial flows face lower resistance to dispersal.

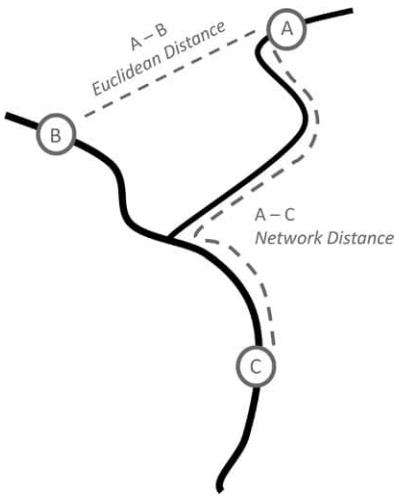

Fig. 2 Illustration of measures of distance in river networks using three hypothetical sampling points, A, B, and C. Euclidean distance is the shortest distance between two points, illustrated by the distance between sites A and B. Network distance is the distance between points, following the contours of the river network, illustrated by the distance between sites A and C.

Experimental approaches

Experimental approaches can be used to disentangle the role of dispersal in driving patterns of biodiversity and community assembly in river networks (Fig. 3). Microcosm experiments have been effectively used to test meta-population and meta-community theory in dendritic systems. Using protozoan and rotifer communities, Carrara et al. (2012) created meta-community networks with different levels of connectivity and examined how network configuration affected patterns of diversity. With this approach, they were able to experimentally demonstrate that the dendritic connectivity of stream networks can produce different patterns of biodiversity than in networks with higher levels of connectivity. Altermatt and Fronhofer (2018) also used a microcosm approach to test how population densities varied within a dendritic network based on network configuration and position within the network. This work confirmed previous theory that communities connected to both headwaters and central nodes emerged as those with the highest population densities.

Investigating the dispersal dynamics of stream organisms is not only important for understanding biodiversity patterns and community assembly, but also for developing a knowledge base for how stream communities will respond to certain management strategies, such as stream restoration. A growing body of recent literature has set out to understand how communities at different locations within stream networks respond to disturbance and habitat manipulation and what role dispersal plays in the resulting community assembly dynamics. Tornwall et al. (2017) manipulated stream habitat complexity within headwater streams and at mainstem sites within stream networks. Only the communities of the headwater streams were affected by the manipulation, providing evidence in favor of the NPH. Similarly, Lancaster and Downes (2017b) manipulated the retention of detritus in a stream to disentangle the roles of environmental condition and dispersal in structuring macroinvertebrate communities. The manipulation revealed an interaction between resource levels and dispersal in which areas with augmented resources were quickly colonized by species not present before the manipulation.

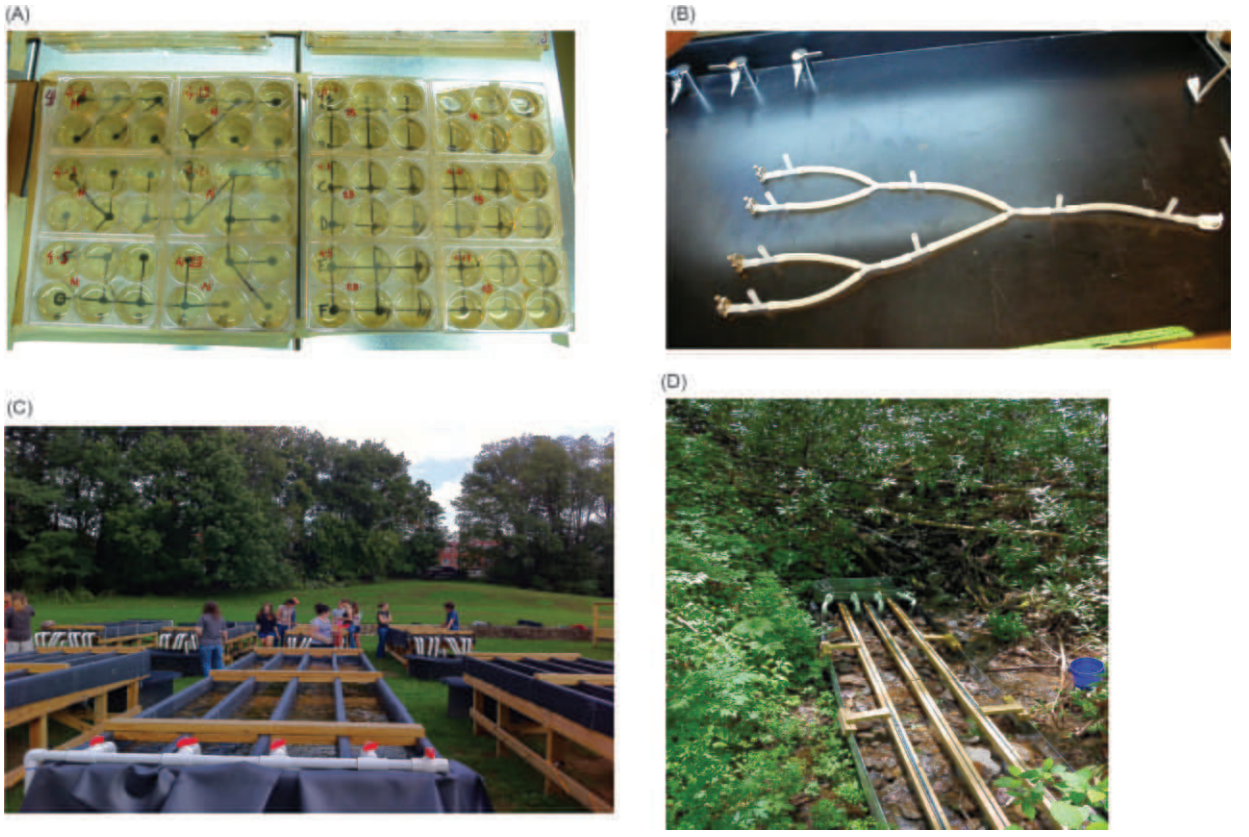

Fig. 3 Representative experimental methods for investigating dispersal in stream meta-communities. (A) Microcosms consisting of eight protist species. Network architecture was controlled by the transfer of medium between "connected" local communities. From Carrara et al. (2012), photo by Florian Altermatt; (B) Microcosms consisting of 14 protist species and 1 rotifer species in physical networks of tubing. From Seymour et al., 2016; photo by Florian Altermatt; (C) Replicated flume systems. Each flume set consisted of four recirculating flumes colonized by macroinvertebrates from local streams. Brown et al., 2018 used eight sets of these flumes to test the influence of dispersal and community source pool. Photo by Chris Swan; (D) In-stream flume system. Flumes are actually located in stream beds but the flumes can be manipulated. In this case, nets over the outflow valves (not shown in this picture) reduced in-network dispersal, while screens over some of the channels (not shown in this picture) prevented aerial dispersal. This research is currently in-progress. Photo by Bryan L. Brown.

Stream ecologists are also experimentally investigating how dispersal mode influences community dynamics and stability. Baumgartner and Robinson (2017) used a field experiment to investigate how upstream active dispersal modes (swimming and crawling) and aerial dispersal dynamics influenced the recovery of agricultural streams following disturbance. After disturbing the uppermost reaches of the streams, the researchers blocked aerial dispersal from half of the stream to differentiate the role of aquatic and aerial dispersal in the colonization dynamics of stream macroinvertebrates. While they didn't find an influence from aerial dispersal, they did find that aquatic, upstream dispersal allowed for the stream benthos to recover rapidly following disturbance.

Theoretical modeling

Modeling based on theoretical principles is a longstanding tradition in ecology. The primary utility of theoretical modeling is that it allows for "tests" of hypotheses that cannot be performed practically, often because of methodological or temporal limitations. Accordingly, theoretical models have strongly influenced thinking on the consequences of dispersal in stream meta-populations and communities.

Early contributions of theoretical modeling in stream networks addressed the so-called "Drift Paradox." The Drift Paradox recognized that, despite empirical measures of large numbers of organisms drifting in a downstream direction, the small headwaters of streams did not become depopulated through time. Initial resolutions to the paradox theorized that adult insect flight was upstream-biased and promoted recolonization of headwaters, and these theories were supported by numerous observations of upstream-biased flight (Hershey et al., 1993; Williams and Williams, 1993). However, such bias was not observed for all stream insects, and the hypothesis did not explain the persistence of non-flying headwater species like amphipods. Modeling studies of the Drift Paradox suggested that an upstream bias in adult flight was an unnecessary condition for promoting persistence in headwaters. Rather, a combination of random or unbiased dispersal and density dependence of populations could theoretically account for persistence (Anholt, 1995; Kopp and Allen, 2021).

Theoretical modeling has also been largely responsible for the appreciation of the effects of dendritic structure on organism dispersal in stream networks. Meta-population modeling of organisms in dendritic networks suggested that the size and architecture of stream dendritic networks strongly affected meta-population persistence and gene flow, and that fragmentation in dendritic networks could have highly variable effects that depended on the specifics of network architecture (Fagan, 2002; Chaput-Bardy et al., 2009; Grant, 2011). Other work extended similar concepts to multi-species communities in dendritic networks. Insights from this work include elucidating the role network architecture and dispersal tradeoffs between species create patterns of community composition in river networks (Auerbach and Poff, 2011). In addition, modeling work has shown that that network structure affects the spread of Proliferative Kidney Disease in salmon (Carrara et al., 2012) and that the stability of communities in river networks is promoted by asynchronous fluctuations in populations at different parts of a network (Anderson and Hayes, 2018). Species coexistence in river networks largely depends on the spatial heterogeneity of environmental conditions in a network and how that heterogeneity interacts with effects of the network on species' dispersal (Holt and Chesson, 2018).

Conclusion

Meta-approaches have permeated much of the theory and practice of ecology in the last few decades, first through the introduction of meta-population theory (Hanski and Gilpin, 1997) and later through meta-community theory (Leibold et al., 2004). Both of these concepts link local-scale patterns, like those occurring in a single stream reach, to larger-scale patterns that occur at the scale of multiple stream reaches, whole watersheds, or even entire river drainages (Schindler et al., 2010). The link between those scales is the dispersal of organisms. The growing influence of meta-frameworks highlights the importance of being able to accurately measure or estimate the dispersal of aquatic organisms.

Macrosystem Ecology of Inland Waters

James H Thorp, Kansas Biological Survey and Center for Ecological Research, and Department of Ecology and Evolutionary Biology, University of Kansas, Lawrence, KS, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Community ecology Research on the organization and simultaneous ecological functioning of multi-species populations within a specified area.
Ecosystem metabolism Chemical reactions associated with the breakdown and synthesis of organic and inorganic molecules and compounds needed by living organisms.
Ecosystems ecology Study of living and both permanently or currently non-living components of multiple communities within an ecosystem, including research on system metabolism, elemental cycling, and other ecological processes.
Endorheic streams Rivers terminating in a desiccation basin or lake (freshwater or saline) and without ultimate flow to the sea.
Food webs Feeding relationships within a community involving pathways for the transfer of energy and nutrients from primary producers to top carnivores.
Landscape ecology Study of effects of spatial heterogeneity on ecological processes at the community and ecosystem level, with a predominant emphasis on terrestrial systems.
Lentic ecosystems Ephemeral pools, semi-permanent wetlands, ponds, lakes, and reservoirs.
Lotic ecosystems Rivers from small ephemeral headwater creeks to large or great rivers.
Macroecology Study of population through community ecology of terrestrial and aquatic systems at large spatial scales (up to continental).
Macrosystems ecology Study of community through ecosystems ecology of terrestrial and aquatic systems at large spatial scales (up to continental).
Metacoupling Interactions between separated macrosystems over either short (pericoupling) or long distances (telecoupling) that involve the movement of material or organisms and can be natural or human-induced.
Nutrient cycling Movement of organic and inorganic matter through the living and non-living components of the ecosystem.

Introduction to macrosystem ecology

Since the middle of the 20th century, ecological research in aquatic systems has gradually increased in functional and spatial scales from an emphasis on species interactions within communities of small spatial extents (typically a few hundred meters or less in rivers) to functional processes occurring within whole, individual ecosystems (often one to hundreds of kilometers), and now in a few cases to studies of structural and functional properties of multiple ecosystems occurring among ecoregions, biomes, and even continents. Simultaneously, the impacts of climate change and invasive species have gained prominence in ecological studies. This newer emphasis on very large spatial scale research is increasingly classified under the overlapping terms "macrosystems ecology" and "macroecology" (Thorp et al., 2021). The former primarily employs techniques of community or ecosystem ecology in studying very large spatial extents (Table 1), while the latter typically focuses on methods in population or community ecology and may encompass comparably large geographic areas. To some readers, the terms ecosystem studies and macrosystem research may seem equivalent. However, past "ecosystem studies" (e.g., analyzes of nutrient cycling) in rivers have occurred at spatial extents as small as one or more stream reaches and have been predominately undertaken in one or multiple headwater sites within a single river, especially when chemical tracers are used.

Ecological research at the macrosystem scale, in particular, may involve many collaborating scientists working in either lotic or lentic ecosystems and having diverse expertise in areas such as hydrology, geology, ecosystem metabolism (including analysis of

Table 1 Perspectives on defining spatial extents and research approaches in ecosystem vs. macrosystem research for lotic and lentic systems, with possible system examples.

Lotic systems	*Ecosystem research projects*		*Macrosystem research projects across multiple ecosystems project*	
	Single river basin	*Small stream sections in many rivers of multiple ecoregions or biomes*	*One very large river basin passing through multiple ecoregions or biomes*	*Many whole river basins in different ecoregions or biomes*
Spatial research category	Single river basin with sampling in one or more stream orders	One to few stream orders but in multiple streams and watersheds	Sampling many stream orders within a large basin consisting of many rivers in different ecoregions	Multiple independent (unconnected) watersheds in similar types of eco-regions or biomes
Example lotic rivers on various continents	AU: Cooper Creek; EU: River Tweed; NA: Kanawha River SA: Rio Traful	Similar stream order in rivers of different basins in different ecoregions or biomes	EU: Rhine River; NA: Mississippi River; AS: Mekong River or large sub-basins	Rivers from different basins in different biomes or ecoregions, such as those on US West Coast
Breadth of dependent variables	Usually system metabolism and elemental cycling in multiple stream orders	A few biotic traits or processes in one or more orders of multiple rivers	One to many of the same dependent variables in one or more stream orders throughout basin	One to many dependent variables present in multiple stream orders of each river

Lentic systems	*Single lake or wetlands*	*One aquatic zone in multiple lakes or wetlands*	*Hydrologically connected lakes from higher to lower elevations*	*Whole lake or wetland studies in multiple ecoregions or biomes*
Spatial research category	Multiple ecosystems with sampling in one or more zones (or throughout wetlands) in multiple ecoregions or biomes	Epilimnion or other zones in multiple lakes distributed across a broad geographic area	Sampling one or more dependent variables from higher to lower elevations in connected lake systems	Multiple ecosystems with sampling in one or more zones (or throughout horizontal zones broad geographic area elevations in connected wetlands) in multiple ecoregions or biomes
Example lentic systems	AF: iSimangaliso Wetland EU: Vättern Lake AS: Lake Baikal	AS: Xinjiang Lakes (CH) EU: Lake District (EN) NA: Lake District (CA)	AF: Lakes of White Nile EU: Plitvice Lakes NA: Paternoster lakes	Multiple lakes across EU and NA in particular; NA: Playa wetlands
Example dependent variables	Multiple dependent variables	Usually one or a few dependent variables	Few to many dependent variables	Few to many dependent variables

Continental abbreviations for potential research sites: A, Africa; AS, Asia; AU, Australia; EU, Europe (including Great Britain and Ireland); NA, North America; SA, South America. Based in part on Thorp et al. (2021).

primary production), nutrient cycling, food web ecology, and trait-based analyzes of invertebrates and fish. In most macrosystem projects, however, only a subset of disciplines is employed when the geographic area is especially large.

Lotic macrosystem research is occurring on multiple continents even though the specific terms "macrosystem ecology" and "macroecology" have not always been applied. Some examples of this research have been undertaken in Asia (e.g., Mekong River), Australia (Murray-Darling River system and rivers of tropical northern Australia), Europe (e.g., Danube River system), and North America (e.g., Mississippi River system and the St. Lawrence River basin). This research has included studies of many ecological attributes in a single, very large basin (e.g., the Danube) spanning multiple ecoregions as well as in many temperate steppe rivers in countries on two continents (e.g., Mongolia and the United States). Other macrosystem studies have emphasized one ecological attribute (e.g., stream metabolism) in many small stream reaches (usually headwaters) in a large number of separate watersheds distributed across a continent or even throughout a single, moderate-sized river basin (e.g., the Connecticut River Basin).

Macrosystem-type research in lentic systems has a long history of studying both hydrologically linked and isolated lakes within and among continents. The former includes, for example, paternoster lakes in Switzerland (the 16 lakes connected by limestone waterfalls in UNESCO's World Heritage Plitvice National Park of Croatia) and the linked Laurentian Great Lakes of the United States and Canada. Macrosystem comparisons among more isolated lakes are even more common among and within continents, including studies in the Windermere Lake District of Great Britain, the Experimental Lakes Area of Canada, and recently the widely distributed ephemeral wetlands (playas and prairie pothole systems) of the North American Great Plains.

Why macrosystem approaches are needed

A reader unfamiliar with macrosystem ecology might ask: "Why do we need to expand the spatial extent from: (a) stream reaches to whole rivers; and (b) single rivers to multiple rivers in different ecoregions, biomes, or even continents?"

The answer to the first part of this question is that biodiversity and ecological processes vary substantially from upstream to downstream in different ecoregions and at different spatial and temporal scales. These differences reflect some combination of predictable to highly variable variations in river width and depth, riparian cover (e.g., organic inputs and stream shading), autochthonous primary production, turbidity (affecting photosynthesis), water velocity and turbulence, and hydrogeomorphic complexity. The last component includes, for example, the presence of side channels in the riverscape and periodically connected floodscapes with their temporally isolated lakes and normally terrestrial floodplains.

The response to the second part of this question is that community characteristics (species diversity and functional attributes) and ecological processes in different locations typically become more disparate with increased latitudinal, longitudinal, and continental separation. A macrosystem approach employed across large geographic areas could reveal hidden ecological drivers not normally apparent in geographically constrained areas, while also better enabling investigators to predict effects of future trends in the environment. These reflect changes in climate, the biotic and abiotic nature of the stream and surrounding basin, and differences in the degree and type of human impacts. Two rivers in the same latitude or longitude might vary tremendously from upstream to downstream if one flows eventually to the sea and the other does not. One example of the latter is the endorheic Carson River that flows from forested mountains in California and Nevada (United States) to an evaporation basin in the scrub desert of Nevada. On the other side of the world, the Khovd River of Mongolia flows from the forested Altai Mountains into the saline Khar-Us Lake in arid western Mongolia and never reaches the sea. Moreover, rivers that flow to the sea in temperate steppe biomes of the North American Great Plains and the mountain steppe and grassland rivers of Mongolia can be located at nearly the same latitude and yet differ substantially in fauna and ecological processes for both natural and anthropogenic reasons. For instance, the Eg River in northern Mongolia and the Yellowstone River in the northern United States overlap in latitudes (though the Eg flows north into the Selenge and eventually into the Arctic Ocean while the Yellowstone eventually flows via the Missouri and Mississippi Rivers into the Gulf of Mexico). Large expanses of both rivers feature relatively clear waters, forested shorelines (except where modified by grazing in both cases), and rocky bottoms. However, the fish diversity in the Yellowstone consists of both native and many introduced species, while all fish species in the Eg are native at present. Downstream in the Yellowstone where it joins the Missouri River, the system has been impounded by multiple large dams, while the Eg presently lacks dams (this is likely to change by the late-2020s). Finally, the average annual temperatures for northern Mongolia are rising three times the north temperate zone average. Combining all these observations provides insights to ecologists which may allow them to predict future trends in both rivers from knowledge of conditions in other rivers.

Ecological conditions within a river or lake macrosystem can be influenced by conditions in distant aquatic macrosystems present within or even among continents in a process called "metacoupling" (LaRue et al., 2021; Tromboni et al., 2021). This process can be subdivided into interactions occurring over relatively short distances ("pericoupling") and those transpiring over long distances ("telecoupling"). Examples of the latter were much less common in the past, but human-influenced metacoupling (=intra-coupling) has greatly expanded these interactions. Aquatic metacoupling can occur through natural colonization, such as the transmission of fertilized eggs, young, or adults via by wind, waterfowl, floods, or adult migration. Two examples of pericoupling include short-distance migration among aquatic systems by flying adult dragonflies (which also may migrate long distances) and overland migration on moist nights by crayfish and "walking" catfish (*Clarias batrachus*). Natural telecoupling is primarily related to transmission of propagules by wind (e.g., freshwater rotifers) and waterfowl (e.g., fairy shrimp eggs on feathers and in a bird's alimentary track) because of the distances involved, but tropical floods can also lead to species migration among previously isolated water bodies. Anthropogenic changes in ambient temperatures and precipitation may be increasing the tendencies of some species to migrate by diminishing the quality of the previous home river, wetland, or lake.

Despite some attempts to control intra-coupling, the diversity and total amount of human-nature interactions are probably rising because of the joint effects of climate change, habitat destruction, and intentional and unintentional species introductions. While intentional and accidental intra-coupling have both been occurring for centuries if not millennia, the increasingly global economy and frequent destruction of tropical forests for crop production (with resulting effects on freshwaters) have substantially caused both local extinctions within the watershed and rarer movement of species among countries and even continents. While current macrosystem research emphasizes fundamental studies, ecosystem management would benefit from integrating macrosystem techniques at regional, national, and global scales. In addition to requiring a greater degree of communication and collaboration among scientists, politicians, and multi-national corporations across the globe through an existing or new international organization, this widespread integration will demand a better understanding and control of potential telecoupled pathways and a recognition of which species have both a greater potential transmission rate and more likely negative environmental impacts in a new geographic location.

Conclusion/Synthesis

Meeting future challenges of a changing environment while enhancing our ecological knowledge of aquatic systems will require an improved understanding of how large, whole aquatic systems (=macrosystems) function. A necessary component of this process will be for groups of scientists with disparate but complementary disciplines to work together in teams. Such projects will require enhanced financial and political support from governments, especially because most projects are likely to cross political boundaries within and among countries.

Knowledge gaps

1. What are the general principles of "macrosystem ecology" that would allow us to predict ecological responses from one geographic location to another?
2. How significant are basin morphometry and geological composition for aquatic macrosystem ecology in lotic and lentic systems?
3. Which factors that are primarily responsible for the functioning of individual macrosystems vary predictably among macrosystems in different ecoregions, biomes, and continents?
4. Do factors primarily controlling the ecology of endorheic river macrosystems differ significantly from those of rivers flowing to the sea?
5. Can the management of rivers benefit from a focus on macrosystem approaches by government agencies and environmental foundations?
6. What characteristics of macrosystems make individual systems more susceptible to the effects of climate change and invasive species?
7. What approach might we develop that would better enable us to predict the ecological effects of impending climate change on the structure and function of macrosystems and constituent communities, and would an international macrosystem rivers organization be useful in achieving these goals?
8. Would better knowledge of macrosystem ecology improve our ability to predict invasion from exotic species and possibly prevent or ameliorate their ecological impacts on macrosystems.

Representative case studies

The number of lotic and lentic macrosystem-type studies are slowly expanding worldwide but are primarily limited by research funds and sometimes by cooperation among governments. As examples, recent stream and river macrosystem research projects funded by the National Science Foundation have focused on: (1) applied and basic ecology of a large river that passes through multiple countries with different natural conditions and human impacts; (2) macroinvertebrate communities in permanent and perennial headwaters located in 10 forested ecoregions; (3) organic matter fluxes within headwaters streams of a single, large river basin; (4) data base development of annual metabolism in streams across a continent; and (5) analysis of the effects of downstream position, hydrogeomorphology, and riparian cover on metabolism, species diversity and traits, and food webs in temperate steppe biomes of two continents. Some representative studies of lake and wetland, macrosystem research include: (a–b) metabolism and nutrient conditions in lakes across a continent; (c) country-wide assessments of climate and land-use on populations of amphibians and waterfowl in wetlands; and (d) latitudinal analyzes of genetic links and transport mechanisms (teleconnections) by wind and waterfowl of fairy shrimp among ephemeral wetlands in a temperate steppe biome.

Acknowledgments

The author appreciates insightful critiques of an earlier draft of this manuscript by Drs. Alain Maasri, Kevin McCluney, and Caleb Robbins. Production of this manuscript and funding for the macrosystem research projects upon which it is partially based were aided by NSF research grants to study rivers in the United States and Mongolia (NSF 1442595) and ephemeral wetlands in five states of the U.S. Great Plains (NSF 1926596).

Glossary

Functional redundancy A single ecological function is provided by more than one species (functional equivalence of species) in a community. If one of the species is lost, the function is maintained for the ecosystem.

Geomorphic unit A discrete patch within a riverine landscape defined by morphology, sediment texture and/or flow pattern.

Metacommunity dynamics Metacommunities are interacting metapopulations determined by exchanges through dispersal. Exchange can be affected by disturbances; recruitment recovery determines the rate of return to preceding exchanges.

Recruitment The processes of regeneration and recolonization that follow disturbance enabling the recovery of the biotic community.

Refugia Used here in a wider sense, that is, sites offering (a) refuge to changing environments and (b) continuity in environmental conditions together with habitat heterogeneity offering opportunities for speciation and specialization.

Regime or state In ecological studies, the regime or state can be defined by the set of abiotic and biotic conditions observed for a focal ecosystem or component. A regime or state of an ecosystem can be characterized as the set of structures, functions and interactions. These structures, functions and interactions are scale dependant.

Regime shift A regime shift refers to large, persistent change in the structure, function and set of relationships of an ecosystem or Social-Ecological Systems associated with the crossing of a tipping point. Regime shifts have major impacts on ecosystem services and human well-being as they are costly, difficult to manage and impossible, to reverse. Regime shifts are similar to social-ecological transformations, but tend to focus on unintended, negative shifts rather than more intentional, positive shifts in SES.

Resilience The classical definition of resilience (cf. Holling, 1973) refers to the amount of change an ecosystem can undergo and still retain its essential structures, functions and feedbacks, i.e., its capacity to return to its pre-disturbance state. In this definition, both the resistance to and recovery after disturbance are accounted for. More recently, resilience has been defined as the capacity of a social-ecological system to persist in the face of disturbance and change, while continuing to adapt and develop along a pathway or transform and navigate new pathways to sustain human well-being. This form of resilience takes into account and integrates notions of governance systems, ecosystem services and human well-being, adaptive capacity and transformation.

Resource facilitation Facilitation is a significant ecological process that produces community-level effects through individual positive interactions. Such interactions are considered "mutualisms" when both species derive benefit from the interaction.

Resource pulses Strong fluctuations in availability of resources occur under pulsed disturbances of floods and droughts in river ecosystems, with consequences to biotic communities.

 https://doi.org/10.1016/B978-0-12-819166-8.00088-8

Resource The use of this term is not restricted to food but it also encompasses elements such as light (especially for primary producers), oxygen, substrate, and temperature.
Shifting habitat mosaic An array of geomorphic units or ecological patches that change over time in response to disturbances and provide areas for pioneer species to invade through to areas of well-established organisms.
Social-ecological systems Social-ecological systems (SES) are complex adaptive systems whereby social and ecological agents and processes are closely linked.
Thresholds Threshold is a boundary separating different behaviors, such as sediment movement and deposition or different river channel planforms like meandering or braider river channels. In ecology, e.g., light thresholds allow photosynthesis of plants, temperature thresholds initiate fish spawning etc.
Tipping points Tipping points are a particular type of threshold. Crossing a tipping point results in a regime shift and once crossed the system cannot revert back to the previous state.

Introduction

The aim of the chapter is to highlight the main elements of the resilience of riverine landscapes. These include factors that contribute to the resistance and recovery of rivers to environmental stress and the determinants of disturbance(s). These will reflect some combination of physical (based in geomorphological features), ecological (based in the biotic community traits), and social-ecological (originating in management of societal policies) conditions. The interplay between resistance, recovery and disturbance can result in a state change of river systems.

There are many perspectives of resilience. Definitions of engineering and ecological resilience emphasize the role of physical and biotic characteristics of river systems. For the physical characteristics, the resilience concept has many parallels in the study of geomorphology (Thoms et al., 2018). A consideration is how geomorphological resilience interfaces with other dimensions of resilience, especially ecological resilience and socioeconomic resilience, the latter commonly being defined in terms of ecosystem service delivery (Stallins and Corenblit, 2017). The geomorphological view on equilibrium conditions is similar to an engineering definition of resilience, which emphasizes efficiency, constancy, and predictability, and focuses on stability and steady state equilibrium conditions; where resistance to disturbance and the speed of return to a steady state equilibrium are used to measure resilience (Tilman and Downing, 1994). By comparison, ecological resilience (Holling, 1973) considers the amount of disturbance an ecosystem (or community) can tolerate before it loses its original structure, internal functions and set of feedbacks. This definition emphasizes persistence, change, and unpredictability, and looks for instabilities that can flip a system into another regime, i.e., another domain or basin of attraction (Holling, 1973). The measurement, from an ecological perspective, is the magnitude of disturbance that can be absorbed before the system changes its structure, functions, and sets of feedback (Walker et al., 1969). In ecological resilience, studies have considered how food webs absorb, recover from and adapt to environmental change (DeBoer et al., 2020), thus emphasizing the importance of biological mechanisms and responses to disturbance. Socioeconomic perspectives of resilience start from viewing river systems as social-ecological systems and responses to disturbance are influenced by societal perceptions and risk evaluation, resulting in management for resilience.

Mechanisms of river resilience are, however, being challenged by human-induced alterations to the characteristic properties of river systems, including hydrologic disturbance regimes, network connectivity, and the coupled longitudinal and lateral resource pulses. The interplay between climate change, land-use intensification and human population growth is likely to bring new challenges to the management and conservation of freshwater ecosystems globally, highlighting the need for a better understanding of and adaptive management approaches for river resilience.

Engineering resilience; the geomorphological perspective

Concepts

Engineering resilience, defined as resistance to disturbance, or the ability of a system to remain close to an equilibrium or steady state, views systems in terms of stability and predictability. This brings us to the physical impact of externally-driven disturbance on the state of a system, with recovery as the operation of intrinsic processes to restore the system towards, or back to, an equilibrium state. The concept of equilibrium in geomorphic systems is based on the notion of balance between process and form. Thus, when a geomorphic system is disturbed, there is a period of time—relaxation time—during which the system returns to a relative state of balance (Phillips and Jerolmack, 2016). In river systems, which are prone to disturbance from a range of variable drivers (e.g., floods and sediment overload), a true steady state is unlikely because disturbance intervals tend to be shorter than relaxation time. Thus, systems may not trend towards a steady state but rather a state of pseudo-equilibrium, which is normative in most river systems (Phillips, 2009).

The geomorphological perspective of river resilience relates to some engineering resilience elements. Here the focus is on the ability of morphological attributes and landforms to absorb, respond or recover from disturbance, within specific degrees of freedom. In riverine landscapes, degrees of freedom are properties such as river channel width, depth, slope, planform and channel

roughness. For example, if river channel banks have the least resistance to change they would adjust over other degrees of freedom. Thus, the concept of resilience is implicit in the study of geomorphology (Thoms et al., 2018). Principles of resistance, recovery and change underpin our understanding of the way geomorphic systems function via equilibrium theories (Stallins and Corenblit, 2017) and of the role that extrinsic and intrinsic thresholds (Schumm, 1979) play in governing the form and behavior of geomorphic landforms. Resistance is an important term in geomorphology, as it controls the likelihood of erosion and sediment transport during floods and, therefore, landforms gaining or losing sediments that are required to change morphological character. In systems with low resistance there is likely to be more geomorphic adjustment and often a longer period of recovery (termed recovery or relaxation time) or a greater likelihood of the river system moving to a new state (e.g., a regime shift from a single-thread actively meandering gravel bed river to a multi-thread wandering gravel bed river).

Definitions of resilience variables relating to a geomorphic process-response system are shown in Fig. 1. The concept of equilibrium in geomorphic systems is based on the notion of balance between process and form. Thus, when a geomorphic system is disturbed, there is a period of time—the relaxation or recovery time—during which the system returns to a relative state of balance or equilibrium (Phillips, 2014). In river systems, which are prone to a range of disturbances (e.g., floods, sediment pulses, wood inputs), a truly steady state is unlikely because disturbance intervals tend to be shorter than recovery time. Thus, riversystems more normatively trend towards a state of pseudo-equilibrium (Phillips 2009). Fig. 1 shows that resilience concepts and ideas can be visualized in relation to geomorphic equilibrium concepts and the associated terminologies of thresholds, relaxation times and meta-stability, magnitude and frequency (cf. Phillips, 2014; Fuller et al., 2019).

To understand implications of changing the magnitude and frequency of hydrogeomorphic processes one has to consider the nature of geomorphic equilibrium—a long-established and normative concept in geomorphology. There are many definitions and classifications of geomorphic equilibrium. Here we classify four types of geomorphic equilibrium (Fig. 2) and equate them directly to types of resilience trajectories. Using the classic ball and cup model of resilience (Scheffer, 1990), the cup can be represented as a geomorphic river type (e.g., meandering, braided etc.) and the ball reflects changes in channel properties of an individual river type, e.g., width.

- *Static* equilibrium is where the disturbance regime does not exceed the system's morphological resistance—a state of no change or where the ball sits unaltered and static in the bottom of the cup i.e., there is no morphological adjustment in the river channel.
- *Steady state or stable* equilibrium: the tendency for a system to move back towards a previous equilibrium condition, i.e., to recover after a disturbance as the ball moves up the sides of the cup but eventually returns to its original position i.e., river morphology (e.g., width) may adjust (widen) following a flood but will return to its original morphology or dimension.
- *Dynamic* or unstable equilibrium: balanced fluctuations about a constantly changing system condition may have a trajectory of unrepeated states that change over time (e.g., meander form changes)—the ball stays in the cup but the nature of the ball (e.g., size) gradually changes over time, or the cup is tilted and the balls sits in another position at the bottom of the cup.
- *Metastable* equilibrium: when a disturbance carries the system state over a geomorphic threshold into a new equilibrium regime (e.g., meandering to braiding) and the ball exits the previous cup and enters a new cup. A new river channel morphology or river type is established following a disturbance—this is also referred to as transformation or regime shift.

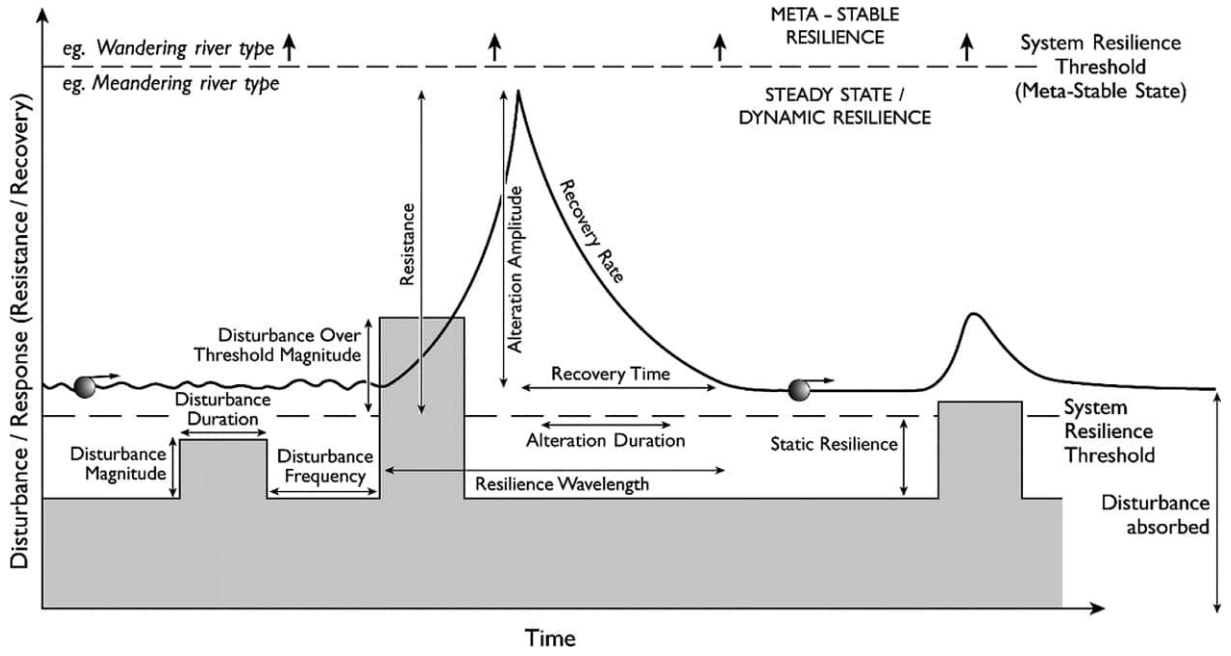

Fig. 1 Resilience concepts and terminology related to river channel equilibrium. Adjustment properties related to the magnitude of change from an equilibrium state and the temporal property of recovery time are depicted. In this example the disturbance would be a flood and the river adjustment (the solid line) represents the changing character of the river channel planform. Adapted from Fuller IC, Gilvear DJ, Thoms MC, and Death RG (2019) Framing resilience for river geomorphology: Reinventing the wheel? *River Research and Applications* 35: 91–106. doi: 10.1002/rra.3384.

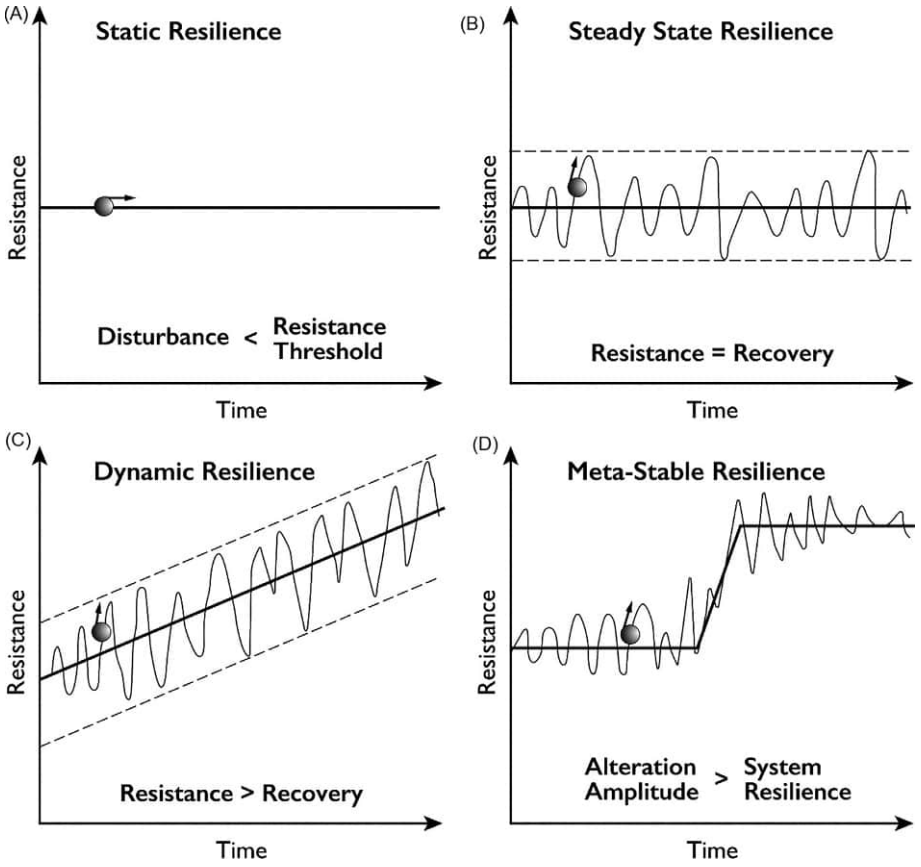

Fig. 2 Geomorphic-resilience trajectories (A) static, (B) steady-state, (C) dynamic, (D) meta-stable (regime shift). The resilience ball would follow the trajectory shown and in the case of (D) flip between resilience domains. Adapted from Fuller IC, Gilvear DJ, Thoms MC, and Death RG (2019) Framing resilience for river geomorphology: Reinventing the wheel? *River Research and Applications* 35: 91–106. doi: 10.1002/rra.3384.

Central to the process of resilience and recovery following disturbance is the concept of feedbacks, which can be negative or positive. Negative feedback is any process that neutralizes the recovery of geomorphic systems following a disturbance. A river widened by a high magnitude flood for example, will result in lower flow velocities for a given size of flood event leading to an increase in sediment deposition in subsequent (smaller) floods. As such, the morphology will have a trajectory back to the pre-disturbance channel morphological state. This is negative feedback and exemplifies a resilience response to disturbance by a high-magnitude, low-frequency event. It also shows the futility of engineering wider channels in that negative feedback processes will occur resulting in the need for channel maintenance to restore the engineered channel design. Such a negative feedback response is enhanced by vegetation colonization and stabilization of deposited sediments, leading to further deposition of fines within the vegetation and accelerated bank construction and channel narrowing. Indeed, vegetation colonization and related feedbacks are a fundamental part of the recovery process on many rivers, increasing resilience by accelerating a negative feedback process. An example of positive feedback is where straightening and reinforcing of a channelised reach leads to enhanced bank erosion in the downstream reach where the banks are unprotected. A typical response would be to install more bank protection, so moving the problem even further downstream and reducing resilience of the system.

Assessing engineering resilience in geomorphic thresholds & state changes

The capacity of a river at the reach scale to absorb (resist or recover) disturbance is conditioned by its proximity to a threshold (Brunsden and Thornes, 1979). Changes in river channel type (meta-stable/regime shift), such as a change from a meandering to a wandering or braided river planform, occur when thresholds relating to stream power, or flow regime and sediment regime are exceeded (Schumm, 1979). A disturbance that fails to exceed the resistance of the channel and its geomorphic units results in no change in river size, morphology or physical habitat composition. In this situation, channel resilience is "static" (Fig. 2A) and may describe the behavior of river geomorphology to frequent floods (>1–2 per year). Such small (within-channel) floods are critical for maintaining the ecological quality of in-channel habitats, e.g., by preventing clogging of gravel spawning habitat with fine sediment.

Where alteration amplitude or recovery following disturbance is rapid, resilience can be considered as "steady state" (Fig. 2B). This is because the system has absorbed the disturbance and returned to its pre-flood condition (i.e., channel form and assemblage of morphological units). Vegetation re-colonization is important for the rapid recovery of fluvial surfaces to the pre-disturbance

state following perturbation (Gurnell, 2014). In this respect, healthy, resilient riverine landscapes are those with well-developed riparian margins. Without rapid vegetation colonization and related sediment retention and stabilization of river margins, the likelihood of changes from meandering to wandering river morphologies greatly increases. In turn, such planform changes pose challenges for river management, as the lateral extent of the active river corridor has to increase.

Phillips (2009) argues that if the pre-disturbance state of a system is not restored, a system can be construed as non-resilient, or having low resilience. Nevertheless, resilience is itself dynamic (Fig. 2C) when progressive change occurs in a system adjusting to new boundary conditions. For example, a progressive increase in discharge and bed load with an increasingly wet climate through time may increase channel width, width:depth ratio, meander wavelength and channel gradient, while reducing sinuosity, but a meandering channel is maintained. In New Zealand, where land-use change has rendered catchments prone to erosion, some rivers have been more dramatically transformed, changing from narrow, single-thread systems to rapidly aggrading multi-thread rivers (Fuller and Rutherfurd, 2021). While in many cases, change can proceed over several decades, centuries, or even millennia. The Raparapariiki River, New Zealand, which transformed within a decade, is an excellent example of this (Tunnicliffe et al., 2018). The adjustment across a threshold by this channel was associated with a major storm event in 1988, a classic example of metastable resilience (Fig. 2D).

The interplay of disturbance frequency, rate of recovery and amplitude of response is important to the resilience of river systems (Fig. 3). Highly dynamic rivers, sensitive to small floods, which absorb disturbance and do not experience changes in the morphologies exhibit robust behavior, are resilient as moderately dynamic or steady state rivers. In this case, each adjusts to the frequency of disturbance, amplitude of response and rate of recovery that are inherited from the catchment boundary conditions. The range of natural capacity for adjustment will be dependent upon the character of each river system (cf. Fryirs and Brierley, 2013). As such, both dynamic and non-dynamic river types in their natural state are resilient to the natural range of disturbance (i.e., floods) in their catchment. In its unaltered condition, a river responds with resilience to even the largest floods, because its natural form and character will adjust and recover over time.

The problem for river management is that many rivers are now no longer in a natural catchment setting. Anthropogenic disturbances have resulted in river systems moving to a new cup—a new regime from which they cannot return. As such there is often mismatch between process and form even where no direct channel modifications have taken place. Resilience defined as the magnitude of the disturbance a system needs to shift to an alternative stable state, is a critical trait in the Anthropocene era. Therefore, we need to orient to specific measures and measurement of the tipping points and especially of the early warning signals to these tipping points. Furthermore, we need to develop guidelines for managing for resilience. However, we are far from having baseline resilience data to guide decision makers towards more resilient river systems. Resilience indicators have to test for the quantitative impact that changes might cause, with indications based on both intensity and relevance. We develop these ideas and discuss the challenges of river management in the Anthropocene below, following discussion of ecological resilience, because river management for resilience must be informed by both geomorphology and ecology.

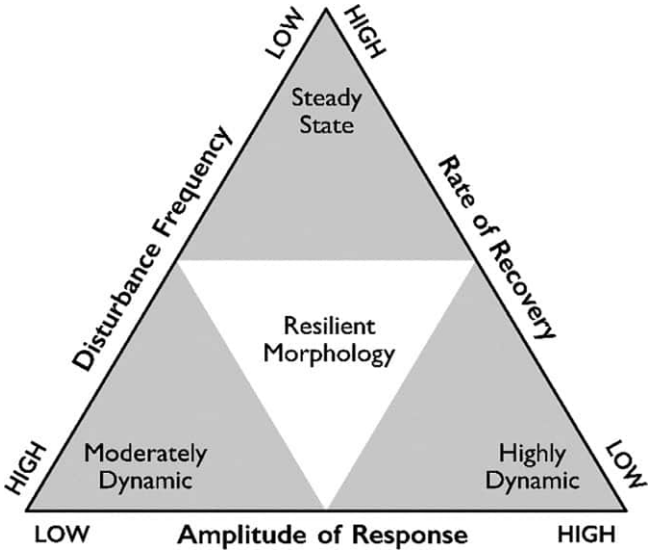

Fig. 3 Resilience in amplitude, frequency and recovery space. Adapted from Fuller IC, Gilvear DJ, Thoms MC, and Death RG (2019) Framing resilience for river geomorphology: Reinventing the wheel? *River Research and Applications* 35: 91–106. doi: 10.1002/rra.3384.

Ecological resilience

Concepts

The Resilience Alliance (https://www.resalliance.org/) defines resilience in terms of system change. It is the amount of change a system can undergo (its capacity to absorb disturbance) and essentially retain the same function, structure and set of feedbacks (Walker and Salt, 2006). This ecological view of resilience focuses on change and unpredictability and is linked to ecological principles of adaptation and evolution. Resilience in ecology has been simply viewed as the recovery phase from disturbance to its original condition.

Resilience in river ecosystems requires that organisms must persist in the face of highly dynamic hydrological and geomorphological variations. Disturbance events such as floods and droughts are postulated to shape life history traits that support resilience, but river management and conservation would benefit from greater understanding of the emergent effects in communities of river organisms. Species in disturbance driven systems like rivers pulsed by floods and droughts (Parasiewicz et al., 2019) have evolved strong fitness and specific life history traits to resist or recover from the disturbance. Relevant traits are, for example, maximum size and longevity, which foster resistance. Young age at maturity and fecundity also enable quick recovery (van Treeck et al., 2020). Organism response to disturbance is further mediated by biological traits related to feeding specialization, dispersal ability and habitat specialization, along with taxonomic and phylogenetic identity. Measures of these factors might also enable assessment of the relative contributions of different mechanisms to community resilience. Community-wide, there are three mechanisms that underlie resilience: (1) partitioning (competition/facilitation) of dynamically varying resources; (2) dispersal, re-colonization and recruitment promoted by lateral and longitudinal connectivity; and (3) functional redundancy in communities promoted by resource heterogeneity and refugia.

The ensemble of individual species' responses to disturbance through competition/facilitation for resources, dispersal that avoids mortality, or persistence through adapted traits in specific niches, result in resilience at the community level through one or more of the three resilience mechanisms (Van Looy et al., 2019).

In contrast to natural pulse disturbances, human-induced alterations, such as flow regime alteration, pollutant inputs, climate change or habitat degradation, are press or ramp disturbances (increasing gradually or incrementally in intensity) (Lake, 2000). Human activities such as land cover modification result in shifts in seasonality, frequency and duration of pulse disturbances, and thus challenge river resilience mechanisms. Further, the timing of disturbances may be more important than pulse magnitude in terms of effects on resilience capacity (Woodward et al., 2016; Poff et al., 2018). Floods and droughts in river systems show specific effects on resources, connectivity and habitat heterogeneity. As a result, organisms respond specifically to events, either in benefiting from resource pulses or avoiding flood disturbance by moving away, or to seek refuge in a specific niche, rather than some combination of response mechanisms (McMullen et al., 2017).

Resource competition/facilitation

Resource competition/facilitation is the mechanism for species that can take advantage of changed (either pulsed or depleted) resource conditions during disturbance. Strong fluctuations in availability of resources such as light (especially for primary producers), oxygen (anoxic conditions occur in river sediments), substrate (such as bare sediment for riparian plants and ground beetles or gravel and branches for benthic organisms), temperature (for thermophilic organisms) and food or habitat (inundated floodplain) occur under pulsed disturbances of floods and droughts in river ecosystems, with consequences to biotic communities.

Resource competition and facilitation are opposite interspecies response mechanisms to temporal resource variation. In response to resource pulses, the resilience mechanism at the community level involves internal re-organization, i.e., reassembly, based on biotic interactions including competition and facilitation. Facilitation is a significant ecological process that produces community-level effects through individual positive interactions. By increasing access to resources, facilitation can impact community structure and diversity. Such interactions are considered "mutualisms" when both species derive benefit from it.

Rivers and adjacent terrestrial ecosystems have permeable boundaries that are frequently crossed by two-way resource subsidies, e.g., from flooding, insect emergence, and vice versa, e.g., floodplain feeding by fish, leaf litter input in autumn (Larsen et al., 2016). Adaptations to both resource pulses and subsidies exist and are reflected in flexible timing in resource use (Holt, 2008).

Recruitment

Recruitment recovery depends on species' abilities to move through space and time (Heino et al., 2015) in combination with reproductive traits (van Treeck et al., 2020). Metacommunity dynamics are determined by exchanges through dispersal and mortality in interacting metapopulations. The strength of these regeneration and recolonization dynamics can be affected by disturbances; recruitment recovery determines the rate of return to preceding conditions. The recruitment mechanism of resilience relies on metacommunity dynamics based on habitat connectivity, species' dispersal abilities and size of the regional species pool.

Studies have elucidated the role of dispersal, landscape connectivity and exchange processes in the resilience of communities and ecosystems (Hughes et al., 2005). This can occur either by active dispersal, by quick regeneration or by resting stages, and serves to avoid disturbance and/or rapidly recolonize afterwards. So, recruitment is supported by life history traits such as high mobility, fecundity and early maturity.

Recovery of riverine biotic communities is presumed to be largely based on dispersal capacity in metacommunities as source-sink dispersal and drift rates are particularly high in river networks (Heino et al., 2015; McCluney et al., 2014). We may expect that dispersal capacities affect recovery rates, with strong dispersers recovering rapidly depending on proximity to source areas. In addition to dispersal, some species may also form seedbanks or resting stages that survive unsuitable periods (e.g., floods or drought-induced drying) inside the sediments. This can be understood as "temporal dispersal" or "traveling in time," observed for both riparian plants (Honnay et al., 2009), aquatic invertebrates (Stubbington and Datry, 2013), and even fish species (Furness et al., 2015) in intermittent rivers.

Through their greater connectivity, downstream locations may be more influenced by mass effects (i.e., high dispersal rates from favorable "source" to unfavorable "sink" localities; Pulliam, 1988) than more isolated headwaters (Brown and Swan, 2010), and thus be more resilient through stronger recruitment recovery. In contrast, species sorting should be stronger in headwaters, because high dispersal rates typical of mainstems do not influence local dynamics in the headwaters (Grönroos et al., 2013; Brown and Swan, 2010). This is especially true for benthic invertebrate communities that appear highly influenced by connectivity to upstream habitats (i.e., sources for drift dispersal) (Göthe et al., 2013). By contrast, fish community response to disconnection is mostly determined by local conditions in combination with barriers to dispersal in downstream sections (Van Looy et al., 2014).

In addition to dispersal capabilities, reproduction traits foster recruitment and recovery after disturbances. Life history traits promoting regeneration comprise high fecundity with the production of many eggs or seeds and seed banks. For fish, multiple spawning (iteroparity) or batch-spawning in combination with a protracted spawning season insure successful reproduction at broad ranges of environmental fluctuations (Wolter et al., 2016).

Refugia

Functional redundancy is the third mechanism of river ecological resilience. A single function can be supported by more than one species (functional equivalence of species) in a community. If one of the species is lost, the function is maintained for the ecosystem. Associated to the notion of response diversity, i.e., the variation in responses to environmental change by species within a functional group (Elmqvist et al., 2003), functional redundancy immediately leads to a resilience mechanism in refugial environments. Refugia are environments characterized by heterogeneity and continuity in habitat conditions favoring increased species survival and hence functional redundancy, as more species of the same functional group will co-exist and show variation in response to disturbance. Species differ in their ability to find and use refugia, but the more heterogeneous the habitat, the more likely many species will survive (Keppel et al., 2012). Refugia is used here in a wider sense, that is, sites offering (a) refuge to changing environments and (b) continuity in environmental conditions together with habitat heterogeneity offering opportunities for speciation and specialization. Environments with strong gradients in moisture and temperature like fluvial ecosystems are rich in micro and macrorefugia, respectively, at site and landscape scales. The role of landscapes as refugia is ruled by local and riverscape scale environmental heterogeneity, together with the continuity of provision of a habitat mosaic under changing environmental conditions (Keppel et al., 2012). River ecosystems offer refugia from disturbance through a mosaic of habitat patches that confer habitat heterogeneity and promote specialization of organisms (Townsend and Hildrew, 1994).

Most resilience literature puts forward functional redundancy as the principal mechanism by which communities persist through disturbances (Angeler and Allen, 2016). In the high dynamics of river ecosystems, we believe the resource and recruitment-based mechanisms that benefit from the disturbance are more prevalent—at least for short-term effects—than the refugia mechanism that depends on the hiding from disturbance.

The redundancy response to disturbance is determined in species habitat-specific resistance and resilience mechanisms that are generally described with life history traits that promote survivorship, such as behavioral and morphological traits (e.g., Lytle and Poff, 2004). The mechanism behind functional redundancy is the functional similarity of species in one trait, but their speciation or conditional differentiation in others.

Assessing ecological resilience

The mode of response to a disturbance can evolve over time. The prevailing response mechanism is influenced by an ecosystem's historical disturbance characteristics, which vary substantially across climatic, geologic and land-cover gradients (Rinaldi et al., 2015). Thus, we assume that rivers with strong resource pulses will host communities that re-assemble more readily, while those in river networks with high connectivity can recover quickly through recolonization after disturbance, and rivers with high habitat heterogeneity at local and riverscape scales offer refugia that promote species persistence and functional redundancy. Trait-based representation of these relationships allows for a better understanding of these interactions and can potentially inform adaptive resilience management (Larsen et al., 2016). Current knowledge in this domain of species interactions and food webs already offers tools for assessing strength and resilience of food web interactions (Wootton and Emmerson, 2005).

Many functional trait metrics and indices of disturbance response exist. In fish, for instance, responses to fluctuations of resources have been observed in batch spawning and extended spawning seasons, while for recruitment recovery high fecundity

promotes resilience. By contrast, multiple spawnings per year increase the probability at least some of the offspring will encounter favorable environmental conditions (Wolter et al., 2016). For benthic invertebrates, mobility by larvae, high drift rates or a hard exoskeleton (or shell) can provide resistance to flow disturbances (Poff et al., 2018). Further, mobility of all stages is seen as a recovery mechanism to both droughts (Leigh and Datry, 2017) and floods (Woodward et al., 2016; Poff et al., 2018). Dispersal through drift, swimming and adult flight ability implies important functional traits in this regard. With disturbance, associated resource pulses/fluctuations should mean generalist species with high fecundity and short life-cycles (multivoltine) have more chances in re-colonization. The refugia and redundancy mechanism, on the other hand, should be promoted by the presence of specialists, like those species that have strategies of oviposition by aerial adults, or survive with buried eggs or under anoxic conditions. The nature of the disturbance regime (magnitude, frequency, timing) of individual streams will result in different expectations of which 'mechanism' dominates based on the local spatio-temporal dynamics (Poff et al., 1997).

The recognition of these three mechanisms and their quantitative assessment based on the trait indices can be used to measure the strength of resilience, in a framework applicable for river management. The arrows in Fig. 4 highlight the external drivers of specific community resilience mechanisms. Strong resource dynamics drive organisms to resource competition or facilitation; high connectivity allows dispersal and re-colonization; and increasing habitat heterogeneity promotes species survivorship and functional redundancy. Hence, community composition as reflected in the prevailing traits indicates the relative contribution of the three specific mechanisms, and thus can indicate a community's potential sensitivity and resilience to specific types of disturbance. A community with a majority of good dispersing species, for example, might be vulnerable to strong resource pulses, while a community with many trophic or habitat specialists might be vulnerable to changes in ecosystem connectivity, which might provide opportunities for generalists to dominate.

Responses to and the relative importance of mechanisms operating at the community level will vary with the severity and predictability of the disturbance (Tonkin et al., 2017). Accordingly, relative changes of trait composition at the community level might offer strong indications of the dominant mechanisms and the strength of community resilience to specific disturbances. We illustrate this framework's application with the longterm data on trophic position of fish guilds of the Upper Mississippi River. Measured in "trophic position diversity," the lock-and-dam construction around 1940 reduced floodplain access and thus diminished refugia leading to diminished functional diversity (Delong and Thoms, 2016) thus a retreat on the Refugia axis (Fig. 5). In the resulting resilience surface, Recruitment also diminished slightly through partial loss of connectivity (loss of diadromous fish species), and resources increased slightly through the increase in peaks of algal blooms due to flow regulation.

Resilience thinking can inform of possible management interventions for long term sustainability. For example, communities characterized by resource resilience traits indicative of specific resource dynamics can be managed around "constraining" or restoring resource pulses and fluctuations, while preserving heterogeneity and connectivity. For recruitment recovery, for communities dominated by species with high dispersal capacities, management should focus on preserving well-connected systems (removing barriers/obstacles for dispersal). Where poor dispersal abilities dominate at the community level, connections should focus primarily on lateral connectivity with floodplain habitats. Finally, for refugia, communities with many habitat specialists can be preserved by maintaining habitat heterogeneity and managing for environmental quality conditions (even for extreme conditions such as in alpine streams).

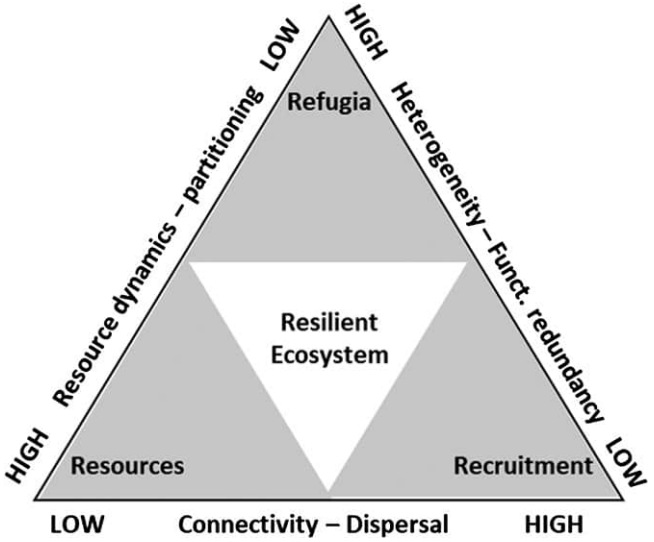

Fig. 4 Conceptual river resilience framework representing the three mechanisms driving ecological resilience: resource competition/facilitation, dispersal-based recruitment recovery and refuge-mediated functional redundancy. The extrinsic drivers at the ecosystem scale (arrows) that steer the prevalence of specific mechanisms are resource dynamics, landscape connectivity and environmental heterogeneity. After Van Looy K, Tonkin JD, Floury M, Leigh C, Soininen J, Larsen S, Heino J, LeRoy Poff N, Delong M, Jähnig S, Datry T, Bonada N, Rosebery J, Jamoneau A, Ormerod S, Collier K, and Wolter C (2019) The three Rs of river ecosystem resilience: Resources, recruitment, and refugia. *River Research and Applications* 35: 107–120. doi: 10.1002/rra.3396.

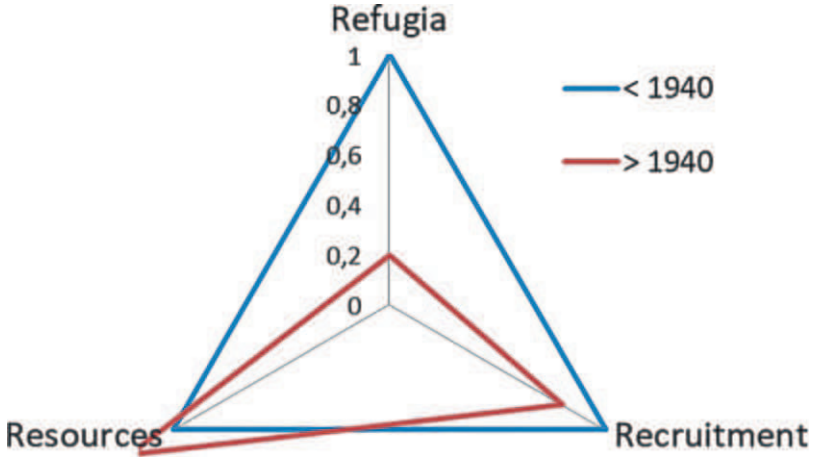

Fig. 5 Radar chart presentation of the resilience of the Upper Mississippi River communities of fish before and after the construction of the locks and dams (example in text). The post-1940 resilience surface is strongly reduced due to diminished functional diversity.

Social-ecological resilience; managing for river resilience

Concepts

Rivers are Social-Ecological Systems (Parsons and Thoms, 2018; Parsons et al., 2016), with interdependency for resources provided by ecosystems and by human activities (Berkes and Folke, 1998). The high degree of coupling between rivers, floodplains and society is a feature of riverine landscapes (Thoms et al., 2020) that requires insight into how ecological and social interactions influence the landscape.

Resilience provides a framework to understand, study and manage rivers as social-ecological systems. However, an important distinction must be made between resilience as a property of river systems and resilience as an approach to understanding social-ecological systems. As a property, resilience is the capacity of a river system to continuously self-organize and adapt to withstand a regime shift or to manage against transforming to another regime. As an approach, resilience thinking focuses on sustainability and stewardship, and seeks to understand social-ecological systems characterized by change and uncertainty. Both meanings are used interchangeably, although the latter tends to apply in policy settings while the former is the basis for empirical studies of resilience.

The concept of social-ecological resilience mirrors the development of the concept of Social-Ecological Systems (SESs), in which biophysical and social structures and processes are inextricably interlinked. There are three key concepts to social-ecological resilience (cf. Parsons and Thoms, 2018): (1) humans are integral component of landscapes in which they live; (2) social-ecological systems are complex adaptive systems; and (3) the key to sustainability is the ability of a system to absorb disturbance. Social-ecological resilience emphasizes the dynamics of SESs as complex and adaptive and their governance, which occur at multiple levels, can collectively increase or decrease system resilience. Environmental governance has the ability to not only influence the response of a SES to a disturbance, but also to mitigate or adapt a system so that it is forcibly transformed to new regimes of function (Chaffin et al., 2016) i.e., management actions can flip a river system into a new regime. A definition for river resilience in a social-ecological systems context is: "the capacity of communities to prepare for, absorb and recover from natural and societal events and to learn, adapt and transform in ways that enhance these capacities in the face of future events" (cf. Parsons et al., 2016).

The integration of resilience thinking into river assessment provides an approach for understanding social-ecological linkages in river systems. However, resilience does not currently have a strong operational and implementation procedure. Components pertinent for the development of a framework for assessing the resilience of rivers as social-ecological systems are provided by Thoms et al. (2020). This framework recognizes three logical levels or tiers representing, respectively, the "why," "what" and "how" of a best practice framework for assessing river resilience (Fig. 6). The first tier has resilience as the highest component of the framework (Fig. 6). Resilience forms the principle that guides the other tiers of the framework. In this case resilience is the context for assessing the socio-ecological linkages of rivers as a means maintaining the capacity of the system to absorb change or disturbance while remaining in essentially the same regime that retains the same function, structure and feedbacks (Walker and Salt, 2006). The second tier defines the components of the framework that represent the essential elements of understanding needed to assess resilience in rivers. The three components of this tier are an ecosystem understanding of rivers, their dynamics, and the influence of social systems. The first two components are directly related to concepts of geomorphic resilience (cf. Figs. 1 and 2). System dynamics can be viewed via adaptive cycles—the cycles of collapse and renewal. The position of the ecosystem within the adaptive cycle influences the characteristics of the system, vulnerability to change, and opportunity for change (Gunderson and Holling, 2002). Social systems represent the social components of assessing resilience in river ecosystems, and pertain to communities,

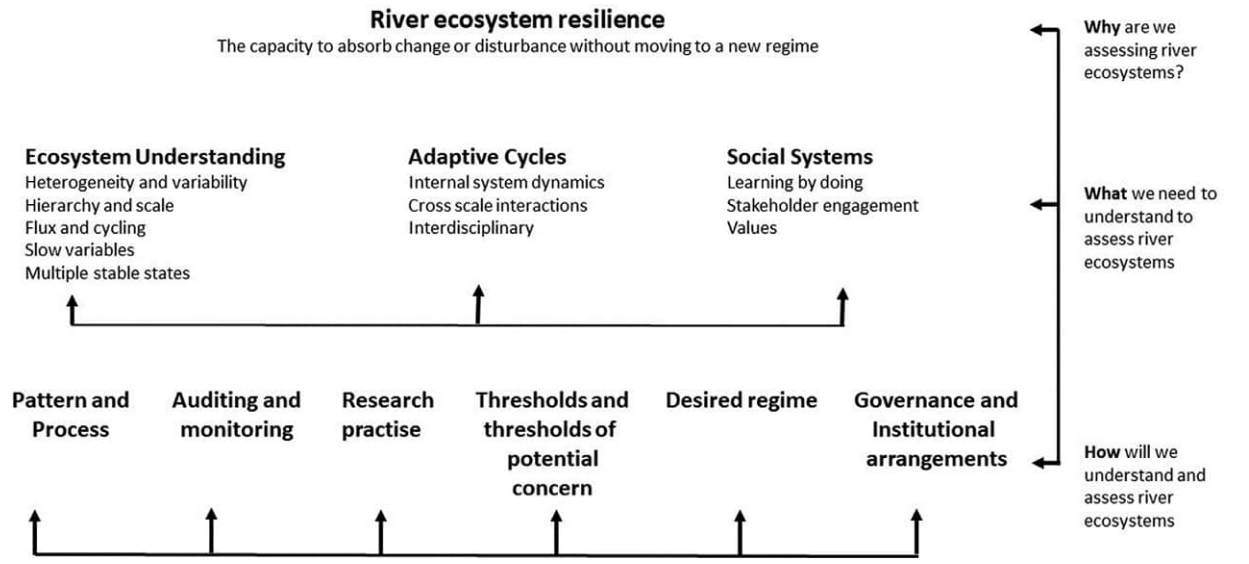

Fig. 6 A framework for assessing the resilience of rivers as social—ecological systems. Modified from Thoms MC, Rayburg S, Neave M, Parsons M and Chiew F (2020) The physical diversity and assessment of a large river system: The Murray-Darling Basin, Australia. In Gupta A (ed.) *Large Rivers*, pp. 587-608. Wiley, Chichester.

stakeholders, governance and institutions. The third tier of the framework describes how the components of understanding will be achieved. These components are essentially methods and tools that can be used to operationalize the understanding about resilience assessment and six components are suggested (Fig. 6). Successful implementation of a resilience paradigm into the assessment of rivers will require major shifts in thinking among all stakeholders, including scientists, citizens, and management agencies.

Resilience and the rivers of the anthropocene: Implications

Humans have modified riverine landscapes through land-use changes, urbanization and the construction of dams and weirs that regulate downstream flow and sediment regimes. These pronounced and sustained modifications result in regime shifts—a state change—of rivers. Viewed through a resilience lens, Anthropocene rivers have a different structure, function and set of feedbacks to their more "natural" cousins (DeBoer et al., 2020).

Establishing the "state" of Anthropocene riverine landscapes is essential for the study and management of these contemporary riverine landscapes. Recent research by DeBoer et al. (2020) showed the Illinois River ecosystem (Illinois, United States), once degraded by pollution from the Chicago metropolis did not recover to its Pre-Settlement state following major system wide restoration efforts. Rather the Illinois River showed "novel" unexpected responses, some of which suggest a reduction in its capacity to absorb future disturbances. Targets for the restoration of Anthropocene riverine landscapes need to be established because those based on our understanding of pristine systems are not applicable (Kopf et al., 2015). Anthropocene rivers are 'novel ecosystems' that do not conform to disciplinary paradigms, especially in terms of their response to drivers of change (cf. Hobbs et al., 2006). Drivers of change are not only disturbances events like floods but also river restoration activities. River scientists and managers must work across biophysical, social, economic and political domains to set objectives and manage for multiple, often competing, outcomes (cf. McLoughlin et al., 2020). This complex and unpredictable setting often paralyzes management actions, particularly those framed within traditional management paradigms. This requires developing our understanding of novel Anthropocene river systems through a far greater depth of interdisciplinary thinking. The dominance of biophysically-focused contemporary river assessment and monitoring approaches can be merged with those for assessing rivers as social-ecological systems. Frameworks describing how the social and ecological components of river ecosystems can be included in river assessment programs, based on principles of resilience thinking and strategic adaptive management, i.e., continuous success monitoring and adjustment of rehabilitation measures and management actions.

Assessing adaptive and resilient river management

Managing for river resilience must take into account the challenges posed by Anthropocene riverine landscapes. Because the fundamental state of these systems has been shifted, their dynamic trajectory has changed and management/restoration must accommodate this (Fuller et al., 2020). Fundamentally, rivers need "room to move" and the space required for this is a fundamental component of the resilience of any river type (Biron et al., 2014). Resilience based river management must incorporate "Freedom Space" to enhance geomorphic resilience and accommodate phase-shifted dynamic trajectories of Anthropocene rivers.

If consistently implemented such an approach not only provides space for current river dynamics and flooding but it could also accommodate river type and flood regime responses to climate change.

From an ecological resilience perspective, tipping points are often searched for in resilience indicators, to determine the critical change from one ecosystem state to another (Scheffer et al., 2015). The highly dynamic nature of natural river ecosystems and their pulsed hydrologic disturbances makes the presence of alternative stable states implausible (Lake, 2000), rather they exist on a continuum of states in response to antecedent flow conditions. On the other hand, anthropogenically altered flow regimes, patch and habitat dynamics, pollutant input or resource depletion can be expected to initiate tipping points. Indications for such tipping points have been observed at the scale of the river section in large rivers with artificial embankments causing significant declines in indicators of community diversity (Wolter and Vilcinskas, 1997; Van Looy et al., 2008). Human induced pulse disturbances might furthermore be better buffered in river systems than press disturbances. Correspondingly, increased frequency of extreme events associated with climate change might be better buffered due to the pulsed nature of such events than, for example, land use changes (=press or ramp disturbances) (e.g., Van Looy et al. 2016; Woodward et al. 2016).

Operating at the edge of instability generates immediate signals of changing opportunity. That surely is at the heart of sustainable development—the release of human opportunity. It requires flexible, diverse, and redundant regulation, early signals of error built into incentives for corrective action, and continuous experimental probing of the changes in the external world. Those are the features of adaptive environmental and resource management, and the societal transition needed to develop river management from a resilience perspective, instead of a curative and constricting "classic" approach.

Conclusion

The three resilience perspectives (Engineering, Ecological and Social-Ecological) can be merged in one framework to operationalize resilience research into management applications. The constraints that natural and anthropogenic disturbances place on river forms and biological communities' persistence have considerable implications for what actions are targeted when, and where to maintain and restore lotic systems. River management and restoration projects should thus focus on the catchment geomorphological context, the biological context of the species pool and underlying network connectivity, the habitat mosaic and resource dynamics, and the social-ecological system interactions. The better understanding of resilience mechanisms in river ecosystems must trigger and guide a sustainable management of rivers under future climates and societies.

Glossary

Biocultural diversity The diversity of life exhibited by interrelating natural systems and human cultures.
Cultural services All material and non-material (intangible) ecosystem services that have a cultural significance, or a symbolic or intellectual meaning.
Ecosystem integrity Characterizes the ability of an ecosystem to maintain its functions, processes, and biodiversity equivalent to that of a natural or healthy condition.
Ecosystem processes and functions Physical, chemical, and biological processes, and their roles and interactions, which underly ecosystem functioning and related ESS.
Ecosystem services (ESS) The benefits society receives from ecosystems. ESS are typically divided into provisioning, regulation and maintenance, and cultural services. River ESS (rESS) are water-related benefits society receives specifically from river systems.
Global critical natural capital The part of the global natural environment that fulfills important and irreplaceable ecosystem functions and is, therefore, of very high value for the services it provides.
Nature's contributions to people (NCP) A framework that builds on the concept of ESS by designating culture as central to all connections between humans and nature, and which recognizes broader values and knowledge systems, e.g. those of Indigenous peoples. Contributions from nature may be perceived as both positive and negative depending on the cultural, temporal, or spatial context.
Provisioning services All ecosystem outputs that can be traded, consumed, or directly used.
Regulating and maintenance services The benefits provided by ecosystems to society from the natural regulation and maintenance of ecosystem processes and functions.
River system All rivers in a hydrologically defined catchment, consisting of a main river and its network of tributaries, and the surrounding catchment or landscape.

 https://doi.org/10.1016/B978-0-12-819166-8.00129-8

Socio-ecological system A system in which different components, such as social, ecological, cultural, economic, and political components, are interconnected and considered as a whole. Interactions between humans and nature are particularly emphasized.
Total economic value A concept to classify different values of an ecosystem, based on the idea that the benefits of nature for society are composed of several elements including present use and non-use values with the latter possibly generating benefits in the future.

Introduction

Rivers, streams, and their floodplains and coastal areas provide an extensive and diverse range of river ecosystem services (rESS) (Fig. 1). They support the provision of drinking water and fish as food, create floodplain areas that retain floods, supply water for crop growing, provide cooling to urban areas during heat waves and spaces for spiritual and recreational activities, offer artistic inspiration and, in many places, are revered by local peoples (Fig. 2). River valleys have been preferential sites for human settlement for millennia, as they provide food, water, flat areas for housing, fertile farming grounds, and construction materials, as well as transport and migration routes. The earliest urbanized civilizations have developed as 'hydraulic empires' (Wittfogel, 1957); for example, the Egyptian civilization has benefitted for several millennia from the predictable annual floods of the Nile River that fertilized their crop fields. Other civilizations have attempted to optimize the use of natural capital available in floodplains for agriculture and settlements through the modification of river systems, e.g. by draining floodplains or building longitudinal and transverse dams, barrages, or water diversions along river channels. These modifications, however, often have been accompanied by major socio-economic trade-offs such as salinization of agricultural soils (e.g. Mesopotamia), increased risk of catastrophic floods when dykes of embanked river channels failed (e.g. Yangtze River in China), and ground subsidence of crop fields below river level resulting in the need for constant pumping of drain water (e.g. The Netherlands). In such highly modified rivers, the dramatic environmental trade-offs that have appeared have affected their ecosystem integrity, biodiversity and, hence, their ability to deliver key rESS. This has resulted in a strong narrowing of options for human uses of the rivers and their floodplains.

In these ways, human impacts have fundamentally transformed many river systems. The resultant state of river ecosystems worldwide is sobering: over the past centuries, 70–100% of floodplain areas have been lost in Europe alone (EEA, 2020a), the majority of the world's large rivers are no longer free flowing (Grill et al., 2019), and there has been an 84% decline in monitored freshwater vertebrate populations (WWF, 2020); for the future, a higher extinction risk has been projected, as compared with

Fig. 1 Rivers, streams, and their floodplain and coastal areas provide an amazingly diverse range of ESS; from left to right, top row: drinking water, food, irrigation; lower row: recreation, flood retention, culture. Photos: pixabay.com.

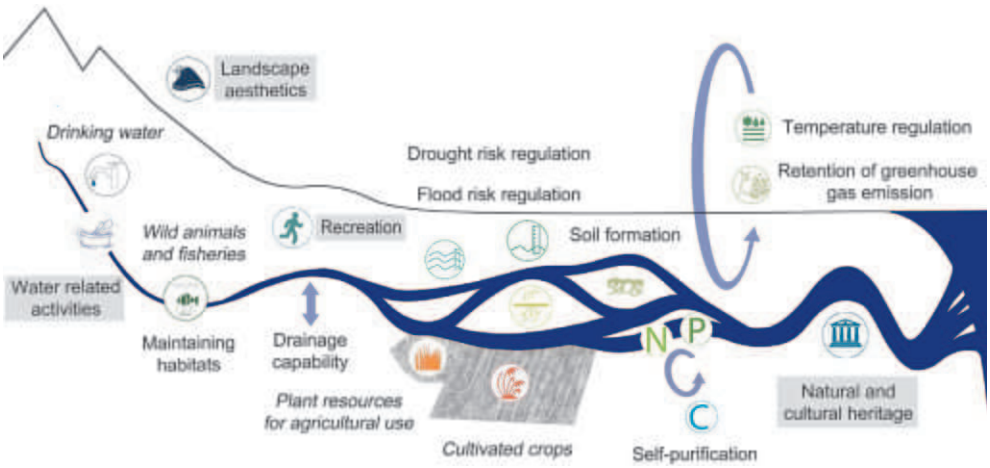

Fig. 2 Overview of major river ecosystem services in a riverscape context (compare Table 1 for further details). Regulating services appear in regular font, *provisioning services* appear in italic font, and cultural services are shaded in gray.

terrestrial and marine realms. On the other hand, there is an increasing awareness that river ecosystems should be protected, actively managed, or restored for multifunctionality, for instance concurrently targeting biodiversity conservation, flood retention, and recreational use (Schindler et al., 2016).

The ESS concept as it applies to rivers as socio-ecological systems

Brief history of the evolution of the ESS concept

The ESS concept can be traced back to the term natural capital (Daily, 1997), the global economic value of which is estimated at $125 trillion per year (Costanza et al., 2014). Lakes and rivers produce a natural capital of ~$12,500 ha^{-1} y^{-1} including contributions to water regulation, erosion control, waste treatment, food production, and cultural services. The Millennium Ecosystem Assessment (MEA, 2005) linked the delivery of ESS to human well-being in a socio-ecological system framework. From this point onwards, ESS received global recognition and gained a policy foothold.

The Economics of Ecosystems and Biodiversity initiative (TEEB, 2010) aimed at reflecting the value of nature's services by emphasizing the global economic benefits provided by biodiversity. Acknowledging the fundamental dependency of society on nature, the Intergovernmental Science-Policy Platform on Biodiversity and ESS (IPBES) was established in 2012 to foster the link between science and policy for matters related to biodiversity and ESS (IPBES, 2019).

Based on the MEA (2005), which originally defined four different types of ESS, the recently developed Common International Classification of ESS (CICES) distinguishes three ESS groups (Haines-Young and Potschin-Young, 2018): provisioning, regulation and maintenance, and cultural services. The CICES dropped MEA's 'supporting services' and considers them as a set of physical, biological, and environmental processes and functions that are fundamental to support and sustain ecological integrity - a change that was implemented to help identify the 'endpoint services' valued by people.

After the provision of ESS were included as a strategic goal in the Convention on Biological Diversity (CBD, 2010), as well as in the UN Sustainable Development Goals (SDGs), the concept gained further momentum in freshwater-related policies (EEA, 2020a). Currently, it is recognized internationally that the ongoing erosion of biodiversity and ESS, including that of rivers, is undermining efforts to achieve sustainable development, and that this pressure must be reduced (e.g., UNEP, 2021).

The concept of ESS has not, however, been without controversy or debate. It has been criticized for being anthropocentric and used to promote the exploitation of nature (e.g. for hydropower development) at the expense of ecosystem integrity and biodiversity conservation goals (Vigerstol and Aukema, 2011). It has also been criticized for being overly focused on economic valuation and the commodification of nature as well as for not moving beyond vague definitions and classifications (Schröter et al., 2014). An attempt has been made to address this critique in the recent 'nature's contributions to people' (NCP) concept, which acknowledges a broader appreciation of all benefits, including social, cultural, spiritual, and religious aspects as well as detrimental contributions such as disease transmission or predation (Díaz et al., 2018).

ESS provided by river ecosystems

The three groups of ESS are all pertinent for river ecosystems (Table 1. Fig. 2): First, provisioning services are defined as material things and bioenergetic products provided by ecosystems, with rivers and their floodplains and estuaries generating these as an interconnected unit. Second, regulation and maintenance services entail all processes that influence the environment (abiotic and

Table 1 ESS of rivers and floodplains as considered in the River Ecosystem Service index (RESI) based on the Common International Classification of ESS (CICES).

Main group	*Subgroup*	*Ecosystem service*
Provisioning	Nutrition	Cultivated crops
		Plant resources for agricultural use
		Wild animals and fish
		Surface water for drinking
		Groundwater for drinking
	Resources	Fibers and other materials from plants for direct use or processing
		Water for non-drinking purposes
	Biomass-based energy resources	Plant-based resources
Regulating	Retention (Self-purification)	Retention of organic carbon (C)
		Retention of nitrogen (N)
		Retention of phosphorus (P)
	Global climate regulation	Retention of greenhouse gas emission/carbon sequestration
	Extreme discharge mediation	Flood risk regulation
		Drought risk regulation
	Drainage	Drainage capability
	Sediments	Mass flow/sediment regulation
		Soil formation in floodplains
	Local climate regulation	Local temperature regulation/cooling
	Habitat	Maintaining habitats
Cultural	Cultural	Landscape esthetics
		Natural and cultural heritage
		Unspecific interactions with riverine ecosystem
		Education and science
		Water-related activities

IGB.

biotic) and refer to both the river and any interlinked features, e.g. the retention of nutrients within the instream water column as well as carbon storage in floodplain soils. Third, cultural rESS continue to evolve rapidly from an early definition as "the nonmaterial benefits people obtain from ecosystems through spiritual enrichment, cognitive development, reflection, recreation, and esthetic experiences" (MEA, 2005). In the freshwater context, MEA's 'supporting services' related to a river's hydrology and maintenance of water flows and levels, i.e. discharge, flow regime dynamics, and connectivity with aquifers and floodplains, as well as to morphology, thus to the physical structure of the river channel and the floodplain.

In an in-depth review of the field, Milcu et al. (2013) discuss current typologies of ESS and different subcategories, such as cultural services: sense of place, cultural heritage values, cultural diversity, social relations, recreation and tourism, esthetic values, spiritual and religious values, educational values, bequest, intrinsic and existence, inspiration, and knowledge systems. They also cover the growing diversity of terms that pertain, such as cultural services, life-fulfilling functions, information functions, amenities and fulfillment, sociocultural fulfillment, and cultural and amenity services. Many of these cultural ESS are inextricably and/or indirectly linked to other types of ESS, as well as to the integrity of the socio-ecological system as a whole. A consistently agreed characteristic (of many, but not all) cultural ESS is their intangibility, which renders them particularly sensitive and complex to appraise, especially quantitatively, which is at least part of the reason why, so far, they have seldom been integrated into management plans.

The broad 'domains' in which cultural heritage is manifested – knowledge and practices concerning nature and the universe, traditional craftsmanship, social practices, rituals and festive events, oral traditions and expressions, including language, as a vehicle of the intangible cultural heritage, and performing arts – encompass various cultural services. The full range of relationships of different cultures and ethno-linguistic groups of people with rivers is vast, and intimately and dynamically linked to the various rESS (Anderson et al., 2019).

Access to rESS and their availability in time and space is often tied to the pulsing hydrology of rivers. As such, cultural, human-river-relationships and dependencies on natural capital can be considered in an analogous way to biotic strategies that aim at benefitting from temporarily available natural resources while trying to avoid risks, which fosters a high biocultural diversity in river-floodplain systems (Wantzen et al., 2016). All over the world, the rhythm of the waters has spurred the evolution of rich cultures, shared use of common goods, well-being and intercultural communication (Wantzen, 2022). The fertile Mekong River floodplains of southeast Asia, for instance, have been sustaining rich cultures since Paleolithic times, and today they support 60 million people with fish as their primary source of protein (Campbell, 2022).

The relationship among river health, ecological integrity and resilience, and rESS

Ecosystem services have long been linked to the health or integrity of ecosystems. Rapport et al. (1998) outline how ecosystem integrity is enabled when an ecosystem's vigor, organization, and resilience is intact. Not surprisingly, a higher delivery of regulating and cultural rESS has been shown to be correlated with a better condition of aquatic ecosystems, while the use of provisioning services more commonly has been associated with stresses and impacts on ecosystems. However, the link between biodiversity and ecosystem functioning, and between biodiversity and rESS, is not yet fully established, and knowledge gaps still exist, including, for example, the multitude of functions supported by aquatic ecosystems, functional distinctiveness of rare species, multitrophic interactions, and the relevance of spatial-temporal scales (Daam et al., 2019).

While the availability and quality of rESS largely depends on ecosystem status, the valuation of rESS will additionally depend on how local stakeholders value the rESS which are accessible to them (Fig. 3). Some rivers are heavily modified from their natural state by channelization, levees, nutrient loading, invasive species, and other stressors, but they still may provide important ESS valued by local communities. For example, the biological retention of nitrogen and phosphorus originating from wastewater runoff from agricultural areas occurs at higher rates in more polluted streams (Gücker et al., 2006). Such systems should still be valued, because they provide waste treatment and carbon storage services, even if they have deficits in terms of biodiversity and esthetics. Identifying and negotiating rESS trade-offs are important parts of the deliberation by stakeholders when envisioning management options.

Managing rESS in a catchment-based approach

Approaches that consider biodiversity conservation and rESS provision in a catchment-context represent a prerequisite for efficient and effective sustainable river management. However, the spatially explicit, sometimes disconnected, and temporally dynamic nature of rESS supply and demand across a river catchment can make it difficult to consider these services in management approaches (Malinga et al., 2015). For example, the use or extraction of freshwater resources is typically local, but often results in a reduction of or change in the resource downstream. Hence, downstream communities (people, organisms) pay the environmental costs caused by e.g. reducing river flows, which can result in conflicts between upstream and downstream water 'users'. Another example is the partial to complete loss of river deltas caused by the retention of river sediments by dams. In the Mekong River, for example, only approximately 1% of the original sediment yield is projected to arrive in the delta (Kondolf et al., 2018). Since rivers integrate the effects of all forms of land and water management (or mismanagement) in their catchments, all territorial policies, including for agriculture, forestry, industrial use, navigation, or urbanization, ideally should be elaborated on the basis of an Integrated River Basin Management (IRBM) plan, respecting political levels and co-created by local decision makers and communities. A complicating factor, especially for large rivers, is that rivers often delineate the borders of political territories, which makes the application of catchment-wide policies difficult. In the past, transboundary river management schemes were mostly based on agreements related to the exploitation of rESS (e.g. navigation treaties) without considering the long-term maintenance of essential ecosystem processes. The historic, first transboundary initiative aiming at protecting a large river from pollution was initiated in 1950 with the establishment of the International Commission for the Protection of the Rhine (ICPR) on the basis of all catchment countries agreeing to overcome national and/or administrative boundaries by sharing the costs and benefits of rESS use (Wantzen et al., 2021).

One of the persistent key management challenges relates to balancing water availability with water use while maintaining healthy, resilient water bodies. Comparisons of trade-offs among multiple rESS under natural flow conditions or with altered flows are increasingly performed (as Table 2 examples illustrate). While few environmental flow determinations explicitly adopt an ESS

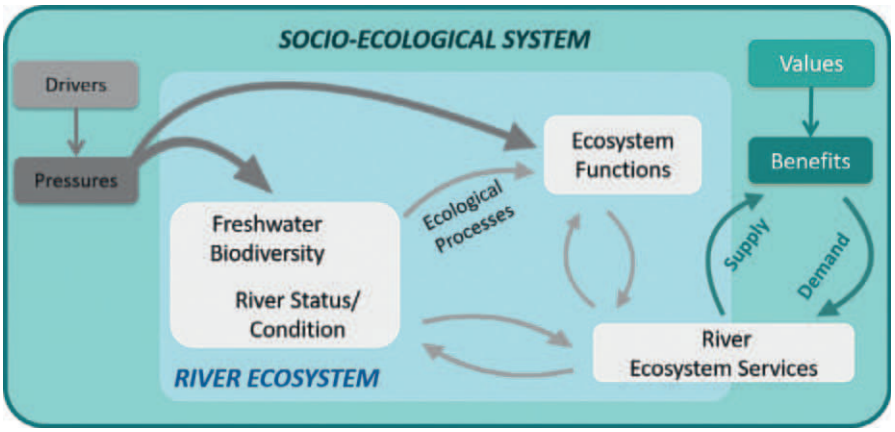

Fig. 3 Relationship between biodiversity, ecosystem functions and ecosystem services within the socio-ecological system. River Ecosystem Services (rESS) connect between the ecosystem and the socio-ecological system. Figured adapted from Nogueira A, Lillebø A, Teixeira H, Daam M, Robinson L, Culhane F, Delacámara G, Gómez CM, Arenas M, Langhans SD, Martínez-López J, Funk A, Reichert P, Schuwirth N, Vermeiren P and Mattheiß V (2016) Guidance on methods and tools for the assessment of causal flow indicators between biodiversity, ecosystemfunctions and ecosystem services in the aquatic environment. Deliverable 5.1, European Union's Horizon 2020 Framework Programme for Research and Innovation Grant Agreement No. 642317.

Table 2 Selected case studies to show diverse ways in which rESS are being addressed.

Location(s)	*Country/Region*	*Purpose/objectives/role/importance of considering ESS*	*Approach used incl. specific services covered, benefits of inclusion*	*References*
80 km of a Bavarian Danube stretch below the city of Ulm	Germany	Testing management options to increase flood retention capacity, balancing key uses and economic interests with floodplain restoration and nature conservation.	Non-monetary scores assigned for 1-km segments of floodplain, separated into river channel, the active and the non-active parts of the floodplain. Indicator value combined from several indices of rESS categories.	Stammel et al. (2021), Thiele et al. (2020), Fischer et al. (2019), Podschun et al. (2018)
Danube Catchment	Europe	Illustrating a model-coupling approach considering biodiversity and rESS supply and demand.	Hierarchical Bayesian models for fish biodiversity; four estimated ESS layers produced through ARIES platform; joint spatial prioritization of biodiversity and ESS using Marxan with Zones.	Domisch et al. (2019)
Intercontinental Biosphere Reserve of the Mediterranean (IBRM)	Spain, Morocco	Allocating restoration zones in a Green and Blue Infrastructure (GBI) network, considering cost-effectiveness, biodiversity, ecosystem services, and ecosystem condition.	Application of Marxan with Zones across freshwater, coastal, and marine ecosystems incl. stakeholder-defined scenarios of Green and Blue Intrastructure in the Intercontinental Biosphere Reserve of the Mediterranean.	Barbosa et al. (2019)
Continental Europe	Europe	Exploring links between ESS and good ecological status. Higher ecosystem service delivery is mostly correlated to improved ecological status. Results show relevance of protecting and restoring aquatic ecosystems.	Quantification of main ecosystem functions and services related to rivers, lakes, coastal waters across Europe (e.g. water purification, erosion prevention, flood protection, coastal protection, and recreation) by producing European performance maps of water ESS capacities, ESS flow and ESS sustainability.	Grizzetti et al. (2019)
Athens (Greece), Emscher River (Germany), Hoffselva (Norway), Llobregat River (Spain), Westland (Netherlands), Aarhus River (Denmark)	Multiple demonstration sites across Europe	Implementation guide for local-level evaluations of changes in water-related ESS related to specific water management measures.	Quantification and monetization of different water management measures showing benefits and impacts. Links between WFD state parameters and specific ESS classes are proposed. River related ecosystem service valuation related to restoration of several case studies.	Anzaldua et al. (2018), Gerner et al. (2018)
Ter River	Catalonia, Spain	Analyzing benefits and trade-offs linked to instream flows and related ESS. Accounting of stakeholders' views and interests, and multiple water withdrawals.	Stakeholder oriented ESS validation and five-step assessment of ESS production related to both diverted and instream flows in the basin.	Jordà-Capdevila et al. (2016)
Lower Mekong Basin (LMB)	Lao PDR, Cambodia, Vietnam	Tradeoff analysis between water use, food security supply and energy production related to proposed mainstream hydropower projects	Comparison of capture fisheries, sediment/nutrients, social mitigation costs, gains from electricity generation, improved irrigation and flood control.	Ziv et al. (2012), Intralawan et al. (2018)
Ganga River Basin	India	Determining the environmental water needs of the river ecosystem and communities, with flow regime alteration and water infrastructure development	Assessment of links between high and low flows and rESS, with focus on cultural services and traditional practices critical to cultural identities (e.g. rituals such as ceremonial bathing and meditation, flood recession farming), to calculate environmental water regimes for priority river reaches, Kumbh religious ceremony, and water management scenarios.	Lokgariwar et al. (2014), Anderson et al. (2019)
Mara River (Kenya and Tanzania), Kihansi and Great Ruaha rivers (Tanzania), and Zambezi River Basin	Sub-Saharan Africa	Balancing water resource use and ecosystem services within areas of nature conservation value. Assessing environmental water needs for priority areas of the river basin under different flow management scenarios	Multidisciplinary, holistic assessments of environmental water needs of river ecology, and associated ESS and other sociocultural dependencies of communities (e.g. tourism, rural subsistence livelihoods, wilderness value, endangered species), economic valuation of benefits and costs of trade-offs, improved flow management, and specific dam operation rules.	LVBC and WWF-ESARPO (2010), WWF-TCO (2010), Tilmant et al. (2010), McClain et al. (2013)
Tana River Basin	Kenya	Modelling the balance of ecosystem services with water, energy and food security	Search for (Pareto-) optimal allocation of benefits among sectors and scenarios. Analysis of trade-offs among achievable benefits from new rice, cotton and biofuel irrigation projects while maintaining ESS.	Hurford and Harou (2014)

framework, rESS are a regular focus of most holistic assessments, from fisheries and flood recession agriculture to sacred ceremonies linked to specific flow events (Horne et al., 2017). Similarly, the application of nature-based solutions in river management and decision-making draws extensively on ESS data to improve outcomes (Barbosa et al., 2019).

ESS in global and national policies, laws, and governance systems

In recent years, political awareness of the high relevance of ESS for human well-being has grown significantly (CBD, 2010; IPBES, 2019). Acknowledging their fundamental importance has already resulted in the development of various approaches for national assessments of ecosystems and their services in several countries such as the UK (UK NEA) and Germany (Albert et al., 2017; Grunewald and Bastian, 2015). However, these national assessments are often not directed toward water-ecosystem related issues, and legal frameworks still focus on individual sectoral objectives without explicitly mentioning ESS (Kistenkas and Bouwma, 2018). Nonetheless, significant scientific progress has been documented, e.g. for groundwater ecosystems (Griebler and Avramov, 2015), ESS quantification approaches (Hanna et al., 2018), or evaluation approaches in general (Anzaldua et al., 2018).

Positive examples are the German Federal Nature Conservation Act and the Water Management Act, which implicitly address rESS. The latter act refers to water services and introduces the principle of cost-recovery to compensate for financial, resource, and environmental costs caused by the user. It thereby stipulates incentive pricing, i.e. the polluter-pays-principle. The European Union Water Framework Directive (WFD) links its objectives to the ESS concept; for example, 'good ecological status' for rivers (and other waterbodies) will only be reached with good water quality, which in turn is a prerequisite for several provisioning and cultural rESS. In addition, at the practical level, most management measures that target WFD-objectives support the availability of different rESS (Hornung et al., 2019). Further, recent documents such as the EEA (2020a) freshwater report or the state of nature report (EEA, 2020b) underline the added value of the ESS concept in integrated management approaches.

Methods, tools and resources for mapping, assessing and reporting on status and trends of rESS

Despite the lag in practical applications of the ESS concept, a multitude of methods have been developed and tested that allow targeting objectives related to rESS in a management context. The methods address different aspects, such as assessing rESS, decision support, trade-off analysis, or stakeholder involvement. Often the data needed for these analyses are complex, since they are related to drivers, pressures, ecosystem states, as well as the capacity, flow and supply of respective rESS (sensu Grizzetti et al., 2016), and they need to be available at the appropriate temporal resolution and spatial grain.

Methods and tools for mapping and quantifying rESS

Ready-to-use software and sets of models that specifically target rESS have become freely available to use. A literature review of ESS mapping, with respect to geographic spatial scale and resolution, is provided by Malinga et al. (2015). One of the most widely known models is InVEST (Sharp et al., 2015). InVEST is a GIS spatially enabled model that allows the user to analyze the supply of various rESS, e.g. sediment retention, water purification, and fisheries (Vigerstol and Aukema, 2011). Recently, models based on machine learning have begun to emerge. For example, ARIES (Artificial Intelligence for Environment & Sustainability; https://aries.integratedmodelling.org/), uses semantics and machine reasoning methods to produce spatial maps of the supply and demand of ESS, from local to global scales (Villa et al., 2014). Currently, the ARIES platform provides several customizable global models, among them three that are contextually linked to rivers, addressing water supply, flood prevention, and recreation.

The 'River Ecosystem Service Index' (RESI) has been developed as an integrated approach quantifying multiple ESS in river corridors to establish a rationale for inter-sectoral decision making in complex management planning (Podschun et al., 2018; Stammel et al., 2021). The RESI provides a catalog of rESS (Table 1) that are spatially explicit and assessed in a non-monetary, uniform way using scores from 1 (very low) to 5 (very high). For example, the value for the provisioning services of agricultural land and pastures is calculated combining land use, soil quality, and flooding frequency data; cultural rESS are also assessed e.g. based on available surface waters, the parts of landscape experienced by different groups of people, and the number of protection categories present.

rESS market and non-market valuation

Many of the rESS provided for societal well-being are public goods, and because they are not traded in markets, do not have a market price. Examples are the esthetic value of river systems or the value of nutrient retention in floodplains. Since market prices remain the dominant expression of value, these services are often not considered in societal and political decisions, which, in an economic sense represents a market failure. Accordingly, the aim of an economic valuation of rESS is to give nature more weight in analyses based on monetary arguments and to be able to better and more transparently incorporate nature's value into decision-making. Different methods to assign value to ESS exist, such as market value, production-based, cost-based, revealed preference, stated preference, and benefit transfer. Provisioning services such as drinking water may be quite straightforward to assess using market-based methods, or regulating services such as carbon sequestration using cost-based methods (e.g. damage costs avoided). ESS not typically appreciated by society, sometimes known as 'hidden' or 'silent services', including cultural services such as

community cohesion, intergenerational knowledge transmission and sense of place, are difficult to address in monetary terms. A commonly used framework to represent such different values of an ecosystem in a more balanced way is that of Total Economic Value (TEV), which considers elements including use and non-use values (Turner and Pearce, 1990). Use values are associated with either a direct (such as food production or recreation) or indirect (such as regulating services) use of environmental goods. Non-use values are independent of a current or potential use, and are based on the assumption that the individuals may benefit only from knowing that an ecosystem exists.

Assigning a monetary value to ESS can be performed using a number of established valuation methods (Tinch et al., 2019). In environmental economics, values are generally measured in terms of preferences regarding the benefit(s) or utilities individuals derive from a change in environmental quality, such as an improvement in water quality. The monetary value of this benefit is measured in terms of the individual's maximum willingness-to-pay (WTP) for this improvement. The basic assumption is that there is a link between the traded goods (e.g. travel costs to a national park) and the benefit people derive from that ESS (e.g. recreational experience). Stated preference approaches directly ask people for their preferences, as a measure of the demand for an ESS. In contrast, market-based approaches use market prices to estimate the value of ESS. Provisioning services (e.g. food and fisheries) are usually estimated through market prices. Cost-based approaches use estimates of the costs that would arise if the services provided by ecosystems had to be provided by a technical substitute (e.g. replacement cost approach) or estimates of the costs caused by environmental damages (e.g. damage cost approach). Meanwhile, many studies demonstrate the substantial economic benefits of river restoration derived from different rESS, such as the improvement of fisheries and wildlife habitats, recreational benefits like angling and boating, or the appreciation of scenic landscapes (Dehnhardt et al., 2019).

Field-based measurements

Although many current rESS assessments are desktop, the foundational calculations to estimate the delivery of some rESS require field measurements. Notably, wastewater treatment and water purification, carbon storage and food production are underpinned by biogeochemical and ecological rates and quantities. These processes, and specifically their magnitude, are ultimately valued by stakeholders when they monetize or otherwise value rESS. For example, nitrate removal can be assessed by measuring denitrification rates in the communities of bottom-dwelling organisms of rivers. Mass balance approaches can reveal whether rivers and connected floodplain wetlands are net storers or releasers of carbon, by measuring the organic and inorganic carbon content of sediment cores (e.g., Shields et al., 2017). Fish yields per year or catch per unit effort of fisheries can act as a measure for provisioning services from rivers and reservoirs (Hoeinghaus et al., 2009). Together, these measurements that quantify the magnitude of a given rESS should inform the ranking or prioritization of the ESS delivered by waterbodies, despite being difficult to incorporate in a WTP-framework because their relative differences are unseen by the public eye. Solutions to this problem include spatial planning (discussed below) coupled with on-the-ground measurements.

ESS in planning and management of river systems

The contribution of the ESS concept to traditional spatial planning is that it explicitly addresses both the current supply of ESS and the present and future demand of ESS. The demand is related to two different perspectives: One is the actual use or consumption of a good or service, the other is the desire or preference for ESS; the latter also encompasses future uses or pure knowledge about the existence of certain ESS. A comprehensive understanding of the relationships between rESS supply and demand, their temporal and spatial patterns of distribution and quantity, and the flow of rESS to beneficiaries, plays a decisive role for the successful integration of the ESS concept into different stages of spatial planning and decision-making. However, integrating this information into planning processes remains conceptually and methodologically challenging, and depends heavily on the nature of the institutional setting, such as the availability of tools to integrate ESS into planning instruments or the sufficiency of knowledge of administrative actors.

Simons et al. (2017) provide a toolbox of state of the art technologies and remote sensing data which can be used to describe, quantify, and compare explicitly water-related ESS in space and time at the catchment scale and under different scenarios. The tools have been applied in relation to different land- and water management policies, and changing conditions of water availability under climate change, in the transboundary Da catchment (a sub-catchment of the Red River catchment in China, Viet Nam and Lao PDR). Concurrent conservation and management of rESS and freshwater biodiversity can be planned based on the concept of ecosystem-based management (Langhans et al., 2019) and operationalized using a variety of spatial optimizers, such as Marxan with Zones (Watts et al., 2009), Gurobi (Gurobi Optimization, Inc., 2021), Zonation (Moilanen et al., 2014), spatial multi-criteria decision analysis (Esmail and Geneletti, 2018) or ARIES accounting for multiple-criteria (Martinez-Lopez et al., 2019). All of these methods provide a robust framework to analyze large-extent, fine-grain spatial data in the light of user preferences and, thus, allow exploring management scenarios that are socio-ecologically relevant. Domisch et al. (2019), for example, used Marxan with Zones to spatially prioritize areas for fish biodiversity conservation and the supply and demand of carbon storage, flood regulation, recreation and water use in the Danube Catchment in Europe. Comino et al. (2014), by contrast, applied a spatial multi-criteria decision analysis model to produce thematic maps of naturalness and stressors to inform management and restoration planning within the Pellice River catchment, northern Italy. Martinez-Lopez et al. (2019) used a spatial multi-criteria analysis approach within ARIES (developed by Villa et al., 2014) to find the best management actions to compensate for the unintended loss of biodiversity and ESS in the Baixo Vouga Lagoon in Portugal.

Participatory assessments, citizen science, social media, and public awareness

Participatory approaches, including interviews, citizen science surveys, and exercises using GIS have in common that they foster the inclusion of local knowledge and preferences in rESS assessments. Recently, rapid technical advances provide the basis to apply these methods to large spatial areas, enabling the mapping of perceived ESS benefits and measures of the links to human well-being (Fagerholm et al., 2020). More than 30% of 89 rESS studies evaluated by Hanna et al. (2018) used data derived from participatory approaches. In contrast to data specifically generated for the purpose of a study, user data crowdsourced from social media (e.g. from Flickr or Twitter), citizen science portals (e.g. eBird, iNaturalist), or from outdoor activity-sharing platforms or applications (e.g. STRAVA, Geocaching) can provide fresh information on reporter location in addition to texts and pictures (Havinga et al., 2020). For instance, several studies have shown that the use of social media data enables a rapid, cost-effective and continuous prediction of visitor counts (Sinclair et al., 2020), which are important in assessing recreational use impacts on freshwater ecosystems and associated ecological and social carrying capacities (Venohr et al., 2018). Using geotagged photos in combination with a survey, Keeler et al. (2015) found a positive relationship between water clarity and visitor numbers.

Two novel research areas, Culturomics and iEcology, have recently gained attention for analyzing human-nature interactions and ecological patterns and processes. Information drawn from webpages, news and social media posts, photo and video documents, as well as from online engagement (i.e. searches, views, comments and shares), is used to study and demonstrate the public interest in nature and to frame conservation issues. Applications range from mapping cultural ESS to identifying potential aquatic flagship species (Jaric et al., 2020). Social media platforms also provide new opportunities for engaging scientists and stakeholders to contribute to raising awareness about the importance of ecosystems and biodiversity, enhance the acceptability of conservation measures to better balance rESS trade-offs or provide science–policy interfaces for interactively planning for nature-based solutions (Varumo et al., 2020).

Broader communication may include outreach by journalists, writers, artists, and other communicators. Documentaries like 'Planet Earth' and 'Planet Earth II' (BBC), 'Our Planet' (Netflix), 'NOVA' (PBS), or promoting certain species on journal covers (He et al., 2021) may bring the wonders of freshwater life into the public eye and call for action. Although social media may help to maintain public engagement, enhancing education about rESS through youth action in schools and educational institutions might be the best long-term investment. New formats, e.g. mixing teaching materials, videos, online content and targeted outdoor experiences are needed for knowledge mobilization that encourages participation, learning and creation.

Conclusion

Rivers and their floodplains provide a range of rESS such as water for drinking or irrigating crops, food, flood protection or spaces for recreational activities. Human use and activities have fundamentally transformed river systems, causing a reduction in the availability of many rESS. Political awareness of the implementation of the concept of ESS has grown significantly and has placed ESS central to multiple policy objectives (CBD, 2010) with the aim of advancing concepts and methods for recording and assessing ESS (Díaz et al., 2018; IPBES, 2019). Despite this promising advance, methods, tools and resources for mapping, analyzing, assessing, and reporting on status and trends in rESS are scattered and currently vary regionally, therefore rendering large scale evaluations of rESS approaches difficult. It is time to follow up with a more coherent, harmonized approach and set of methodologies for rESS assessment, and to develop and test guidelines of how to use these assessments in catchment restoration and management.

The climate crisis manifests in most regions of the world as a water availability crisis; therefore, key rESS that depend on water availability or are related to the presence of healthy, resilient water bodies have recently received increased attention. With increasing competition among various societal groups for water, the rESS concept provides a unique opportunity toward effectively negotiating the different interests in a sustainable way that also considers the need to combat the concomitant biodiversity crisis. The UN Decade of ecological restoration and the revision of the CBD with its 2050 biodiversity vision offer much-needed possibilities to position rESS as a central element of new policies and agendas for action toward sustainable development.

Knowledge gaps

1. Documentation and use of assessments of status and trends in the world's ESS for rivers and other freshwaters and the risks associated with future development, independent of assessments for terrestrial and marine systems.
2. Methodologies for scenario-based assessment of rESS comprehensively at the socio-ecological system and governance scales characteristic of large rivers.
3. Methodologies for examining trade-offs and synergies among rESS and biodiversity conservation.
4. Analyzing digital data or develop stakeholders' participation tools for the management, conservation, and restoration of rivers by culturomics and iEcology methods in the freshwater realm and beyond case studies.
5. Adaptation of technologies that use artificial intelligence (AI) to include big data and remote sensing data to quantify rESS at different spatial and temporal scales, and better aid decision making.

6. Develop common indicators for rESS to foster the uptake of rESS assessments in catchment conservation and management planning. As a prerequisite, the quantity and quality of input data need to be homogenized across countries at a level that allows the monitoring of the spatial patterns and temporal dynamics of rESS.
7. Define standards for data collection in cultural rESS research and methods that consider local and traditional ecological knowledge for catchment conservation and management.

Case studies

Glossary

Biotic resistance The reduction in invasion success caused by the negative interactions with native (recipient) communities, most often through competition, predation, herbivory and/or pathogens.

Early detection and rapid response A coordinated set of actions to find and eradicate potential invasive species in a specific location before they spread and cause damage.

Establishment The process of a nonnative species in a new habitat successfully producing viable offspring with the likelihood of continued survival.

Hybridization The process by which interbreeding individuals from genetically distinct populations produce a hybrid.

Invasion meltdown The process by which a group of nonnative species facilitate one another's invasion by increasing the likelihood of establishment and/or of ecological impact.

Invasion A series of sequential stages (transport, introduction, establishment, spread and integration) through which individuals or populations need to pass to be considered invasive.

 https://doi.org/10.1016/B978-0-12-819166-8.00083-9

Invasive species Nonnative species whose introduction in a particular location causes or is likely to cause undesirable economic or environmental impacts, or negative impacts to human, animal, or plant health.
Nonnative species Populations that have become introduced and often established outside their native ranges but do not necessarily cause impacts so to be considered "invasive".
Pathway Any means, intentional or unintentional, that allows the entry or spread of a nonnative species.
Propagule pressure A composite measure of the number of individuals in each introduction event (propagule size) and the number of separate introductions (propagule number) for a given species in a particular recipient region.
Risk assessment The assessment of the consequences of the introduction and the likelihood of establishment and impact of an invasive species using scientific information.

Introduction

Aquatic invasive species (AIS) are a primary threat to streams and rivers across the world. Although not all introduced species successfully establish in their nonnative range, and a large fraction of those that do have little appreciable effects on their new ecosystems, some are associated with significant ecological, evolutionary, and economic consequences. Ecological effects of AIS have been shown to be severe and range from behavioral shifts of native species in the presence of invaders, to the complete restructuring of freshwater food webs and the extirpation of entire faunas (Gallardo et al., 2016). Economic impacts of invasive freshwater species are equally significant, with estimates of damage and management costs totaling at least $23 billion USD annually (Cuthbert et al., 2021). For researchers, managers, and policymakers seeking to ensure the integrity of riverine ecosystems (hereafter referring to flowing waters and their adjacent riparian zones), understanding the ecology of AIS is of utmost importance.

Freshwater invasion biology involves the study of diverse taxonomic groups from myriad geographies, ecosystems, and management contexts (Fig. 1). Here, we first provide an overview of invasion biology as it applies to riverine ecosystems. We summarize the invasion process depicting how species are introduced, attempt to establish, potentially spread, and potentially cause ecological and economic impacts. Each stage is supported with illustrative examples. Next, we discuss the management strategies and policy options available to prevent, contain, control and eradicate AIS in the future.

Fig. 1 Aquatic invasive species with demonstrated ecological, economic and societal impacts in riverine ecosystems. Photos depict (with photo credit): (A) Mozambique tilapia (Creative Commons); (B) rainbow trout (Creative Commons); (C) Eurasian milfoil (Tip of the Mitt Watershed Council); (D) Tamarisk (Gardenia); (E) northern snakehead (Associated Press); (F) red swamp crayfish (Julian Olden); (G) New Zealand mud snail (National Park Service); and (H) zebra mussel (USFWS).

Invasion process

The invasion process can be envisioned as a series of five stages—uptake and transport, introduction, establishment, spread, and integration—where barriers exist at each stage that must be overcome for a species or population to transition to the next stage. These stages reflect how individuals of a species are:

1. transported out of their native range via uptake into a vector and transit
2. introduced (disembark) into a new location
3. established in self-sustaining populations by surviving and reproducing
4. spread to new locations via dispersal into new environments
5. integrated into the recipient ecosystem resulting in effects that range from negative to positive.

In order to successfully progress as an invasive species, the barriers of the stage-based framework must be repeatedly overcome (Blackburn et al., 2011). Failure to overcome these barriers eliminates the invasiveness of a population. As such, a considerable amount of research within invasion biology focuses on understanding which traits facilitate species success across all invasion stages to ultimately define the final outcome of failure or success (Fig. 2).

Species introductions

The motives for, and mechanisms by which, AIS have been introduced to riverine ecosystems have been many and varied. There are three general mechanisms through which nonnative species may enter a new region (Hulme et al., 2008). First, importation as or with a commodity arises from direct human movement of goods. Species introduced as commodities occur when people identify a species as having desirable qualities and intentionally move it beyond its native range, resulting in intentional release (e.g., stocking fish for recreational angling, introduction of species as biological control agents) or unintentional escape (e.g., pet aquarium organisms released into the wild, ornamental plants and fish escape facilities). Species transport with a commodity occurs when traded organisms are contaminated with other nonnative species, including diseases and parasites. Second, arrival with a transport vector, refers to species that hitchhike on human modes of transport to regions beyond their native ranges. Modes of transport

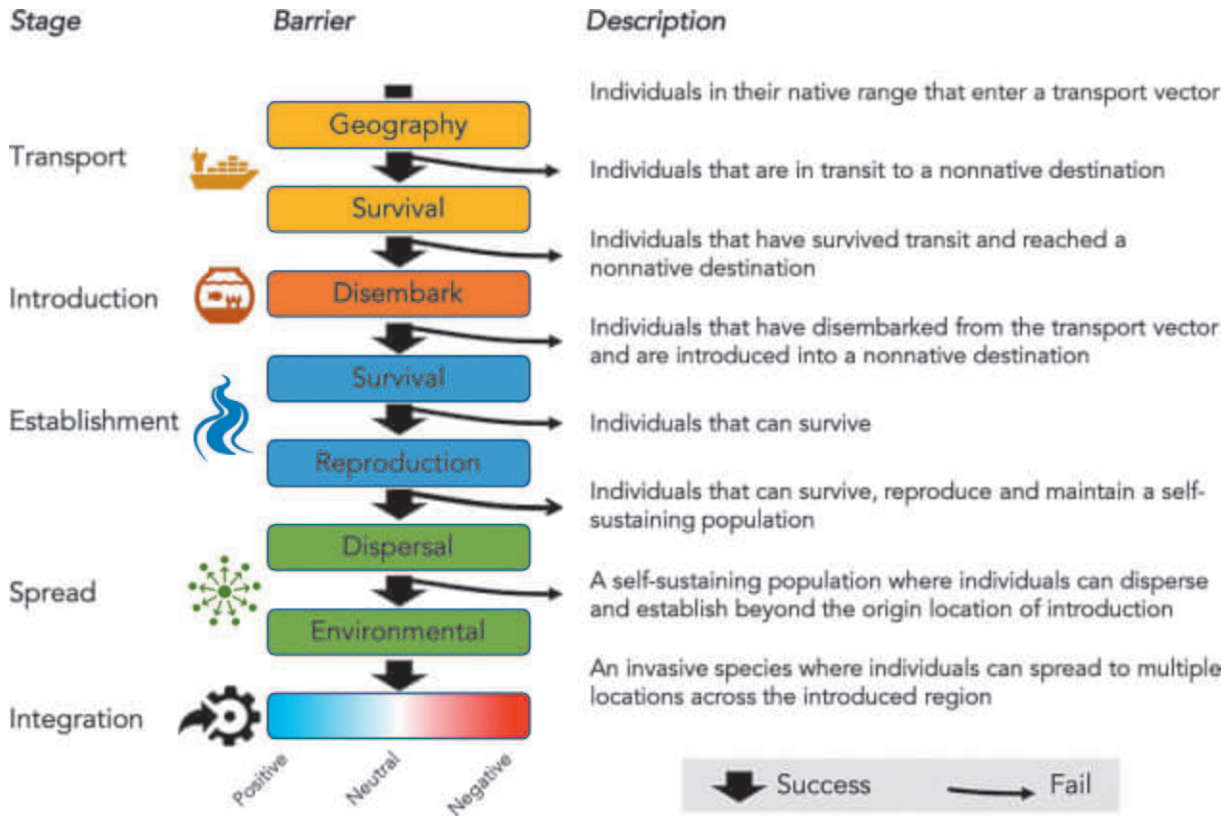

Fig. 2 The invasion process can be represented by a sequence of five stages (transport, introduction, establishment, spread, integration) through which individuals of nonnative species must transition to become successful invaders. Each stage has one or more barriers to overcome, whereby individuals are either successful (downward-pointing arrow) or fail (right-pointing arrow). Figure is inspired by Blackburn et al. (2011) and Chapple et al. (2012).

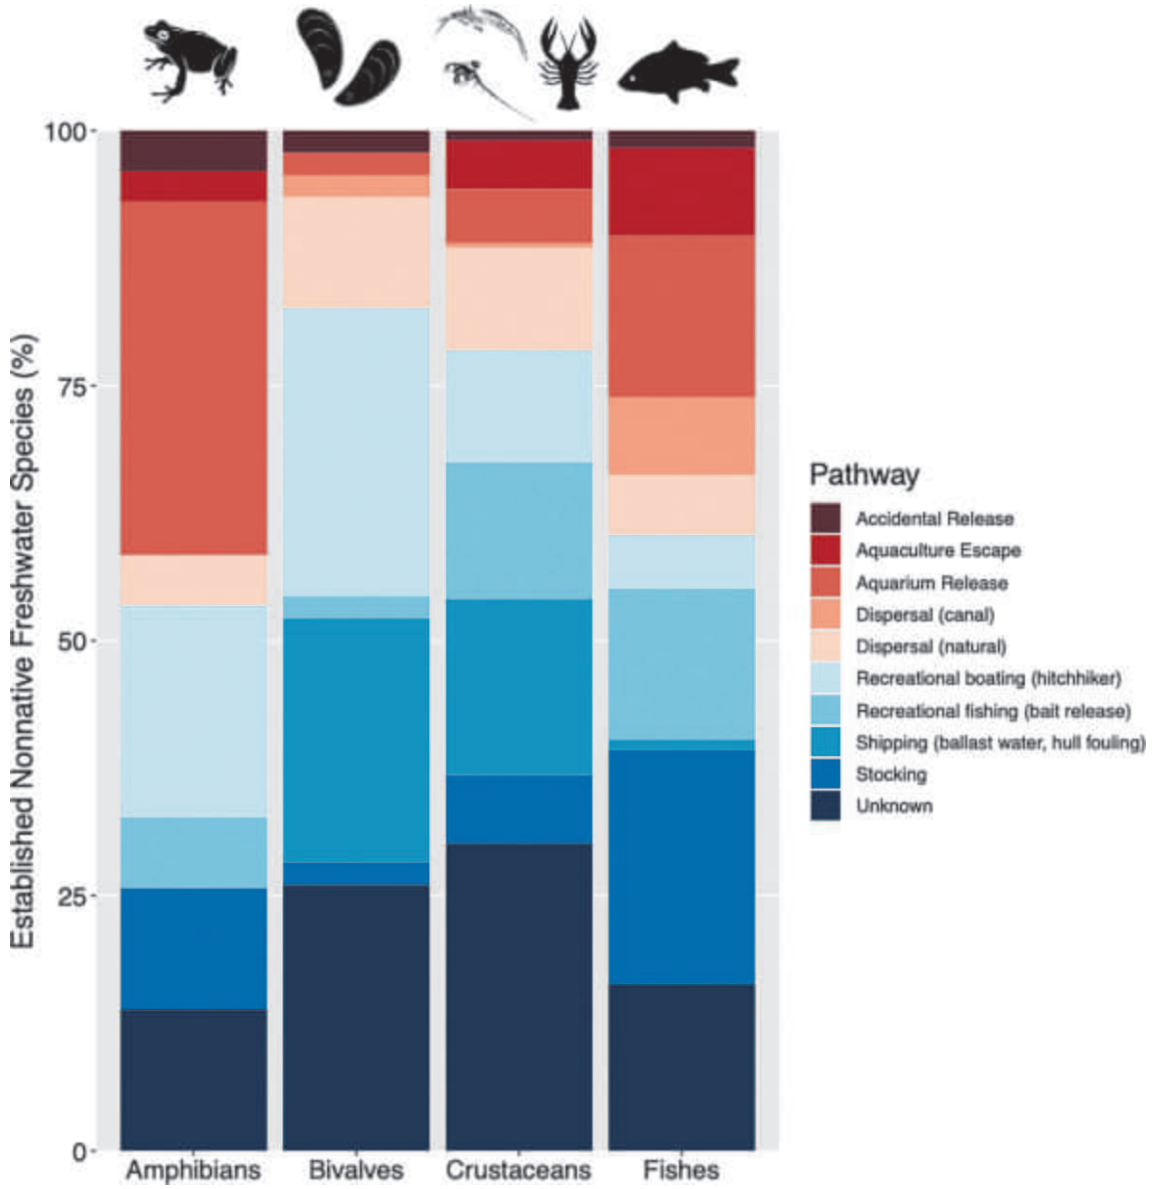

Fig. 3 Frequency (%) of established nonnative species introduced via major pathways for amphibians, bivalves, crustaceans, and fishes in the fresh waters of the United States. Total number of species are not reported because a single species can be introduced by more than one pathway and may therefore be counted more than once. Relatively more minor pathways (see text) are not included. Data source: USGS Nonindigenous Invasive Species Database; accessed June 24, 2021.

include ships (e.g., organisms in ballast water or attached to hulls) and angling equipment and recreational watercraft (e.g., boat motors, hulls and trailers). Third, self-dispersal, either along infrastructure corridors (e.g., irrigation or transportation canals) or unaided. Below we discuss a number of these major introduction pathways, noting that their importance varies taxonomically (Fig. 3) and that their strength and geographic routes have changed, and will continue to change, over time.

Stocking for sport and food

The primary motivation for early AIS introductions was for extensive fish culture and stocking of plants and animals for the "national good" (i.e., acclimatization societies). Introductions of common carp (*Cyprinus carpio*) to Western Europe occurred about 2000 years ago and were most likely facilitated by the Romans and later by Catholic monks who reared them in monastery ponds for food (Copp et al., 2005). Nowadays, fish are deliberately introduced for the enhancement of recreational fisheries and to establish new food resources. For example, rainbow trout (*Oncorhynchus mykiss*; Fig. 1) is perhaps the most introduced sportfish in the world, being primarily stocked by government agencies and private organizations in approximately 90 countries. Growing

awareness of the impacts of AIS has led to tighter regulations on sanctioned stocking in many countries; however, the unauthorized intentional release of aquatic animals to facilitate a local recreational fishery by so-called "bucket biologists" continues to be a significant problem.

Aquarium pet trade

The aquarium trade has been responsible for the introduction of many fish, plant, and invertebrate species worldwide. For example, studies report that the aquarium trade could be responsible for about 19% of fish introductions in Iberian Peninsula, 14% for the Laurentian Great Lakes (Canada and United States), 65% for Florida (United States), and 45% for England. Pet aquarium species are introduced when owners release unwanted organisms into the wild for various reasons, including large size, aggressiveness, no longer wanted or humane treatment (Padilla and Williams, 2004). The most popular fish sold in the aquarium trade are also the most likely to be introduced and established (Duggan et al., 2006). In addition to traditional "brick-and-mortar" stores, nonnative aquarium species are increasingly purchased from Internet marketplaces and online peer-to-peer platforms (Olden et al., 2020).

Aquaculture and the live food trade

Freshwater aquaculture, referring to the propagation of captive freshwater organisms, is undergoing a rapid worldwide expansion. Of significant concern is the increasing use of nonnative species, which may escape into the wild and cause direct ecological damage or indirect damage through spread of their associated pathogens and parasites (Cook et al., 2008). The aquaculture industry typically selects species that are fast growing, thrive in local conditions, and are tolerant of a wide range of environmental conditions. These qualities also predispose many aquaculture species to become invasive if they escape. Notable examples include silver carp (*Hypophthalmichthys molitrix)*, Mozambique tilapia (*Oreochromis mossambicus*), and signal crayfish (*Pacifastacus leniusculus*). AIS can also be unknowingly introduced when intentionally stocked fish are accidentally contaminated with other non-target species. An example is topmouth gudgeon (*Pseudorasbora parva*), which was accidentally introduced into Europe from China in the 1950s through the transfer of contaminated batches of large Asian carp being used in aquaculture. Topmouth gudgeon has since achieved a pan-European distribution through both further accidental introductions and natural dispersal (Copp et al., 2005). In another example, the crayfish plague disease (*Aphanomyces astaci*) was introduced to Europe on North American crayfish imported for aquaculture; this disease now widely endangers European native crayfish populations (Holdich et al., 2009).

Shipping activities

Ship-mediated vectors, including ballast water and hull biofouling, are a dominant global vector for unintentional translocation of freshwater, euryhaline and marine species. Ships fill their ballast with water at an origination port to control trim and draft, provide stability, and enhance voyage safety. Ballast water often contains a wide diversity of invertebrates (plankton and mussels) and vertebrates (fish). Discharge of ship ballast releases both water and the surviving organisms and pathogens into waters of destination ports when ships intend to unload and take on additional cargo. Similarly, organisms can become encrusted on ship hulls and transported between different regions. Transoceanic shipping activities continue to be an important vector for the transport of AIS, especially to North America. For example, since the 1970s, 75% of the flora and fauna introduced into the Great Lakes has been linked to ballast water releases by ships of Eurasian origin (Ricciardi and MacIsaac, 2000).

Recreational fishing and boating

Freshwater fishing generates significant economic benefits; however, anglers have repeatedly been implicated as vectors of AIS by entraining organisms on fishing lines and on boat motors, hulls and trailers, and releasing in live bait (Rothlisberger et al., 2010). Insufficient gear cleaning allows hitchhiking invaders to be moved short and long distances overland, promoting both their initial introduction into new catchments and secondary spread into adjacent waters. In North America, higher numbers of nonnative species have been found to coincide with areas of greater recreational fishing demand (Davis and Darling, 2017). Examples of ubiquitous nuisance species whose translocation has been partly attributed to angler activities include zebra mussel (*Dreissena polymorpha*) and quagga mussel (*D. rostriformis*), Eurasian milfoil (*Myriophyllum spicatum*) and rusty crayfish (*Faxonius rusticus*).

Dispersal through human infrastructure

Canals connecting different river basins have allowed for range extensions of many AIS, either by eliminating natural barriers to movement and/or by promoting shipping activity (Galil et al., 2007). For example, the complex European network of inland waterways built during the 20th century comprises >28,000 km of navigable rivers and canals that connect countries throughout Europe and facilitate the introduction of AIS. Similarly, the construction of the St. Lawrence Seaway, consisting of a system of locks, canals and channels in Canada and the United States, has permitted oceangoing vessels to travel from the Atlantic Ocean to the Great Lakes of North America, and has facilitated the unaided movement and establishment of AIS including the round goby *(Neogobius melanostomus)* and sea lamprey (*Petromyzon marinus*).

Other

A number of other pathways of introduction exist, albeit at lower frequency in relation to the pathways discussed above. These include: release of laboratory animals associated with scientific experiments, ceremonial wildlife release events, intentional release after school classroom use, and stocking for biological control (see "Management strategies" section), aesthetics and conservation purposes.

Species establishment

Species establishment refers to the stage of the invasion process where an AIS maintains self-sustaining populations (i.e., reproducing populations that do not depend on the immigration of new individuals). Establishment success of an AIS is linked directly to the number and condition of individuals introduced (propagule pressure), biological traits of introduced individuals, dispersal abilities and opportunities, and to the characteristics of the receiving environment.

Propagule pressure

Biological invasions can largely be considered a "numbers game," in that the probability that a population becomes established increases with both the number of individuals and the number of introduction events (defined as propagule pressure: Lockwood et al., 2005). Propagule pressure is considered a key determinant of establishment success as species are more likely to become established if many individuals are released simultaneously and if multiple introductions occur over long time periods. When propagule pressure is low, too few individuals may survive long enough to establish, and sexually reproducing individuals may not find mates. In addition to propagule pressure, the success of AIS establishment can also be dependent on the selection of favorable invasive traits in the original population (Chapple et al., 2012) and favorable conditions during the transport phase (Briski et al., 2015). Selection of favorable traits in the transported invading sub-population can facilitate local adaptation, potentially increasing the likelihood of invasion success (Briski et al., 2015).

Biological traits

Ecologists have analyzed common features that separate successful invaders from those that fail. Although each successful invasion has some unique properties, generalizations on biological traits allow better prediction of species that are most likely to invade. Invasion success largely depends upon four groups of characteristics that: (1) facilitate nonnative species to be entrained, transported and introduced to a new area ("Species introduction" section); (2) influence the ability of a colonizing species to succeed (described in this section); (3) affect the probability of dispersion beyond the point of introduction ("Species spread" section); and (4) influence the direction and magnitude of impacts in the recipient ecosystem ("Ecological implications" section).

Comparisons of biological traits between successful versus unsuccessful species invasions and native versus established introductions has revealed a suite of species attributes associated with the establishment of AIS populations. For example, greater establishment success has been linked to reproductive strategy, diet breadth and environmental tolerance in fishes (García-Berthou, 2007), large body size, fecundity, and aggression in crayfishes (van Kuijk et al., 2021), and traits related to resistance to hydraulic disturbance and greater dispersal (e.g., floating propagules, regrowth capacity, rapid growth from small segments even after desiccation) in riparian plants (Catford and Jansson, 2014). In one example, high fecundity and ovoviviparity (eggs and embryos carried inside the female's body) are fundamental reproductive traits to the establishment success of guppy (*Poecilia reticulata*) in riverine ecosystems of South America because offspring are less influenced by harsh external conditions such as temperature, turbidity, and predation (Oliveira et al., 2014). Beyond biological traits, attributes related to taxonomy and degree of human use/value (e.g., association with aquaculture, use as fishing bait or aquarium pet) have also proven to predict establishment success (Alcaraz et al., 2005). Biological traits have been found (or hypothesized) to be predictive of successfully overcoming barriers associated with each stage of species invasion; this is illustrated for crayfish in Table 1.

Environmental conditions

Nonnative species are expected to have greater likelihood of establishing new populations in those locations where their environmental requirements are met. Broad physiological tolerances to temperature, salinity, pH, and other environmental factors are often strong predictors of AIS establishment. For example, the ability to tolerate wide salinity variations can favor AIS arriving on cargo ships from other regions, and increase the probability of using estuaries as "saline bridges" to colonize adjacent rivers connected only by the ocean (Gutierre et al., 2014). One of the most accepted truisms in the field of invasion ecology is that disturbance - defined as any discrete event in time that disrupts population, community or ecosystem structure and changes resources or the physical environment—promotes biological invasions. In riverine ecosystems, land-use conversion (i.e., increase agriculture or urbanization), alteration of hydrology by dams, and climate change can all favor the establishment of AIS. For example, nonnative red swamp crayfish (*Procambarus clarkii*), American bullfrog (*Lithobates catesbeianus*), and nonnative fishes were all more abundant in more urbanized watersheds in southern California (Riley et al., 2005), and dam-regulated rivers have been

Table 1 Biological attributes of crayfish associated with successful transition of barriers across stages of invasion.

Stage	*Barrier*	*Associated biological traits*
Transport	Geography and Survival	Size of native range
		Bright body coloration (increase popularity in trade)
Introduction	Disembark	Preference or tolerance of lentic habitats
		Able to reproduce in aquarium conditions
		Absence of specialized hatching requirements
		Small or large body size
Establishment	Survival	Wide environmental and climatic tolerances
		Generalist diet
	Reproduction	Single parent reproduction
		High reproductive potential (fecundity)
		Short generation time
		High growth rate
Spread	Dispersal & Environment	Good dispersal
Integration		Ability to escape or survive natural enemies
		Long lived (resist mortality)
		Large body size
		High competitive ability

Modified from van Kuijk T, Biesmeijer JC, van der Hoorn BB and Verdonschot PFM (2021) Functional traits explain crayfish invasive success in the Netherlands. *Scientific Reports* **11**. doi: 10.1038/s41598-021-82302-4.

shown to promote greater establishment of nonnative Tamarisk (*Tamarix ramosissima*) (Stromberg et al., 2007). Substantial efforts have sought to forecast the potential geographic range of AIS by predicting areas of suitability establishment according to the invader's ecological requirements (defined by their biological traits) and environmental conditions in the foreign region.

Biotic resistance and facilitation

AIS establishment is less likely to occur where the recipient ecosystem is inhabited by closely-related native species, either with respect to phylogeny or function. So called 'biotic resistance' is often defined in terms of diversity-invasibility, where it is hypothesized that higher native species diversity (typically, the number of species) intensifies interactions with nonnative species (i.e., direct and indirect competition and predation), thus decreasing the probability of AIS establishment. Although long considered important, recent reviews show relatively low support for biotic resistance (29% of studies) and, further, that support was declining over time as more studies were published (Jeschke et al., 2012). Despite this, evidence does exist that biotic resistance may play a role in AIS establishment. For example, a quarter of all introduced fish species in the Parana River, Brazil, successfully established, and those that did demonstrated very different functional traits compared to native fishes (Skora et al., 2015). Studies have also revealed that native species may require time, leading to learned experience, to effectively control AIS populations. For example, predation by blue crab (*Callinectes sapidus*) caused high mortality and changed the population structure of invasive zebra mussels over time in the Hudson River (Carlsson et al., 2011).

Biotic facilitation (positive interactions) among AIS may lead to greater establishment success; this is termed the invasional meltdown hypothesis (Simberloff and Von Holle, 1999). Invasional meltdown describes the process by which a group of nonnative species facilitate one another's invasion by increasing the likelihood of establishment and/or of ecological impact. Evidence for invasional meltdowns in riverine ecosystems are inconclusive. For example, Jackson et al. (2014) examined interactions among two pairs of invasive crayfishes in the Thames River catchment, United Kingdom, and found amplified negative effects on benthic invertebrate communities, benthic algae and leaf litter decomposition rates. By contrast, in a series of experiments, Braga et al. (2020) showed that three AIS—Oscar fish (*Astronotus crassipinnis*), golden mussel (*Limnoperna fortunei*) and the aquatic macrophyte hydrilla (*Hydrilla verticillata*)—demonstrated only additive effects, thus providing no evidence for an invasional meltdown.

Species spread

Spread or dispersal is a defining feature of species invasions. This process, composed of multiple, sequential introduction and establishment events, describes the manner in which individuals move and populations expand in size beyond the initial point of introduction (Fig. 2). Rates of spread depend on the strength of the introduction pathway, propagule pressure, biological attributes of the AIS, and environmental characteristics of the landscape, including geographical barriers to movement.

Pathways implicated in the initial introduction of a species are similarly responsible for the secondary spread of AIS. For example, the overland movement of trailered boats has inadvertently spread AIS to new waters by carrying live organisms in bilge

water, live wells, and bait buckets, as well as being entrained on boat exteriors (Rothlisberger et al., 2010). Mobile organisms also disperse; this often occurs more in the downstream direction because upstream movement is limited by the physical forces of river flow and a variety of natural and artificial barriers. Invasive signal crayfish, for example, were found to move 1.5 km year^{-1} in a downstream direction according to radio-tagging study in northern England (Bubb et al., 2004). All downstream movements made by crayfish appeared to be active movements and related to water temperature and not the result of passive movement during periods of high discharge. Hydrology also plays a critical role in the spread of invasive riparian vegetation. For example, the successful spread of invasive plants are influenced by flooding events and the creation of colonization opportunities for seed propagules (Foxcroft et al., 2008). In many dryland rivers of the southwestern United States, seeds of invasive Tamarisk and Russian olive (*Elaeagnus angustifolia*) are viable for longer, and have longer dispersal time periods, than native species, resulting in rapid rates of downstream spread over time (Reynolds and Cooper, 2010).

A number of mathematical and statistical approaches have been used to model the spread of AIS at both large- and local-scale (Thompson et al., 2021). Reaction-diffusion models, for example, are spatially explicit spread models employing a continuous description of space which provide good descriptions of observed spread patterns for a variety of invasive species. Gravity and random-utility models can also be used to AIS spread, where nonrandom dispersal is primarily human-mediated (Thompson et al., 2021). For example, although detailed boater movement data is often not available, gravity models have been used to estimate the probability of boater movements among sites as a function of boat usage at individual sites and of the distance among sites. Such models become particularly useful for modeling potential invasive species spread when they incorporate invasive species life history and dispersal information, as well as the relative positioning of invaded and suitable sites on the landscape (Vander Zanden and Olden, 2008).

Agent-based models are another approach to modeling AIS spread. These models reproduce ecological events by simulating individuals that follow distinct rules by accounting for the effects of stochasticity and environmental factors on the biology and behavior of each individual organism in the population. Messager and Olden (2018) modeled the rapid spread of rusty crayfish in a tributary of the Columbia River from the putative time and location of initial introduction to present-day, and forecasted the spread into the future. This study reported that rusty crayfish had spread incredibly fast (c. 20 km year^{-1}) since their initial introduction to a single location (Fig. 4), and it predicted that the invasion may number on the order of 100 million individuals occupying over more than 1100 km of river by 2025.

Ecological implications

The environmental impact of a nonnative species can be defined as any measurable change that is caused to the properties of the recipient ecosystem (Blackburn et al., 2014). Generally, deleterious environmental or biological impacts are considered but they can be bidirectional in the sense that nonnative species can benefit ecosystems from a human perspective (e.g., increase regional species diversity, provide recreational angling opportunities). Negative ecological impacts are caused by numerous mechanisms (e.g.,

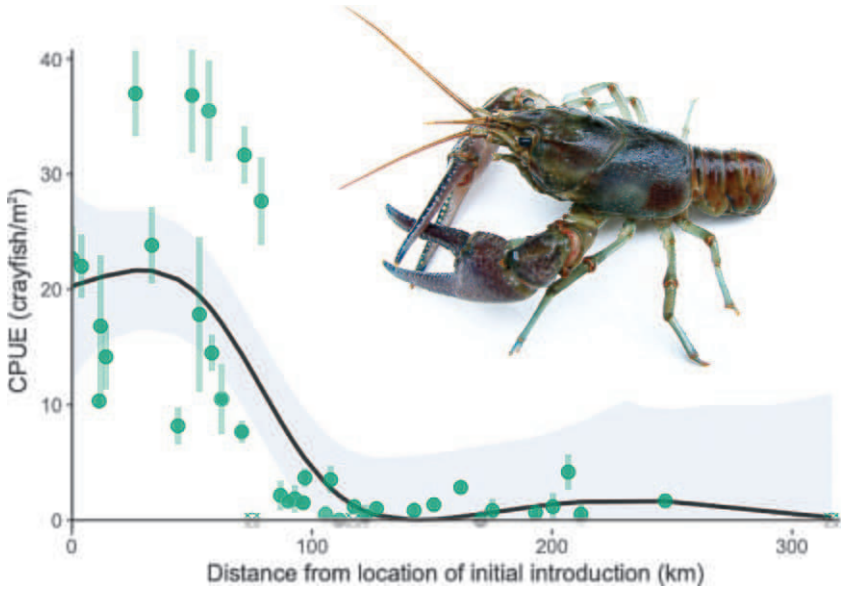

Fig. 4 Density of rusty crayfish as a function of distance from putative location of initial introduction in the mainstem John Day River, United States. Crayfish densities are expressed as the mean (points) and 95% confidence interval (bars) of the catch per unit effort (CPUE). The smooth solid line and shaded region represent the predicted mean CPUE and 95% credible interval. Data from Messager ML and Olden JD (2018) Individual-based models forecast the spread and inform the management of an emerging riverine invader. *Diversity and Distributions* **24**: 1816–1829. doi: 10.1111/ddi.12829. predation, competition, hybridization, disease) manifested across different levels of organization from genetic to the landscape and scales from local to global (Blackburn et al., 2014), as discussed in detail below.

Genetic

Genetic impacts of AIS include changes in gene expression and hybridization (Vitule et al., 2009). Hybridization affects native species through lost reproductive opportunity and introgression. For instance, many fishes within the cyprinid, centrarchid or salmonid families produce fertile hybrids, even between different genera, thus altering the genetic composition of the native population and sometimes resulting in the extinction of native genotypes. Examples of introgressive hybridization include alien rainbow trout (*Oncorhynchus mykiss*) with cutthroat trout (*Oncorhynchus clarki*) subspecies and other salmonids in North American streams, and nonnative mallard (*Anas platyrhynchos*) with native ducks in South Africa, Australia, and elsewhere.

Individual

Impacts at the individual level include changes in behavior, morphology or life history of native species (Cucherousset and Olden, 2011). Nonnative predators can change habitat use, diel activity and vital rates of native species. For instance, brown trout (*Salmo trutta*) and other salmonids introduced in rivers and streams worldwide often compete with native fishes altering their habitat use, activity and diet which indirectly reduces their growth, condition and survival. Many other invasive fishes are generalists and can similarly affect invertebrates, amphibians and other animals by direct predation and competition for resources (e.g., common carp). Introduced brown trout have also changed the behavior of stream invertebrates to be more nocturnal and less active during the day, thus reducing their grazing pressure on periphyton, and causing changes to entire food webs (Townsend, 2003). Comparative functional responses, whereby the relationship between resource availability and resource uptake rate is derived and compared among species (Dick et al., 2017), have consistently revealed that high ecological impact invaders have higher maximum feeding/consumption rates than trophically analogous natives. This was demonstrated, for example, for invasive channel catfish (*Ictalurus punctatus*) versus native *Rhamdia quelen* in a series of experiments in Brazil (Faria et al., 2019; Fig. 5).

Population

Population impacts include changes in the abundance and distribution of native species and the transmission of pathogens and parasites. For instance, the parasitic sea lamprey, which is native to the North Atlantic Ocean and spawns in rivers across Europe and eastern North America, invaded the Laurentian Great Lakes after opening canals for navigation. In the Great Lakes, this jawless fish caused dramatic population reductions of large fish such as lake trout (*Salvelinus namaycush*) and associated fisheries and extirpations of endemic whitefishes (Cucherousset and Olden, 2011). Similarly, nonnative crayfishes reduce the abundance of basal resources like aquatic macrophytes and aquatic invertebrates (e.g., snails, mayflies) through direct predation, and compete for habitat and prey with native amphibians and fish (Twardochleb et al., 2013). In Europe, native crayfishes have been extirpated in many streams, mostly because of the crayfish plague, a disease caused by the fungus-like oomycete *Aphanomyces astaci* that is carried by North American crayfishes (Holdich et al., 2009).

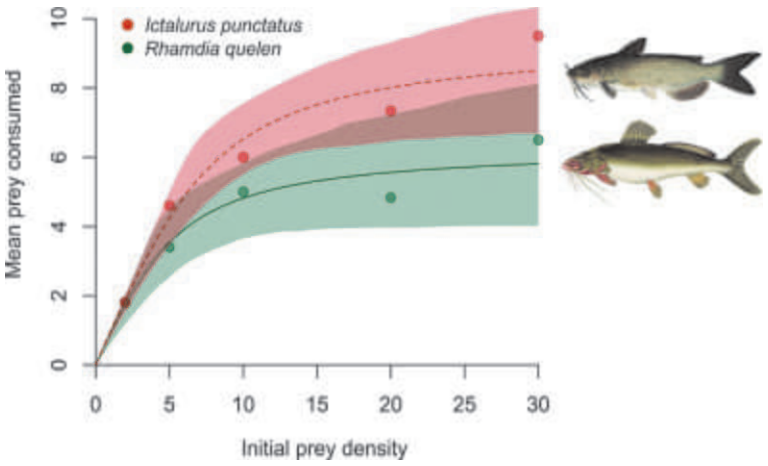

Fig. 5 Functional responses of ecologically damaging invaders have higher asymptotes compared to those of native analogues, as shown here for the consumption of a prey fish by invasive channel catfish (*Ictalurus punctatus*; top right) vs. native *Rhamdia quelen* (bottom right). Modified from Faria L, Alexander ME and Vitule JRS (2019) Assessing the impacts of the introduced channel catfish Ictalurus punctatus using the comparative functional response approach. *Fisheries Management and Ecology* **26**: 570–577. doi: 10.1111/fme.12353.

Community

At the community level, AIS contribute to the local extinction of native species, and modify species composition and diversity. For example, the giant reed (*Arundo donax*), originally native from southwestern Asia, is one of the oldest plant invasions and has invaded many Mediterranean-climate and subtropical riparian areas of the world. This species promotes the loss of native diversity of riparian vegetation, leading to changes in the abundance and diversity of riparian invertebrates and birds (Maceda-Veiga et al., 2016). By dissolving physical barriers to movement and connecting formerly isolated regions of the world, human-mediated species introductions have also dramatically homogenized the present-day biogeography of riverine species. At the global scale, invasion by numerous species of cyprinid, salmonid, cichlid, and centrarchid fishes have fundamentally changed the composition of major river basins; elevating the number of fish species per river by 15% on average, and increasing the similarity of the world's fish faunas (Villéger et al., 2011). In the United States, pairs of states now have over 15 more species in common when compared to pre-European settlement times, representing a homogenization of 7.2% (Rahel, 2000). These changes in species composition have also been associated with modifications to functional trait diversity, which have clear implications for ecosystem functioning.

Ecosystem

Riverine ecosystems can experience significant change as a result of AIS, in particular those which are classed as "ecosystem engineers" (Gallardo et al., 2016). Invasive bivalves, such as the zebra and quagga mussel, the Asian clam (*Corbicula fluminea*), and the golden mussel (*Limnoperna fortunei*) act as ecosystem engineers through capture and consumption of suspended particles, production of feces and pseudofeces, functioning as an important resource subsidy, bioamplification of pollutants throughout the food chain and various biotic interactions (Sousa et al., 2014). At the ecosystem level, due to their high filtration rates, they typically reduce phytoplankton, increase water clarity, and thus change primary productivity and food webs to those more based on macrophytes and benthic algae. Other examples include the water hyacinth (*Pontederia crassipes*), hydrilla, giant salvinia (*Salvinia molesta*), and Eurasian milfoil, which alter nutrient cycling, reduce water quality (increasing water temperature and decreasing dissolved oxygen) and water quantity (high evapotranspiration rates), and have leaves of lower nutritional quality that have potential effects on food webs (Gallardo et al., 2016).

Economic costs

Aquatic invasive species have the potential to cause serious economic impact, either in the form of management- or damage-related costs (Cuthbert et al., 2021). Management costs relate to investment by legislative bodies with regards to prevention, control, containment, and eradication schemes (described more in the "Management strategies" section). For example, water companies in the United Kingdom spend approximately $18,000 GBP per year to control zebra mussel biofouling on infrastructure, while in the United States the daily cost of chemical control measures are estimated to be $1–$13 USD per million gallons (Chakraborti et al., 2016). Recently, the U.S. Army Corps of Engineers have proposed a new $778 million USD electric barrier to prevent Asian carp from entering the Great Lakes and threatening a $7 billion USD fishing industry (see below). Expenditures to manage invasive species generally vary according to the economic status of the region or funding body. The Australian government committed $15 million AUD to the National Carp Control Plan in 2016 to develop pathogen biocontrol methods. By contrast, the monetary investment needed to control and eradicate water hyacinth in South Africa was thought to exceed the perceived costs to ecosystem services. In North America, however, the cost of investment in biological control was shown to have a huge cost-benefit ratio in terms of ecosystem services gained as a result (Wainger et al., 2018).

Damage-related costs are a direct result of AIS impact on an economic commodity, supply chain, or ecosystem service. These costs are more commonly reported and are often of higher magnitude. The Eurasian ruffe (*Gymnocephalus cernua*), at one point the most abundant fish in the Saint Louis River Basin, United States, is estimated to be among the costliest freshwater invasive species worldwide. This species may have incurred damage costs, via predation, of up to $53 billion USD to native fisheries over a 40-year period (Cuthbert et al., 2021). In South America, biofouling of hydropower structures by nonnative golden mussels have resulted in damage to equipment and caused costs to escalate from servicing to massive energy losses when hydropower stations have to be shut down during repair. In the United States, financial losses due to tamarisk invasion (see "Ecological implications" section), estimated at $169–$362 million USD, are associated with water loss and resulting impacts on consumptive end uses by households and irrigators as well as non-consumptive uses like hydroelectric power generation and fishing (Zavaleta, 2000). Millions of dollars more are spent annually on management costs associated with mechanical removal, fire treatments, herbicide treatments and the introduction of biocontrol agents.

Nonnative species can simultaneously cause negative and positive economic impacts in different sectors. For example, nonnative species represent a significant proportion of inland fisheries both for subsistence and recreational purposes. In this respect they contribute to the income and livelihoods of tens of millions globally through direct fishing activities, as well as other financial opportunities along the value chain, e.g., gear provision and maintenance, processing, and distribution (Lynch et al., 2016). Interestingly, perceptions of costs and benefits from an invasion may also vary among people living with an invasive species and may change over time following an invasion. Examples include the marbled crayfish (*Procambarus virginalis*) in Madagascar, where

the species is now valued as a crucial source of food and income (Andriantsoa et al., 2020), and invasive salmonids in Argentina which are regarded as naturalized in legislation due to their socio-economic contributions (De Leaniz et al., 2010).

Management strategies

The management of AIS can involve four general strategies—prevention, containment, control, and eradication—each aiming to eliminate or reduce the ecological, economic, and human health impacts. The use of control options should actively consider the risks and benefits of implementing different strategies commensurate with its likelihood of success, costs, and socio-cultural considerations.

Prevention

Prevention is widely recognized as the cornerstone of invasive species management, as decades of experience have demonstrated that, following establishment by nonnative species, eradication or control is costly and difficult (Fig. 6). Preventing the transport and introduction of AIS can involve legislation to regulate or prohibit importation of unwanted species, for example associated with trade in ornamental pets and plants. Some nations and regions have created 'blacklists' of high risk of invasive species that are prohibited from use and trade (e.g., Australia *Environment Protection and Biodiversity Conservation Act*, European Union *Regulation 1143/2014 on Invasive Alien Species*, United States *Lacey Act*). Although firm preventive measures such as border controls may seem expensive, preventing the importation or illegal spread of an invasive species is considered an investment in eliminating or reducing future management and damage costs that they may cause (Vander Zanden and Olden, 2008; Box 1). Prevention strategies have also sought to limit the transport and introduction of AIS associated with particular pathways. For example, mandatory ballast water treatment and exchange in the ocean and anti-fouling hull treatments seek to prevent AIS associated with transoceanic shipping

Fig. 6 Management strategies for preventing, containing, controlling and eradicating aquatic invasive species. Photos depict (with photo credit): (A) ship ballast water exchange (International Maritime Organization); (B) small boat inspection (Monte Drape); (C) detection of AIS using environmental DNA (National Genomics Center for Wildlife and Fish Conservation); (D) physical carp barriers (Leigh Thwaites); (E) artificial crayfish barriers (Clyde River Foundation); (F) electrical carp barrier (Iowa DNR); (G) mechanical harvesting of aquatic plants (Don Seabrook); (H) biocontrol Tamarisk beetle (Doug Von Gausig); and (I) application of rotenone to eradicate invasive fish (William DeShazer).

Box 1 Risk Assessment for Aquatic Invasive Species.

Due to the significant socioeconomic and environmental impacts of AIS, many countries are increasingly regulating the introduction of nonnative species for commercial or personal use to reduce opportunities for invasions. This often takes the form of "black lists" (i.e., species forbidden because they were identified as potentially harmful AIS) or "white lists" (i.e., species that can be introduced because they were identified as safe) (Genovesi et al., 2015). The development of these lists generally entails a detailed risk assessment, referring to a process of evaluating biological and economic evidence to identify potential invasive species and determine the level of invasion risk associated with a species or pathway (Roy et al., 2018). Many useful scoring protocols for such risk assessments exist (González-Moreno et al., 2019). In the European Union for instance, a "List of Invasive Alien Species of Union concern" was implemented (Regulation (EU) 1143/2014) and is periodically revised to identify species with strong restrictions regarding possession, importing, and selling. As of May 2021, the list contains about 36 plants and 30 animals, including many AIS in rivers. Prevention remains the most efficient management tool to avoid invasions and their costs, and risk assessments play an important role in guiding management and policy in support of these efforts.

(Briski et al., 2015), and road-side inspections and educational campaigns that promote cleaning of small boats and angling gear are implemented to help reduce the spread of AIS (Rothlisberger et al., 2010).

Even when legislative controls exist, intentional or accidental introductions of AIS do unfortunately occur. Early detection of invasive species before they spread is critical, as once an invasive species is established, it can be nearly impossible to eradicate. Early detection allows for rapid response control programs to be implemented that are more likely to be effective and affordable. Rapid detection can be extremely difficult however, as initial populations often exist at very low abundances, and they are often only detected inadvertently through chance citizen and angler reports or regular assessment programs. The effort required to detect a potential invasive species introduction can also be costly. Surveillance efforts may be more cost-effective if they target more likely invasion hotspots such as regions of high aquaculture or ornamental production, and high human population centers. The early detection and surveillance of invasive species has also been transformed recently with the use of environmental DNA (eDNA) and citizen science technologies (Larson et al., 2020; Baird et al., this volume). This allows for potentially more cost-effective programs to detect AIS both in pathways before introduction and in locations where populations have been recently established (Snyder et al., 2020).

Containment

Once an invasive species is established it is often challenging to eradicate it, and thus management efforts often turn to containment methods that focus on limiting the secondary spread of individuals and further range expansion (Fig. 6). Containment barriers have been used throughout the world, and can take many forms, including screens, weirs or nets, and velocity, electrical or chemical barriers (Jones et al., 2021).

Physical exclusion involving screens or weirs are the most prevalent form of barrier (Jones et al., 2021). Physical barriers reduce or prevent direct movements of animals such as fish and crayfish (Krieg and Zenker, 2020), but they are less effective barriers for smaller organisms such as plants propagules, invertebrates and the early life stages of fishes. For example, exclusion screens have been used to restrict adult common carp from entering wetlands to minimize their ecological impacts and spawning and recruitment potential, but they do not stop the movement of young carp (Hillyard et al., 2010). Constructed exclusion barriers can be used to isolate whole river catchments for the effective exclusion of AIS. For example, the construction of artificial barriers has been used to limit sea lamprey from accessing spawning tributaries of the Laurentian Great Lakes, and to stop upstream movement of invasive rainbow trout into native cutthroat trout habitats and subsequent genetic hybridization of populations. However, the restriction of movement potentially comes at a considerable risk and trade-off for the need to maintain river connectivity for native organisms and ecological processes (Rahel, 2013).

Electric fields have been used to deter or stun fish attempting to pass particular key points. For example, two large electric barriers in the Chicago Sanitary and Ship Canal were installed in 2002 to prevent invasive Asian carp from colonizing Lake Michigan. However, the need for constant power supply can prohibit electric barrier use in remote locations and also has increased risks of accidental transfer if the power supply fails. Other barrier types include the use of chemicals, bubble curtains, light and sound as behavioral deterrents for fish. Most containment barriers (of all types) tested seem to be very successful, deterring >70% of targeted individuals (Jones et al., 2021); however, long-term monitoring is extremely limited at present, and few studies investigate any negative impacts on native species. The use of multiple deterrents has also only rarely been attempted.

Control

Control methods aim to reduce the ecological impact of invasive species by reducing their abundance by acknowledging that their eradication is likely to be impossible (Britton et al., 2011; Hussner et al., 2017). Control options include mechanical/physical removal, chemical treatments to kill fish or plants (e.g., piscicides or herbicides), and biological control; these approaches vary in their suitability for different taxa, effectiveness, scale of application and costs (Fig. 6).

Mechanical harvesting approaches are commonly used to control invasive aquatic plants (Hussner et al., 2017). Although effective in reducing total plant biomass, the cutting of aquatic plants can produce large amounts of plant fragments that introduce new opportunities for spread. Physical capture and removal is also commonly used to control invasive fish and crayfish species, with techniques such as netting, trapping and electrofishing often highly effective in suppressing abundances, reducing recruitment and limiting dispersal, particularly at smaller scales (Rytwinski et al., 2019). The effectiveness of these techniques varies greatly depending on the targeted species and environmental conditions of the removal location. Water level drawdowns can also be used in highly regulated waters such as irrigation canals, to expose invasive plants to either summer drying or winter frosts to reduce vigor and increase mortality rates. Multiple temporary drawdowns, coupled with harvesting, have also been shown to be an effective control technique for signal crayfish in England (Chadwick et al., 2021). The effectiveness of chemical treatments varies considerably with environmental conditions (e.g., water quality, wind, depth, discharge), target species susceptibility, and application effectiveness. Typical chemical applications involve herbicides to control invasive plants (e.g., Eurasian milfoil), rotenone piscicides to control invasive fishes (e.g., northern snakehead, *Channa argus*) and biocides to control invasive crayfishes (e.g., red swamp crayfish); although unintended consequences on non-target species remains a concern.

Biological control options typically involve the intentional introduction of predators and herbivores to reduce the reproductive capacity or density of an AIS (Box 2). Biocontrol is commonly used for large-scale management of invasive plants, such as the release of grass carp (*Ctenopharyngodon idella*) for controlling submerged plants; or the Tamarisk beetle (*Diorhabda* spp.) introduced to

Box 2 Challenges to Controlling Invaders: A case study of common carp.

Common carp is one of the world's most invasive freshwater fish species. In Australia, carp can exceed 90% of total fish biomass in some regions, and the species has been implicated in the decline of native fishes, invertebrates, aquatic vegetation, and water quality. Management approaches to carp have included a diverse range of techniques to control abundance and dispersal, including screens on wetlands (to limit adult entry and spawning), traps on fishways, active harvesting, water management to discourage recruitment, commercial fishing and community 'carp buster' fishing events. In 2016, the Australian Government started the development of the National Carp Control Plan (NCCP), which included examining the feasibility of introducing a biocontrol agent (cyprinid herpes virus, CyHV-3) to control carp across Australia's waterways. Research on non-target species susceptibility and carp lethality suggested that the virus might be a potentially useful biocontrol agent (McColl et al., 2016). The NCCP also embarked on a large program of community consultations in regions affected by carp and of research on virus release and clean-up strategies, estimating carp biomass, water quality risks, risk and benefit assessments and the potential longer-term ecological outcomes of carp reduction (see https://carp.gov.au/). External studies also highlighted the ecological risks of removal, and questioned the effectiveness and benefits of the virus control (Kopf et al., 2017). At the time of writing, the Australian Government is considering the final outcomes of the NCCP.

control the riparian tree tamarisk. Biocontrol agents are often nonnative as well (sourced from the native range of the targeted AIS), thus risking the introduction of another AIS. Genetic biocontrol is also increasingly being considered to disrupt the reproduction of invasive species; however, further research is needed to ensure that genetic biocontrol methods can be deployed in a way that minimizes potential environmental harm (Teem et al., 2020).

Eradication

Eradication as a management objective for invasive species usually has the best chance of success when applied early after detection, and where control techniques are applied heavily and in contained areas (Fig. 6). Piscicides, such as rotenone, are a reliable and cost-effective tool for controlling or eradicating invasive fishes particularly at smaller localized scales. For example, rainbow trout and smallmouth bass (*Micropterus dolomieu*) have been successfully eradicated in small streams in Australia and South Africa, respectively, using rotenone, with minimal ecosystem side-effects (e.g., Bellingan et al., 2019). There are few examples of successful large-scale eradication of established invasive species throughout the world. One such example, however, comes from large lakes in Tasmania, Australia, where after 14 years of intensive management using multiple control methods, common carp have been successfully eradicated in one large lake, and over 99% of the original population have been removed from another nearby lake (Yick et al., 2021). Similar examples from large river systems do not exist.

Conclusion

Aquatic invasive species are a primary threat to streams and rivers across the globe, impacting biodiversity, disrupting key ecological functions, and compromising ecosystem services. Threats posed by AIS often combine synergistically with other environmental challenges, including habitat loss and fragmentation, dams and river regulation, land-use conversion, water extraction, pollution, and climate change (Reid et al., 2019). River regulation by dams can promote invasion success by altering downstream hydrology, temperature, and substrate, to favor AIS and offering new opportunities for them to thrive in upstream reservoirs (Johnson et al., 2008). Global declines in wild freshwater fisheries have promoted the expansion of nonnative species aquaculture, leading to accidental escapees and longstanding ecological impacts (Cucherousset and Olden, 2011). Finally, climate change is expected to result in warmer water temperatures, shorter duration of ice cover, altered streamflow patterns, increased salinization, and increased demand for water storage and canals, which collectively bolster the pathways for and establishment of new freshwater invasions (Rahel and Olden, 2008). The future biodiversity, integrity and functioning of riverine ecosystems will depend on how societies manage current AIS and on whether the arrival of future AIS can be successfully prevented or minimized.

Knowledge gaps

- What are the ecological consequences of multiple invasive species to recipient ecosystems? Do synergistic or antagonistic interactions occur?
- How do ecological impacts of invasive species transverse multiple levels of ecological organization, from genes to ecosystems?
- What evidence is there for sleeper populations of invasive species, that is, established populations that persist at low abundance and have negligible impact for years until they are triggered by an environmental or anthropogenic change to become highly abundant and disruptive AIS?
- How will climate change promote or inhibit the introduction, establishment and spread of AIS in the future?
- How does the perception of costs and benefits of an invasive species change over time and vary among different sectors of human society?
- How might genetic biocontrol (genomic modification tools) offer novel risks or solutions to managing invasion?
- If large-scale biocontrol of AIS does occur, will ecosystem condition recover to its previous state?
- Is it possible for rapid evolutionary shifts to cause native and nonnative populations to become invasive?
- Can invasion syndromes—describing a combination of pathways, species traits, and characteristics of the recipient ecosystem—be used to develop more robust predictions of the dynamics and impacts of AIS?
- Can horizon scanning and scenario modeling be used to effectively prioritize decision-making and action against AIS?
- How can we better use and combine the tools of internet and mobiles and citizen science to help in studies of management and control of invasions in rivers and streams?
- How can we amplify and improve the importance of transversality between actors and the role of relationships between academia and decision makers and legislators?

Inland Waters—Rivers: Land Use and Water Quality

Jason R Bohenek and S Mažeika Patricio Sulliván, Shiermeier Olentangy River Wetland Research Park, School of Environment and Natural Resources, The Ohio State University, Columbus, OH, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Biochemical Oxygen Demand (BOD) Measure of the oxygen consumed by the metabolism of aerobic bacteria.
Catchment/watershed Area of land, bounded by hill or mountain ridges, that directs and controls the flow of water downhill to a stream.
Combined Sewer Overflow (CSO) Discharge of raw sewage and stormwater into the environment due to the limited capacity of wastewater treatment plants, mostly occurs during precipitation events.
Contaminants Harmful biological, chemical, physical, or radiological substances in the environment, typically, but not always, due to anthropogenic activity.
Eutrophication Excessive levels of nutrients, commonly nitrogen and phosphorus, in waterbodies that often lead to elevated algal growth and death of aquatic organisms due to lack of oxygen.
Headwaters Small streams and wetlands in the upper parts of a catchment.
Land Use and Land Cover (LULC) Human purposes of land for economic and cultural activities (land use) along with the physical materials and vegetation that cover the land such as forests, wetlands, impervious surfaces, agriculture, and water (land cover).
Land Use and Land Cover Changes (LUCC) Patterns of land conversion over time due to the continued interaction between humans and the natural environment.
Non-point source (NPS) Pollution or environmental impacts that do not have a single, identifiable origin, but rather an integration of multiple sources over large spatial scales.
Point source (PS) Single, identifiable origin of pollution or environmental impact.
Sedimentation Processes by which sediment is eroded from land into waterbodies such as rivers, where it is suspended, transported, and deposited.
Water Quality Physical, chemical, and biological aspects of water and waterbodies.

Introduction

Among the most pervasive environmental effects of human activities are unprecedented rates and scales of changes in land use and land cover (LULC) (Crist et al., 2017). Land cover describes the physical land type such as forest or open water whereas land use indicates how people are using the land such as development or agriculture. Land-use and land-cover changes (LUCC) represent the interaction of multiple factors including socioeconomic, institutional, and environmental (Lesschen et al., 2005).

Inland waters, especially streams and rivers, are intimately linked to their surrounding environment through various pathways. In this sense, rivers are products of their landscapes whereby the "valley rules the stream": geology regulates the availability of ions and the supply of sediments, topography determines the slope and degree of containment, climate and soils determine vegetation type and coverage and therefore the availability of organic matter and extent of stream shading, and hydrologic processes including precipitation, runoff, and subsurface flows regulate water movement through the catchment (Hynes, 1975). The amount and condition of catchment and riparian vegetation are particularly critical variables influencing catchments (Naiman and Decamps, 1997).

LUCC have emerged as critical processes affecting many aspects of catchment structure and function as well as the quantity, distribution, and availability of clean, fresh water. Owing to the hierarchical structure of river systems (Fig. 1), patterns at one spatial

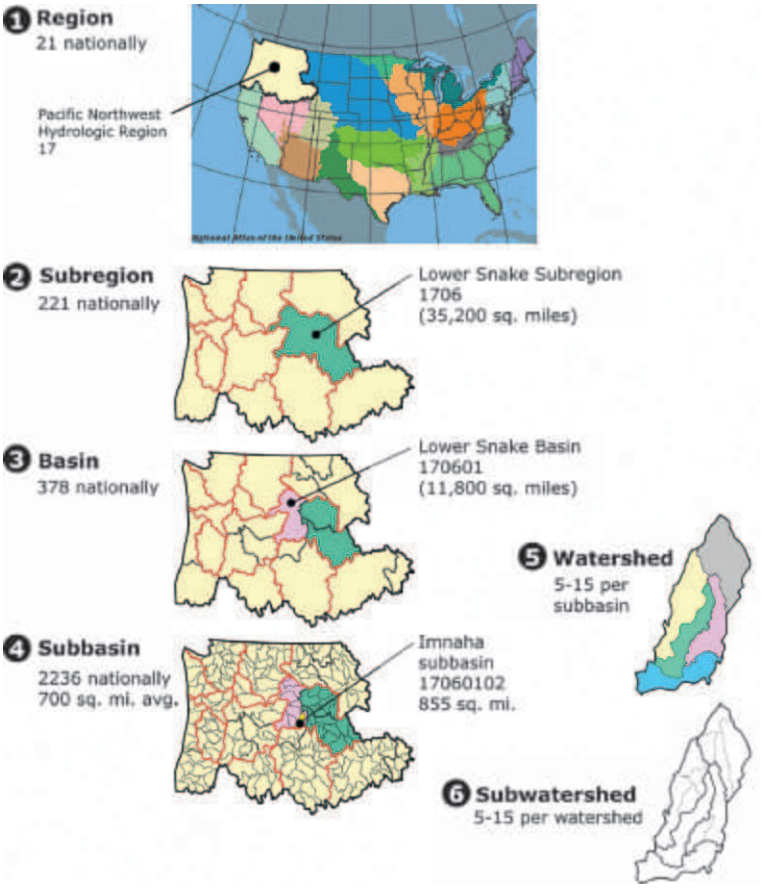

Fig. 1 Example of the hierarchical nature of catchments/watersheds across different spatial scales: the Lower Snake River basin in the Pacific Northwest of the United States, along with the Imnaha River subbasin and its tributaries (courtesy of Bruce McCammon, United States Forest Service, Portland, Oregon).

scale may be influenced or generated by processes operating at different scales or extents (Tagwireyi et al., 2017). Thus, the combined effects of both riparian and broad, catchment-scale LULC patterns on rivers are important to consider (Kautza and Sullivan, 2016).

This chapter explores how LUCC integrate many anthropogenic impacts (Fig. 2). Given their widespread global extent, we focus on agriculture, urbanization, and natural resource extraction as primary examples of the impacts LUCC can exert on water quality (Fig. 3). In particular, *we discuss the effects of these activities on the multiple dimensions of water quality—chemical* (e.g., *contaminants, nutrients)*, *biological* (e.g., *abundance, biodiversity, disease)*, *and physical* (e.g., *sedimentation, hydrology, fluvial geomorphic characteristics, light availability, habitat structure)*. The effects of land use on water quality are myriad and often context-dependent (Table 1), with specific catchments each having distinct responses to LUCC. However, general patterns can be observed that can inform us of risk factors and mitigation strategies.

Main topics

Agriculture

Global agriculture has ballooned from 7.3% of total land in 1700 to 29.4% in 1950 to 37.1% in 2015, with most change in the last century driven by increased pastureland for livestock (Goldewijk et al., 2017), a shift caused by an increasing global population and meat becoming a larger portion of the diet in developed countries (Sans and Combris, 2015). In the United States, the Lower Mississippi, Upper Mississippi, Ohio, Missouri, Colorado, Arkansas, and Red River catchments consist of over 40% agriculture (Allan, 2004). Some agricultural operations represent point sources of pollution (e.g., livestock and aquaculture), whereas row-crop, timber, and other agricultural activities that lead to excess fertilizers, pesticides, and sediment are non-point sources of pollution.

Within agricultural catchments, multiple factors might negatively affect river conditions. For instance, increased water turbidity and sediment deposition associated with increased sediment loads affect aquatic food webs (Power et al., 1996). In particular, agricultural practices including livestock grazing, tilling, and tile drainage can dramatically affect hydrology, channel morphology, and aquatic biota (Cuffney et al., 2000). Excessive fine sediment delivery to rivers—largely from agricultural practices—is the

(B) Toxic hospital waste dumped directly into the Huallaga River in the city of Tingo María, Perú (Hutchinson, 2016). (C) Concrete lined channel of the Shibuya River in Tokyo, Japan (Syced, 2021). (D) Trash pollution in the Marilao River in Marilao, Philippines (Velasquez Floro, 2021). (E) Agriculture surrounding a canal connected to the Yakima River in Washington, United States (Prechtel, 2006). (F) Sediment from an upriver logging operation mixes with unpolluted river channel near Sabah, Malaysia (Butler, 2019). (G) Paper mills on the banks of Tungabhadra River in Karnataka, India (Jangam, 2014).

leading river pollutant worldwide and can affect stream biota and ecosystem function through chemical (i.e., toxicity) or physical processes (i.e., impaired habitat, smothering) (Sullivan et al., 2019). For instance, sediment pollution can decrease primary productivity and macroinvertebrate biodiversity by decreasing light availability, substrate suitability, and filling interstitial spaces (Izagirre et al., 2009; Larsen et al., 2011). As agricultural land use expands to keep pace with a growing human population, more riparian systems are burdened with associated negative impacts.

Nitrogen (N) and phosphorus (P) are essential nutrients applied to crops as fertilizers to increase crop yields (Elser et al., 2007). Much of this fertilizer is not absorbed by target crops, and instead enters groundwater through leaching or flows into streams and rivers via surface runoff after precipitation or irrigation events (Domagalski et al., 2008). These nutrients commonly exist in aquatic ecosystems in various organic or inorganic forms. Inorganic nitrogen can be dissolved as biologically–unavailable gaseous nitrogen (N_2) or as biologically-available ammonia (NH_4^+), nitrite (NO_2^-), or nitrate (NO_3^-) ions, with nitrate being most common, mobile, and impactful. Inorganic phosphorus is dissolved as biologically-available orthophosphate (PO_4^{3-}). Both nutrients are also present as organic molecules, which contribute to total N and total P and can break down to more biologically-available inorganic forms. The addition of these fertilizers causes nutrient enrichment and excessive algae growth (Houser and Richardson, 2010), which can progressively worsen into a state of eutrophication in downstream waters such as reservoirs, lakes, and large rivers.

Eutrophication decreases macroinvertebrate (Gong and Xie, 2001), fish (Wang et al., 2007), and aquatic primary producer (Leibold, 1999) biodiversity by limiting or eliminating sensitive species and facilitating the success of pollution-tolerant organisms, many of which are typically non-native. Eutrophication also leads to harmful algal blooms (HABs) of green algae and cyanobacteria (Anderson et al., 2002) that cover water surfaces, substrate, and organisms (Landsberg, 2002). Harmful algal blooms in surface layers can prevent oxygen from effectively diffusing into the water column creating hypoxic zones. The death and decomposition of HABs increase aerobic bacteria and biochemical oxygen demand (BOD), which is largely a measure of the metabolic activity of microbes. High BOD can diminish dissolved oxygen concentrations below that which is necessary for fish and invertebrate life (Watson et al., 2016). Thus, HABs are a primary factor in mass die-off events, such as fish kills (Harrison et al., 2017).

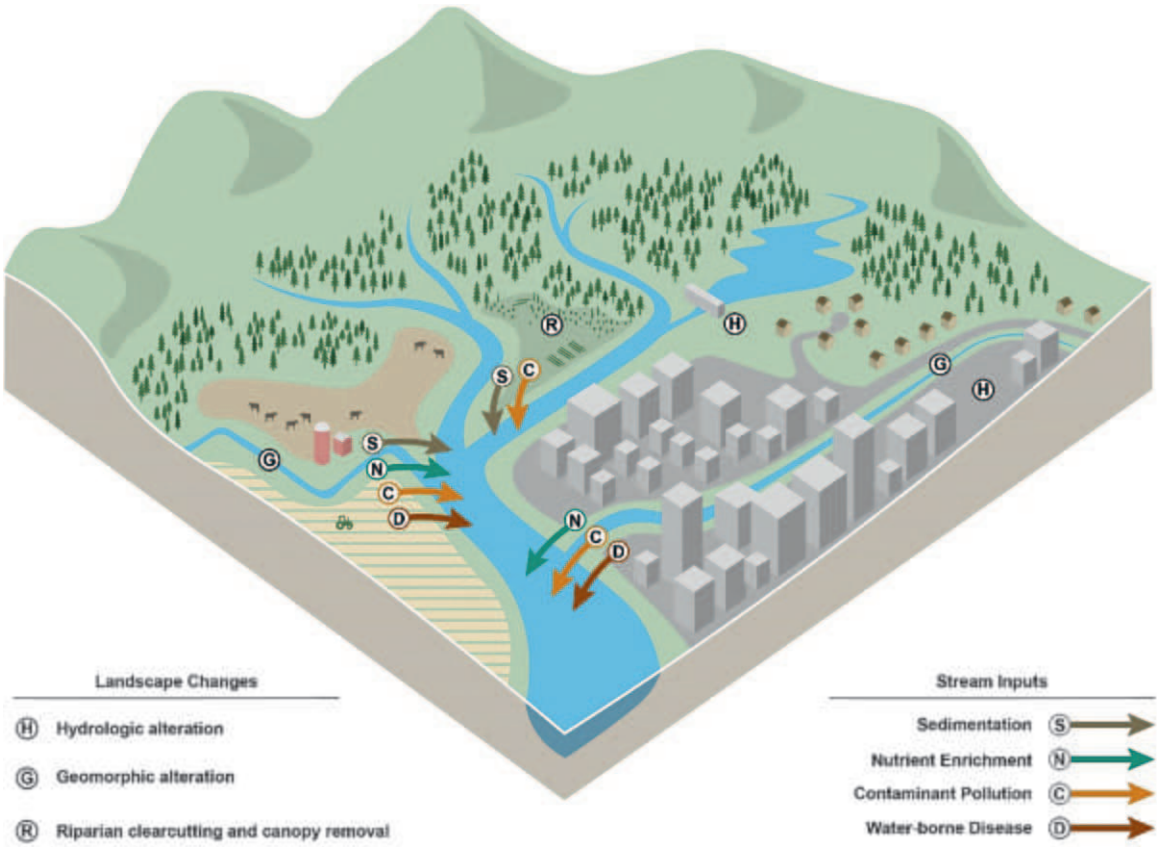

Fig. 3 Urbanization, agriculture, and resource extraction (i.e., mining, timber harvest, and dams/water withdrawal) represent globally common anthropogenic LULC types with significant consequences for water quality. Illustration: Robert Keast.

Cyanobacterial blooms can be particularly harmful because they also produce cyanotoxins, which affect the nervous system, liver, skin, or blood of aquatic organisms, and also humans (Christensen and Khan, 2020). Substrate can be particularly impacted by the prolific growth of nuisance filamentous algae that traps sediment (Berger et al., 2003), cements benthic substrata (Dodds, 1991), and leads to overall declines in macroinvertebrate diversity (Tonkin et al., 2014). The effects of HABs are only expected to get worse with climate change as warm temperatures exacerbate hypoxic conditions (Griffith and Gobler, 2020).

Pesticides (fungicides, herbicides, and insecticides) are contaminants commonly associated with agricultural land use (Fig. 4). Pesticides are applied to crops for pest control, but during precipitation events they enter streams and rivers where they can be toxic to aquatic life (Schäfer, 2019). There are over 2000 different pesticidal compounds used globally, along with hundreds of known metabolites deriving from their decomposition (Lewis et al., 2016). Tebuconazole and carbendazim, two commonly applied fungicides that are widely detected in surface waters (de Souza et al., 2020), negatively impact detrital pathways (Zubrod et al., 2011) and the health and survival of aquatic organisms (Singh et al., 2016). Three of the most widely used herbicides in the world are glyphosate, atrazine, and metolachlor, which are primarily used as weed-control agents in corn and soybean crops, but they are also commonly detected in surface waters (Medalie et al., 2020). Glyphosate has been shown to impact periphyton development and composition and cause acute toxicity in fish, amphibians, and crustaceans, among other developmental effects (reviewed in Annett et al., 2014). Atrazine and metolachlor are endocrine disruptors. Atrazine demasculinizes and increases hermaphroditism in frogs (Hayes et al., 2002), while metolachlor disrupts thyroid activity in fish (Jin et al., 2011). Furthermore, atrazine has transgenerational reproductive effects in fish (Cleary et al., 2019), and metolachlor has developmental effects in crayfish (Velisek et al., 2018). Although these pesticides can break down in the environment, even their degradation can be harmful, as the metabolites of glyphosate, atrazine, and metolachlor are also toxic (e.g., Maazouzi et al., 2016), sometimes even more toxic than the parent compound (Velisek et al., 2018).

Organophosphates have been the primary class of insecticides for decades, but their use has been declining in favor of pyrethroids, neonicotinoids, and other classes. That said, they are still widely used. Chlorpyrifos is one of the most widely used insecticides (Atwood and Paisley-Jones, 2017; de Souza et al., 2020) that has been shown to negatively impact aquatic macroinvertebrate assemblages (Ward et al., 1995). Pyrethroids like lambda-cyhalothrin, cypermethrin, and bifenthrin are seeing increased usage, but they are highly toxic to, and cause endocrine-disrupting effects in, aquatic organisms (Brander et al., 2016).

Table 1 Anthropogenic stressors of inland waters, examples of LULC type with which they are associated, whether they originate mostly from a point or non-point source, and common effects (see also Allan, 2004).

Anthropogenic environmental stressors	*Description*	*Examples of LULC Associations*	*Point or non-point source*	*Effects*	*References*
Sedimentation	Fine particulates sourced from runoff and erosion that are either suspended in river water or deposited onto the riverbed.	Agriculture Timber harvest	NPS	Fills interstitial refugial spaces, covers and homogenizes benthic habitat, increases turbidity, increases scouring, coats organisms and gill structures leading to loss of periphyton and sensitive taxa, bottom-up effects by decreasing primary productivity	Davies-Colley and Smith (2001), Sullivan and Watzin (2010), Burdon et al. (2013) and Blöcher et al. (2020)
Nutrient enrichment	Excess nutrients (primarily nitrogen and phosphorus) that enter rivers through agricultural runoff, erosion, or wastewater effluent.	Agriculture Urban	PS/NPS	Increases primary productivity with bottom-up effects; increases filamentous algae; increases tolerant, energy-inefficient taxa; may act as stressor in very high concentrations; leads to eutrophication and harmful algal blooms; increases bacterial abundance that decreases dissolved oxygen (e.g., BOD); facilitates species invasions; increases decomposition rates	Heiskary and Markus (2001), Ferreira et al. (2015), Ouyang et al. (2018) and Canning and Death (2021)
Hydrologic alteration	Deviations from natural annual flow patterns that result in brief, but extreme, peaks ("flashiness") caused by removal of natural vegetation, increased impervious surfaces, and decreased base flows from water extraction or damming.	Agriculture Urban Dams Water withdrawal	NPS	Increases peak flow magnitude and frequency, but also lowers base flows (more variability); increases erosion and channel instability; alters downstream transport of sediment, nutrients, and contaminants; decreases survival and growth of organisms; decreases metacommunity functional diversity	Roy et al. (2005), Dewson et al. (2007), Nilsson and Renöfält (2008) and Ruhi et al. (2018)
Fluvial geomorphic alteration	Channel modification that results in bank erosion, lateral or vertical channel adjustment; and loss of floodplain connectivity; related to alterations in hydrology and sediment load.	Agriculture Urban	NPS	Increases erosion and sedimentation; leads to channel widening, incision, aggradation, or change in channel planform; can cause entrenchment that can increase flows; alters habitat, community composition and abundance of aquatic biota, and food webs	Walters et al. (2003), Sullivan et al. (2004, 2006), Bey and Sullivan (2015) and Rieck and Sullivan (2020)
Contaminant pollution	Harmful chemicals (pharmaceuticals, synthetics, heavy metals, pesticides) from industry, agriculture, wastewater treatment plants, or non-point sources that are dissolved or suspended in river water or deposited in riverbeds.	Agriculture Urban Industrial Mining Oil & gas extraction Landfills	PS/NPS	Direct toxicity to organisms; decreases survival, fecundity, and growth rates; causes endocrine disruption, growth defects and developmental abnormalities	Schulz (2004), Golovanova (2008), Oehlmann et al. (2008), Pal et al. (2010) and Schäfer (2019)
Acidification	Anthropogenically lowered pH of streams and rivers due to acidic precipitation or acid mine drainage.	Urban Powerplants Mining	PS	Direct toxicity to organisms, mobilization of toxic metals from substrate, alteration of leaf litter breakdown rates, reduced species richness and abundances	Gerhardt (1993), Jardine et al. (2013) and Ferreira and Guérold (2017)
Deforestation Riparian clearing	Removal of vegetation from riparian areas, which reduces or eliminates canopy cover and allochthonous input.	Agriculture Urban Timber harvest	PS	Canopy removal increases temperature and filamentous algae growth, decreases allochthonous leaf litter and wood inputs that shifts invertebrate assemblages and functional traits, reduces refugia, decreases bank stability and increases erosion, increases tolerant taxa	Reid et al. (2008), Hubble et al. (2010) and Sturt et al. (2011) and Peres et al. (2017)
Water-borne disease	Prevalence and transport of water-borne diseases in rivers due to poor sanitation of human and/or animal wastes.	Agriculture Urban	PS	Transmit human and zoonotic diseases (e.g., diarrheal diseases, schistosomiasis, trachoma, ascariasis, trichuriasis, hookworm disease, malaria, avian influenza), transmit animal diseases (mastitis, foot and mouth diseases, parasitic and bacterial infections), reservoir of antibiotic resistant bacteria	Prüss et al. (2002b), Elahi et al. (2017) and Bailey et al. (2018)

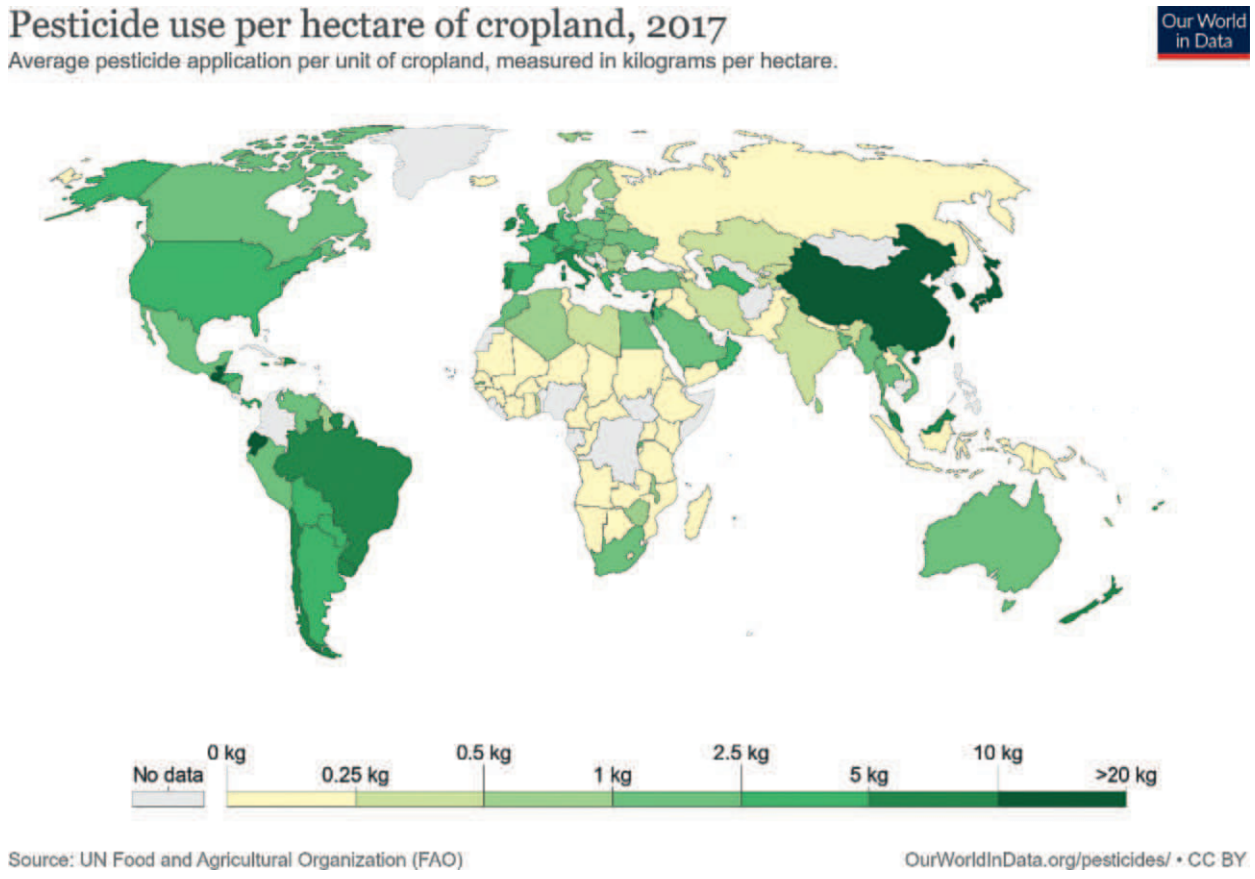

Fig. 4 Pesticide usage in kilograms per hectare by country (Roser, 2019).

Similarly, neonicotinoids have been show to negatively affect the abundances of macroinvertebrate and their avian predators (Van Dijk et al., 2013; Hallmann et al., 2014). In addition, pesticides run off into rivers where they form mixtures, which can be potentially up to 40 times more toxic than single compounds (Yang et al., 2018). Lastly, genetically modified crops such as glyphosate-resistant soybeans (e.g., Monsanto's "Roundup Ready" variety), facilitate overuse and overreliance of herbicides (Benbrook, 2012), whereas crops like Bt-corn contribute detritus to streams that harbor proteins toxic to stream insects (Rosi-Marshall et al., 2007).

Agriculture also directly uses water and accounts for 90% of all freshwater consumption (Shiklomanov, 2000) (Fig. 5). Irrigation of cropland by redirection of surface waters and pumping of hydrologically connected groundwaters directly decreases annual streamflow (Yin et al., 2021). Surface drainage, in particular, increases erosion and N, P, sediment, and pesticide inputs into rivers. Subsurface drainage mitigates P and pesticide inputs due to soil adsorption, but this is not commonly true for N because it is more mobile through soils. Likewise, sediment is physically trapped more readily by the soil matrix in subsurface flows compared to surface flows (Gramlich et al., 2018).

Livestock farming poses a significant threat to maintenance of water quality because it produces nutrient-rich animal wastes, leads to erosion-prone fields, and release of major ions, primarily Ca^{2+}, Mg^{2+}, K^{+}, Na^{+}, HCO_3^{-} (Cesoniene et al., 2019). Effluent from intensive livestock farming increases the overall organic pollution in rivers (measured by BOD; Wen et al., 2017). This type of organic pollution lowers oxygen levels, thereby suffocating aquatic organisms, and spreads pathogens, including those that cause diarrheal diseases, schistosomiasis, trachoma, ascariasis, trichuriasis, and hookworm disease in humans (Prüss et al., 2002a). This concern is especially prevalent in developing nations where BOD is only expected to increase (Wen et al., 2017). The cumulative effects of livestock grazing have also been shown to decrease aquatic macroinvertebrate species richness and increase the number of tolerant taxa (Herbst et al., 2012).

Estrogenic steroids (estrone, estradiol) and antibiotic pharmaceuticals in wastewater from intensive dairy farms and leachate from cattle burials (Matthiessen et al., 2006) enter surface and ground water. These hormones act as endocrine disruptors in aquatic organisms, where they have carcinogenic and mutagenic effects (Wang and Zhou, 2013). Antibiotics are used liberally in intensive livestock farming and many of these pharmaceuticals enter riparian systems through livestock waste. Research has shown that antibiotic contamination can induce antibiotic resistance in aquatic pathogens and impact the health of aquatic organisms (Bottoni et al., 2010).

Urbanization

The proportion of the human population living within urban areas is increasing rapidly, with projections that 68% of the total global population will live in urban centers by 2050 (United Nations, 2018). Urban land use within river catchments is estimated at 5–10% in catchments with the most urban development (Benke and Cushing, 2011). However, despite the small relative amount of total catchment land use, the effects of urbanization on water quality is disproportionately large due to many factors, including the integration of waste from a large, dense human population. Urban centers contain both point (wastewater treatment plants, industrial effluent) and non-point sources (impervious surface runoff) that contribute to water-quality impairment.

The "Urban Stream Syndrome" (USS) is a central concept used to describe a set of characteristics that commonly emerge in urban catchments once a stream is sufficiently impacted by urbanization. These characteristics include large fluctuations in hydrology, with high peak flows and low base flows, alteration of fluvial geomorphic patterns and processes, high relative concentrations of contaminants and nutrients, and deviations from natural mass and energy transfers (Booth et al., 2016). These effects can be largely traced to widespread impervious surfaces in urban areas that prevent precipitation from percolating through soils into groundwater. Impervious surfaces greatly increase the speed with which water moves from land into streams and rivers, leading to extreme flow variability (Fig. 6). Extreme flows not only contribute to erosion and contaminant input, but also can directly affect biota by increasing mortality and decreasing growth rates and functional diversity (Roy et al., 2005).

Stream geomorphic adjustment comes in concert with changes in hydrology and sedimentation resulting from LUCC, which represent major mechanisms regulating physical water quality. Channel adjustment can lead to alterations in sediment-size distribution, turbidity, streamflow variability, and habitat quality with impacts on aquatic insects (Sullivan et al., 2004) and fish (Sullivan et al., 2006; Rieck and Sullivan, 2020) (Fig. 7; also see Table 1). Highly incised streams limit the connectivity between the stream and its floodplain, having consequences for biodiversity (Sullivan and Watzin, 2009). Since channel instability can pose

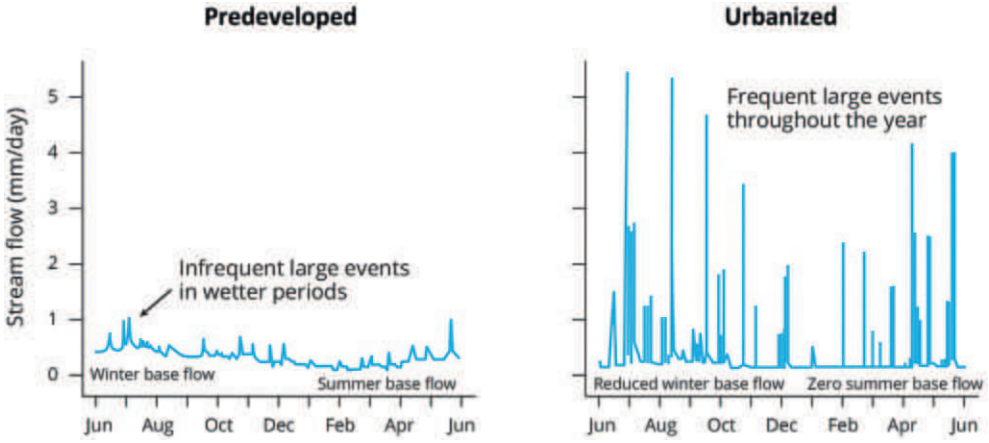

Fig. 6 After urbanization, streamflow becomes more variable with greater peak flows and lower base flows. From Stewardson MJ, Acreman M, Costelloe JF, Fletcher TD, Fowler KJA, Horne AC, Liu G, McClain ME, and Peel MS (2017) Understanding hydrological alteration. In: Horne AC, Webb JA, Stewardson MJ, Richter B and Acreman A (eds). *Water for the Environment.* pp. 37–64, Academic Press. ch. 3.

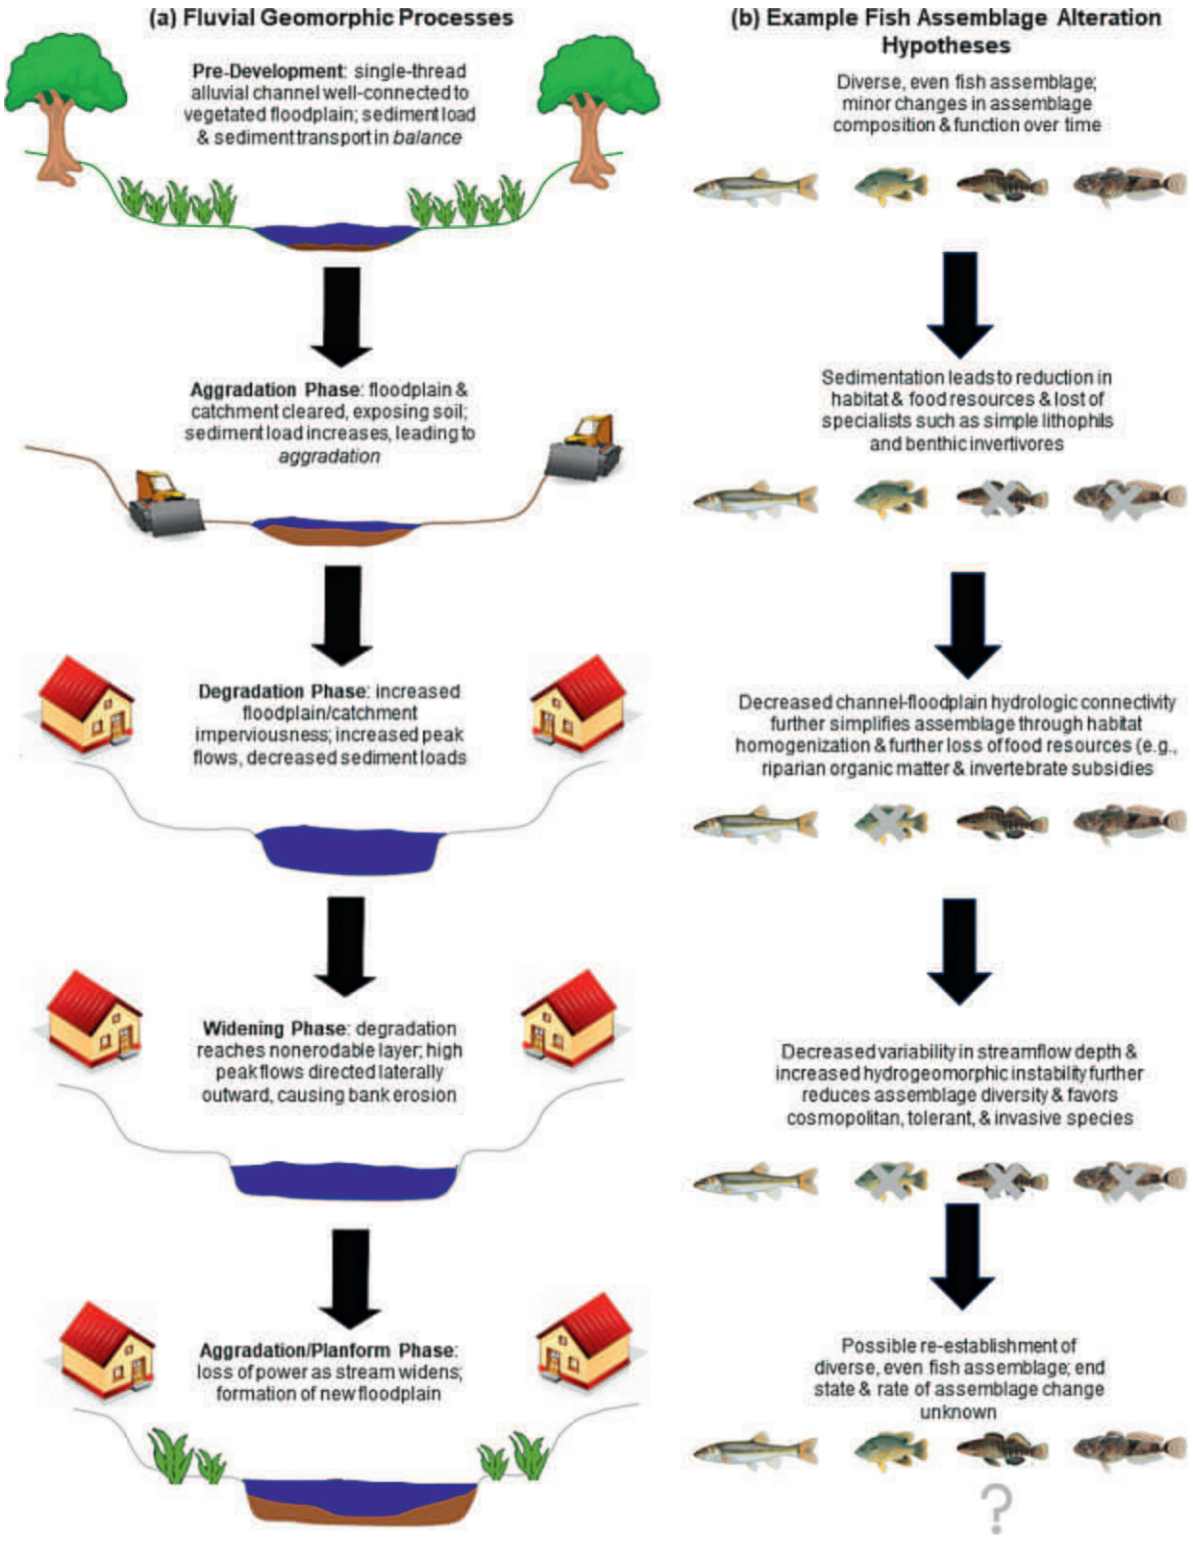

Fig. 7 Conceptual depiction of urban stream channel hydrogeomorphic evolution with example fish assemblage alterations. Hydrogeomorphic changes can lead to significant shifts in physical water quality. From Rieck LO and Sullivan SMP (2020) Coupled fish-hydrogeomorphic responses to urbanization in streams of Columbus, Ohio, USA. *PLoS One* **15**: e0234303.

risks to property owners, streams are often channelized with concrete or coarse riprap to improve channel stability, but these "solutions" homogenize structural habitat in morphologically-adjusted streams and further decrease the abundance and diversity of organisms (Cooke et al., 2020).

Urban areas support large human populations that produce substantial amounts of nutrient- and contaminant-rich waste. Combined sewer systems are common urban drainage systems that transport sewage to wastewater treatment plants (WWTPs), but they have limited capacities that are often exceeded during rainfall events resulting in raw combined sewer overflow (CSO) discharged directly into rivers (Yu et al., 2013). Untreated wastewater contributes significant contaminants, nutrients, and pathogens into rivers and represents a major challenge to water quality. For example, a diverse array of pharmaceuticals, but especially carbamazepine, sulfamethoxazole, and diclofenac, are discharged into the environment through WWTP effluent (de Voogt et al., 2007), along with other trace contaminants like polycyclic aromatic hydrocarbons, heavy metals, and hormones (Phillips et al., 2012). Fecal coliform bacteria, mostly *Escherichia coli* and fecal streptococci and enterococci are prevalent in combined sewer overflows, can cause a variety of diseases, and can exceed dry weather conditions by two orders of magnitude (Passerat et al., 2011). The combination of these pollutants create an environment that selects for and harbors antibiotic resistant bacteria (Honda et al., 2020), along with elevating BOD that can lead to oxygen depletion (Wen et al., 2017). These issues are especially problematic for people in regions that lack infrastructure to treat wastewater including, for example, areas of sub-Saharan Africa, Latin America, and southern Asia (Okoh et al., 2007; Wen et al., 2017). Lastly, though no transmissions have yet been detected via water or wastewater, SARS-CoV-2 has been detected in these sources (Godini et al., 2021).

Urban centers produce a wide range of contaminants that enter streams and rivers, but they are highly variable among cities and reflect local industry, technology, and cultural landscapes. Sources range from residential chemical usage to landfill runoff and leachate to WWTP and industrial effluent. Whereas pesticides are generally more closely associated with agriculture LULC, a number of pesticides are used in residential areas of urban centers to control weeds and household pests, such as the herbicide 2,4-D and the toxic pyrethroid insecticide bifenthrin (Weston et al., 2005; Atwood and Paisley-Jones, 2017). Heavy metals (e.g., Cd, Cu, Cr, Ni, Pb, Zn, and Hg) are contaminants found in urban-impacted rivers due to poorly managed landfills, industrial and domestic wastewater effluent, and atmospheric deposition from proximate industrial areas. These contaminants are toxic to aquatic invertebrates (Armitage et al., 2007) and are especially prevalent in rapidly urbanizing or underdeveloped regions that have little infrastructure (e.g., Islam et al., 2015). Lastly, salts (primarily Na^+, Cl^-, K^+, Ca^{2+}, CO_3^{2-}, HCO_3^-, SO_4^{2-}) contaminate urban rivers from de-icing applications, industrial effluents, and sewage leakage (Kaushal et al., 2005; Rose, 2007). Other emerging contaminants include microplastics (fragmented plastic particles <5 mm) and engineered nanoparticles (particles ranging from 1 to 100 nm used in certain manufacturing applications) but little is yet known about their general effects.

Natural resource extraction

Logging, or commercial deforestation, is a common precursor to agricultural or urban land use. Deforestation—including removal of riparian vegetation—increases erosion, sediment inputs, and temperature (via increased solar input from canopy removal); alters hydrology and geomorphology; and, eliminates aquatic-terrestrial connectivity and energy subsidies (Sweeney and Newbold, 2014; Kautza and Sullivan, 2016). Typically, macroinvertebrate grazing pressure and light limitation from canopy cover prevents nuisance algae growth from negatively impacting aquatic ecosystems (Sturt et al., 2011). However, anthropogenic removal of vegetation increases light availability and facilitates nuisance algae growth. The relationships among light availability, macroinvertebrate diversity, and aquatic-terrestrial energy subsidies also vary naturally in predictable ways.

Forested or vegetated riparian areas act as natural buffers of LUCC effects that protect waters from a host of impairments including elevated stream temperature and nutrient inputs, loss of organic input (leaf litter) and woody material, bank instability, erosion, and sedimentation (Dosskey et al., 2010). Sweeney and Newbold (2014) established that forest buffers (Fig. 8) ≥30 m are necessary to protect water quality of small to mid-size streams (~5th order streams), but almost half (44%) of riparian systems of all sizes in the United States have disturbed or poor buffers (US Environmental Protection Agency, 2016).

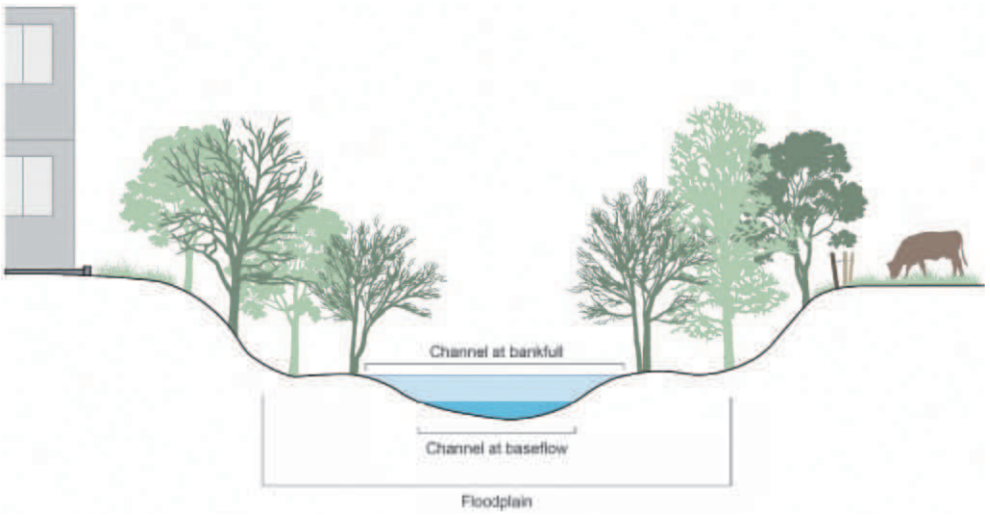

Fig. 8 Sufficiently wide vegetated riparian buffers can ameliorate the negative effects of anthropogenic land use by removing excess nutrients and trapping sediment and contaminants. Illustration: Robert Keast.

Surface and subsurface mining, including mountaintop removal mines and associated valley fills, have also been shown to exert strong negative effects on water quality in streams. For example, Giam et al. (2018) show that streams impacted by surface coal mining (mountaintop mining-valley fill) exhibited 32% lower taxonomic richness, and 53% lower total abundance of invertebrates, fish, and salamanders when compared to reference streams. In areas with extensive subsurface mining, particularly for gold or coal, acid mine drainage (AMD) is a common water- quality problem. Exposed sulfide mineral ores (typically pyrite) are oxidized through multiple pathways resulting in acidic water that dissolves and mobilizes toxic heavy metals (Fe, Al, Zn, Cu, Pb, and Cd), metalloids, and sulfates (Blodau, 2006). Streams receiving AMD have reduced pH (<3) and are coated with heavy metals and metal hydroxide precipitates, such as iron hydroxide FeO(OH), also known as "yellow boy," which is the most common and conspicuous precipitate of AMD (Fig. 9) (Winterbourn et al., 2000). AMD eliminates sensitives taxa through smothering, coating, direct toxicity, and bioaccumulation through food webs, having far reaching effects from macroinvertebrates to top predatory fish (Hogsden and Harding, 2012).

Fossil fuel production and use have myriad impacts on water quality. Oil sand extraction and oil and shale gas drilling (i.e., hydraulic fracturing—"fracking") incur land disturbances that affect water quality through processes of erosion, deforestation, and sedimentation. The storage, import, and export of liquid chemicals at operation sites pose point-source spill risks for streams. For example, a crude oil spill in the Gasconade River, Missouri, United States immediately decreased macroinvertebrate abundance and diversity. Whereas riffles flushed contamination from sediments rapidly and macroinvertebrates recovered, backwaters retained contaminants and showed no recovery after 18 months of monitoring (Poulton et al., 1997). Fracking fluid is mainly a mixture of brine, sand, and various chemical additives such as anti-scalants, biocides, corrosion inhibitors, gelling agents, solvents, and surfactants (for detailed list of chemicals, see Burton et al., 2014). This fluid is injected into wells to fracture rock to facilitate natural gas retrieval and only 10–30% is recovered as wastewater flowback (NYSDEC, 2011). The fate of unrecovered fluids is unknown. Flowback, which is often stored on-site or transported to other wells, contains concentrations of metals, chlorides, sulfates, barium, dissolved solids, organics, and radionuclides that are difficult for WWTP to remove (Entrekin et al., 2011). Between 2005 and 2014, there were 6648 fracking fluid spills reported across the states of Pennsylvania, New Mexico, North Dakota, and Colorado, United States (Patterson et al., 2017). A spill from a ruptured wastewater flowback pipeline impacted Blacktail Creek, North Dakota, United States resulting in elevated levels of Na^+, Cl^-, Br^-, Sr^{2+}, B^{3+}, Li^+, NH_4^+ and hydrocarbons that reduced fish

Fig. 9 Point source acid mine drainage (S) in the Lackawanna River near the confluence with the Susquehanna River in Pennsylvania, United States (41°21′32″ N 75°45′05″ W). Reaches downstream (D) of the point source (S) are visibly contaminated with iron oxide precipitates ("yellow boy") compared to upstream (U) reaches. A historical legacy of anthracite coal mining in the region scars the surface (C) and subterranean landscape. This site is the largest point source of pollution in the Chesapeake Bay and is estimated to discharge 150–380 million liters of AMD per day for the last 60 years (Falchek, 2012). National Agriculture Imagery Program USDA (2021) National Agriculture Imagery Program (NAIP). USDA Farm Service Agency (FSA) Through Aerial Photography Field Office.

survival by 97.5% in some contaminated reaches and caused widespread endocrine disruption (estrogenic inhibition) (Cozzarelli et al., 2017). Streams in northwestern Pennsylvania impacted by fracking, including some directly impacted by fluid spills, had decreased pH, increased methylmercury concentrations, decreased macroinvertebrate and fish diversity, and microbial assemblages enriched in methanotrophic and methanogenic bacteria (Grant et al., 2016; Ulrich et al., 2018).

Other processes related to energy and resource use also come with their own problems for stream water quality. Dams, for example, of all sizes and usages (hydroelectric, reservoir-forming, flood control) directly modify flow regimes causing changes to physical, chemical, and biological aspects of water quality. Fossil fuel combustion either by automobiles or coal/methane burning powerplants emits sulfur and nitrogen oxides (SO_x, NO_x). These oxides hydrolyze in the atmosphere into sulfuric (H_2SO_4) and nitric (HNO_3) acid resulting in acidified precipitation. The bicarbonate buffer system (Eq.1; Fig. 10A) of natural waters resists pH changes, but this system is maintained by the alkalinity provided by underlying carbonate (CO_3^{2-}) lithology (e.g., limestone). Alkalinity is often closely related to water hardness, which is a measure of the mineral content (typically $CaCO_3$ or $MgCO_3$) of water. However, the capacity of the buffer system is quickly exhausted in drainages with limited carbonate reserves (e.g., igneous drainages), leading to a rapid decrease in pH. Acidified streams are directly toxic to organisms, disrupt ecosystem process like leaf litter breakdown rates (Ferreira and Guérold, 2017), and mobilize sorbed metals (Al, Hg, Cu, Pb, Cd, As, Zn) from sediments into soluble toxic forms (Fig. 10B, Gerhardt, 1993). Metals have a variety of toxic effects on aquatic biota. Aluminum is acutely toxic because it disrupts osmoregulation of plasma membranes in plant roots and animal gills. Mercury is converted to highly toxic methylmercury and is biomagnified in the food web causing myriad deleterious effects, most notably on the nervous system (reviewed in Jaishankar et al., 2014). Though acidic precipitation has declined in the past several decades in many regions of the

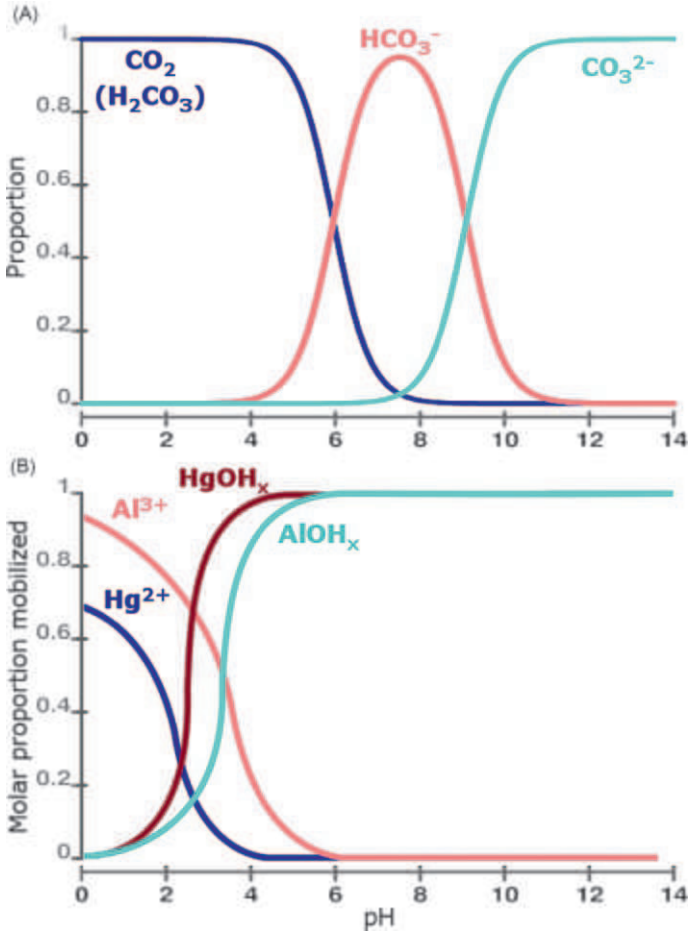

Fig. 10 (A) The bicarbonate buffer system showing the proportion of each dissolved inorganic carbon molecule in relation to pH. The buffer system resists changes in pH, but can be disrupted by excessive acidic pollution. (B) Metals (here, we illustrate Al^{3+} and Hg^2) are mobilized from sediments into more reactive, soluble forms at lower pH. As pH increase, these forms are converted to metal hydroxide forms, that can also be have deleterious effects on organisms. Other heavy metals (As, Cu, Cd, Pb, Zn) show similar patterns relative to pH. (A) Reproduced from Wetzel (2001) *Limnology: Lake and River Ecosystems*. 3rd edn. Academic Press: Sand Diego. (B) Reproduced from Sánchez España J (2007) The behavior of iron and aluminum in acid mine drainage: Speciation, mineralogy, and environmental significance. world and there have been liming efforts to restore the pH of acidified streams (Lawrence et al., 2016), acidification is still an ongoing issue due to inputs from acid mine drainage.

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \rightleftharpoons 2H^+ + CO_3^{2-} \quad (1)$$

Conclusion

Land-use and land-cover changes continue to strongly affect chemical, physical, and biological characteristics of water quality and represent a global threat to inland waters. The world's burgeoning human population relies on streams, rivers, wetlands, and lakes for the provisioning of multiple ecosystem services and functions that support human health, economic activity, and cultural and recreational practices. This dependence on water will only increase as the human population has grown exponentially over the past century and is expected to continue rising to 9.4–12.7 billion people by 2100 (United Nations, 2019). Over half the world's potable water supply is extracted from rivers (Barnett et al., 2005). Each hectare of land converted to human uses is one lost from its historic natural state. When excluding Antarctica, only 23% of terrestrial land has been unmodified by humans (Allan et al., 2017). River biodiversity is most threatened in landscapes with high agriculture and settlement pressure (Vörösmarty et al., 2010). Indeed, this dramatic reduction in natural habitat is also one of the main contributors to the ongoing sixth mass extinction event (Ceballos et al., 2020).

Here, we reviewed the effects that major anthropogenic LULC types have on inland waters worldwide, with a focus on rivers (Table 1). Human interactions with river catchments are complex and the natural connectivity among waterbodies can lead to far-reaching consequences of LUCC for downstream and downslope waters, including lakes, rivers, and coastal zones. For example, human alterations to headwater streams in the northeastern United States have led to reduced capacity of headwaters to remove nitrogen and to excess nutrient export to downstream waters such as coastal ecosystems (Schmadel et al., 2020). Impairment of aquatic ecosystems is also intimately tied to impairment of terrestrial environments and species. For example, impaired water quality has been linked to declines in species of aerial insectivorous birds across the United States (Manning and Sullivan, 2021) and some contaminants (e.g., mercury) can move from aquatic to terrestrial systems via food-web interactions (Sullivan and Rodewald, 2012).

Water quality is critical to human and ecosystem health, food production, and economic growth. Protecting water quality is, thus, is one of the principal challenges that humanity will face in the 21st century. Individuals to societies will need to be effective stewards of the water and other natural resources, with "beyond government" (i.e., collective governance with state and non-state actors working together) and transboundary (i.e., international teams working together to manage rivers and aquifers that cross borders) approaches increasingly viewed as part of the solution (Cosgrove and Loucks, 2015). Finally, risks to water quality from the interactions among LUCC, climate change, and other stressors will have to be predicted and appropriately managed in order for inland waters to continue to provide the ecosystem services needed for resilient and robust environments, communities, and economies.

Knowledge gaps

- Most of the research on LUCC and water quality comes from North America, Western Europe, Australia, and New Zealand. More research is needed in underrepresented regions like sub-Saharan Africa, South America, and Asia.
- The effects of many, individual anthropogenic stressors are well-studied, but the effects of their interactions have received less attention. Future research should focus on the interaction of multiple stressors to assess their combined effects and evaluate whether they are additive, synergistic, or antagonistic.
- Further integration, research, and monitoring of the physical, biological, *and* chemical components of water quality will be a critical step in long-term sustainability of inland aquatic ecosystems.
- Many solutions have been proposed and implemented to improve riparian ecosystems, but there is a need for long-term evaluation of the efficacy of restorations, policies, and regulations.
- Transdisciplinary approaches that combine both natural (e.g., ecology, toxicology, chemistry, hydrology) and social (e.g., sociology, human dimensions of natural resources, risk decision, etc.) sciences will be necessary effectively protect water quality (Table 2).

Table 2 Examples of recent river case studies addressing land use and their associated anthropogenic stressors.

Inputs, Occurrence and Effects of Pharmaceuticals and Microplastics in Freshwater Ecosystems

Emma Rosi[a], Megan Fork[a,b], Timothy Hoellein[c], John J Kelly[c], and Erinn Richmond[d], [a]Cary Institute of Ecosystem Studies, Millbrook, NY, United States; [b]West Chester University, Department of Biology, West Chester, PA, USA; [c]Loyola University Chicago, Chicago, IL, United States; [d]Monash University, Clayton, VIC, Australia

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Biosolid Solid waste in wastewater treatment facilities. These solids contain residues of pharmaceuticals, personal care products and microplastics.

Microplastic small particles (<5 mm) of plastics that are either designed to be small or are the result of the breakdown of larger plastic particles.

Pharmaceutical Compounds used as prescription and over the counter medications. Use, adoption and regulation of pharmaceuticals can vary by country.

Personal Care Product Compounds that are used in everyday lives such as detergents, skincare products, fragrances, cosmetics, insect repellants, etc.

EcoDC - Ecologically disrupting compound A compound or contaminant, typically a pharmaceutical, that may not be toxic at concentrations present in the environment, but has the capacity to elicit non-lethal effect on organism behavior, ecological processes and functions (Please see Richmond et al. 2017 for further details).

Freshwater ecosystems, especially rivers and lakes, have been exposed to pollution since the earliest human settlements, which were often located near these freshwater ecosystems as they provide drinking water, transportation, hydropower, and waste disposal. The contamination of freshwater ecosystems with a range of pollutants, including human waste, industrial chemicals, and agricultural chemicals, has been studied for decades. More recently, a field of research has developed that focuses on novel pollutants of emerging concern within freshwaters. This class of pollutants includes a wide array of compounds such as pharmaceuticals, including prescription and over-the-counter drugs, personal care products, and microplastics (i.e., particles 1 μm–5 mm), among others. Personal care products include products such as antiseptics, cleansers, skin care products, detergents, insect repellants, fragrances, etc. Many pollutants of emerging concern are found as ingredients in consumer products and many are synthetic chemicals. Synthetic chemicals include a diversity of chemical structures and their increasing variety, global use, and potential biological effects contribute to the recent categorization of synthetic chemicals as agents of global change (Bernhardt et al., 2017). Pharmaceuticals, personal care products, and microplastics are pollutants of emerging concern that are typically discussed together because they enter the environment through normal use of consumer products and thus they are commonly found together when human wastes are discharged into freshwater ecosystems. For this reason, in this chapter we will discuss these pollutants together; however, it should be noted that there are over 3000 pharmaceuticals on the global market today, and microplastics are composed of many different types of polymers and can include a wide variety of chemical additives. Therefore, although these pollutants will be discussed together, their behavior, transformations, fate, and effects on the environment may vary widely.

The sources of novel pollutants such as pharmaceuticals, personal care products, and microplastics to the environment are numerous. At each step in their life cycle (from synthesis to human use and disposal), some fraction may be released into the environment, so exploration of these life cycles can shed light on release dynamics.

Sources and fates of pharmaceuticals and personal care products

Pharmaceuticals and personal care products (PPCPs) are created at manufacturing facilities, and release from these facilities represents a significant source of pollution that is often not regulated. Such releases may occur throughout the world wherever these compounds are produced. In the US for example, some manufacturing facilities are located adjacent to rivers, which subsequently receive discharge from pharmaceutical manufacturing facilities, creating hotspots of pharmaceutical contamination (Scott et al., 2018).

Once sold, PPCPs are used in the day-to-day lives of people and animals, including livestock and pets. PPCPs that are ingested can be metabolized within the body, but many are excreted or egested in urine and feces either entirely or as some fraction of the ingested amount. There is also a large suite of PPCPs that are designed to be used topically in humans or other animals (e.g., antiseptics, sunscreens, insect repellents, analgesics, fungal medications, shampoos, and detergents). After use, these compounds can be released unchanged into wastewater (e.g., via bathing). Some classes of drugs, especially antibiotics, are given to animals in large amounts in confined animal feeding operations (e.g., cows, chickens, and pigs) and to household pets. For example, over two thirds of the medically important antibiotics (for human disease) in the US are used in animal feeding operations (Patel et al., 2020). Antibiotics used in animal agriculture can be readily measured in manure. If livestock manure from animal feeding operations is applied to land for use as fertilizer, as is common, the associated pharmaceuticals can enter the environment and nearby freshwater ecosystems.

The fate of human sewage is also directly related to the fate of PPCPs and their entry into freshwater ecosystems. Direct release of sewage, both through the lack of infrastructure, combined sewer overflows, and leaking of waste from old infrastructure, is a common pathway through which these compounds enter freshwater ecosystems. For sewage that is treated prior to release, the ability of wastewater treatment processes to remove PPCPs varies widely, depending on the specific compound and the specific treatment processes. The incomplete removal of PPCPs by onsite (e.g., septic systems) or centralized wastewater treatment facilities can lead to discharge into freshwater ecosystems through the release of treated effluent. A rich literature exploring the concentrations of PPCPs downstream of wastewater treatment plants and how various treatment technologies mitigate discharges is now available. There is also evidence that in rural areas septic systems are a source of PPCPs to freshwater ecosystems. In addition to the liquid effluent released by wastewater treatment facilities, the solid portion of the wastes (known as sludge or biosolids) may also contain a wide diversity of PPCPs (McClellan and Halden, 2010). The fate of biosolids then provides an additional route for entry of PPCPs into the environment. In the United States, for example, municipal biosolids are applied to land to be used as a fertilizer, disposed of in landfills, or incinerated. Land application of biosolids can be a route by which PPCPs enter the environment as they desorb from the solid materials and potentially enter freshwater ecosystems.

It is also important to note that most human sewage generated around the world is not treated. The World Health Organization (WHO) estimates that more than 80% of human sewage, globally, is discharged untreated to the environment (https://www.unwater.org/water-facts/quality-and-wastewater/). Therefore, although concentrations of pollutants of emerging concern vary depending on the degree of treatment and the specific compounds, many of these compounds are likely discharged, unchanged, into the environment throughout the world and may pose a threat to the health of aquatic ecosystems.

Sources and fates of microplastics

The same principle of exploring the life cycle of a potential pollutant applies to the movement of microplastics to freshwater systems; however, due to their particulate nature, microplastics can enter freshwater systems through a greater variety of pathways than PPCPs, which are typically dissolved in water. Microplastics are categorized as either 'primary', which are particles designed to be small (e.g., 'virgin' plastic pellets or microbeads), or 'secondary', which are particles generated when larger plastic items break apart. Key sources of microplastics in the environment include sewer systems, solid waste management, and direct littering into the environment (Hoellein and Rochman, 2021) (Fig. 1).

Plastics are a ubiquitous part of our everyday lives, thus a major pathway for primary and secondary microplastics to freshwater ecosystems is human sewage (Carr et al., 2016) or brown water discharges. For example, laundry can be a major source of microplastic fibers. As polyester clothes are washed, a fraction of the material ends up as loose fibers in the washing machine water and is discharged with household sewage (Napper and Thompson, 2016). Again, depending on both the sewage treatment process in place and the fate of the biosolids, microplastics can be discharged to the environment directly via direct release of sewage, treated wastewater effluent, land application of biosolids from wastewater treatment plants, or septic systems (Carr et al., 2016; Crossman et al., 2020). In wastewater, plastic may interact with PPCPs and other chemical contaminants, as some plastic surfaces attract chemical pollutants, causing chemicals to sorb onto the plastic.

Another route of entry to the environment that both PPCPs and microplastics share is via solid waste management (i.e., trash). The fate of PPCPs and microplastics depends on how solid wastes are processed in any given area. Some plastics might be recycled, although plastic recycling rates are relatively low at a global scale (Geyer et al., 2017). In municipal landfills, some PPCPs and microplastics in solid waste may enter the environment if there are leaks in the landfill structure. If the solid waste is incinerated, the PPCPs and microplastics associated will be incinerated as well. Landfills and incineration may represent a permanent sink for microplastics, however, some portion of the plastic litter will be converted into smaller microplastics, as well as greenhouse gases via combustion, UV oxidation, or biodegradation (Gewert et al., 2015). Finally, solid waste may be shipped among countries (often to developing nations) as a form of solid waste management, including microplastic and associated PPCPs.

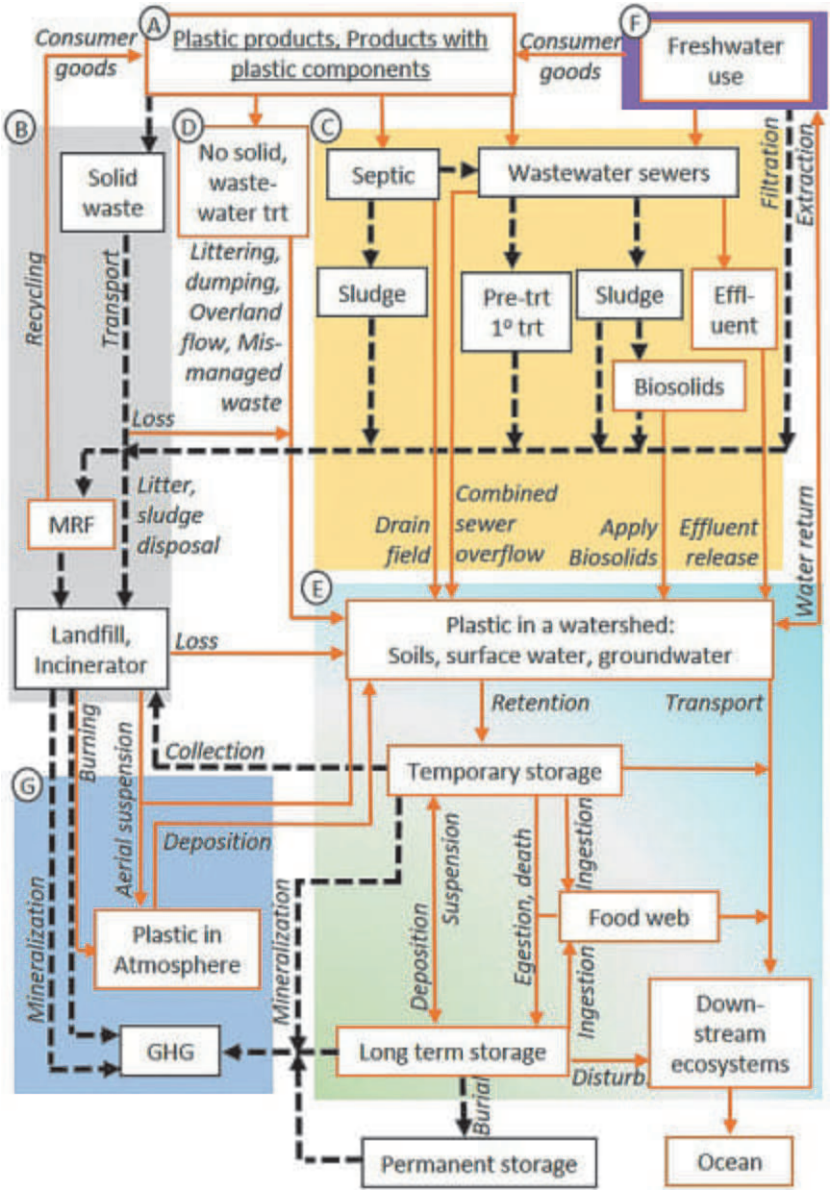

Fig. 1 Conceptual model of the plastic cycle at the watershed scale, including pools (rectangles) and fluxes (arrows). Dashed black lines indicate pathways toward waste containment, storage, or greenhouse gases (GHGs). Solid orange lines show fluxes that represent movement of plastic among pools. Letters A–G correspond to each section of the paper that discusses that portion of the figure, and each letter is placed on a rectangle to coalesce major pools of plastic for a watershed budget. (A) in-use consumer goods; (B) solid waste management; (C) wastewater management; (D) direct littering and mismanaged waste (litter that does not enter solid waste collection or wastewater treatment); (E) watershed litter; (F) freshwater use; and (G) the atmosphere. *MRF*: materials recovery or recycling facility; *trt*: treatment; *Disturb*: disturbance. From Hoellein TJ and Rochman CM (2021) The "plastic cycle": A watershed-scale model of plastic pools and fluxes. *Frontiers in Ecology and the Environment* 19:176–183.

The last major source of plastic litter to the environment is direct littering. In communities without access to solid waste or wastewater management, littering is an informal management process (i.e., dumps, ditches, rivers), however, littering also occurs where waste management is available and can be a major source of plastic litter locally (Vincent et al., 2017). Secondary microplastics are generated from plastic litter once it enters the environment, when larger plastic litter items break down through abrasion, sunlight (UV oxidation), or biodegradation (Gewert et al., 2015).

PPCPs and microplastics in the environment

Once in the environment (via solid waste, wastewater, or littering), PPCPs and microplastics are readily moved throughout the world. Fig. 2 illustrates the microplastic cycle in the environment with pools and fluxes such as deposition from the atmosphere and

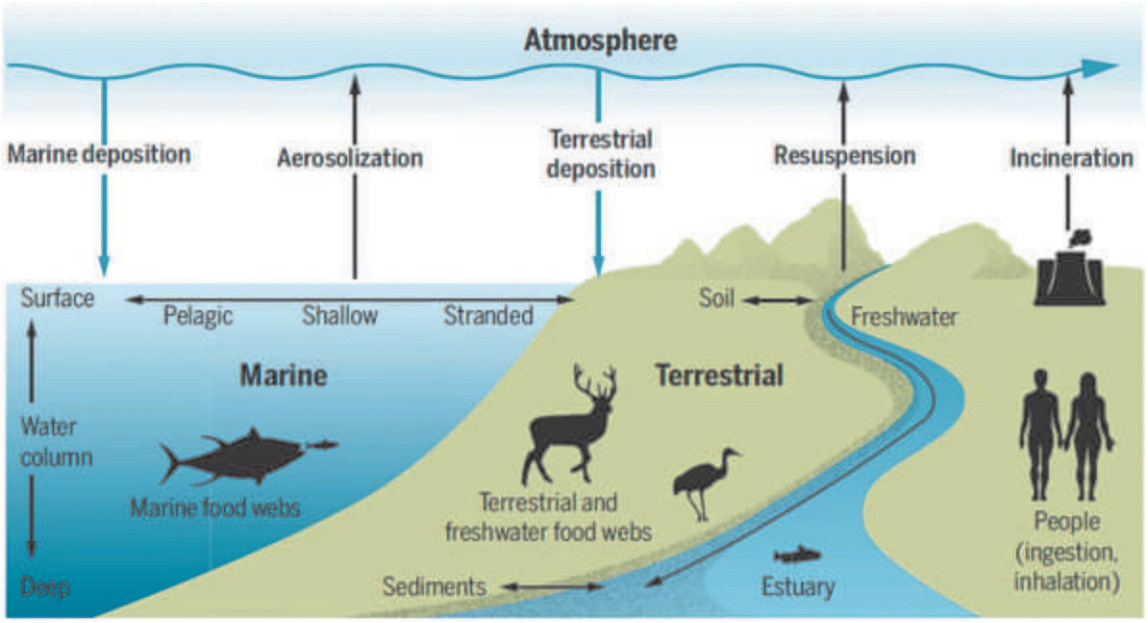

Fig. 2 Microplastic pollution is pervasive. Emerging research pinpoints atmospheric deposition as a mode of microplastic transfer. Mapping microplastic pools (water, land, organisms) and fluxes (arrows) will guide delineation of the global microplastic cycle. From Rochman CM and Hoellein T (2020) The global odyssey of plastic pollution. *Science* 368:1184–1185.

transfer along river corridors, including continual deposition and resuspension accompanied by downstream transfer (Rochman and Hoellein, 2020).

For both PPCPs and microplastics, there continue to be advances in measuring their concentrations in freshwater ecosystems. The challenge has been detecting very low concentrations of PPCPs and collecting and identifying very small plastic particles, including microplastics (<5 mm) and nanoplastics (<1 μm). New methods have revealed some surprising findings, such as detection of PPCPs associated with tourism in US National Parks (Weissinger et al., 2018), in Antarctica (González-Alonso et al., 2017) and in the Alps (Mandaric et al., 2017), and detection of microplastics in Arctic sea ice (Peeken et al., 2018) and in atmospheric deposition in the Pyrenees in France (Allen et al., 2019). Research into the movement of plastic particles through the environment in particular is in its infancy, and the case has been made that much more research exploring these pathways is needed (Rochman and Hoellein, 2020). With respect to freshwater systems, it is important to understand that the sources and fate of PPCPs and microplastics may be varied across the landscape. For example, in urban areas below wastewater treatment plants, the concentrations of PPCPs and microplastics may be high and consistent over time, but in urban streams affected by leaking infrastructure concentrations of PPCPs are highly variable from week to week (Fork et al., 2021). The same is true for rural areas where concentrations of these compounds maybe variable in space and time. Evidence is mounting that there are few places left on earth where these compounds are not detectable in freshwater ecosystems, albeit at low concentrations.

The types of pharmaceuticals detected in freshwater ecosystems represent a wide range of compounds. For the past two decades, most of the information available has been the concentrations of pharmaceuticals and personal care products (PPCPs) in solution in surface waters. In general, if a compound is regularly used by the human population and the compound is relatively persistent, on the order of days to years, it has been detected in the environment, provided there are analytical methods to screen for it. The first detection methods were developed using liquid chromatography combined with mass spectrometry (LCMS). Continual methodological advancement is allowing increasingly more compounds to be investigated. Indeed, non-target analytical approaches are now being proposed as a means for understanding the wide range of synthetic chemicals found in the environment (Singer et al., 2016). In recent years, techniques have expanded to include detection of PPCP compounds in sediments and organisms, including animal tissues. In both cases, sediments and biota tend to have much higher concentrations of PPCPs (Richmond et al., 2018) than are dissolved in water. Moreover, information on the concentrations of PPCPs in biological samples is crucial for understanding their potential to move through food webs via trophic transfer, similar to what has been found for legacy pollutants such as PCBs and DDT. At the time of writing this chapter, our understanding of PPCPs in food webs is limited to a handful of studies, but these suggest that this route may be an important aspect of environmental risk.

In contrast to PPCPs, our measurement of microplastics in the environment has only emerged in the last 10 years. Microplastics are also a highly diverse suite of materials (Rochman et al., 2019). Plastic is a catch-all term for many polymers (e.g., polyethylene, polyvinyl chloride, and synthetic rubber) and plastics are mainly manufactured from petroleum products. The polymer represents the 'skeleton' of a plastic product, but there is also a diverse array of chemical additives embedded within the polymer 'bones' during production. Additives offer properties such as heat resistance, flexibility, and color, and may be leached from plastic litter once in the environment. Some microplastics are semi-synthetic, and consist of mixtures of plastic and other materials. For example, a single microplastic fiber may contain a combination of polyester and cotton. Finally, microplastics are found in a variety sizes

(1–5000 μm) and shapes, such as beads, fragments, and fibers. Techniques for measuring microplastics often involve separating particles from the natural matrix (water, sediment, tissue), and using microscopy to count and measure the particles. Additional analyses (e.g. FTIR) are needed to identify the chemical composition of the plastic polymers.

Ecological effects of PPCPs

In the past 20 years, as the analytical capacity to measure pharmaceuticals and personal care products has increased, the number of studies documenting their occurrence and concentrations has increased in tandem. The first US nationwide survey was published in 2002 by a group of scientists at the United States Geological Survey (Kolpin et al., 2002). This study focused on rivers below wastewater treatment plants in larger cities and detected numerous PPCPs in river water. Since that time, the research on this topic has expanded to include sampling of freshwater ecosystems throughout the world, as well as groundwaters, sediments, and the tissues of insects, fishes, and spiders. Moreover, the number of compounds that have been detected in any given place continues to grow. This suggests that more research is needed to understand the effects of complex mixtures of compounds on biological and ecological endpoints. For example, it is known that drugs can interact in the human body in significantly deleterious ways and drugs are prescribed with drug interactions in mind. In contrast, in the environment, much less is known about how complex mixtures of drugs may interact to affect non-target organisms.

Since the discovery that PPCPs can be detected in surface waters, researchers have investigated whether they also have toxicological and ecological effects on aquatic organisms and ecological processes (Rosi-Marshall and Royer, 2012). The research on this topic has been increasing over the past decade. Much of the work investigating the potential effects of pharmaceuticals and personal care products has used ecotoxicological approaches such as studies of the concentrations needed to result in mortality of aquatic animals. Less work has been done to investigate the ecological effects of these compounds, but as seen in Fig. 3, this work is occurring and expanding our understanding of the potential of these compounds to affect aquatic organisms (Richmond et al., 2017).

Combined with their ubiquity, PPCPs are of particular environmental interest because of their potential to have a biological effect on non-target organisms. Many PPCPs, especially very potent pharmaceuticals, are used in the everyday lives of humans precisely because of their ability to alter biological processes. For example, antibiotics are used to disrupt bacterial growth associated with an infection, and insect repellents are used because they are noxious to insect pests. However, once these compounds are released to the environment, their biological activity does not simply cease to occur. Therefore, these compounds have the potential to disrupt non-target organisms and ecological processes, and for this reason Richmond et al. (2017) made the case that PPCPs should be viewed as ecologically disrupting chemicals.

Recent research has demonstrated that PPCPs at concentrations that have been detected in the environment can disrupt microbial community structure and functions. For example, research has shown that a wide variety of pharmaceuticals can alter algal community structure (Lee et al., 2016; Robson et al., 2020) and the rates of photosynthesis of algal biofilms, e.g., communities of algae and bacteria that grow on solid surfaces in freshwater ecosystems (Rosi-Marshall et al., 2013; Lee et al., 2016; Gallagher and Reisinger, 2020). Moreover, bacterial community structure and function are sensitive to exposure to pharmaceuticals. For example, exposure to the generalized antimicrobial triclosan significantly altered bacterial composition and the proportion of triclosan resistant microbes in a mesocosm study (Drury et al., 2013). An *in situ* experiment comparing the effects of nutrients and drugs on stream biofilms found that increased nutrients led to dominance by a few microbial taxa, whereas pharmaceuticals led to increased richness of microbial taxa (Ogata et al., 2020). There is mounting evidence that a wide variety of PPCPs can influence both the structure and function of bacterial communities (e.g. Rosi-Marshall et al., 2013; Corcoll et al., 2015; Rosi et al., 2017; Robson et al., 2020).

PPCPs have also been shown to affect aquatic animals, even at very low concentrations. The effects of these compounds are highly variable among compounds and the effects represent a wide suite of consequences for animals that are exposed. For example, the insect repellent picaridin caused significant deformities and mortality for salamander larvae (Almeida et al., 2018). A variety of pharmaceuticals have been shown to affect aquatic insect life history patterns such as rates of larval growth and timing of adult insect emergence (Hoppe et al., 2012; Lee et al., 2016; Richmond et al., 2016, 2019). Exposure to illicit drugs significantly altered the oxidative status of zebra mussels, which is indicative of the health of these animals (Parolini et al., 2015). The drug oxazepam significantly altered the feeding behavior and activity levels of European perch, at concentrations found in nature (Brodin et al., 2013). Additional studies continue to demonstrate the effects of numerous drugs on the behavior of aquatic animals (e.g. Jonsson et al., 2014; Reisinger et al., 2021).

As analytical approaches for measuring pharmaceutical concentrations in animal tissues have advanced, recent work demonstrates that pharmaceuticals are accumulating in aquatic animals (Lagesson et al., 2016; Ruhí et al., 2016; Richmond et al., 2018). Fig. 4 illustrates the diversity of drug compounds that were detected in aquatic animals collected from below a wastewater treatment plant in Melbourne, Australia (Richmond et al., 2018). These studies demonstrate that intake of PPCPs via both water and transfer within the food web are likely, and further, PPCPs may be transferred to terrestrial animals that prey on larval or flying aquatic insects, such as riparian spiders, birds, and bats (Richmond et al., 2018). There is also the potential that aquatic animals could serve as an important biomonitoring tool to explore human use of illicit drugs or pesticides (Miller et al., 2019). Recent research also demonstrates that some pharmaceuticals can disrupt aquatic animals' perceptions of their surroundings via chemical signals. For example, it has been demonstrated that drugs disrupt the "smell-scape" by disrupting detection of some compounds and mimicking other compounds. This disruption may have numerous consequences for mating behavior, prey detection, and other species

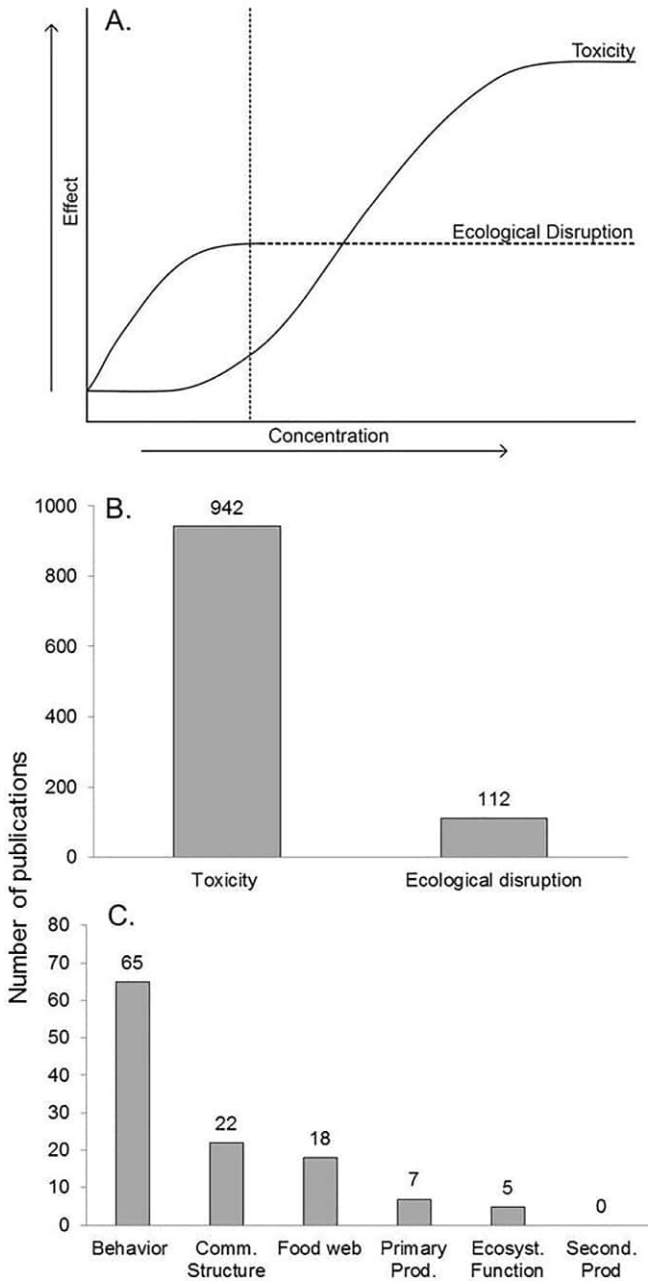

Fig. 3 PPCPs as EcoDCs influence aquatic ecosystem function and biota. (A) Conceptual figure demonstrating the potential non-lethal effects of EcoDCs at low concentrations on aquatic biota and ecosystem function, in contrast to toxic effects observed at high concentrations. The dashed horizontal line at the end of this curve represents uncertainty at high PPCP concentrations. The dashed vertical line indicated where lethality is becoming increasingly important relative to ecosystem disruption. (B) Number of publications indexed in Web of Science measuring toxic endpoints (including LC50 and EC50 toxicity testing) versus those measuring non-lethal, ecological disruption (EcoD) endpoints at environmentally relevant concentrations. (C) Number of publications in Web of Science demonstrating various endpoints related to ecosystem disruption associated with environmentally relevant concentrations of PPCPs. Details of literature search are available in supplementary material. From Richmond EK, Grace MR, Kelly JJ, Reisinger AJ, Rosi EJ, and Walters DM (2017) Pharmaceuticals and personal care products (PPCPs) are ecological disrupting compounds (EcoDC). *Elementa* 5:66, doi:10.1525/elementa.252.

interactions in aquatic food webs (Van Donk et al., 2016). Moreover, there has been a particular focus on the effects of pharmaceuticals on wildlife and growing concern about the general phenomenon of medicating wildlife (see Arnold et al., 2014).

Considerations about the environmental risk of PPCPs and microplastics pose to freshwaters

A few important general principles have been identified with respect to PPCPs. The first is that these compounds can be considered pseudo-persistent (Daughton and Ternes, 1999). This means that although some of these compounds degrade quickly in the environment, because they are continually released or resupplied from various sources, their presence "persists." For example,

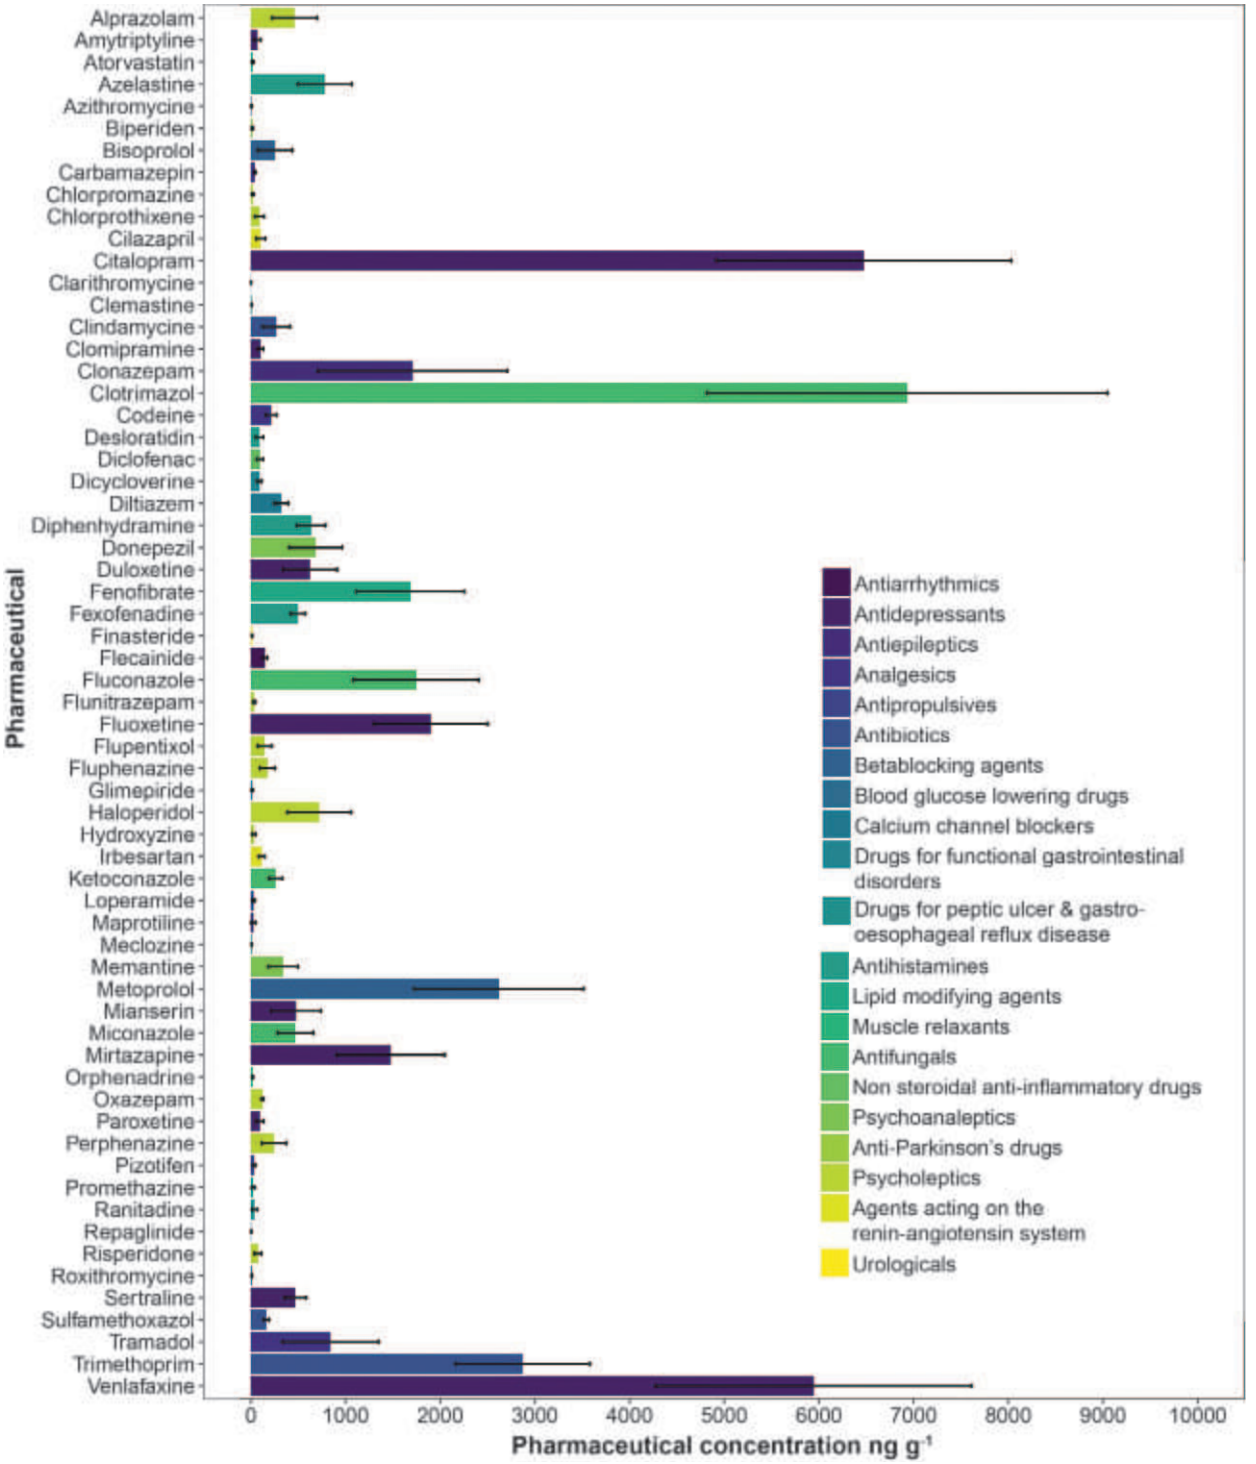

Fig. 4 Pharmaceutical concentrations in caddisfly larvae. Mean pharmaceutical concentrations (ng g^{-1} dry weight ± 1 SE) in caddisfly larvae(Hydropsychidae) ($n = 6$) at wastewater-influenced Brushy Creek. Each bar represents the mean concentration of a pharmaceutical compound in the six individuals collected over two sampling dates. Colors represent therapeutic drug classes. From Richmond EK, Rosi EJ, Walters DM, Fick J, Hamilton SK, Brodin T, Sundelin A, and Grace MR (2018) A diverse suite of pharmaceuticals contaminates stream and riparian food webs. *Nature Communications* 9:4491.

caffeine is readily degraded by microbes and yet it is consistently found in the environment because so many people use this compound in their daily lives. The second important characteristic of these compounds is their role as endocrine disruptors. For example, it has been shown that a number of these compounds can disrupt important endocrine systems in animals leading to problems such as increasing frequency of intersex animals or altered sex ratios in animal populations, both of which have been

shown to have negative consequences for reproduction and long-term population dynamics. For example, the active ingredient in human birth control medication can influence the sex ratios and population dynamics of fishes. When experimentally added to a lake in environmentally realistic concentrations, the active birth control ingredient led to altered sex ratios and population decline of fathead minnow (*Pimephales promelas*) populations (Kidd et al., 2007). Third, there is increasing evidence that PPCPs can lead to ecological disruption (e.g., see Fig. 3) at concentrations lower than those that cause mortality as measured by traditional ecotoxicological approaches. These compounds may disrupt ecological interactions, community structure and/or ecosystem functions. Fourth, there is an increasing need to consider the effects of mixtures and interactions among drugs when investigating the effects of these compounds. Numerous studies demonstrate that a wide variety of compounds can be present in the environment and it is known that drugs interact with each other. Although it is challenging to generalize about such a broad class of compounds, research has demonstrated that, for example, antibiotics disrupt certain members of stream bacterial communities, fungicides disrupt fungal communities, and antidepressants and stimulants can alter algal communities, the life cycles of aquatic insects, and fish behavior, as presented above.

The effects of microplastics on freshwater ecosystems has been very recently emerging as a field of research (Horton et al., 2017; Li et al., 2020). Key ecological dynamics of microplastics in the environment include its movement in the environment, effects on microbial habitat, chemical interactions, ingestion and use by aquatic animals in case building. Plastic particles move through streams and rivers in a fashion similar to natural particles (Fig. 5), so their movement in the environment is akin to naturally occurring particles (Windsor et al., 2019). Microplastics accumulate in stream sediments with fine particulate organic matter (Vincent and Hoellein, 2021), suggesting that organisms that feed on fine particles may be targets for assessing ecological impacts. Plastic surfaces select for very different microbial communities than natural substrates found in the same habitats (McCormick et al., 2016; Harrison et al., 2017). Moreover, the plastic particles harbored a larger proportion of gastrointestinal microbes (e.g., human pathogens) and microbes that may actually degrade the plastic polymers.

Microplastics also interact with chemicals in aquatic ecosystems, including leaching of plastic additive compounds from microplastics to the environment, and sorption of additional pollutants from the environment onto microplastics. Microplastics have especially high capacity to adsorb organic compounds due to their high surface area and hydrophobicity. Consumption of microplastics by aquatic organisms is widespread in aquatic ecosystems and the known effects include a range of ecotoxicological responses including mortality, reproduction, neurotoxicity, and a range of physiological and behavioral effects (see review by de Sá et al., 2018). Microplastics may pass through an animal's gut with no effects, although the presence of plastic in the gut may cause calorie deficits or starvation if microplastics cause animals to feel satiated or microplastics may create intestinal blockage. In addition, compounds adsorbed or embedded within microplastics may pose a threat to animals after ingestion (Foley et al., 2018). Finally, in experimental conditions, macroinvertebrates incorporate microplastics into their cases and incorporation of microplastics destabilized the cases, suggesting an additional threat these compounds may pose to aquatic organisms (Ehlers et al., 2020).

A significant research challenge posed by pollutants of emerging concern such as PPCPs and microplastics is the sheer number of compounds potentially present in aquatic ecosystems. In the United States, for example, the number of pharmaceuticals approved for sale is in the thousands of compounds. Moreover, this does not include the myriad personal care products such as cosmetics, detergents, fragrances, sunscreens, insect repellants, etc. that are used in everyday life. Aquatic ecosystems can have upwards of 500 different compounds (Bradley et al., 2017) with potential varying biological effects. Thus, the ecological consequences will likely be complex and varied, including possible disruption at multiple trophic levels and alterations of ecological interactions and dynamics. For example, a recent study found 69 different compounds, from many different drug classes, in the tissues of caddisflies downstream of a wastewater treatment plant (Fig. 4, Richmond et al., 2018). Recent work has investigated the interactions of PPCPs with other ecological variables such as after a drought (Corcoll et al., 2015) or in response to varying degrees of canopy cover

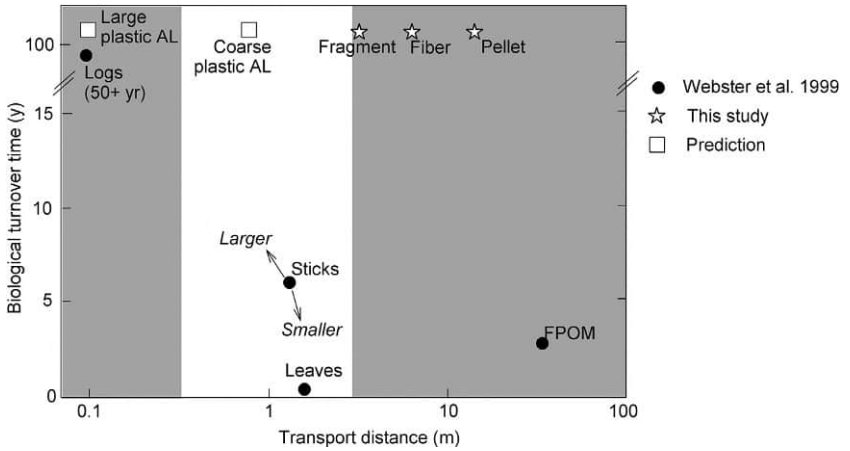

Fig. 5 Transport distance and biological turnover time for naturally occurring allochthonous carbon including leaves, sticks, fine particulate organic matter (FPOM) and wood, originally synthesized in Webster et al. (1999). We added to this diagram by including direct measurements of transport distance for microplastic particles (i.e., fragment, pellet, and fibers), and an estimate of biological turnover time. We also included predictions of transport distance for coarse plastic anthropogenic litter (AL, i.e., shopping bags, bottles, and food wrappers), and large plastic AL (i.e., construction debris, shopping carts). From Hoellein TJ, Shogren AJ, Tank JL, Risteca P, and Kelly JJ (2019) Microplastic deposition velocity in streams follows patterns for naturally occurring allochthonous particles. *Scientific Reports* 9(1): 3740.

(Robson et al., 2020). It has also been shown that the degree of urbanization and the exposure to nutrients influences the effects of pharmaceuticals on algal and bacterial communities (Rosi et al., 2017). We do not yet understand how drugs may interact to potentially pose a threat to aquatic animals. The effects of these compounds are often studied piecemeal, and thus the complexity of effects that may result are both hard to measure empirically, challenging to predict, and extremely challenging to regulate (Kortenkamp and Faust, 2018). Similarly, microplastics are also a complex mixture of chemical types that may have distinct influences on aquatic ecosystems, yet the effects of different types of polymers, plastic additives, and their interactions with other pollutants is yet to be studied and represents a research frontier (Foley et al., 2018). For example, because PPCPs and microplastics share many routes of entry into aquatic ecosystems, there is ample opportunity for these pollutants to interact, e.g. via adsorption of PPCPs to microplastic surfaces, which could have significant implications for the fate, transport, and biological interactions of both of these pollutant types.

Conclusion

A wide variety of pharmaceuticals and personal care products and microplastics are present in aquatic ecosystems around the world. Understanding the effects of these novel compounds and particles represents a significant frontier in freshwater science. In addition, there are many opportunities for researchers to explore the interactions among these novel pollutants and the many types of environmental contexts in which they occur. More research in this area will continue to shed light on the role of these compounds in aquatic ecosystems of the Anthropocene.

Knowledge gaps

- What are the concentrations of PPCPs and microplastics and how do they vary in space and time?
- How persistent are these compounds in different aquatic environments and geographical locations?
- What are the concentrations in food webs both aquatic and terrestrial (e.g. birds, bats, lizards)? What trophic levels are most at risk?
- What are the effects of these pollutants on whole ecosystem processes?
- How do PPCPs and microplastics interact with each other and other stressors like road salt, nutrients, invasive species, climate change, etc.?
- How sensitive are different organisms to PPCPs and microplastics?
- How can we assess the effects of complex mixtures of novel pollutants?
- What are the most effective management and regulation strategies?
- How can we reduce the sources of these pollutants or improve design to reduce inputs?
- Can we make PPCPs and microplastics more biodegradable?
- Are there human health risks when freshwater systems and food webs are contaminated?

Multiple Stressors in Streams

Sebastian Birk, University of Duisburg-Essen, Aquatic Ecology, Essen, Germany

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Additive stressor effect Multiple stressors affect the receptor, with the overall effect being equal to the effect sum of single stressors.

Antagonism The overall multiple stressor effect is smaller than the effect sum of single stressors.

Dominant stressor effect Only one of the multiple stressors affects the receptor despite distinct presence of both stressors.

Interactive stressor effect Multiple stressors affect the receptor, with the overall effect being different from the effect sum of single stressors.

Multiple stressors Two or more co-occurring or sequential stressors.

Phenomenological knowledge In this context defined as knowledge gained from empirical studies measuring the effect of multiple stressors without explicitly examining the underlying cause or pathway of that effect.

Receptor Indicator of stress response, ranging from physiological processes at the cellular level of individual organisms to behavioral patterns of individuals, changes in species populations, biological communities, food webs or ecosystem functions. The term is a synonym for 'biological response.' 'Stressor' and 'receptor' always form a conceptual pair, with one implying the existence of the other.

Stressor interaction Modification of a stressor's intensity or the sensitivity of an organism or ecosystem toward this stressor by another stressor or multiple other stressors. Not to be confused with biotic interactions among organisms.

Stressor Any natural or anthropogenic variable that causes a quantifiable change, irrespective of its direction (increase or decrease), in a biological response. The term 'stressor' is usually associated with an anthropogenic variable that has a negative impact.

Synergism The overall multiple stressor effect is larger than the effect sum of single stressors.

Introduction

Among inland waters, riverine systems are particularly affected by human activities due to their physical structure. They form open spatial networks that cross the landscape, draining higher grounds and concentrating runoff with its associated substance load. The linear shape of streams and rivers determines their tight connection with the surrounding land which often gets in the way of areal land use such as agriculture or urbanization. Rivers form a unity with their floodplain, and the riparian land-water-interface shaped by the fluvial dynamics represents one of the most diverse habitats highly sensitive to anthropogenic stressors. Riverine systems are also longitudinally connected by their directional transport of water, solutes, sediments and biota, with even locally restricted human intervention having potential implications for the entire network. Their very nature thus makes streams and rivers highly susceptible to multiple stressors.

By definition, stressors are external factors modified by human intervention that move a 'receptor' out of its normal operating range (Sabater et al., 2019). Receptors are indicators of stress response, and they range from physiological processes at the cellular level of individual organisms to behavioral patterns of individuals, changes in species populations, biological communities, food webs or ecosystem functions (including implications for biodiversity and ecosystem services). At the scale of river ecosystems, integrative indicators such as 'ecological status' (Lemm et al., 2021) or biodiversity loss represent common stress receptors of societal relevance.

It should be noted that the term 'stressor' differs from the term 'pressure' which is used, for instance, in the conceptual DPSIR framework elucidating socio-environmental relationships. Stressors are conceived as (putative) causes in a cause-and-effect chain, thereby accessible to empirical research and disclosure of mechanistic pathways. Strictly speaking, 'stressor' and 'receptor' always form a conceptual pair, with one implying the existence of the other.

Individual stressors acting on streams

Main stressor categories

A variety of anthropogenic stressors can be active in stream ecosystems worldwide (Table 1). In their study on global threats to human water security and river biodiversity, Vörösmarty et al. (2010) rank physical stressors (water abstraction, river fragmentation) and chemical stressors (water pollution) among the most pervasive in streams and rivers. Reid et al. (2019) complement 12 freshwater stressors threatening biodiversity, which can be grouped into three main categories:

Physical stressors

Agriculture is one key driver accounting for 90% of global water consumption, with about 20% of which is currently abstracted from rivers and other freshwater resources. Further driven by land use and climate change, this share is expected to increase to 25% by the end of the 21st century (Huang et al., 2019). At the global scale, less than 25% of rivers flow uninterrupted to the ocean (Grill et al., 2019), with highly developed regions in the world such as Europe evincing on average 0.74 barriers per kilometer of river length (Belletti et al., 2020). With the global hydropower boom river fragmentation is likely to substantially increase in many regions in the world in the coming decades. With about 90% of natural floodplain habitats lost, Europe also ranks highest regarding the impacts of lateral river fragmentation due to flood control structures (Globevnik et al., 2020). This level of decline is in line with the overall loss of natural wetlands globally, estimated at 87% of natural wetlands lost at end of the 20th century (Davidson, 2014). Other river basins worldwide already show similar degrees of floodplain loss (e.g. along the Mississippi), and substantial increases in other regions are expected for the future (Tockner et al., 2008). Physical stressors are furthermore exerted by the excessive sand and gravel extraction to supply the rapidly expanding building industry especially in the Asian-Pacific region. Severe physical stress manifests at larger spatial scales, allowing for detection and quantification by earth observation (e.g. Globevnik et al., 2020). Many of the physical stressors, however, represent small scale interventions that require costly field inspection to be detected, suggesting that the bulk of physical stressors currently goes undetected (e.g. Belletti et al., 2020).

Chemical stressors

Likewise, water pollution continues to be a major issue in rivers globally, with diffuse pollution mainly from agriculture and point source pollution from households (Ligtvoet et al., 2018). Nutrient stressors generally predominate, originating from aquaculture production, fertilized croplands or incompletely treated waste waters. These sources also increasingly produce pollutants of "emerging concern" such as pesticides, pharmaceuticals, microplastics or industrial chemicals, which may persist conventional sewage treatment and contaminate as parent compounds, metabolites or transformation products. These substances are also referred to as "micropollutants," which are generally present in water bodies in low concentrations but which can have detrimental biological effects in these concentrations. Moreover, the concentrations of inorganic ions in rivers are rising globally. This so-called secondary salinization is mainly caused by agricultural irrigation in arid regions, although mining activities and road de-icing can also play a significant role (Cañedo-Argüelles et al., 2013).

Table 1 Categorization of individual stressors acting on streams and rivers.

Category	*Group*	*Form*	*Main source*	*Main driving factor*
Physical	Hydrological stressors	Flow alteration	River flow regulation	Energy production, Navigation, Agriculture
		Water scarcity	Water abstraction	Agriculture
	Morphological stressors	Longitudinal fragmentation	Dams and barriers	Energy production, Agriculture
		Lateral fragmentation/floodplain loss	Levee dykes	Agriculture, Urbanization
		Channelization	River training	Agriculture, Navigation, Urbanization
		Siltation	Erosion of fine sediments	Agriculture
	Thermal stressors	Water warming	Heat emissions (from thermoelectric power plants)	Energy production
			Lack of riparian shading	Agriculture, Urbanization
		Water cooling	Release of cold bottom water of a reservoir	Energy production
	Radiation stressors	Light pollution	Artificial light; Lack of riparian shading	Urbanization, Agriculture
		Ultraviolet radiation	Stratospheric ozone depletion and climate change	*Drivers of climate change*
		Radioactivity	Nuclear accidents	Energy production
Chemical	Nutrient stressors	Nitrogen, Phosphorus	Soil fertilization; Insufficiently treated wastewater	Agriculture, Urbanization
	Other chemical stressors	Organic matter	Untreated wastewater; Excretion from aquaculture breeding	Urbanization, Aquaculture
		pH	Acid deposition; Acid mine drainage	Energy production, Industry, Mining
		Humic substances	Diffuse emissions from organic soils	*Drivers of climate change*
	Toxic stressors	Salinity	Mining effluents; Road de-icing; Soil fertilization; Water abstraction	Mining, Road transport, Agriculture, Urbanization
		Heavy metals	Acid mine drainage; Storm and surface water runoff; Hull coatings; Soil fertilization	Mining, Urbanization, Navigation, Agriculture
		Contaminants of emerging concern		
		Microplastics	Fragmentation of plastic litter; Untreated or insufficiently treated wastewater	Urbanization
		Pesticides	Diffuse emissions from agricultural soils; Application in aquaculture; Storm and surface water runoff	Agriculture, Aquaculture, Urbanization
		Pharmaceuticals	Insufficiently treated wastewater; Intensive livestock and aquaculture farming	Urbanization, Agriculture, Aquaculture
		Cyanotoxins	Harmful algal blooms caused by nutrient stress	Agriculture
		Other organic chemicals	Insufficiently treated wastewater; Storm and surface water runoff; Hull coatings and bilge water; Oil spills	Industry, Urbanization, Navigation
Biological	Biological stressors	Invasive alien species	Intentional or accidental releases; Bilge water	Navigation, Aquaculture
		Waterborne pathogens	Untreated or insufficiently treated wastewater	Urbanization
		Overexploitation	Commercial fishing	Fisheries

Biological stressors

Biological stressors represent the third category of threats affecting streams and rivers worldwide. Above all, the impacts of invasive alien species on the native biodiversity are noteworthy. Deliberate or accidental introductions of exotic species, mainly by trade and transport, can lead to severe changes of the original communities by out-competing native species, altering food webs and ecosystem functioning. Rivers already affected by physical or chemical stressors may facilitate invasions (Strayer, 2010). The number of alien species in freshwaters strongly increased over the last decades and are expected to exceed today's rate by 20% in 2050 (Seebens et al., 2021). These may go alongside water-related infectious diseases observed to increase in prevalence (Poulin et al., 2011).

The threats of fishery exploitation by humans to large freshwater species such as sturgeons, river dolphins, and turtles are well documented (e.g. He et al., 2018). By-catch rates however, estimated at 40% of total catches globally for marine fisheries, to be detected but assumed to be substantial, leading to species decline and even extinction (Raby et al., 2011). The biological threats of aquaculture include overexploitation of wild fish for feed, introduction of alien species through accidental release, and transmission of pathogens (Martinez-Porchas and Martinez-Cordova, 2012).

Human activities driving multiple stressors

The multitude of stressors in streams and rivers is driven by eight human activities and climate change (Fig. 1): Fisheries, energy production, navigation and quarrying occur in, on or close to the river; agriculture, urbanization, mining and industry take place

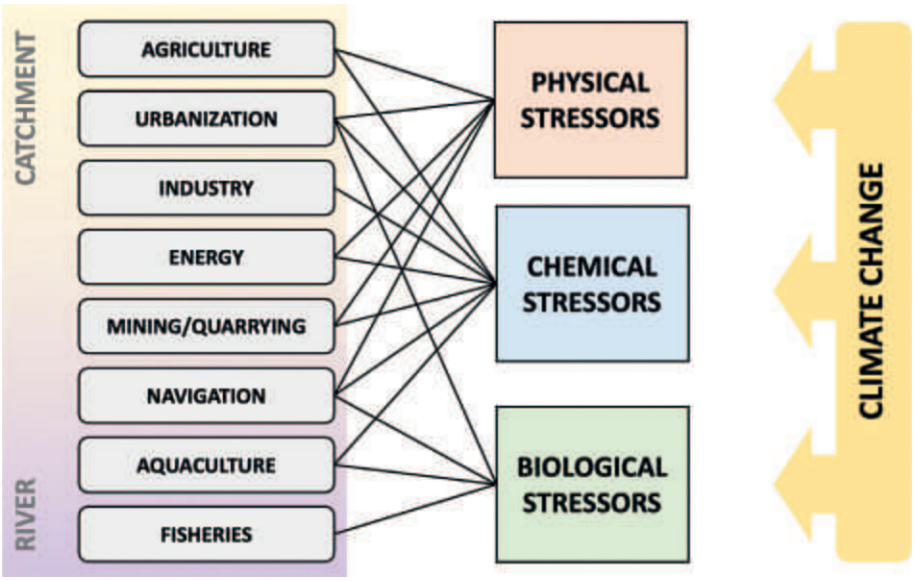

Fig. 1 Human activities and climate change driving multiple stressors in rivers.

anywhere in the catchment; climate change acts globally. Each of these drivers has the potential to cause multiple stressors itself. The "Urban Stream Syndrome" (Walsh et al., 2005) is a case in point: rivers draining urban land feature flashier hydrographs, elevated concentrations of nutrients, fecal pathogens and contaminants (driven by combined sewer overflows), altered channel morphology and complete floodplain loss. The effects of various drivers in the catchment often accumulate and exert more of the same or a spectrum of different stressors. Many of the drivers are closely interlinked by their socio-economic context, calling for a systemic perspective to fully understand all relevant driving forces (e.g. water-food-energy nexus-concept). Stress intensities are likely to increase and exacerbate the multi-stressor situation in the coming decades, in that future models project growing resource demand from the rising world population (EEA, 2020).

The role of climate change

Climate change is not considered a stressor per se, but as a driver boosting individual stressors (Johnson and Penaluna, 2019; see Fig. 1). Direct climate change effects on streams and rivers include increased water temperatures and altered streamflow patterns, locally manifested in extreme events such as floods, droughts and heatwaves. Physical stressors intensify through climate-induced water scarcity or disastrous flooding, which may require climate change adaptation measures such as water reservoirs and conveyance structures, or enhanced flood protection measures. Chemical stressors intensify through reduced dilution of pollutants during dry periods, or flash-flooding which flushes pollutants from urban and rural areas into the rivers. Biological stressors intensify through the spread of alien species and diseases due to warmer climate, facilitated by reservoir constructions. Future models generally predict exacerbated effects of climate change, yet with highly uncertain and variable prospects regarding specific regions.

Multiple stressors acting on streams

Given the wide variety of stressors, river systems are frequently impacted by multiple stressors, especially in densely populated world regions with emerging or high-income economies (North America, Europe, East and South Asia; Vörösmarty et al., 2010). European rivers, for instance, are mainly threatened by the interplay of physical and chemical stressors including hydrological, morphological and nutrient stress (EEA, 2018). Accordingly, these stressor combinations are investigated most often in the scientific literature (Nõges et al., 2016).

Phenomenological knowledge

The effects of multiple stressors are studied on the basis of empirical data covering different stressor intensities, either manipulated in experimental settings or sampled across spatial or temporal gradients under field conditions. Multi-stressor studies often limit their investigations to two stressors acting together, thus simplifying the multi-stressor "cocktail" in favor of paired stressor-response analyses. This allows for separating between three basic multi-stressor effect types:

- Dominant effects: Only one of the two stressors affects the receptor despite distinct presence of both stressors.
  Example: Hydrological stress (river low flow) but not nutrient enrichment showed a significant effect on the benthic macroinvertebrate community composition in a lowland stream experiment (Graeber et al., 2017).
- Additive effects: Both stressors affect the receptor, with the overall effect being equal to the effect sum of single stressors.
  Example: Physical and chemical stressors added up in their effects on various biological community parameters in a mountainous river catchment (Gieswein et al., 2017).
- Interactive effects: Both stressors affect the receptor, with the overall effect being different from the effect sum of single stressors.
  - Synergism: The overall effect is larger than the effect sum of single stressors.
    Example: Increasing nutrient enrichment and temperature amplified/magnified the phytoplankton growth in a boreal river system (Rankinen et al., 2019).
  - Antagonism: The overall effect is smaller than the effect sum of single stressors.
    Example: Hydropeaking (peak flow events from hydropower plant operation) dampened/mitigated the effects of nutrient enrichment on benthic algae biomass in an oligotrophic alpine river experiment (Bondar-Kunze et al., 2016).

A synthesis analysis covering 195 paired stressor-response cases acting on riverine biological community parameters (e.g. diversity, biomass, functional traits mainly affected by morphological, hydrological, toxic or nutrient stressors paired with each other) revealed almost equal shares of multi-stressor effect types (36% dominant, 31% additive, 32% interactive; analysis based on Birk et al., 2020). Data covering larger spatial scales showed higher shares of additive and interactive effects, likely related to the extended stressor gradients investigated. The interactive effects relevant in the cases with significant interactions explained on average about 20% of the community responses, with nutrient and toxic stressors as well as nutrient and morphological stressors interacting most frequently. A recent study analyzing seven stressors acting on the ecological status of European rivers attributed more than half of the multi-stressor response to interactive effects, indicating the complex interplay of the stressors considered (Lemm et al., 2021).

Behind the phenomena: The dearth of mechanistic understanding

Stressor interactions seem to play a significant role in river systems, as they do in other ecosystems (e.g. Brook et al., 2008; Hunsicker et al., 2016). Yet, little is known about the actual mechanisms and pathways underlying stressor interactions. This ignorance obstructs the prediction of multi-stressor effects and gives way to ecological surprises when "perceived reality departs qualitatively from expectation" (Holling, 1986). The inability to predict is one of the biggest scientific challenges, detaining effective policy-making and management intervention (Schindler and Hilborn, 2015).

Three aspects are key to the advancement of multi-stressor knowledge in river systems:

Rivers as hierarchical systems obscuring stressor manifestation

Rivers are natural systems with a hierarchical organization incorporating, on successively lower levels, subsystems from the basin down to the microhabitats (Frissell et al., 1986). This implies that riverine habitats and their biota are controlled by processes acting at different spatiotemporal scales. Human activities often modify these processes at higher scales with cascading implications for the lower scales. Dam construction in the upstream part of a river system, for instance, is an intervention that affects the river system at a high hierarchical level. Its effects on river flow and sediment dynamics downstream alter patterns of flooding and sediment deposition with detrimental consequences for all subsystems. This hierarchical organization complicates the understanding of how, where and when driving forces cause multiple stressors in river systems.

Patterns of stressor interplay

The effect of multiple stressors is dependent on the types of stressors acting together. The biotic response to nutrient stress, for instance, varies when paired with different stressors (Birk et al., 2020). The effect is also dependent on the intensity of co-occurring stressors, with individual stressors at low intensities being ineffective, but at high intensities being potentially no longer effective (e.g. due to saturation effects). This suggests interactive effects are relevant only along certain intervals of stressor intensity. Another likely important factor is the relative duration of individual stressors. Stressor exposure needs to be understood against species-specific life-histories. For example, a stressor lasting a certain time span may be experienced discretely by long-lived species but continuously by short-lived species (Jackson et al., 2021). This suggests varying stressor effects in biological communities will depend on the life-history traits of the different species forming the community. Moreover, the sequential order and frequency of stressor occurrence influence multi-stressor effects, determining specific community vulnerability and recovery potential (Sabater et al., 2021). For example, Brooks and Crowe (2019) demonstrate greater effects on community respiration when copper was applied before the insecticide chlorpyrifos than vice-versa in an experimental treatment. Stressor effects were also influenced by time-lags in the arrival of the two stressors.

Varied responses across levels of biological organization

Multi-stressor effects differ between levels of biological organization, indicating the relevance of different mechanisms at various organizational levels (Galic et al., 2018). At the level of the individual, stressor response is related to the "stressor mode of action". Schäfer and Piggott (2018) distinguish between stressors acting from the outside or from the inside on the individual organism. Stressors acting from the outside affect the whole organism (e.g. physical stress of flooding) leading to destruction or displacement. Stressors acting from the inside affect the organism's physiology, either non-specifically (e.g. salinity, thermal stressors) by

increasing energy costs, or specifically (e.g. toxic stressors) by altering specific physiological processes. Stressors can also be mediated through environmental factors that affect the organism's physiology. Oxygen availability, for instance, is reduced for aquatic organisms at higher temperatures or flow cessation, which can conflict with specific niche or habitat requirements of the organism (Statzner and Bêche, 2010).

At the population level, regulating mechanisms such as density dependence can obscure direct stressor effects by affecting intraspecific competition (e.g. cannibalism and agonistic behavior), predation or increases in food ration. Dispersal dynamics may offset stressor impacts through recolonization (e.g. drift compensation; Chará-Serna and Richardson, 2021) and life-cycle traits determine the species' sensitivity and exposure to stressors. A significant example are insect species whose larval and adult stages occupy different (aquatic and terrestrial) habitats with respective exposition to different stressors.

At the community level, composite biological mechanisms induce more complex responses. Different stress-tolerances among species, for instance, render communities more resistant or more vulnerable to multiple stressors, depending on whether these tolerances are positively or negatively correlated to each other (Vinebrooke et al., 2004). Species interactions are known to mediate community-level responses to multiple stressors, and multi-stressor effects are likely to propagate across the food web. Stressors can have direct trophic effects (top-down on the resource or bottom-up on the consumer) and indirect effects cascading through the trophic levels. Combined with biotic interactions (e.g. competition or facilitation) so-called 'trophic amplification' generates non-trivial multi-stressor responses (Bruder et al., 2019). Besides evolutionary adaptation to stressors including natural selection over multiple generations, potential legacies of past stressors complicate the understanding of multi-stressor effects at community level (Jackson et al., 2021).

Refining the analytical approach to multi-stressor effects

Empirical evidence gained from experiments and field studies provide the critical foundation to the mechanistic understanding of multi-stressor effects. Key is the formulation of appropriate "null models" for the statistical effect analysis (Schäfer and Piggott, 2018). On this basis, more complex mapping and modelling approaches can be conducted as part of an advanced "cumulative effects assessment" (Hodgson and Halpern, 2019). For example, multi-stressor mapping affords insights into species exposure and vulnerability to stressors within their distribution, directing spatial management (e.g. Schinegger et al., 2018). Multi-species modelling allows for integrating direct stressor effects and indirect effects of biotic interactions across the food-web, with ever-increasing predictive accuracy (Schuwirth and Reichert, 2013). Multi-model ensembles, in which multiple alternative models are run and results are compared, would allow for quantifying uncertainties to fortify conclusions.

Orr et al. (2020) aptly summarizes the key issues of multi-stressor research: (1) Our effect understanding needs to integrate ecological complexity and its increasingly intricate patterns from the individual to the ecosystem. (2) The relevance of the temporal scale at which stressors co-act should be scrutinized, with experimental simulations truly striving to imitate real-world stressor situations. (3) Improved analytical models should ultimately enhance our predictive capacity to forecast multi-stressor effects instead being staggered by ecological surprises.

Managing multiple stressors acting on streams

Uncertainty calls for adaptive management

The dearth of mechanistic understanding makes environmental management under conditions of multiple stressors very challenging. Ideally, management is guided by causal diagnosis and prediction. The systematic review of existing evidence for cause-effect hypotheses, a technique adopted from epidemiology, offers support to informed decision making (Norris et al., 2012). This information can feed into probabilistic networks assisting the diagnosis of potential causes for ecosystem deterioration (Feld et al., 2020). In reality, comprehensive system understanding is often scarce, leading to decision making in the face of high uncertainties. This setting calls for an adaptive management approach, that is an iterative process managing the system on the basis of current knowledge while acquiring further information needed to improve future management (Clark, 2002). Yet, "no-regrets" measures, which make the system more resilient toward currently unknown impacts, can be effected immediately (Côté et al., 2016). An example often suggested as a "no-regret" for tackling multi-stressor problems is the establishment of riparian buffers.

Scale of managing multiple stressors

Local action cannot halt global stressors. This poses a dilemma for environmental management, which can only attempt to compensate for the impacts of global stressors by reducing local stressors. Depending on the multi-stressor effect type, such compensation needs to be tackled differently. An additive effect setting, for instance, allows for mitigating any of the relevant stressors, while an antagonistic setting results in worsening of environmental conditions when removing the dampening stressor. In river systems the hierarchy of spatial scales is particularly relevant, with measures to mitigate local stressors (e.g. on river morphology) remaining ineffective if catchment-scale stressors (e.g. diffuse pollution from agriculture) still prevail.

Integrated water resources management

It is a truism that managing multiple stressors acting on rivers falls short when focused only on the watercourse itself. Any effective management of environmental resources requires a landscape-perspective, and in the case of rivers this perspective can be clearly delineated as the watershed or river catchment. From this fundamental landscape unit, the concept of integrated water resources management evolved, recognizing the close linkage of water, energy and food within and across river catchments (Ibisch et al., 2016). Integrated management suggests a comprehensive, participatory planning and implementation approach for managing and developing water resources by embracing all three (social, economic and environmental) "pillars of sustainability" (Purvis et al., 2019). Management solutions should be based on an integrated understanding of the socio-ecological system, in which the interplay of social, economic and environmental matters is respected. Such a "systemic management" is highly ambitious and poses major challenges to implementation (e.g. of the European Water Framework Directive; Voulvoulis et al., 2017).

Nature-based solutions

Multiply stressed rivers are indicative of the environmental crisis increasingly threatening economic and social stability, public health and well-being. In the face of this global crisis manifesting in climate change and biodiversity loss, "systemic solutions" are called for, promoting a shift from human-engineered technical solutions (often employing concrete and steel at high direct and collateral costs) to "nature-based solutions" (Cohen-Shacham et al., 2016). Such solutions are conceived as measures generating multiple benefits by reducing environmental and social vulnerabilities, mitigating climate change, improving human health and well-being, and providing jobs and business opportunities at best (EEA, 2021) — an ideal prospect to meet the pressing global challenges. This is the vision popularized by the Millennium Ecosystem Assessment (2005) and signed up to in the European Green Deal (EC, 2019). At its heart lies the extensive conservation and restoration of riverine (and other) landscapes. In the years to come, the success of this venture will, in no small part, be indicated by the state of rivers, which represent the sentinels of mankind's sustainable relationship with nature.

Conclusions/synthesis

The "great acceleration" (Steffen et al., 2015) describing the simultaneous rise in various human activities and degradation of natural resources is rushing onward across the globe. The surge in driving forces amplifies the intensity of environmental stressors. At the global scale, streams and rivers affected by multiple stressors can now be considered the norm rather than the exception. However, the lack of monitoring data and systems understanding obstructs causal diagnosis and the prediction of effects. The active mitigation of multiple stressors is thus uncertain – it requires approaches that integrate across all (direct and indirect) driving forces within the catchment and beyond, demanding the high price of a societal transformation away from single-purpose sectoral interventions toward multi-benefit sustainability solutions. The words are on everyone's lips these days – truly efficient measures are yet to be taken.

Knowledge gaps

- Mechanistic understanding of the effects of stressor interactions is scarce.
- Causal diagnosis and prediction of multi-stressor effects are highly uncertain.
- The interplay of biodiversity loss and climate is not yet been fully understood.
- The size and combination of measures to mitigate multiple stressor effects are unclear.
- Effective solutions require upscaling to the catchment-level integrating socio-economic factors – such integrative approaches are still in their infancy.
- Necessary governance structures required to mitigate multi-stressor effects are unknown.

This article was reviewed for the *Encyclopedia of Inland Waters*, Second Edition by Section Editor LeRoy Poff.

Glossary

Combined sewer system Urban water management system using a single network of pipes that conveys both wastewater and stormwater either to a treatment plant or to a distant, large receiving water (see also Separate sewer systems).
Effective imperviousness The proportion of a catchment covered by effective impervious surfaces (see *Imperviousness*), where "effective" connotes those surfaces that have a damaging effect on the receiving water. Impervious surfaces with direct stormwater drainage connection to a stream are effective; the effectiveness of other surfaces is usually considered to be near zero, but depends on the degree to which their runoff is retained, diverted or treated.
Flashiness (of stream flows) Increased magnitude and frequency of storm flows to streams, and shorter recession times of high-flow events.
Imperviousness The proportion of a catchment covered by surfaces that are impermeable to water (primarily, roofs, roads and paved areas). This may be referred to as 'total imperviousness' to distinguish it from *Effective imperviousness.*
Receiving water The stream, river, estuary, lake or coastal water into which an area of land or a pipe drains.
Separate sewer systems Urban water management system using a network of sewerage pipes that direct wastewater to a treatment plant, and a separate network of stormwater drainage pipes that direct urban stormwater runoff, usually untreated, to the nearest receiving water (see also Combined sewer systems).
Urban karst The network of drainage, sewerage and water-supply pipes, and high-permeability trenches around them and around other conduits constructed under urban areas, which influence groundwater and piped flows to streams.
Urban stormwater Runoff from impervious surfaces during and immediately after wet weather.
Urbanization The process of converting land, either from its native state or from agricultural use, to uses that support the concentrated assemblage of humans and their activities.
Wastewater Sewage, and domestic or industrial effluent.

Introduction

Rivers and streams have been at the heart of human settlements, towns and cities throughout history (Mumford, 1961). Their primary attraction for our earliest cities was as a supply of fresh water, but this ecosystem service was soon compromised by inflows of wastewater and runoff from the settled land. Smaller streams and drainage lines became eroded and polluted by the increased volumes of runoff from roofs, roads and compacted soils of these settlements. These challenges for early human settlements, together with the hazards of riverine flooding for settlements on floodplains, led to an evolution of approaches to urban water

☆*Change History:* October 2021. C Walsh made small updates in all sections.

management that continue to evolve today (Brown et al., 2009b). The deleterious changes to the natural functioning of rivers and streams flowing through our urban lands are the product of those management approaches.

While human population growth is likely to slow over the next century, peaking at 9–13 billion (United Nations, 2019), almost all of the additional 1–5 billion people beyond today's population will be urban dwellers (United Nations, 2018). As a result, the coverage of the world by urban lands will continue to increase over the next century, and many more reaches of many more rivers and streams globally will be affected by the ways urban land and water is managed.

This chapter provides an overview of the effects of urban land, and of urban land and water management, on streams and rivers. I begin by proposing a definition of urban land that quantifies dominant stressors to rivers and streams with urban land in their catchments. I describe the diversity of approaches to urban water management that determine the condition of urban rivers and streams, and the resulting in-stream hydrologic, geomorphic, and biological responses. I conclude by describing emerging approaches to urban water management that show potential for protecting and restoring urban streams.

Defining 'urban' as it affects rivers and streams

Urbanization is the process of converting land, either from its native state or from agricultural use, to uses that support the concentrated assemblage of humans and their activities. Most studies seeking to assess the effect of urbanization on stream ecosystems have used a measure of the density of agglomeration as a proportion of catchment area as the metric of 'urbanization'. Urban areas are most evidently defined by the replacement of vegetation and soil cover by hard surfaces, such as roofs, roads and paving, which are designed to be impermeable to water. These surface changes have led to 'imperviousness' being a primary measure of urban density in many studies of urban impacts on streams and rivers (Arnold Jr. and Gibbons, 1996). Other studies have used composite metrics that include measures such as the density of areas zoned as 'urban' land use or population- or socio-economic--based metrics (e.g., McMahon and Cuffney, 2000; Feist et al., 2017). In most cases, such studies have demonstrated responses in a range of stream indicators as a function of urban density when sites across a gradient of urban density are compared. The general conclusion from such studies has been that urbanization degrades streams.

If the mechanisms that drive the commonly observed degradation of streams with urban catchments are to be understood and better managed, then simple measures of urban density without a direct causal link to stream ecosystems are of limited use. To understand mechanisms of stream degradation, urban land changes need to be measured by the changes in vegetation and soil properties (including conversion to impervious surfaces), and in flow paths for water across (and under) the landscape.

Imperviousness is an important metric for assessing impacts on streams, because impervious surfaces prevent infiltration of water into soils, reducing both water lost to the air by plant transpiration and flows through soils to downstream waters. Less evident superficially than impervious coverage, urban areas are equally defined by networks of underground piped infrastructure for flows of water supply, wastewater disposal, and drainage of runoff. In addition, networks of gravel-filled trenches carrying conduits for services such as electricity, gas and telecommunications, can also act as conduits for subsurface flows of water. These complex underground networks of flow paths, termed the 'urban karst' by Kaushal and Belt (2012) lead to profound changes to catchment hydrology that dominate the impact of urban areas on rivers and streams.

Greater volumes of water run off impervious surfaces than from vegetated land because of reduced soil storage and uptake and loss of water to the air by transpiring plants (Fig. 1). The rapid drainage of this runoff through hydraulically efficient drainage networks greatly increases the frequency and severity of disturbances to receiving streams. Resulting changes to channel form, to in-stream animals and plants, and to ecological processes in streams are observed when as little as 1–2% of a catchment is sealed and drained in such a way (e.g., Walsh and Webb, 2016). Therefore, urban impacts on streams can be detected in streams and rivers that might not obviously be recognized as being 'urban'.

The degree to which stormwater infrastructure is implemented in catchments with only a little urban land is much more variable than in more densely urbanized catchments, because there is often less need for formal drainage at lower urban densities. Several studies have shown that stream degradation is better explained if imperviousness and drainage connection are both accounted for (Walsh et al., 2005a; Walsh and Kunapo, 2009; Hale et al., 2015; Baruch et al., 2018; Blaszczak et al., 2019). The longest-standing metric that does this is effective imperviousness, arising from Leopold's (1968) demonstration that hydrologic changes in urban catchments are a function of both imperviousness and the degree to which impervious areas are serviced by sealed stormwater drainage. The simplest definition of effective imperviousness is the proportion of a catchment covered by impervious surfaces with direct drainage connection to a stream, assuming that only directly connected surfaces are 'effective' (i.e., have a damaging effect on downstream waters). Variants that weight impervious surfaces by their degree of connection have also been proposed (e.g. Walsh and Kunapo, 2009), but directly connected impervious surfaces remain the dominant influence (Walsh et al., 2022). Despite their superior prediction of stream degradation, metrics that account for drainage connection in studies of urban impacts have relatively rarely been used, perhaps because they require drainage infrastructure data that, in many areas, can be difficult to source.

Thus, in this chapter, I define urban land by the increased imperviousness of its surfaces and by features of the underground urban karst, particularly the stormwater drainage network. Rather than defining an urban river or stream, I focus on the nature of urban stressors on streams, and how streams respond to them, noting that these stressors can potentially apply to a stream with even a very small area of urban land in its catchment.

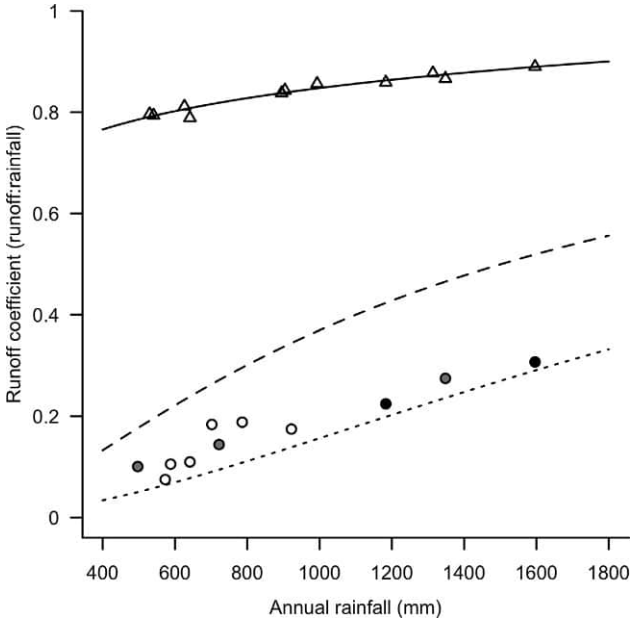

Fig. 1 Impervious runoff and streamflow coefficients for the Melbourne region. Estimated annual runoff coefficients (C) from impervious surfaces (open triangles) from sites across the Melbourne region as a function of mean annual rainfall (MAR). Regression line: $C = 0.230 + 0.206 \times \log_{10}(MAR)$. $R^2 = 0.94$. Annual streamflow coefficients from 11 streams with forested (closed circles), grassland (open circles) or mixed forested and grassland catchments (grey circles) across the Melbourne region as a function of mean annual rainfall. The lines surrounding these stream points are the relationships between streamflow derived by Zhang et al. (2001) for grassland (dashed curve) and forested catchments (dotted curve) of the world. Urban land and water management approaches that affect rivers and streams

Urban land use alters the water balance of catchments and the resulting flow regimes of rivers and streams primarily through one major influence, impervious runoff (stormwater) generation and the way it is drained or routed to stream channels. These effects can be moderated or compounded by other aspects of urban water management: wastewater and sewage disposal, infiltration of water into catchment soils, extraction of water from streams or the aquifers flowing to them, and channelization to mitigate riverine flooding. In this section, I discuss the history, nature and interactions of these influences.

Stormwater

When the increased runoff from roofs, road and compacted soils of human settlements exceeds the capacity of surrounding soils to absorb it, local flow lines become eroded and polluted. From the earliest human settlements to today, the primary solution to this problem has been to channelize, seal, or more recently, pipe the flow line from the source of the runoff to a downstream drainage line or stream. The cumulative effect of many such small drainage actions in an urban area is to increase flow volumes, erosion and pollution downstream. As the world's cities have grown, the positive feedback of many small-scale drainage actions has led to increasing the size of pipes and channels required to carry the increased flows and to armor or seal the beds and banks of streams and rivers downstream. In many cities, this process has resulted in some streams being obliterated entirely: buried and built over, the dominant flow path of water through stream sediments replaced by hydraulically efficient piped flow (Elmore and Kaushal, 2008; Walsh et al., 2016b).

Other aspects of urban water management (water supply and wastewater disposal) can ameliorate, worsen or displace these effects. However, stormwater drainage systems are fundamentally designed to alter catchment hydrologic processes and rapidly transport runoff and its associated pollutants to streams and rivers. Therefore, the way urban stormwater runoff is managed is a primary determinant of the condition of downstream rivers and streams.

Wastewater

Without reticulated sewerage or water supply, urban settlements historically relied on some variant of cesspools, essentially holes in the ground, for sewage disposal. With the advent of flush toilets and reticulated water supply, unsewered areas today more commonly deal with wastewater using septic tanks, which separate and disperse liquid waste into soil nearby. As long as septic systems, or indeed cesspools, do not overflow into drainage lines, their impacts on streams are likely to be restricted to the slow release of a subset of contaminants that are mobile through soil, such as nitrate (Walsh and Kunapo, 2009).

Reticulated sewerage is needed in more densely populated areas, and such systems are commonly classified into either (a) combined sewers, which convey both wastewater and stormwater either to a treatment plant or to a distant, large receiving water, or (b) separate sewers, where a network of sewerage pipes directs wastewater to a treatment plant, while stormwater drainage is directed in a separate network, usually untreated, to the nearest receiving water. Despite the binary classification, the two systems span a continuum. If their flow capacity is small, combined sewers can overflow untreated into local streams with a small amount of rain, creating hydraulic and chemical disturbances to the stream almost as frequently as separate sewers. At the other end of the continuum, separate sanitary sewers commonly receive some runoff inflows, either through leaky pipes or illicit cross-connections with stormwater drainage, and they are therefore also fitted with overflow structures that allow (infrequent) untreated sewage discharges during large storm events. Combined and separate sewers thus both vary in the frequency of stormwater flows and the frequency of flows contaminated by sewage.

Combined sewers have not been legally sanctioned in most legislatures since the mid-20th century, and are thus often considered characteristic of 'older' cities (e.g., Radcliffe, 2018). Yet the promotion of separate sewerage and drainage networks dates back to the earliest European efforts to formalize urban water management (Chadwick, 1842). Shifts in engineering preference, first for combined systems and increasingly in the 20th century for separate systems, were the result, in large part, of evolving understanding of water-borne disease transmission (Tarr, 1979). Until the late 1800s, it was thought that running waters purify wastewater, so that discharge of sewage effluent untreated into rivers upstream of drinking water intakes was acceptable. Combined sewer systems continue to operate today in North America, Europe and Asia; in most cases, they now include diversion to treatment plants which discharge a constant flow of treated effluent to usually larger receiving waters.

Combined sewer overflows into rivers and streams remain a widespread phenomenon and the focus of considerable municipal expenditure (e.g., USEPA, 2004). Management responses to reduce and mitigate overflows range from increasing the capacity of sewers by constructing bigger pipes (e.g., the Tunnel and Reservoir Plan of Chicago, Dalton and Kenny, 1981, and the underground discharge channel of Tokyo, MLITT, 2014), to increasing stormwater retention using methods discussed below under 'Protection and Restoration', to in some cases, conversion to separate sewers (e.g., Thorndahl et al., 2015). But reducing the impacts of sewer overflows does not address the environmental damage of separate stormwater flows into rivers. Indeed, when sewer overflows are infrequent, their impacts can be secondary and difficult to detect over broader degradation caused by stormwater drainage networks (Kellar et al., 2014).

In most modern cities of the world, sewage and wastewater disposal are well managed by being directed to treatment plants, which discharge treated effluent with reduced loads of pollutants to a larger receiving water downstream or to the sea for coastal cities. For inland cities, the effluent can be a point source of pollution to a river or stream. However, while sewage treatment technologies have improved and become widespread practice in most of the world, untreated sewage draining directly to rivers remains a problem for many cities of low-income countries (Capps et al., 2016).

Infiltration and extraction

Pipes and concrete drains are expensive. It is thus common to direct impervious runoff from at least some constructions into surrounding soils in areas, where the soils have sufficient infiltration capacity to absorb additional impervious runoff. For instance in Perth, Australia, where sandy soils are common, runoff from many roofs and roads drain to soak wells rather than connect to street drainage (Middleton et al., 2020). Where such practices are common, heightened water tables, potentially polluted, may increase groundwater flows to local streams and rivers. The prevalence of such practices in a city is likely to be influenced by a combination of soil properties, rainfall intensities and volumes, potential evaporation, and local regulatory norms. Infiltration into soils is increasingly being used as a 'low-impact' approach to stormwater management (see Protection and Restoration section).

Groundwater is an important water source in many regions of the world, and overextraction has caused land subsidence in areas such as the Mekong Delta (Minderhoud et al., 2017). Groundwater extraction can potentially lead to reduced flows in streams (e.g., Rosburg et al., 2017), but groundwater extraction has not commonly been reported as a cause of reduced stream flows in urban areas.

Channel engineering

The conversion of streams to lined drains and pipes is usually motivated by the increased frequency and intensity of floods caused by runoff from impervious surfaces in urban catchments. Such motivations can extend to engineering larger rivers downstream. However, channelization, leveeing or armoring of large rivers flowing through cities and towns is more commonly aimed at protecting urban lands from riverine flooding, i.e., infrequent large floods from larger, non-urban catchments upstream.

The effects of urban land on stream ecosystems

The changes to catchment processes, arising from the manifold urban land and water management activities, degrade streams and rivers. Around the world, streams of cities and towns are typified by in-stream habitats, biotic assemblages, food webs, and ecosystem processes that are altered, and by ecological values and services, provided by healthy stream ecosystems, that are diminished or lost (Paul and Meyer, 2001; Walsh et al., 2005b). The dominant impact is the increased frequency and magnitude

of disturbance, both *hydraulic* (arising from larger, more frequent high-flow events) and *chemical* (arising primarily from the complex conglomeration of pollutants in impervious runoff and secondarily and more variably, in wastewater and altered groundwater flows). Hydraulic changes also simplify or homogenize in-stream habitat by increasing the capacity of streams to transport sediments. In this section, I first consider the hydrologic changes that drive the hydraulic and chemical disturbances, then the resulting geomorphic and chemical changes, before considering changes to biotic assemblages and ecosystem functions of streams.

Hydrology

Runoff from impervious surfaces through sealed drains tends to increase the total volume of runoff (Fig. 1), and the 'flashiness' of flows: i.e., increased magnitude and frequency of storm flows to streams, and shorter recession times of high-flow events (Fig. 2; Burns et al., 2012). While increased flashiness is commonly observed, it is reduced in regions where precipitation falls as snow, and runoff is buffered by snow-melt (Hopkins et al., 2015). The degree of flashiness from impervious runoff can also be ameliorated if the runoff is infiltrated into catchment soils. The effect of infiltration and evaporation from retention systems has even been reported to reduce the flashiness of flows compared to non-urban streams in arid Phoenix, Arizona (Hopkins et al., 2015). It has also been noted that urban-induced increases in flashiness of stream flows can be smaller in regions with naturally flashy streams (e.g., the tropical streams of Puerto Rico, Ramirez et al., 2009).

Because impervious surfaces and sealed drains prevent infiltration into soils, urban stormwater runoff and drainage contribute to reduced baseflows in streams. While reduced baseflows are observed in streams of some urban catchments (Fig. 2), baseflow responses vary among urban catchments within and between cities (Bhaskar et al., 2016; Hopkins et al., 2015). The size and direction of change in baseflows downstream of urban areas depend on the complex interactions of the degree of baseflow contribution to the stream before urbanization, the extent to which the stream channel has been incised, the amount of infiltration of urban stormwater runoff in the catchment, the amount of catchment vegetation (which drives evapotranspiration losses), and inflows into the stormwater drainage system or the stream from catchment water supply and wastewater systems (Bhaskar et al., 2016). While stormwater infiltration is likely to increase flows to receiving streams, the extent to which such flows become baseflow similar to a pre-urban catchment is highly unpredictable given the complexities of the urban karst (Bonneau et al., 2017).

Geomorphology

Altered flow regimes resulting from urban runoff increase erosive forces on stream channels. Sediment supply in urban catchments rises rapidly during urban construction, followed by a decrease when development is complete (Wolman, 1967), usually stabilizing higher than pre-construction levels (Chin, 2006; Russell et al., 2017). Supply of coarse sediments from established urban land can

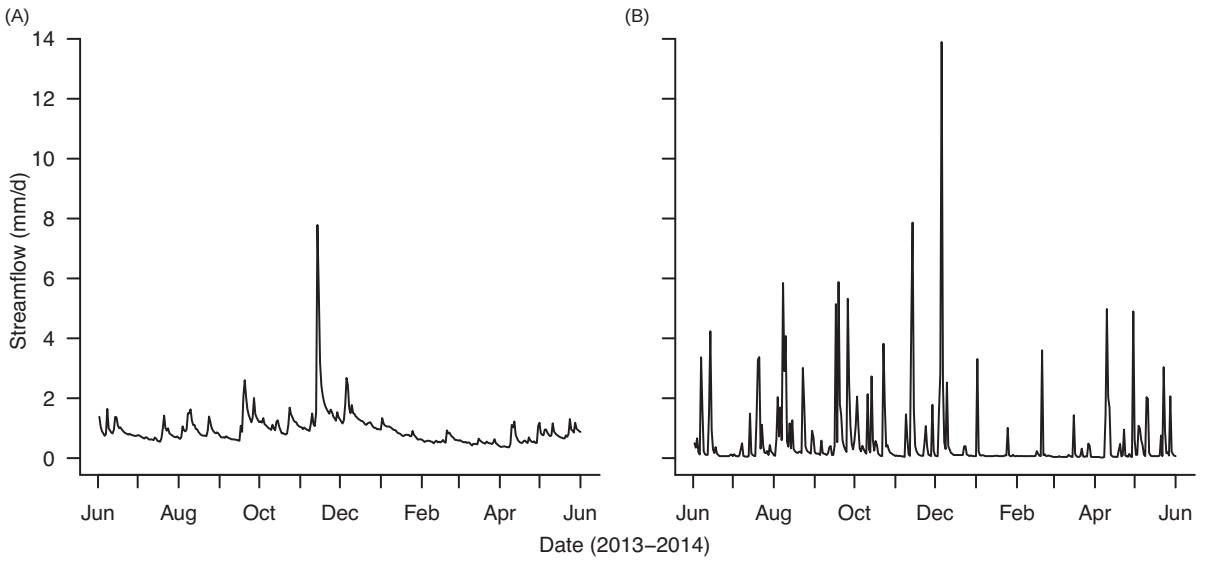

Fig. 2 After Burns MJ, Fletcher TD, Walsh CJ, Ladson AR and Hatt BE (2012) Hydrologic shortcomings of conventional urban stormwater management and opportunities for reform. *Landscape and Urban Planning* **105**: 230–240, contrasting daily stream flow patterns over a typical year in: (A) Olinda Creek with a forested catchment; and (B) Brushy Creek, a comparable, nearby stream with an urban catchment. Note higher baseflows, and much smaller high-flow responses to most rain events, with longer recession times in Olinda Creek. There was a single large high-flow disturbance in Olinda over the year compared to >20 in Brushy Creek. (A) catchment area 9.1 km^2, effective imperviousness (EI) 0.1%, data from research flow gauge used by Walsh et al. (2015). (B) catchment area 14.9 km^2, EI 23.5%, Melbourne Water flow gauge station 229,249.

be substantial, with yields well above those from comparable non-urban land (Smith and Wilcock, 2015; Russell et al., 2018). Increases in sediment supply can persist for decades from informal settlements in poorer cities, because of unsealed roads and poor environmental controls (e.g., Taniguchi et al., 2018). However, the increased sediment supply delivered to streams through stormwater drainage networks is generally moved efficiently through streams by stream flows that are greatly increased by stormwater runoff (Russell et al., 2020).

As a result, eroded, widened, and incised channels are a common characteristic of streams in urban catchments, and such changes reduce habitat heterogeneity, even at low levels of effective imperviousness (Vietz et al., 2014; Hawley et al., 2013). When permitted to erode, "natural" stream channels (i.e., that are not armored, lined or piped) adjust to a new urban flow and sediment regime. The longest-standing, and most commonly reported model of channel evolution in response to urbanization is a sequence of channel incision, and bank failure to create a deeper, wider channel, followed by re-establishment of a lower floodplain or channel system (e.g., Hawley et al., 2020). However, channel responses can vary depending on initial conditions and constraints, such as slope and erodibility of bed and bank materials, multi- vs. single-thread channels (Booth and Fischenich, 2015), and road crossings (e.g., Taniguchi et al., 2018). Concerningly for restoration potential, if a channel has enlarged, erosive hydraulic conditions are likely to persist, even if flashy flows from the catchment are mitigated (Anim et al., 2019).

Water quality

Streams of urban catchments typically carry higher concentrations, and export larger loads of a greater diversity of contaminants than non-urban streams. This results from two overarching attributes of urban areas. First, cities and urban areas in general are remarkable global features for the amount and diversity of materials (e.g., water, food, chemicals, building materials) that their human populations import into them (Kennedy et al., 2007). As a result, urban areas have greatly increased sources and stores of potential pollutants to downstream waters. The second attribute is stormwater drainage, which when designed in its conventional form, greatly increases the likelihood that a spill of a chemical on an impervious surface will flow to its receiving water, or that leaf litter (and other litter), sediments and associated pollutants on urban surfaces will be carried to the stream during a rain event. Chemical and physical weathering of the carbonate-rich materials, such as concrete, that make up much of the urban built environment, add to the cocktail of pollutants that the drainage system delivers to receiving streams (Kaushal et al., 2017). Groundwater flows can also contribute to stream pollution (Roy and Bickerton, 2012), particularly when stormwater (or imported water) are directed to catchment soils at greater rates than can be used by catchment vegetation. Stormwater and groundwater pollution will be worsened if untreated wastewater also mixes with these water sources. And finally, effluents from wastewater treatment plants can be a source of some pollutants.

The combination and quantity of contaminants in urban stream water are highly variable, given the diversity of potential sources and processes. In addition to contaminants, temperature is an important element of water quality, as a fundamental regulator of chemical transformations in catchments and streams (Kaushal et al., 2014a) and of in-stream biological processes. Efficient drainage of water from warm impervious surfaces and the widened channels and often cleared streamside vegetation of streams in urban catchments result in elevated stream temperatures (Somers et al., 2013).

Nitrogen enrichment from human activities is a growing global problem to which streams of urban catchments are significant contributors (Bernhardt et al., 2008). Atmospheric deposition of nitrogen, which is the primary source of nitrogen in natural catchments, is augmented in urban catchments by nitrogen in imported water, food and chemicals. Urban stormwater drainage delivers catchment nitrogen to streams from diverse sources such as: leaks, cross-connections, or combined flow paths with sanitary sewer systems; deposition on roofs and roads, which can be heightened from vehicle exhausts (Bettez and Groffman, 2013); or garden fertilizers through volatilization and deposition or flow to drainage or groundwater (Kaushal et al., 2020). Nitrogen seepage to groundwater, particularly as mobile nitrate-nitrite, from septic tanks (Walsh and Kunapo, 2009; Kaushal et al., 2006) or from leaky sanitary sewers can also contribute to increased dry-weather concentrations. Drainage systems and the compacted soils of urban catchments tend to reduce the opportunity for nitrogen transformation processes, such as denitrification—which reduces dissolved nitrate to gaseous nitrogen—although areas such as urban riparian groundwaters can act as hotspots for such processes.

Urban catchments are also rich in sources of phosphorus (e.g., food, sewage, fertilizers), which can lead to increased concentrations in streams. Phosphorus from these and other sources, particularly fine sediments on impervious surfaces, can be efficiently transported by stormwater drainage systems. Increased phosphorus concentrations can lead to increased algal and microbial growth. Unlike nitrogen, which can be lost from aquatic ecosystems through denitrification, phosphorus can only be removed by biological uptake, sorption onto particles that are then buried, or incorporation into a mineral that is precipitated. Sorption onto particles can be negatively affected by other chemical processes such as increased salinity (Kaushal et al., 2020).

Increased salinity is a particular problem where road salting is common practice (e.g., Wallace and Biastoch, 2016), potentially collecting in groundwater and chronically increasing salinity levels throughout the year (Cooper et al., 2014). However, increased salt concentrations are also observed in urban areas without snow accumulation, as a result of sewage inputs (Kaushal et al., 2014b) and leaching and weathering from built surfaces, particularly concrete (Wright et al., 2011; Kaushal et al., 2017). The weathering of concrete tends to make stream water more alkaline, typically affording streams in urban catchments a strong acid neutralization capacity. As a result, streams of urban catchments can remain alkaline, even in cases where disturbance of catchment soils has resulted in soil acidification (Kaushal et al., 2020).

Streams of urban catchments also tend to be enriched with dissolved organic matter with low molecular weight compared to humic organic matter that is more common in natural streams (Kaushal et al., 2020), potentially driven by increased algal growth

Table 1 Selected sources of trace elements in the urban built environment and the typical dominant elements for each source.

Urban source	*Trace elements*
Gasoline combustion	Pb, Mn
Coal combustion	V, Ni, Cr, Pb, Mn, Zn, Cu, As, Mo, Sb, Ti, Hg, Cd, Se, Mo
Oil combustion	V, Ni, Cr, Pb, Mn, Zn, Cu, As, Mo, Sb, Ti, Cd
Refuse incineration (highly variable)	Pb, Zn, Cr, Mn, Cu, As, Ni, Hg, Sb, Sn, V, Se, Cd
Municipal wastewater treatment	Mn, Ni, Zn, Cr, Cu, As, Pb, Cd
Sewage sludge	B, Cr, Pb, As, Zn, Sb, Sn
Motor oil	V, Zn, Cr, Cu, Pb, Ni, Mo
Vehicular and industrial discharge	Zn, Pb, As, Cr, Cu
Vehicle brake and tire wear	Cd, Cu, Zn, Pb, Sb, Ni, Zn
Leakage from pipes	Sr, Se
Corrosion of metal objects	Mn, V, Co, Mo
Atmospheric deposition	Pb, Zn, Cu, Ni, As, Mn, Cr, V

Adapted from Kaushal SS, Wood KL, Galella JG, Gion AM, Haq S, Goodling PJ, Haviland KA, Reimer JE, Morel CJ and Wessel B (2020) Making 'chemical cocktails'–Evolution of urban geochemical processes across the Periodic Table of elements. *Applied Geochemistry* 119: 104632.

(Imberger et al., 2014). They also typically carry trace-level concentrations of a cocktail of synthetic organic compounds, such as pesticides, polycyclic aromatic hydrocarbons, and legacy contaminants including polychlorinated biphenyls. Compounds such as steroidal hormones, pharmaceuticals and chemicals found in personal care products are also common, presumably associated with sewage contamination.

The complex cocktail of pollutants also includes elevated concentrations of a vast array of metals (Table 1), delivered efficiently to streams by stormwater drainage systems. The mobility and toxicity of metals are modified by interactions with other contaminants, particularly inorganic and organic colloids. More broadly, the complex mixture of pollutants interact in many ways, including potentially synergistic effects in their effects on stream biota. Management of such complexity is likely to only be possible through a holistic approach that seeks shared sources, transport mechanisms and transformation processes (Kaushal et al., 2020).

Biology

The inter-related effects of physical disturbances resulting from altered flow and sediment regimes and altered channel forms, reduced habitat heterogeneity, and the complex changes to stream chemistry in both storm and base flows result in substantial changes to in-stream biotic communities. These changes are typified by loss or reduced abundance of sensitive species, increased abundances of (usually fewer, often cosmopolitan or invasive) tolerant species, and altered ecosystem processes (Paul and Meyer, 2001; Walsh et al., 2005b).

Microbial assemblage composition both in the water column and in stream sediments shifts with increasing urban impacts, including altered composition of denitrifying bacteria assemblages, possibly mediated by changed sediment size (Perryman et al., 2011). Hosen et al. (2017) concluded that microbial community composition in the water column is driven by regional factors related to watershed land use, while sediment bacterial community composition is more strongly controlled by local physicochemistry. Function of microbial assemblages can also be affected by urbanization. Microbial biofilm communities of urban streams in Baltimore streams have developed drug resistance, maintaining respiration rates in response to pharmaceutical exposure that depresses respiration in less urban streams (Rosi et al., 2018). Pathogenic microbes can also be found in streams of urban catchments from variable sources such as animal feces on impervious surfaces washing into stormwater drainage systems, through sewage contamination of stormwater flows, and through discharge of inadequately treated sewage (Ahmed et al., 2019).

Increasing urban impacts also shift the composition of algal assemblages on stream beds, with tolerant species replacing sensitive species, often with little change in species richness, both in streams dominated by stormwater flows (Sonneman et al., 2001; Newall and Walsh, 2005) and those with sewage pollution (Tornés et al., 2018). In severely degraded streams, streambeds can be covered by mats of organic matter, cyanobacteria, iron bacteria, sewage fungus, and algae, replacing the basal food sources such as leaf-litter and biofilms that are typical of less disturbed streams (Faulkner et al., 2000; Yule et al., 2015). Increased light and nutrient concentrations associated with stormwater runoff tend to increase algal growth (Taylor et al., 2004). For example, under controlled conditions of light, algal growth increased with increasing effective imperviousness (Catford et al., 2007). Physical scouring by frequent stormflows can reduce algal growth, but algal regrowth can be rapid (Murdock et al., 2004). However nutrient concentrations in stormwater are variable: a mesocosm study of differing concentrations of collected stormwater found no difference in algal growth, but substantial difference in algal assemblage composition with different amounts of stormwater (Johnson et al., 2011) The effects of nutrient enrichment on algae can also be countered by herbicide pollution (Waite et al., 2019).

The diversity of stream invertebrates declines with increasing urban impacts, with many sensitive species becoming rare or absent in streams with as little as 2.5% effective imperviousness (Walsh and Webb, 2016; King et al., 2011). Mayflies, stoneflies and caddisflies are commonly cited as sensitive taxa, but sensitive species occur in all taxonomic groups, including groups such as oligochaete worms that tend to be dominated by species that are tolerant to disturbance. The diverse group of sensitive species is

replaced by a smaller group of tolerant species dominated by oligochaetes, chironomid midges, and gastropod snails. Where it has been measured, stormwater drainage connection explains the shifts in invertebrate assemblages better than simple measures of urban density (Walsh, 2004; Baruch et al., 2018). The invertebrates that can tolerate urban stormwater impacts tend to contain higher levels of contaminants such as metals in their tissues (Baruch et al., 2018). Stormwater impacts to invertebrates are worsened by intermittent flow (King et al., 2016) and by barriers to dispersal such as road culverts or lack of catchment forest cover (Smith et al., 2009; Blakely et al., 2006). Stormwater impacts on invertebrate assemblages can be ameliorated to some extent by improved habitat afforded by riparian vegetation (Walsh and Webb, 2016). In Perth, Australia, where the landscape is highly permeable, stormwater infiltration is common, and the regional pool of invertebrate taxa is small, riparian vegetation was found to be a stronger determinant of invertebrate assemblages than urban density (Gwinn et al., 2018).

Fish assemblages also shift with increasing urban impacts, with sensitive species being replaced by more tolerant, often exotic species (e.g., Roy et al., 2005; Meador et al., 2005; Pompeu et al., 2005). Fish species of urban streams tend to be backwater, substrate-generalist species rather than riffle specialists associated with boulders and gravel (Brown et al., 2009a). However, such effects are less pronounced in coastal tropical streams, where diadromous species (i.e., those that migrate between the sea and streams) dominate assemblages (Ramirez et al., 2012; Lisi et al., 2018). For such species, local physical habitat conditions can be more important determinants of their abundance than catchment urbanization (Engman and Ramirez, 2012). Exotic species can be more abundant in such urban systems during drought (Ramírez et al., 2018). More broadly, mobile species such as many fish (and the stream-dependent platypus in Australia: Martin et al., 2014) can inhabit streams with high degrees of catchment urbanization if there is connectivity with a meta-population in less disturbed streams (Czeglédi et al., 2020). Nevertheless, there are diadromous species that are very sensitive to urban stormwater impacts (e.g., Puget Sound coho Salmon in Washington USA: Scholz et al., 2011).

Stream-dwelling amphibians are also susceptible to urban impacts. The complex inter-related effects of urban stormwater are likely to be primary drivers of declines in stream amphibian populations. Barrett et al. (2010) demonstrated that increased flow disturbance was a primary mechanism for loss of larval two-lined salamanders, whereas Canessa and Parris (2013) inferred that the effects of urban stormwater were indirect via its negative effect on aquatic vegetation. Other factors potentially causing decline in stream amphibian richness include barriers to movement such as roads (Canessa and Parris, 2013) and predation by invasive species (Riley et al., 2005).

These changes to the structure of biotic communities in streams affected by urban land use are associated with a range of changes to ecosystem function. However, studies seeking relationships between measures of ecosystem function and those of urban land use are less common than studies of biological structure, making generalizations difficult. Gross primary productivity (GPP) was higher in urban streams than reference streams across the US, but there was no difference among land use categories for ecosystem respiration (ER) (Bernot et al., 2010). The ratio of GPP to ER was higher in urban streams than rural streams in Japan (Iwata et al., 2007). GPP and ER are both greatly reduced by stream burial (Pennino et al., 2014). Increased volumes and flashiness of flows with urbanization lead to greatly reduced retention of contaminants in catchments. Contaminant retention, including denitrification, at least during low flows, can be increased where water can interact with sediments, in the catchment, in the stream or through floodplain soils (Newcomer Johnson et al., 2014). Denitrification is also affected by the changes in carbon sources that typify urban areas (Newcomer et al., 2012). Mechanisms by which leaf litter in streams is broken down changes under urban impacts, in that shredder invertebrates tend to be less abundant, but microbial breakdown and physical abrasion from flows both increase (Imberger et al., 2008; Paul et al., 2006). Snails that scrape biofilms from leaf material may also play an increased role in breakdown (Xiang et al., 2019).

Protection and restoration

Despite this chapter's focus on the severe impacts of typical urban land and water management practices, there is evidence that stream ecosystems need not be strongly degraded in urban catchments. For instance, Sassafras Creek on the eastern edge of Melbourne has 8% of its catchment covered by impervious surfaces, but there is very little piped infrastructure, with almost all runoff being directed informally to the deep forested soils of the catchment upslope of the creek. The flow regime, water quality and stream biota of the creek closely resemble those of comparable undeveloped catchments nearby, except for elevated nitrate concentrations from its septic tanks (Walsh et al., 2012; Hatt et al., 2004; Walsh, 2004). This unplanned protection of a stream from its catchment's urban development points to the potential for protection and restoration of other urban streams, if urban water were to be managed differently.

However, this example is a rare exception to the general observation that streams of urban catchments support fewer species and provide lesser ecosystem services than comparable streams without urban impacts. Substantially improving the state of the world's urban streams will require systemic changes to urban land and water management practices. The challenge of reducing loads of pollutants flowing into streams could be aided by reducing imports of resources (water, food, chemicals, building materials) into cities (Kennedy et al., 2007), requiring increased uptake of local production, recycling and reuse. A primary water management imperative is the prevention of untreated sewage or wastewater flows into streams and minimizing treated wastewater flows. However, even with wastewater well managed, streams of urban areas will remain degraded if urban stormwater runoff is permitted to drain uncontrolled to them.

Technologies for low-impact stormwater management are well developed and widely applied around the world (Fletcher et al., 2015). However, they have rarely been applied at a scale and intensity that is required for stream protection. Walsh et al. (2016a)

proposed that stormwater management for stream protection requires mimicking the predevelopment water balance of evapotranspiration, stream flow and infiltration through the application of stormwater control measures that filter runoff from all catchment impervious surfaces, providing filtered flows in a pattern and quality similar to the predevelopment flow and water quality regime. Achieving such aims requires the use or loss of a large proportion of urban stormwater runoff to prevent it from becoming stream flow, which would subsequently present a large, largely untapped freshwater resource for the world's cities (Walsh et al., 2012). Water supply is only one of many co-benefits to human populations that could be gained by stormwater management for stream protection (Walsh et al., 2016a).

Transformation of urban water management is an aim that remains elusive in most of the world. Yet, some benefits to stream ecosystems can be accrued through smaller-scale management actions (Smith et al., 2016). Reduced habitat heterogeneity of streams is often compounded in urban settings by clearing of riparian vegetation. Loss of riparian trees increases erosion of banks, and together with widened channels, increases light falling on the stream and temperature of stream water, and decreases inputs of leaf litter and woody debris. While several studies have found that the effects of riparian vegetation on stream ecosystems are diminished by catchment urbanization (e.g., Roy et al., 2007; Walsh and Webb, 2016; White and Walsh, 2020), taxa that are tolerant to some degree of urban impacts are benefitted by riparian forest cover (Walsh and Webb, 2016; Gwinn et al., 2018) or by an increase in habitat complexity (White and Walsh, 2020). Riparian forest can also improve water quality (Middleton et al., 2020), and re-engaging flow through floodplain soils can increase soil denitrification rates (Newcomer Johnson et al., 2014).

Small-scale restoration of habitat heterogeneity remains a common management action on streams of urban areas despite the overarching mismatch between the small scale of the action, and the large catchment-scale of the problem (Bernhardt and Palmer, 2011). However, examples of stream protection or restoration through better stormwater management at the catchment scale are increasingly common (Roy et al., 2014; Walsh et al., 2015; Hopkins et al., 2020). Increasing uptake of new approaches to stormwater management brings hope that the nexus between cities and towns, and degraded streams and rivers can be broken, but it will require changes to governance and economics. This will require new approaches to planning, including more landscape ecological input into planning processes to permit reservation of important parts of the landscape for ecosystem services of water and contaminant retention. It will also require that construction and maintenance of drainage become an integral part of broader urban water management to allow increased harvesting and use of stormwater. To accelerate the process of change, stronger scientific evidence is required. Such an aim calls for better standardization and adoption of more causal measures of urban impact on streams (such as effective imperviousness), and more experimental studies to assess and improve the efficacy of stormwater control and other management approaches across the world's cities.

Effects of Dams on Rivers

John C Schmidt, Center for Colorado River Studies, Department of Watershed Sciences, Utah State University, Logan, UT, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

Bedload The part of the sediment load transported by a river that occurs near the channel bed and intermittently bounces or rolls along the bed. Typically, bedload is medium and coarser sand, gravel, cobbles, and boulders.
Edge habitat The transition zone between the area directly affected by a dam and reservoir and distant unaffected areas.
Epilimnion The upper layer in a stratified reservoir.
Hydropeaking The practice of releasing water from a reservoir to produce hydroelectricity during times of day when demand for electricity is greatest.
Hypolimnion The lower layer of a stratified reservoir, typically cooler and more saline than higher layers and more stagnant.
Penstocks The pipes at a dam that carry water from a reservoir to the powerplant and turbines where electricity is generated.
River outlets The pipes at a dam that carry water from the reservoir directly downstream and by-pass the powerplant. Typically, these facilities are used in emergencies and to generate occasional controlled floods.
Suspended load That part of the sediment load of a river that is transported aloft in the stream flow and is supported by the turbulence of the fluid. Typically, the suspended load is medium and finer sand, silt, and clay.
Tailwaters The thermally altered regulated river immediately downstream from a dam.

Introduction

Damming of rivers is "one of the most dramatic and widespread deliberate impacts of humans on the natural environment" (Petts, 1984; Dynesius and Nilsson, 1994). A large body of scientific and management literature has emerged during the past 40 years that documents the many ways that dams, and the associated reservoirs and off-channel diversions, have altered natural riverine ecosystems.

The impacts of dams are widespread. The World Commission on Dams (2000) reported that there are more than 45,000 large dams, and the National Inventory of Dams for the United States listed 91,457 barriers (U. S. Army Corps of Engineers, 2020). The total active storage of the world's reservoirs is 9% of the natural flow of the affected rivers, and reservoir storage greatly exceeds mean annual flow in some places, such as the Riviere Manicouagan, Colorado River, Rio Grande, and La Grande Riviere in North America (Hirsch et al., 1990; Dynesius and Nilsson, 1994). Vorosmarty et al. (2003) estimated that 25–30% of the total natural flux of sediment is now trapped in reservoirs and is not delivered to the sea.

Metrics that describe the size and significance of dams

Dams are typically described by their height, reservoir storage capacity in relation to mean annual inflow, the capacity of the dam's withdrawal structures in relation to the pre-dam flood regime, and the elevation and adjustability of the dam's withdrawal structures. The World Commission on Dams (2000) defined large dams as any constructed barrier whose height is at least 15 m, or barriers at least 5 m high and whose storage capacity is at least 3×10^6 m^3. Hirsch et al. (1990) identified the ratio of watershed reservoir storage to mean annual flow as representative of the ability of dams to regulate and transform the natural flow regime. They calculated this ratio for the 36 water resource regions of the United States and Canada and showed that the Colorado River basin has the largest ratio of 3.34. Other regions where the ratio is >1 are the upper Colorado River, Rio Grande, South Saskatchewan, Missouri, and Churchill. Batalla et al. (2004) referred to this ratio as the *impounded runoff index* and calculated this value for 38 gage sites in the Ebro River watershed in northeastern Spain. Singer (2007) modified this ratio by changing the denominator to the median annual flood volume, rather than the mean annual flow. Although there have been no comprehensive classifications of dams by capacity or elevation of withdrawal structures, the ratio of the maximum capacity of the penstocks to the mean annual pre-dam flood characterizes the ability to regulate floods. Dams that can release water from the bottom of reservoirs have the ability to flush sediment downstream, whereas dams with higher elevation release structures cannot. The Three Gorges Dam on the Yangtze River is the largest dam in the world with low elevation river outlets that allow sediment flushing downstream (Ren et al., 2021). Another metric that describes the significance of dams is the proportion of a river's length that has been converted to reservoirs.

The many effects of dams and reservoirs

There are three attributes of dams that affect rivers and river ecosystems: the direct effects of the existence of dams, the effects of depletions or additions of stream flow facilitated by dams, and the effects of reservoir operations (Fig. 1). It is useful to distinguish these different effects, because it is typically cheaper and less controversial to change operations than it is to remove or re-engineer infrastructure.

The primary effect of the existence of dams is fragmentation of the channel network. The degree of fragmentation depends on the height of each structure (Fuller et al., 2015). Tall dams are complete barriers to the movement of most organisms, and the large reservoirs created by these dams transform the river upstream from each barrier. Reservoir releases may affect water quality and ecosystems for 100s of kilometers downstream. Shorter dams, including diversion dams, are typically more permeable barriers, do not block the movement of most organisms at high discharge, and the downstream effects typically extend for shorter distances.

Other effects of dams are caused by the style of reservoir operation that might be for flood control, hydroelectricity generation, or provision of a water supply. Some effects are transitional between those associated with the existence of the infrastructure and those with operations. For example, the existence of large dams allows the incoming sediment and organic matter loads to be trapped, and the trap efficiency partly depends on the size of each reservoir in relation to the magnitude of the incoming flow. However, trap efficiency also depends on how each reservoir is operated, because reservoirs that vary greatly in water storage during the year are less efficient in trapping sediment than reservoirs that maintain relatively constant storage contents (Kondolf et al., 2014a).

Another example of transitional effects of dams concerns the temperature of reservoir releases. These effects depend on both the size of the dam and on reservoir operations. Large reservoirs thermally stratify in summer. If the engineering structures that release water downstream are at a fixed elevation, as is typically the case, then the released water from the reservoir's hypolimnion when the reservoir is relatively full is cooler than is naturally the case in summer. However, the temperature of summer releases is warmer

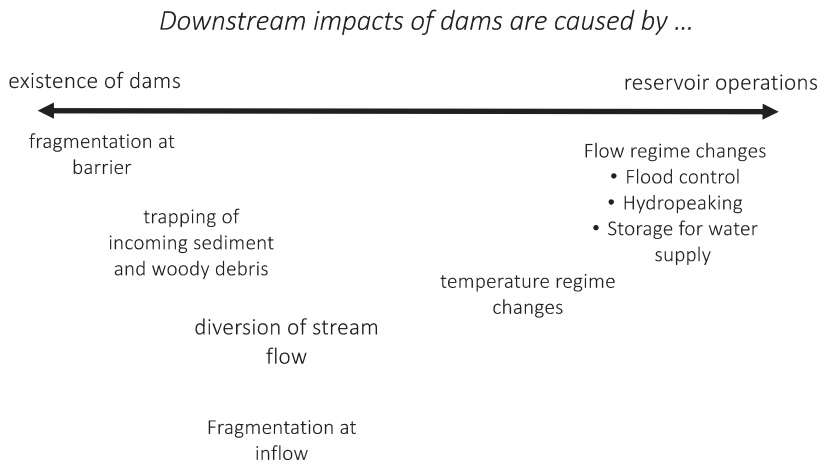

Fig. 1 Types of impacts caused by dams.

if the reservoir is relatively empty, and water is drawn from the epilimnion. Water is warmer in the winter and may reduce the frequency of downstream ice cover. Additionally, releases from the epilimnion have the potential of entraining reservoir fish and delivering those species to the downstream river environment.

Stream-flow diversion is often facilitated by reservoirs, and the reduction in total annual flow may disproportionately reduce the magnitude of floods or base flows. Depletions of flood flow reduce sediment transport and may lead to downstream channel aggradation if the sediment supply exceeds the transport capacity of the regulated flow. Conversely, augmented stream flows associated with trans-basin delivery to an adjoining watershed increases the flow regime of the receiving stream, potentially causing increased sediment transport capacity and channel enlargement.

Reservoir operations are the primary control on the downstream flow regime of regulated rivers. Operations that emphasize flood control maintain relatively low reservoir storage when the flood season begins and have an objective to store the incoming flood within the reservoir. Operations that emphasize water supply typically maintain relatively full reservoir storage. Operations that emphasize hydroelectricity production increase reservoir releases in those months and hours when electricity demand is greatest.

Effects of the existence of dams

Fragmentation

Although river networks can be naturally fragmented by waterfalls, cascades, or beaver dams, barriers constructed or caused by humans have significant impact on the world's freshwater ecosystems (Benke, 1990). Dynesius and Nilsson (1994) found that 77% of the total discharge of the large rivers of the northern third of Earth are strongly or moderately affected by dam-caused fragmentation. Barriers affect biodiversity by blocking the movement of organisms, and the degree of blockage is called barrier permeability. Another way that biodiversity is affected is that the perturbations in flow, sediment supply, and thermal regimes caused by dams and reservoirs that are described below can persist far downstream. The area where these perturbations are significant constitute *edge habitat*, defined as the transition zone between the area directly affected by each barrier and reservoir and distant areas whose flow, sediment supply, and thermal regimes are unaffected (Fig. 2). The entire mainstem of many extensively developed rivers is edge habitat (Fuller et al., 2015).

Large dams are impermeable to upstream migrating fish and aquatic organisms, unless fish passage structures such as fish ladders are constructed. On the Columbia River, for example, such structures have been built at many mainstem dams to facilitate the spawning migration of salmon upstream to the points where Grand Coulee Dam and the Hells Canyon complex of dams completely block migration. Elsewhere, mitigation strategies have been proposed to increase barrier permeability by trucking fish around barriers and reservoirs, such as on the Yuba River in California (Yuba Water Agency, 2020).

Large reservoirs created by high dams may be impermeable to downstream migrating fish and other aquatic organisms, especially where native fish larvae or juvenile fish are prey for nonnative reservoir fish or where larvae cannot swim across long reservoirs. Nevertheless, these barriers are not completely impermeable, and non-native reservoir fish can be entrained in the penstocks that transfer water through turbines that generate hydroelectricity. Even though the survival rate of these fish may be very low, this mechanism is one way that competing and predatory non-native fish invade a native fish community downstream from a dam. Low dams, including diversion dams, may only be impermeable to upstream migration of fish at very low flow.

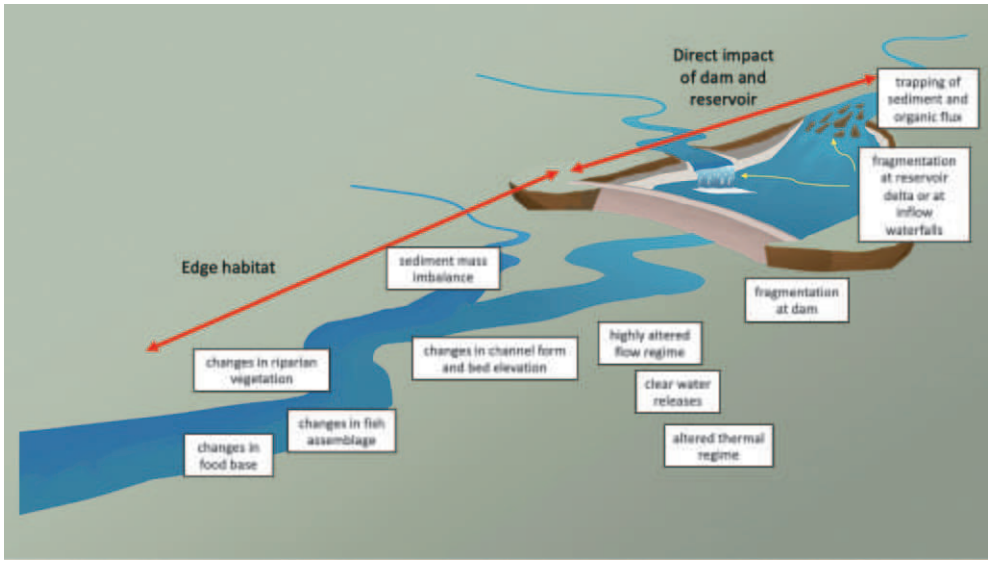

Fig. 2 Diagram showing geographic extent of effects of dams and reservoirs.

In the absence of large tributaries that enter a regulated river downstream from a large dam, edge effects may extend far downstream. For example, the flow regime and temperature of the Colorado River 400 km downstream from Glen Canyon Dam is highly perturbed from natural conditions, because more than 90% of the river's annual flow is released from the dam, and there are few tributaries that contribute supplemental flow.

Another aspect of edge effects is the change in channel form, especially incision or aggradation of sediment and associated changes in channel form that occur where there are large changes in flow and sediment supply regimes. These changes in channel form, and in aquatic and riparian habitat, are discussed below.

Where reservoir storage has decreased due to decreased inflow and/or increased consumptive uses and where there has been a large amount of sediment deposited in reservoirs, fragmentation has occurred in the reservoir inflow areas. For example, the delta of Lake Mead, the largest reservoir in the United States, is 70-m thick. In 2021, Lake Mead was ~30% of capacity and was ~47 m below the elevation when the reservoir is full. The inflowing Colorado River had incised a new channel into the delta, crossing a ledge of resistant bedrock that formed Pearce Ferry Rapid, which is unnavigable. The same had occurred in the San Juan River arm of Lake Powell, the second largest reservoir in the United States (Cathcart et al., 2018).

The ecological implications of this type of fragmentation depends on their longevity, and longevity depends on whether reservoirs remain low or refill and inundate the fragmentation. The waterfalls and steep rapids in the inflow areas are of value to native fish assemblages in some places, because they block upstream migration of non-native, warm water, reservoir fish into the upstream river ecosystems, thereby limiting competition and predation on native species. This is the case in western Grand Canyon, immediately upstream from Lake Mead, where the native fish assemblage is of high value (Kegerries et al., 2020). Conversely, valued native fish successfully occupy reservoir habitat elsewhere but cannot access spawning habitat because of this type of fragmentation, such as in the San Juan arm of Lake Powell (Cathcart et al., 2018).

Transitional effects caused by the existence of dams and by their operation

Changes in downstream sediment supply caused by trapping of sediment and organic flux

The trap efficiency of a reservoir is the ratio of the incoming sediment to that deposited in the reservoir. The proportion of incoming sediment deposited in a reservoir is determined by the size and fall velocity of the incoming sediment, the rate of flow through the reservoir, the distance between the points of significant inflow and the dam, the elevation at which water can be released from the reservoir, and the rules of reservoir operations. Typically, all the bed load and a proportion of the suspended load transported into a reservoir is trapped (Kondolf, 1997), and the trap efficiency of suspended load is generally proportional to the ratio of reservoir storage to inflow (Brune, 1953). Higher ratios of reservoir storage are associated with more effective trapping.

Sedimentation in some large reservoirs of the western United States has the potential to adversely affect water storage. Graf et al. (2010) evaluated 6 dams on the mainstem Missouri River and estimated that the life of these reservoirs varied between 240 and 1250 years. Gavins Point Dam, whose life expectancy is the shortest, is nevertheless estimated to remain functional until the end of the 21st century. The estimated life of Lake Powell is 300–700 years, and the reservoir's delta at the inflow of the Colorado River has advanced ~50 km. This reservoir is ~300 km long at full capacity.

Changes in thermal regime

Most large reservoirs created by large dams thermally stratify in summer, such as at Lake Powell (Vernieu et al., 2005), and released water typically comes from the hypolimnion (Fig. 3). These waters are typically cooler than ambient summer conditions, creating unfavorable conditions if the life history of some native species are dependent on warmer, unregulated conditions. Cool releases, however, may be advantageous to nonnative salmonid species that have been introduced to many tailwaters for sport fishing. The ecological effect on the upper Colorado River's ecosystem was described by Ward and Stanford (Ward and Stanford, 1983; Stanford and Ward, 2001), and Dibble et al. (2021) estimated summer conditions throughout the Colorado River system (Fig. 4). The large dams of the Colorado River were primarily built between the 1930s and the 1960s, and the penstocks that transfer water from those reservoirs to their respective powerplants are at fixed elevations (Fig. 3). As reservoir storage declines, release temperatures are increasing because the penstocks are withdrawing water that is closer to the epilimnion.

Effects by reservoir operations

Changes in flow regime

Changes in the flow regime caused by dams are related to the purpose of each reservoir that determines the rules of reservoir operation (Williams and Wolman, 1984). The ratio of the storage capacity of each reservoir to the inflow determines the flexibility in reservoir operations, and the size of the dam and its reservoir is typically determined by the purpose of the structure. For example, the changes in flow regime downstream from a flood control reservoir differ from a reservoir operated to provide irrigation or municipal water supply. In some cases, water is diverted directly from a reservoir, and the total volume of downstream flow is less that the volume of incoming flow, but, in other cases, the total volume of flow is not changed.

The natural flow regime of any river can be categorized into five components (Poff et al., 1997), and reservoir operations can affect each of these attribute categories. These components are the magnitude, frequency, duration, timing, and rate of change of high and low flows. Richter et al. (1997) identified 21 hydrologic parameters among these five components and proposed a methodology, the *Indicators of Hydrologic Alteration*, to quantify the degree of change in the natural flow regime caused by reservoir

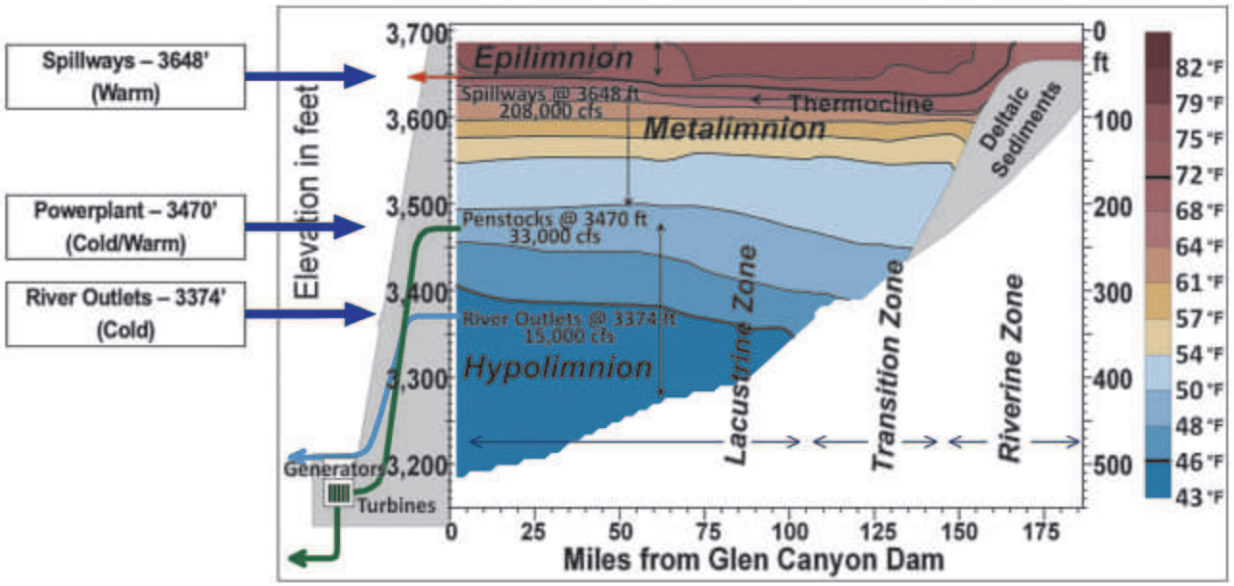

Fig. 3 Diagram showing summer thermal structure of Lake Powell when the reservoir is relatively full. There are three facilities by which water is released downstream. Most water is withdrawn through penstocks into the powerplant where hydroelectricity is produced. The river outlets that by-pass the powerplant are occasionally used to increase releases. The spillways can only be used when the reservoir is completely full. Each facility withdraws water of different characteristic temperature. From Vernieu WS, Hueftle SJ, and Gloss SP (2005) Water quality in Lake Powell and the Colorado River, in *The State of the Colorado River Ecosystem*. Grand Canyon SP, Gloss JE, Lovich and Melis TS (eds.) *U.S. Geological Survey Circular 1282*, p. 69–85. Maximum release volumes (in cubic feet per second) are given for each facility.

operations or other perturbations. Subsequent studies have identified parameters most sensitive to reservoir operations (Table 1). These differences are primarily related to the different purposes of reservoirs, as recognized by Williams and Wolman (1984), who stated "The uniqueness of release policy at each dam precludes simple generalizations about the discharge distributions, except that flood peaks will be decreased." Some recent studies (Batalla et al., 2004; Singer, 2007) characterized the downstream extent of flow regime changes, essentially quantifying the extent of edge habitat. Poff et al. (2007) demonstrated that reservoir operations are homogenizing the natural distinctness of flow regimes that arises from the different climate and geology of parts of the United States.

Another significant change to the flow regime of many rivers is caused by fluctuation of reservoir releases to match hydroelectric power demand, which is called *hydropeaking* or sometimes called load following. The intensity of hydropeaking has been estimated by the hydropeaking index, defined as the daily coefficient of variation in discharge averaged over five or more years (Dibble et al., 2015; Kennedy et al., 2016). Typically, reservoir releases are lowest at night and increase in early morning (Fig. 5). Production of hydroelectricity also affects the monthly flow regime, because reservoir releases are typically highest in months of highest demand. In the Intermountain West, those months are winter to meet heating needs and summer to meet the demands of air conditioning. There is speculation that the shift to renewable energy has the potential to shift the hourly pattern of energy demand, such that the role of hydroelectricity in regional power grids may increase at night or on windless days. Such a change in hydropeaking might cause reservoir releases to vary erratically in response to weather patterns at the sites of renewable power production.

Downstream changes and consequences of dams and reservoirs

The downstream impacts of dams and reservoirs can be distinguished among the physical changes to the stream-flow and sediment-supply regimes that cause change in channel form, changes in water quality especially river temperature, and the biological consequences of these changes (Rood et al., 2005). Changes in the flow and sediment supply regimes may cause disconnection between the river and its floodplain either by reduction in the magnitude of floods or due to incision of the channel bed. The consequences of changes in the hydrologic and geomorphic systems may have significant consequences to the aquatic and riparian ecosystems far downstream from the dam.

Hydrologic and geomorphic changes

Disruption of the flow and sediment delivery regimes causes downstream changes in channel form that may extend hundreds of kilometers (Stevens, 1938; Borland and Miller, 1960; Schumm, 1969; Petts, 1979; Williams and Wolman, 1984; Andrews, 1986; Carling, 1988; Brandt, 2000a; Grant et al., 2003). Typically, channel response immediately downstream from dams involves

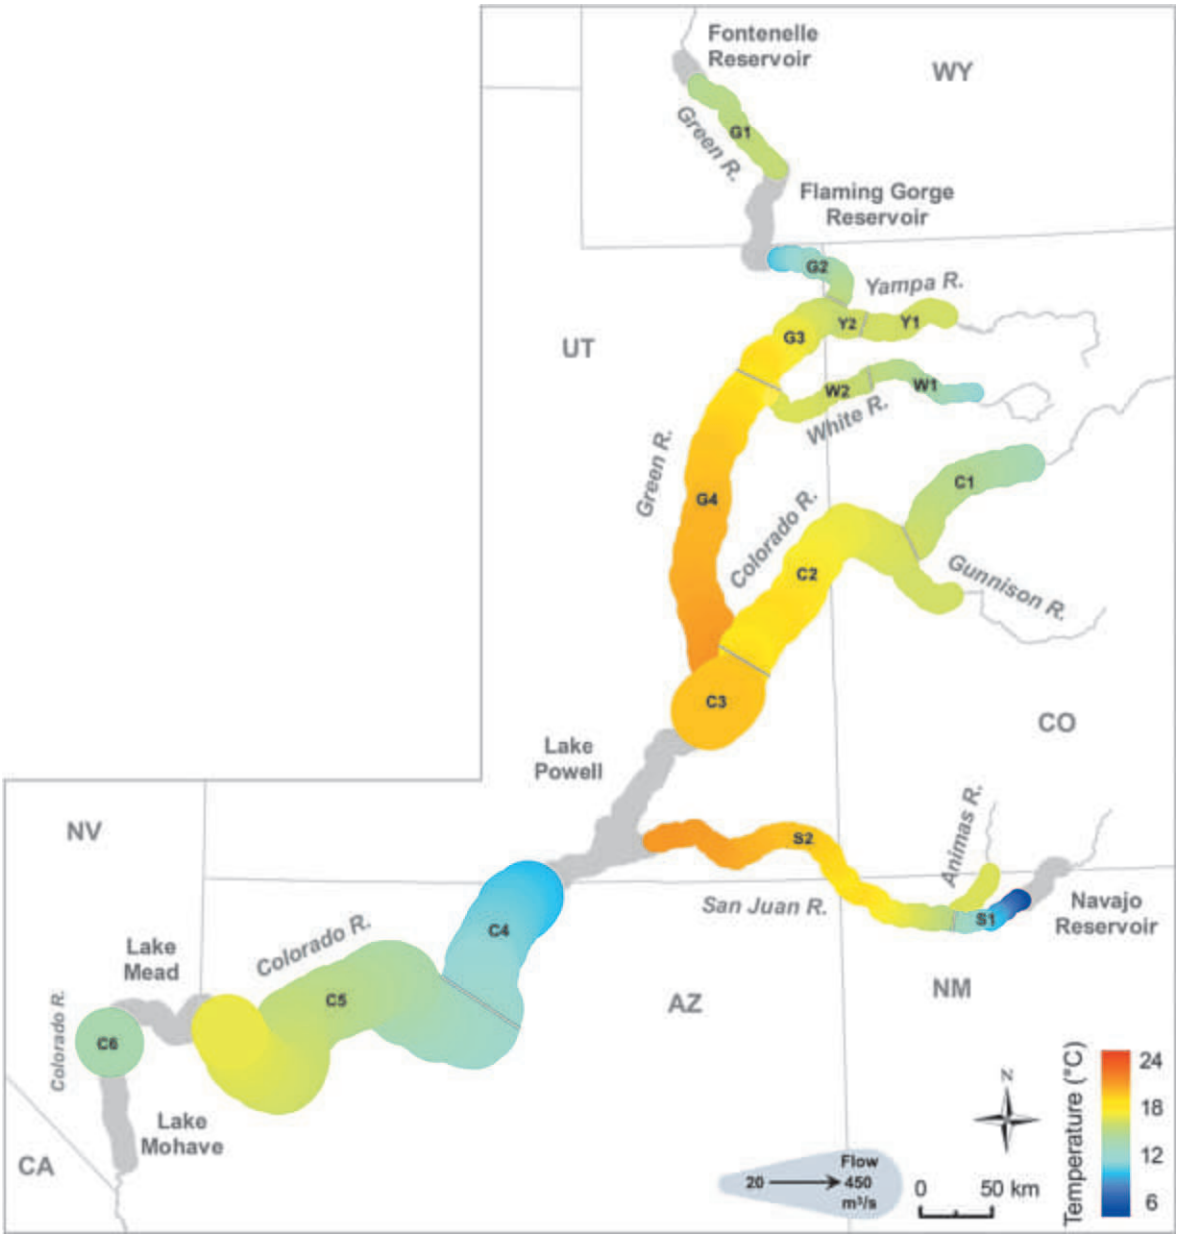

Fig. 4 Diagram showing predicted river temperature for the Colorado River upstream from Davis Dam and Lake Mohave reservoir. This figure demonstrates the releases of cool water that form the tailwaters of each reservoir and shows that river temperature gradually increases downstream from each dam. Color of each river segment represents the warmest growing season months, and the width of each segment is proportional to the mean monthly flow in summer. From Dibble KL, Yackulic CB, Kennedy TA, Bestgen KR, and Schmidt JC (2021) Water storage decisions will determine the distribution and persistence of imperiled river fishes. *Ecological Applications* 31(2): e02279, Fig. 1.

evacuation of sediment and may include incision of the bed (Fig. 6). Channel response further downstream may involve aggradation if unregulated tributaries deliver sediment to a regulated flow regime whose floods have been greatly reduced, as shown by Everitt (1993) (Fig. 7). Williams and Wolman (1984) summarized channel change in degrading reaches downstream from 21 dams in the western United States and developed empirical relations to predict the duration of incision and the magnitude of changes in channel width.

Brandt (2000a) summarized many case studies and identified nine styles of channel change involving either degradation or aggradation. Brandt (2000b) and Grant et al. (2003) suggested metrics that consider changes in both water and sediment supply. Brandt (2000b) predicted post-dam channel form from bed entrainment, sediment transport, extremal hypothesis, hydraulic geometry, and empirical relations. Grant et al. (2003) evaluated the relative effects of changes in flow and sediment delivery. They suggested that channel change is related to changes in the fractional change in duration of sediment-transporting flows and the ratio of sediment supply downstream from dams to the supply upstream from dams. Schmidt and Wilcock (2008) proposed three

Table 1 Hydrologic parameters significantly affected by reservoir operations.

Flow regime characteristic	*Hydrologic parameter (required data)*	
Magnitude, timing	Monthly flow regime (monthly mean flow)	Batalla et al. (2004)
Magnitude, duration	Annual minimum 1-day (mean daily discharge)	Singer (2007)
	Annual maximum 1-day (mean daily discharge)	Richter et al. (1998), Magilligan and Nislow (2001), Magilligan et al. (2003), Batalla et al. (2004), Poff et al. (2007), and Singer (2007)
	Annual minimum 1-day mean daily flow	Poff et al. (2007)
	Annual minimum 30-day flow (mean daily discharge)	Richter et al. (1998)
	Volume of flood flows above a threshold (mean daily discharge)	Singer (2007)
	Total annual flow (annual total flow)	Batalla et al. (2004)
	Flow standard deviation (i.e., annual duration of mean daily flows) (mean daily discharge)	Batalla et al. (2004)
Timing	Date of annual 1-day maximum flow (mean daily discharge)	Richter et al. (1998) and Poff et al. (2007)
	Date of annual 1-day minimum flow (mean daily discharge)	Richter et al. (1998)
Magnitude, frequency/ duration	Mean duration of high flow pulses (i.e., floods) (mean daily discharge)	Richter et al. (1998)
	Number of days mean daily flow exceeds a threshold (i.e., average annual maximum predam mean daily flow)	Poff et al. (2007)
	Number of days mean daily flow less than a threshold (i.e., average annual predam 7-day mean daily flow)	Poff et al. (2007)
Frequency, rate of change	Frequency of hydrograph reversals (mean daily discharge)	Richter et al. (1998)
	number of days in flood rise (mean daily discharge)	Singer (2007)
	number of days in flood recession (mean daily discharge)	Singer (2007)
	Number of days flows less than a threshold (mean daily discharge)	Singer (2007)
	Hydropeaking index (instantaneous discharge)	Kennedy et al. (2016)
Spatial extent of flow regime changes	Downstream persistence of flow changes (mean daily discharge)	Batalla et al. (2004) and Singer (2007)

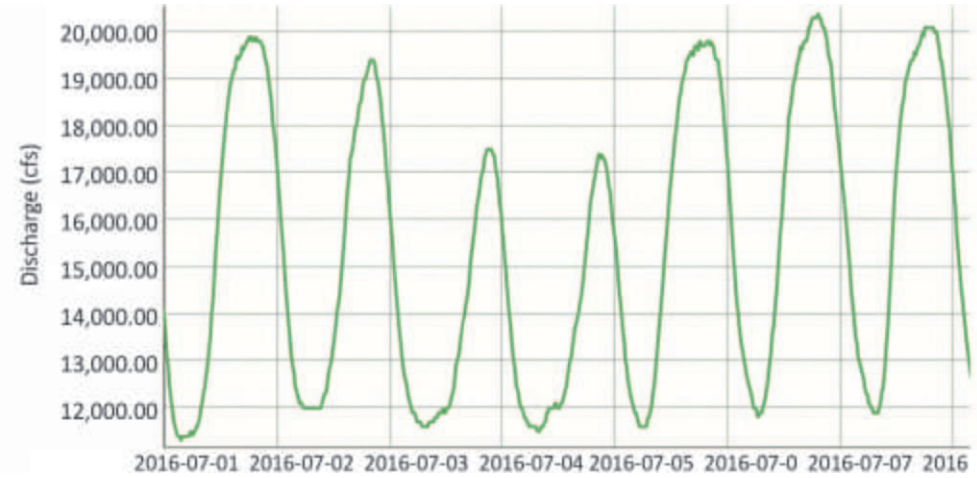

Fig. 5 Graph showing instantaneous hydrograph of 1 week of typical reservoir releases from Glen Canyon Dam in July 2016. July 3 and July 4 (7-03 and 7-04) are weekend and holidays when electricity demand was less.

metrics that they argued were the primary drivers of channel change. One metric represents the shift in balance between sediment supply and transport capacity and, thus, the tendency for sediment to accumulate or evacuate in channels. Another metric characterizes the post-dam stream competence and, hence, potential for channel incision. The third metric is the relative reduction in flood magnitude. Channel incision and flood reduction typically alter the inundation frequency of the pre-dam floodplain, thereby restructuring the disturbance regime and physical template of the riparian ecosystem. Flood reduction is also an important determinant of channel narrowing and the extent to which riparian vegetation invades the post-dam channel.

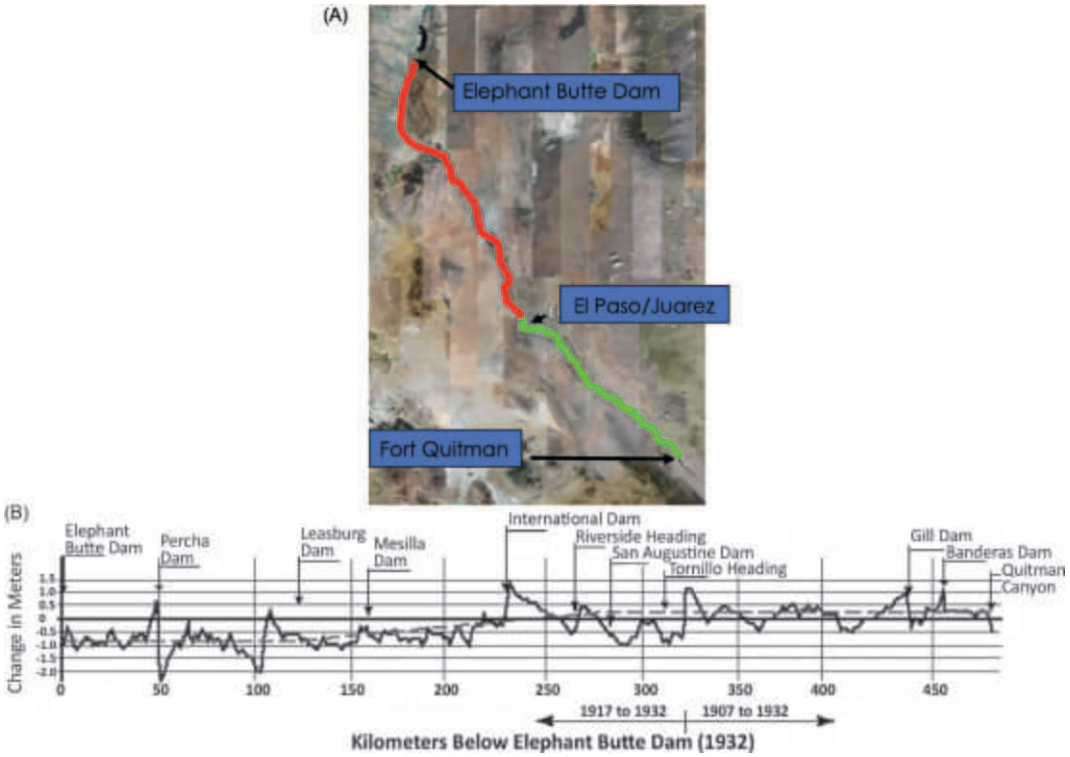

Fig. 6 Channel response to the existence and operations of Elephant Butte Dam and reservoir on the northern branch of the Rio Grande. A. Between 1917 and 1933, the Rio Grande incised its bed (in red) as much as 1 m within 225 km downstream from the dam, and the bed aggraded (in green) about 0.25 m further downstream. B. Change in water surface elevation between 1917 and 1932 for 300 km downstream from Elephant Butte Dam. Grey dashed line is the average change in elevation for 80 km segments. From Stevens JC (1938) The effect of silt-removal and flow-regulation on the regimen of Rio Grande and Colorado Rivers. *Transactions of the American Geophysical Union* 653–659, Fig. 1.

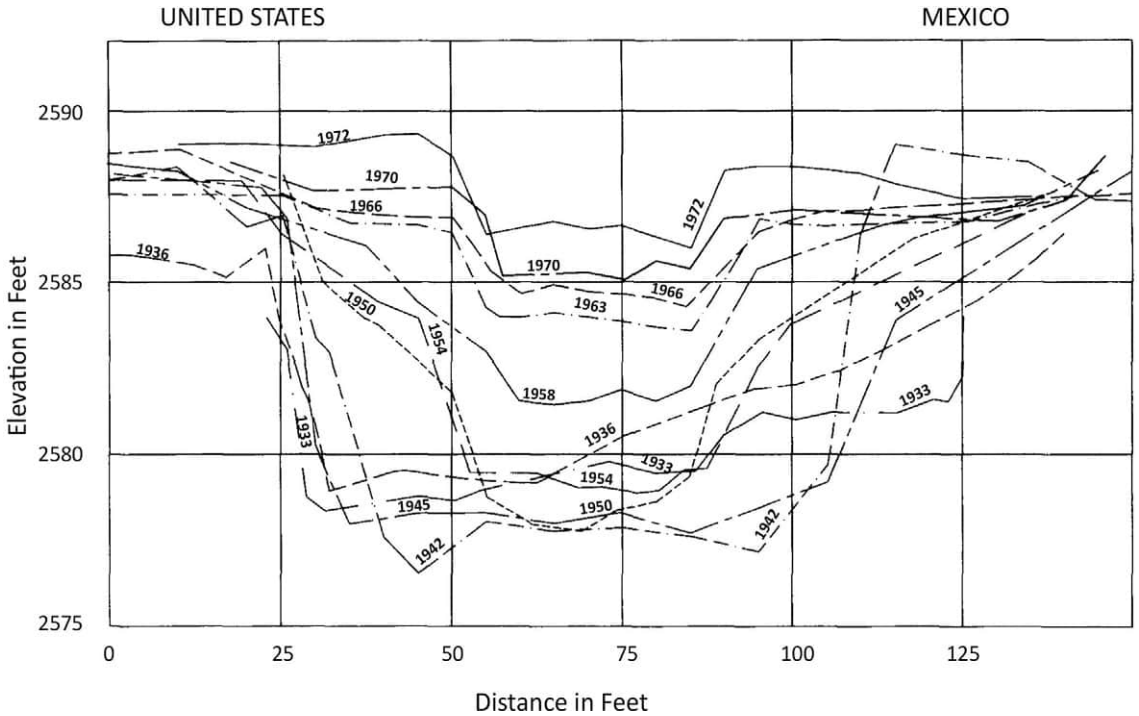

Fig. 7 Graph showing cross-section of the Rio Grande near Presidio, TX, and upstream from the Rio Conchos, surveyed at various times. The channel bed aggraded and the banks narrowed in response to depletion of ~90% of the total annual stream flow, although sediment continued to be episodically delivered to the channel by tributary flash floods. From Everitt B (1993) Channel responses to declining flow on the Rio Grande between Ft. Quitman and Presidio, Texas. *Geomorphology* 6: 225–242, Fig. 3.

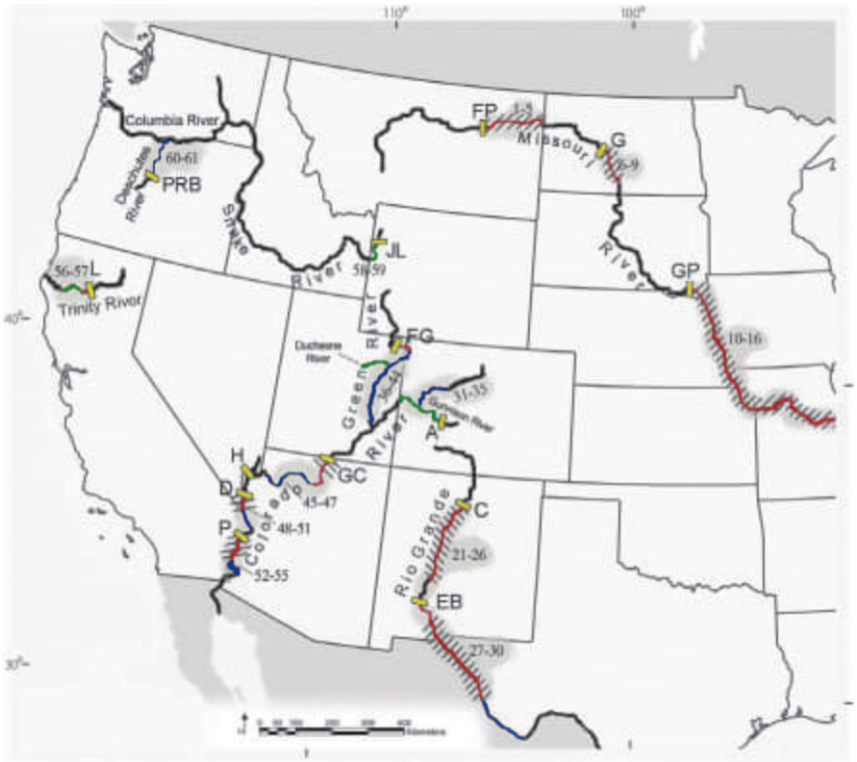

Fig. 8 Map showing perturbations in sediment mass balance of some of the large rivers of the western United States. Red indicates river segments perturbed into sediment deficit, green into sediment surplus, and blue where the perturbation is indeterminate. Cross-hatched segments are those where bed incision is likely. From Schmidt JC and Wilcock PR (2008) Metrics for assessing the downstream effects of dams. *Water Resources Research* 44: W04404. doi:10.1029/2006WR005092., Fig. 1.

Schmidt and Wilcock (2008) computed these metrics for 61 dam-impacted segments of five large river systems in the western United States (Fig. 8). The metrics adequately predict channel changes concerning perturbations in sediment mass balance and post-dam channel incision and poorly predict changes in channel width. Uncertainty in these predictions is caused by a number of factors. Change in the 2-year recurrence flood oversimplifies changes in flow regime, especially where there are large post-dam depletions in total annual flow, and these changes must be estimated between gaging stations. There is uncertainty in the period of record to be used to characterize the pre-dam period, and post-dam reservoir operations change with time. Tributary sediment delivery often must be estimated, although the ratio of post-dam to pre-dam sediment delivery can be more accurately estimated than can the absolute values of the delivery. Changes in the 2-year flood poorly predict changes in channel width, presumably, because factors such as changes in riparian vegetation are not considered in such a simple metric. Nevertheless, these metrics present a spatially robust characterization of the extent to which dams and reservoir operations affect the natural characteristics of river channels.

It is difficult to mitigate the adverse effects of undesirable channel change caused by perturbations of sediment mass imbalance, especially where large dams were built decades ago and completely block the sediment supply once delivered from the upstream watershed. Recently constructed dams in regions of high sediment delivery now include low-elevation release facilities so that sediment laden water can be sluiced through a drawn-down reservoir and delivered further downstream (Kondolf et al., 2014a,b). The Three Gorges Dam on the Yangtze River creates one of the largest reservoirs on Earth, and reservoir sedimentation is being reduced by trapping in smaller reservoirs further upstream, sluicing of high suspended load inflows through the reservoir, and dredging (Ren et al., 2021). To date, sedimentation within Three Gorges reservoir is 33% of what had been predicted, and this success in sediment management has also mitigated adverse downstream impacts of sediment deficit.

In many cases, sediment cannot be rerouted around dams and only clear water can be released, because there is no way to release water from low elevation and there is a very long distance from reservoir inflow to the dam. Intentional large releases of clear water have been released in circumstances where sediment delivery from an unregulated tributary immediately downstream from the dam episodically delivers sediment to the bed of the regulated river. The purpose of these controlled floods is to entrain the sand stored on the bed and redistribute some of that sand to desired locations, such as to eddy sand bars. This management strategy is used to manage sand resources along the Colorado River downstream from Glen Canyon Dam (Webb et al., 1999).

Consequences to aquatic ecosystems

Reservoir operations have the potential to significantly impact aquatic ecosystems, primarily by the effects of thermal changes determined by the temperatures of reservoir releases and by the effects of hydropeaking. Novel, post-dam ecosystems have developed far downstream from many large dams. For example, in the case of the Colorado River, native and nonnative species have developed novel fish assemblages in the cooler releases from the hypolimnion of relatively full reservoirs. Warmer releases that are predicted to occur when reservoir storage declines have the potential to affect the competitive and predatory interactions between native and nonnative species (Dibble et al., 2021). These interactions will also be affected if nonnative reservoir fish species expand their range upstream from each reservoir. In some cases, fragmentation caused by barriers at the upstream end of reservoirs will prevent upstream migration of nonnatives, allowing native fish to prosper in a warming river but elsewhere, nonnatives may outcompete native fish in warming conditions.

Hydropeaking operations significantly affect benthic aquatic insects. Changes in the monthly distribution of flows associated with generation of power during months of high demand, coupled with very cool summer temperatures released from the hypolimnion of Flaming Gorge reservoir on the Green River caused the macroinvertebrate genera to decline from >70 to <30 (Vinson, 2001). Kennedy et al. (2016) demonstrated that aquatic invertebrate abundance is dramatically reduced by hydropeaking operations (Fig. 9), especially wherever flows decrease during the primary hours when insects lay their eggs along the river margin (Poff and Schmidt, 2016). In rivers where there are long segments of edge habitat, it is inevitable that adverse effects will arise due to large fluctuations in river stage. These effects are partially mitigated by eliminating hydropeaking on weekends during spring and summer, thereby providing a 48-h period when invertebrate eggs laid only the river's margin are not desiccated. This management strategy was used downstream from Glen Canyon Dam in 2019 and 2020.

Consequences to riparian ecosystems

Dams and the operations of reservoirs may cause increase or decrease in downstream riparian vegetation. Flood control operations typically lead to a shift in ecosystem function on the pre-dam floodplain from a system dependent on regular flooding or access to shallow ground water to a mesic or xeric ecosystem dominated by upland plants. In some cases, deposition of inset floodplains within the pre-dam channel is the mechanism by which channels narrow, and these new surfaces may be colonized by native and non-native vegetation (Fig. 10) (Dynesius et al., 2004; Merritt and Poff, 2010). Turner and Karpiscak (1980) matched old ground-level photographs and documented the widespread expansion of non-native tamarisk (*Tamarix* spp.) throughout 400 km of the Colorado River downstream from Glen Canyon Dam, and Webb et al. (2007) documented this style of change throughout the Colorado River watershed. Sankey et al. (2015) measured the lateral and longitudinal rate and extent of increase in riparian vegetation throughout the Grand Canyon. Elsewhere, diversion of large amounts of stream flow that are facilitated by dams leads to dewatering of riparian ecosystems and large decreases in floodplain forests (Rood et al., 2005). Numerous field and modeling studies have documented the magnitude and style of riparian vegetation change throughout the western U.S., including in the upper Colorado River watershed (Auble et al., 1994, 2005; Merritt and Cooper, 2000; Grams and Schmidt, 2002), the lower Colorado River watershed (Shafroth et al., 2002), Snake River in Wyoming (Hauer and Lorang, 2004), and the Tietar River in western Spain (Bejarno et al., 2012).

Obviously, different mitigation strategies are required to remove unwanted riparian vegetation that has narrowed channels subject to flood control in contrast to strategies intended to increase riparian vegetation. In most of the Colorado River system, flood control and increased base flows have caused great expansion in riparian vegetation that covers formerly bare fine sediment deposits that are valued as campsites by recreational boaters or that form the architecture of valued low-flow aquatic habitat. In this situation, long-duration high flows have the potential to scour undesired vegetation, but many plant stems have physical characteristics that resist scour. In some circumstances, mechanical removal of undesired vegetation has been followed by high dam releases, such as along the Green River in Dinosaur National Monument.

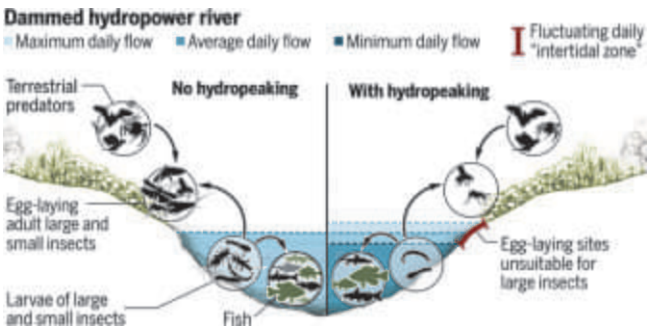

Fig. 9 Dams alter the daily and seasonal flow regime. in cases where reservoir releases are for the purpose of hydropeaking, sites may be desiccated after eggs are laid. From Poff NL and Schmidt JC (2016) How dams can go with the flow. *Science* 353(6304): 1099–1100.

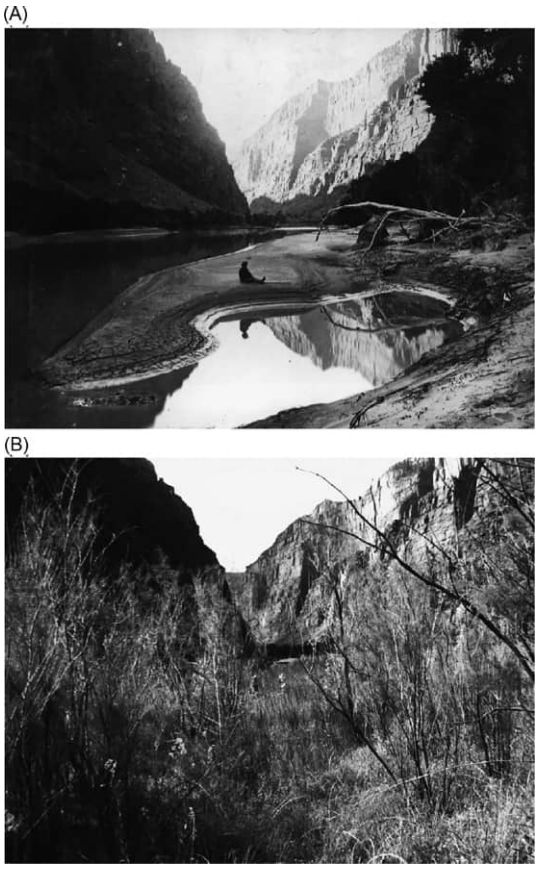

Fig. 10 (A) Photograph taken by E. O. Beaman in 1871 along the Green River in the Canyon of Lodore, downstream from modern Flaming Gorge Dam. (B) Matched photograph taken in 1993 after approximately 30 years after completion of Flaming Gorge Dam. From Grams PE and Schmidt JC (2002) Streamflow regulation and multi-level floodplain formation: Channel narrowing on the aggrading Green River in the eastern Uinta Mountains, Colorado and Utah. *Geomorphology* 44:337–360, Fig. 8.

Where there has been a large loss in riparian forests due to dewatering, establishment of adequate baseflow throughout the year as well as higher "growth flows" that provide additional stream flow to recharge alluvial aquifers during periods of high growth rate of vegetation have been very successful (Rood et al., 2005). Over-bank, flood flows are another critical part of the flow regime needed to rejuvenate riparian forests, because these flows provide a critical disturbance to the riparian ecosystem. The rate of recession of flows from peak flow to base flow are another essential part of re-operating reservoirs to enhance riparian forests. New seedlings of cottonwoods or willows require a gradual flood recession to assure that seedlings survive until the next period of high flow.

The future

The energy demands of underdeveloped societies, changing runoff patterns caused by climate change, and the need to expand renewable energy production all encourage construction of new dams. In regions experiencing an increasing frequency of unusually large floods, dams have the potential to provide some measure of increased flood control. In regions experiencing decreased runoff, new dams have been proposed to provide additional water storage, such as in California and the Colorado River watershed. In the developing world, there are extensive plans for new dams in Africa, Asia, and South America. More than 450 new dams are proposed in the watershed of the Amazon, Congo, and Mekong Rivers (Winemiller et al., 2016). These new projects have the potential to significantly affect the most diverse fish assemblages on Earth (Fig. 11) because of the many impacts described in this review. In the Mekong basin, for example, sediment trapping in new reservoirs is predicted to reduce sediment delivery to the Mekong Delta between 51 and 96%, depending on the number of dams constructed (Kondolf et al., 2014a). Thus, there will be an increasing need to understand, predict, and anticipate the impacts of new dams to identify the best strategies for locating new barriers and whether to build those dams at all.

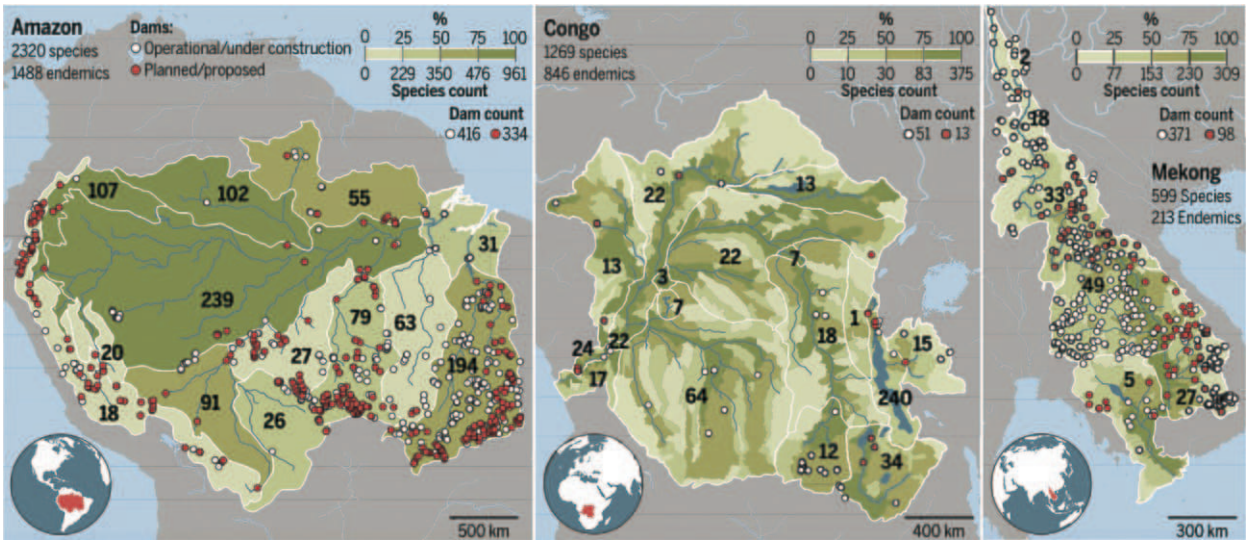

Fig. 11 Maps showing existing and planned dams in the Amazon, Congo, and Mekong basins and the estimated fish diversity in these basins. Basin-wide biodiversity summaries are shown in upper left in first two panels and middle in third panel. The ecoregions (white boundaries) in each basin are also shown. Many species are found only in a single ecoregion (black numbers), and subbasins within each river basin differ widely in their total species richness (shades of green illustrate breakpoints between quartiles in rank order within each basin). Ecological Effects of Mining on Stream Ecosystems

William H Clements, Department of Fish, Wildlife, and Conservation Biology, Colorado State University, Fort Collins, CO, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Glossary

BACI designs A study design that compares data collected from control and impacted sites before and after a planned perturbation. In restoration studies the design can be employed to measure responses to the removal of a disturbance.
Bioassessment Using biological systems (e.g., populations or communities) to assess the effects of an anthropogenic disturbance such as pollution.
Biotic ligand model (BLM) An integrated physiological and biogeochemical model used to predict the bioavailability of metals to aquatic organisms.
Bioconcentration The uptake of contaminants from water.
Bioaccumulation The uptake of contaminants from food.
Biomagnification The increase in the concentration of a contaminant through a food chain.
Context-dependent responses Spatial or temporal variation in the response of an ecosystem to a perturbation based on the biotic composition of a community.
Remediation Treatment of a watershed that is designed primarily to improve water quality.
Restoration Treatment of a watershed that is designed primarily to improve habitat.
Species traits Physiological, morphological, behavioral, or natural history attributes of a species that can be used to measure responses to natural or anthropogenic factors.
Water quality criteria Established concentrations of chemicals that should not be exceeded in order to protect aquatic life.

Scope and scale of mining contamination

Among the many anthropogenic stressors that negatively impact inland waters, discharges from abandoned and active mines are likely the most widespread and pervasive sources of chemical contamination. Active and abandoned mines are broadly distributed around the world, but over 50% of the mining areas are concentrated in 5 countries: China, Australia, the United States, Russia, and Chile (Maus et al., 2020). The distribution of active mines in the U.S. varies geographically, with the majority of metal mines occurring in western states and the largest concentrations of coal mines located in the central and southern Appalachians (Fig. 1). Although the number of active coal and metal mines have declined since 1983 (by 79% and 69%, respectively), abandoned mines remain a significant environmental threat in the U.S. Accurate estimates of the number of abandoned mines, most of which are located on federal lands (https://www.abandonedmines.gov/), are difficult to obtain. The Bureau of Land Management and the U.S. Forest Service estimate that a total of 52,000 and 29,000 abandoned mines are located on lands they manage, respectively. Between 2008 and 2017 total expenditures to identify, clean up, and monitor hazards at abandoned mine sites exceeded $2.9 billion, with about 90% of these funds used to address environmental hazards. Because discharge of metals and other contaminants from abandoned mines can persist for centuries after mining has ceased, many of these sites will require perpetual on-site treatment. Finally, although the discharge of metals from abandoned mines is generally considered an issue of local concern, mining pollution often has broad regional impacts. For example, approximately 23% of streams in Colorado's central Rocky Mountains were identified as degraded by metals from historical mining disturbance (Clements et al., 2000).

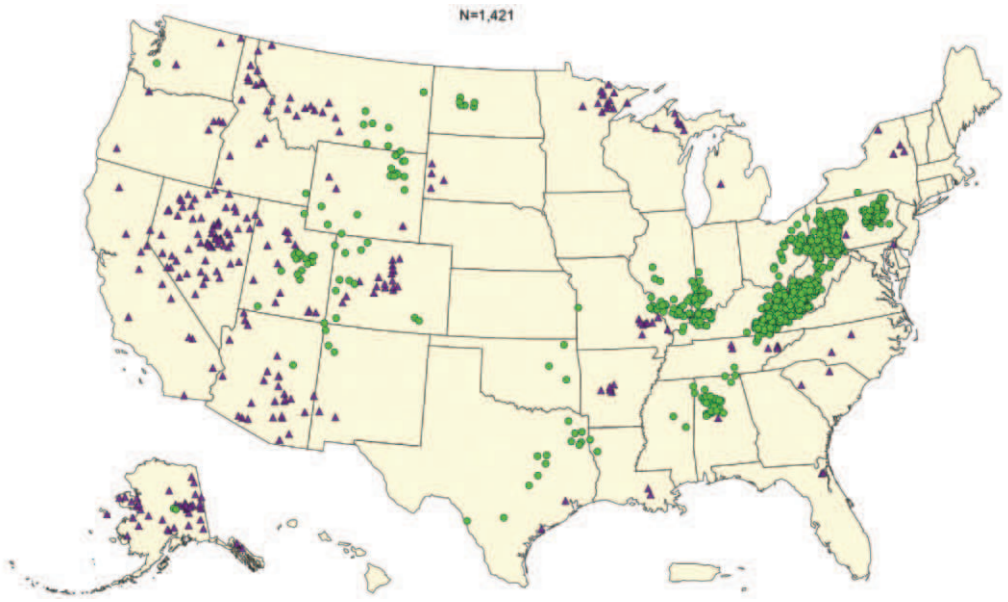

Fig. 1 The distribution of active metal mines (triangles) and coal mines (circles) in the U.S. Data obtained from the Mine Safety and Health Administration, U.S. Centers for Disease Control and Prevention.

Fate and effects of mines on inland waters

Toxicity and bioavailability of metals to aquatic organisms

Many of the chemicals typically associated with mining discharges (e.g., arsenic, cadmium, copper, iron, lead, mercury, nickel, zinc) have severe detrimental effects on aquatic species and ecosystems. Although some of these constituents are associated primarily with physical habitat alterations (e.g., iron deposition), others are highly toxic to aquatic organisms at very low concentrations. For example, the U.S. EPA water quality criterion value for cadmium, defined as the concentration that should protect 95% of aquatic species, is less than 0.5 $\mu g\, L^{-1}$ (parts per billion) in waters that are typical of many western streams where mining occurs. Concentrations of Cd significantly exceeding this safe threshold are frequently measured in discharges downstream from abandoned mines.

Because the toxicity and bioavailability of metals are determined by numerous water quality characteristics, simply measuring the concentration of a metal is not sufficient to predict potential effects. For example, the toxicity of many metals is strongly influenced by water hardness, typically expressed as mg L^{-1} $CaCO_3$. As water hardness increases, the toxicity of metals such as Cu, Cd and Zn decreases. A similar relationship between the toxicity of metals and the amount of dissolved organic carbon (DOC) that occurs naturally in water has also been demonstrated. These complex relationships between potential effects of metals and water quality characteristics have been employed to develop site-specific modifications to water quality criteria for metals from mine discharges. For example, the biotic ligand model predicts the likelihood that metals will accumulate on gill surfaces of organisms based on factors such as pH, water hardness, DOC, water temperature, and concentrations of major ions (Paquin et al., 2002). Although the influence of these water quality characteristics on metal effects have been demonstrated in laboratory experiments, our understanding of how these factors influence toxicity of metals in nature is limited.

Distribution of metals in biotic and abiotic compartments

Once discharged into an aquatic ecosystem, metals and other chemical constituents become associated with one of several abiotic or biotic compartments. Metals dissolved in the water column are readily bioconcentrated by primary producers (phytoplankton, attached algae, including diatoms), invertebrates, and fish (Kim et al., 2012). The major pathways for metal uptake from water vary among these groups. Passive absorption is responsible for elevated levels in algae, whereas bioconcentration of metals by fish occurs primarily across the gills. The bioconcentration of metals by invertebrates typically occurs through the exoskeleton but is also influenced by respiration mode (cutaneous versus gills) and body size. The effects of body size on metal bioconcentration reported in the literature are likely determined by surface area to volume relationships, as small invertebrates have greater relative surface area for metal adsorption and absorption (Kiffney and Clements, 1996).

Sediments represent a second major compartment where metals occur in aquatic ecosystems, with concentrations typically several orders of magnitude greater than those in the water column (Burton, 1991). In systems receiving mine discharges, it is not

unusual for metal concentrations in water to be below levels known to cause harm, whereas sediment concentrations in these same systems can significantly exceed toxic thresholds. In fact, contaminated sediments may continue to contribute metals to the water column long after of the original source of metals has been eliminated. Because of significantly elevated metal concentrations, benthic organisms associated with sediments are at especially high risk of exposure. Most of our understanding of how metals in sediments affect aquatic ecosystems was derived from studies with benthic organisms. In addition to dietary exposure to metals (described below), much of the metal uptake in benthic organisms occurs through interstitial water.

Direct and indirect effects of metals

To characterize the impacts of mine discharges on aquatic systems, it is necessary to distinguish between the direct toxicological effects of metals from the physical effects that cause habitat loss (Fig. 2). As noted above, many of the metals associated with mining discharges are highly toxic to aquatic organisms. Typical responses of aquatic communities to elevated metals include reduced species diversity and abundance, shifts in the composition of communities, and the loss of sensitive species (Clements et al., 2000). Although some aquatic organisms are relatively tolerant to metals (e.g., some caddisflies and many dipterans), others will be eliminated at relatively low metal concentrations (e.g., many mayflies). These differences in relative sensitivity among groups are routinely employed in stream bioassessments to characterize degradation associated with mining discharges. In addition, because these different groups of organisms play different functional roles, shifts in the composition of communities downstream from mining discharges have implications for ecosystem processes such as nutrient cycling, detritus processing, and energy flow. We also know that organisms affected by exposure to metals have lower resilience when challenged by other stressors. For example, experiments have shown that in systems recovering from the long-term effects of mining pollution, metal-tolerant communities are more sensitive to other physical (acidification and UV-B radiation) and chemical (hydrocarbons) stressors compared to reference communities (Wolff et al., 2019).

In addition to these direct toxicological effects of metals, indirect effects from active and abandoned mines can occur as a result of reduced food quality and the loss of prey resources. Lower quality of basal food resources (e.g., algae and biofilm) and reduced prey abundance alter aquatic food webs and limit the transfer of energy to higher trophic levels. In addition, metals that are readily bioconcentrated (through water) and/or bioaccumulated (through food) will be transferred through food webs (Landers et al., 2019). However, unlike many organic contaminants, with a few important exceptions (e.g., Hg and Se) most metals associated with mining discharges do not biomagnify. In fact, because of relatively inefficient transfer, concentrations of most trace metals are usually lower in predators than in other trophic levels. For example, data collected downstream from California Gulch, a U.S. EPA Superfund site on the Arkansas River (Colorado, U.S.), demonstrates how inefficiently Zn in transferred through an aquatic food web (Fig. 3). Although metals were bioconcentrated >6000 X from water to biofilm, concentrations in caddisflies, a major prey item for brown trout in this system, were much lower, and levels in brown trout were ~70% lower than in caddisflies (Kiffney and Clements, 1993). It is important to note that inefficient transfer through aquatic food chains does not imply metals are not harmful to higher trophic levels. Because basal food resources such as biofilm in mining-impacted watersheds are often highly contaminated, even the inefficient transfer of metals can result in elevated and potentially harmful concentrations in consumers.

Emerging adult insects represent an important pathway by which metals can be transferred from aquatic ecosystems to riparian consumers (Fig. 4). Ecologists have long recognized the role of emerging adult insects in providing aquatic-derived subsidies in the form of nutrients or energy to adjacent riparian communities (Fausch et al., 2002). Metals (and other contaminants) are also readily transferred to terrestrial systems and elevated concentrations have been detected in riparian predators, including spiders, birds, and bats that consume emerging aquatic insects (Kraus et al., 2014). Similar to the bioaccumulation of metals within aquatic food webs, the transfer of metals to riparian communities is relatively inefficient, in part because metals are shed in the exoskeleton of emerging

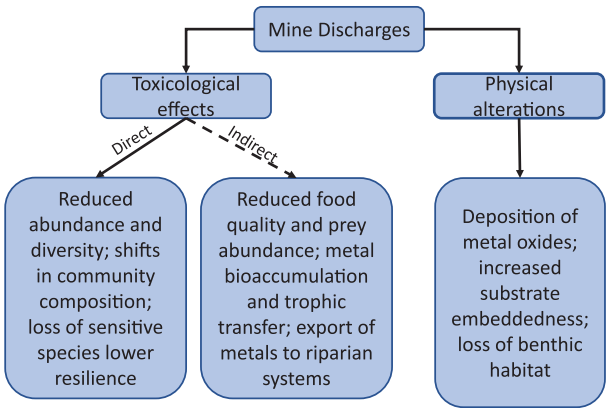

Fig. 2 Conceptual model of the major direct and indirect toxicological effects and physical alterations commonly associated with mine discharges to inland waters.

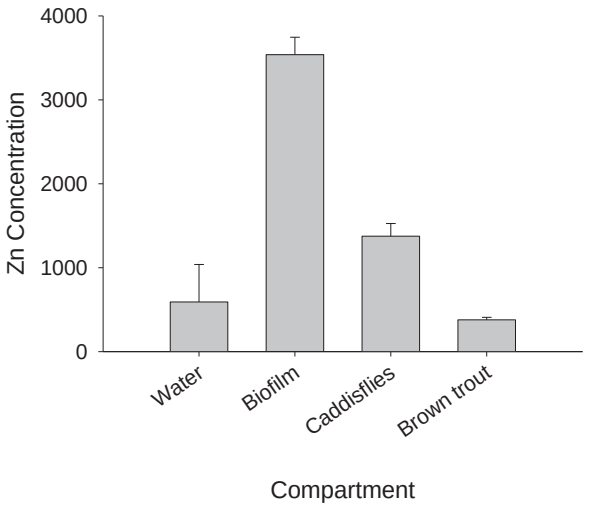

Fig. 3 Concentrations of Zn in water, biofilm (algae and diatoms), caddisflies and brown trout (*Salmo trutta*) measured in the Arkansas River, Colorado (USA). Data were collected downstream from California Gulch, a U.S. EPA Superfund Site in 1993 prior to remediation. Note that metal concentrations in water are shown in μg L^{-1} (ppb) whereas concentrations in other compartments are in μg g^{-1} (ppm).

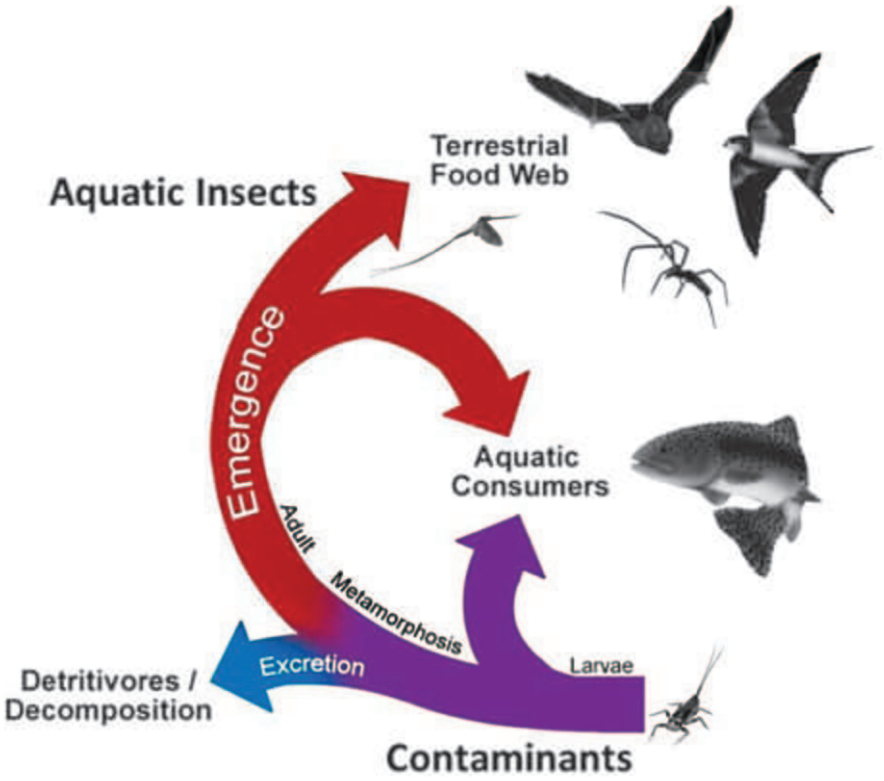

Fig. 4 The movement of contaminants within aquatic ecosystems and the export of these materials to riparian consumers. From Kraus JM, Walters DM, Wesner JS, Stricker CA, Schmidt TS, Zuellig RE (2014) Metamorphosis alters contaminants and chemical tracers in insects: Implications for food webs. *Environmental Science & Technology* 48: 10957–10965.

adults are therefore often much lower than in aquatic life stages. However, as described above, the inefficient transfer of metals in highly contaminated systems can result in elevated concentrations and potential effects on riparian consumers, a phenomenon coined as the "dark side of ecological subsidies" (Walters et al., 2008).

Physical effects of mine discharges

The direct and indirect toxicological effects of mine discharges have received most of the attention in the literature. However, the physical effects of mine effluents can also significantly degrade aquatic habitats, especially for benthic organisms (DeNicola and Stapleton, 2002). The formation of ferric hydroxide, commonly referred to as "yellow boy," occurs through a series of chemical reactions when iron sulfide (pyrite) is exposed to air and water:

$$FeS_2 + O_2 + H_2O \rightarrow\rightarrow Fe(OH)_3 + H^+$$

As pH of a receiving system increases (e.g., beyond approximately 3.5), ferric hydroxide precipitates from the water column as a yellowish-orange solid, staining the substrate, filling interstitial spaces, and resulting in significant degradation of benthic habitats (Fig. 5). Experiments conducted in mine-polluted streams have shown that even in situations where the materials deposited on substrate are not directly toxic, macroinvertebrate colonization of substrate coated with metal oxides can be significantly reduced (Courtney and Clements, 2002).

Assessing the effects of mining discharges on aquatic ecosystems

Study designs and bioassessment approaches

A variety of study designs and bioassessment approaches have been used to quantify the effects of mine discharges on aquatic ecosystems, but most involve comparisons of abundance, species richness, diversity, and/or community composition of aquatic organisms along a gradient of contamination within a single watershed. An alternative but less common approach is to sample a large number of reference and polluted streams in an area with a high density of mines. This study design has been employed in the southern Appalachians to measure the effects of coal mining (Cormier et al., 2013) and in the Rocky Mountains to assess effects of abandoned hard rock mines (Schmidt et al., 2012). An alternative design employed in the Rocky Mountains as part of the U.S. EPA Environmental Monitoring and Assessment Program (EMAP), was to sample a large number of randomly selected streams (Clements et al., 2000). Because these sites were selected randomly, investigators were able to make much broader generalizations about the total number of streams within the region that were affected by abandoned mines.

Studies of the effects of abandoned mines commonly include assessments of algae, benthic macroinvertebrates, and/or fish and have been conducted across multiple levels of biological organization from individuals to populations to communities. In one of the earliest field assessments of metal mining effects on streams, Carpenter (1924) investigated several rivers in the U.K. polluted by lead, concluding that "The correlation of fauna lists with tables of analyses of water samples shews that poverty of fauna, with absence of fishes in particular, always accompanies the presence of lead salts in diffusible form." In what is likely the first study to

Fig. 5 Photograph of North Fork Clear Creek, a U.S. EPA Superfund Site near Blackhawk, Colorado (U.S.). The orange-yellow color of the stream and the staining on the substrate is a result of iron hydroxides that precipitate in the water column.

employ a before-after design to investigate recovery of a stream from mining pollution, Carpenter concluded that "The cessation of the last of the lead mining and washing operations affecting the Rheidol and Ystwyth was followed by a marked and rapid increase in the flora and fauna of the rivers." Since the publication of Carpenter's study, literally thousands of papers have documented the effects of metal or coal mining on inland waters. In addition to the "poverty of fauna" describe above, these studies have identified consistent and predictable shifts in the composition of algal, macroinvertebrate and fish communities downstream from mine discharges.

With respect to which organisms should be sampled in these assessments, there has been some debate in the literature regarding the suitability of using algae, macroinvertebrates or fish for measuring effects of mining discharges (Namba et al., 2020). Difficult taxonomy often precludes the assessment of algal communities by non-experts, whereas logistical considerations and difficulties obtaining sampling permits may limit the use of fish assessments by some organizations. In the U.S. there appears to be a distinct geographic preference for which group to include in stream bioassessments. Because of greater species diversity, responses of fish communities to coal and metal mining have been much better characterized in watersheds of the eastern U.S. In contrast, because of naturally low diversity of fish communities in mountain streams of the western U.S., there has been more emphasis placed on macroinvertebrate communities in this region.

Effects of mines and mining effluents on aquatic ecosystems have been measured across different levels of biological organization. Responses at lower levels of organization, such as elevated levels of metal-binding proteins, have been observed in a wide range of taxonomic groups. Similarly, morphological deformities (e.g., chironomid mouthparts) and anomalies in the capture nets of caddisflies have also shown strong correlations with elevated metal concentrations (Hudson and Ciborowski, 1996; Balch et al., 2000). These responses are often specific to metal exposure in mining-polluted streams. In contrast, responses at higher levels of organization, such as reduced species diversity, are more general and could result from the direct toxicological effects of metals, increased acidification, or the loss of habitat. Surprisingly, despite the well-documented importance of assessing functional characteristics of aquatic ecosystems and their connection to ecosystem services, far fewer studies of mining-polluted watersheds have measured effects on ecosystem processes (e.g., production, nutrient cycling, and detritus processing). The general but largely untested perception that ecosystem processes are less sensitive to contaminants and other stressors compared to population and community responses may account for this disparity (Schindler, 1987).

The use of species traits to assess mining effects

A relatively recent approach derived from basic ecology that is being employed in stream bioassessments is to use species traits to quantify effects of metals and other stressors associated with mine discharges (Poff, 1997; Verberk et al., 2013). Instead of measuring responses of individual species to a contaminant, the idea is to examine how species traits, such as physiological, morphological, behavioral, life history, and functional characteristics are affected (Clements et al., 2021). The assumption is that species traits are more closely linked to attributes that confer sensitivity or tolerance to a particular stressor and therefore provide a mechanistic link between stressors and responses. For example, we know that the toxic mode of action for many metals is damage to gill structures. Therefore, we would expect organisms that respire by gills would be especially sensitive to metals. Similarly, because metal concentrations are often significantly elevated in algae and biofilm, we expect organisms that graze on these materials to have greater exposure to metals. The use of species traits offers distinct advantages over traditional taxonomic approaches when assessing effects of stressors over broad geographic regions. Comparisons of abundance and distribution among regions are often difficult because of natural variation in community composition. In contrast, we expect species traits, which are presumably responding directly to environmental conditions, would be less influenced by natural biogeographic variation compared to taxonomic abundances. The use of this approach in bioassessment is much more effective if species traits are selected a priori based on expected sensitivity to a stressor rather than analyzing data and then providing mechanistic explanations for patterns of individual traits post hoc.

Effects of metals within the context of water quality criteria

Water quality criteria developed in the U.S. are designed to protect aquatic organisms from the adverse effects of chemicals (Adams et al., 2020). These criteria are based primarily on results of laboratory toxicity tests and typically use organisms that are easily cultured in the laboratory (e.g., *Cladocera*; fathead minnows; rainbow trout). Not surprisingly, there has been considerable debate in the literature regarding the ecological relevance of short-term toxicity tests for guarding against adverse effects in nature (Cairns, 1986). The major criticisms of laboratory tests include their short duration (typically 4–7 days), failure to consider dietary exposure to chemicals, and the inability to account for either indirect effects (e.g., competition; predator-prey interactions) or responses at higher levels of biological organization. We also know that most watersheds contaminated by mine discharges receive multiple metals, and the potential additive or greater than additive effects of individual chemicals are not considered when developing water quality criteria. In addition, despite a highly sophisticated understanding of how site-specific variation in water quality characteristics influences metal toxicity and bioavailability (Paquin et al., 2002), we know very little about how populations or communities from different watersheds will be affected by metals. Research into these context-dependent responses has shown that the composition of communities strongly determines their responses to contaminants (Clements et al., 2012).

Finally, certain groups of organisms are poorly represented in the database used to develop water quality criteria for metals. For example, toxicity tests conducted with aquatic insects, a diverse and dominant group of organisms in most inland waters, are quite limited because of difficulties rearing and culturing these organisms in the laboratory (Brix et al., 2011). The data available on effects of metals derived from laboratory experiments suggest that aquatic insects are relatively tolerant to metals. In contrast, field studies of streams receiving mining effluents have shown that some aquatic insects are highly sensitive to metals and often the first group eliminated. Explaining these discrepancies between laboratory-based responses to metals versus what is observed in the field remains a significant research need.

Despite these criticisms and the inherent limitations of single species toxicity tests, much of the research conducted with metals suggest that laboratory-derived criteria are reasonably protective of aquatic ecosystems. Their effectiveness in protecting species in the field is in part because they are ultimately based on experiments conducted with highly sensitive (although ecologically irrelevant) test species. However, there is evidence that even a modest exceedance of metals criteria in streams (~2X) can result in significant loss aquatic insect biodiversity (Clements et al., 2021).

Recovery of aquatic ecosystems from effect of mining

Although thousands of active and abandoned mines continue to discharge metals and other contaminants globally, there are examples where remediation at these sites has significantly improved water quality and restored their natural ecological integrity. Remediation of mine sites involves a variety of approaches, including active or passive treatment of mine effluents, removal or treatment of mine tailings from riverbank and floodplain soils, and revegetation of riparian areas. Assessing the effectiveness of mine remediation requires regular monitoring of physical, chemical, and biological conditions. Ideally, monitoring would be conducted before, during, and after completion of remediation and would include both control (non-remediated) and treated sites. This particular monitoring approach allows investigators to employ a highly effective before-after control-impact (BACI) study design whereby improvements in water quality and biological conditions can be causally linked to the remediation treatments and compared with natural variation in control sites. BACI designs have been traditionally used to quantify impacts of anticipated perturbations and are considered the "gold standard" in aquatic bioassessments (Stewart-Oaten et al., 1986); however, in the situation described above the "impact" is actually the removal of stressors associated with the mine. The basic expectation of a BACI design is that reference sites would show little difference before versus after remediation, whereas treated (remediated) sites would show significant improvements in biological conditions (Fig. 6).

Unfortunately, because of budget constraints or other logistical challenges, these ideal study designs are rarely employed to assess remediation effectiveness. In fact, despite significant expenditures on remediation and restoration programs across the U.S. (and other countries), our ability to quantify their effectiveness is often limited by poor study designs, insufficient post-remediation monitoring, and a lack of broadly accepted criteria that define success (Bernhardt et al., 2005). This is unfortunate because in those instances where appropriate study designs have been implemented and sufficient post-remediation monitoring has occurred, results show that aquatic communities in heavily contaminated streams can rapidly recover after the discharge of mine effluents has been eliminated. For example, investigators comparing recovery of streams located in California, Colorado, Idaho, and Montana reported similar recovery trajectories, despite very different watershed characteristics, discharged metals, and remediation techniques (Clements et al., 2021). The fact that these streams, all former U.S. EPA Superfund sites and among the most metal-contaminated watersheds in the western U.S., rapidly returned to reference conditions demonstrates the potential for restoration success under the most extreme conditions.

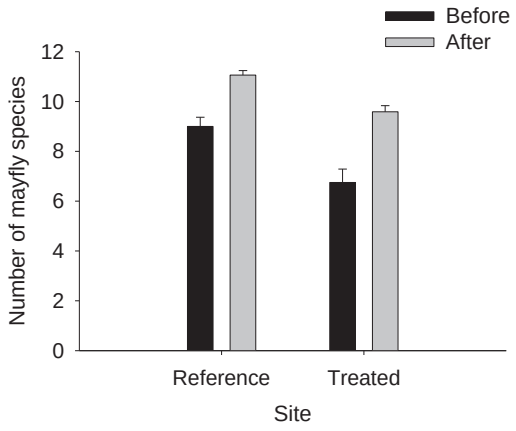

Fig. 6 Example of a before-after control-impact design showing the total number of mayflies (Ephemeroptera) in the Arkansas River, Colorado (U.S.), upstream and downstream from a former U.S. EPA Superfund Site. Data were collected from an upstream Reference site and a downstream Remediated site before and after mine cleanup. Data from Clements et al. (2021).

Conclusions

Discharges from abandoned and active mines are a widespread and pervasive source of contamination in aquatic ecosystems. Metals released from abandoned mines are readily bioconcentrated by aquatic organisms, transferred through aquatic food chains, and can be exported to riparian ecosystems. Typical responses of aquatic communities exposed to elevated metals include reduced species diversity and abundance, shifts in the composition of communities, and the loss of sensitive species. In addition to these direct toxicological effects of metals, indirect and physical effects of abandoned mines can occur as a result of reduced food quality and the loss of prey resources. Although aquatic insects are poorly represented in the database used to derive water quality criteria for metals, these standards appear to be protective of most aquatic organisms. However, modest exceedances of metals criteria in streams can result in significant loss of aquatic insect biodiversity. Finally, several studies have demonstrated that streams can rapidly recover following improvements in water quality. The success of these projects is encouraging and demonstrates the importance of continuing to invest in stream remediation and restoration programs.

Knowledge gaps

- What is the relative importance of dietary versus aqueous exposure of aquatic organisms to metals from mines?
- Why are some aquatic communities more sensitive to metals than others?
- Why do laboratory experiments conducted with aquatic insects show relatively high tolerance to metals, whereas field studies of mine-polluted streams show that insects are highly sensitive and often the first group eliminated?
- What are the likely effects of climate change on the responses of stream ecosystems to mine pollution?
- Does the exposure to metals from mines alter the relative importance of species interactions in aquatic communities?

Glossary

Assemblage A subset of the species in a community. The species in an assemblage are typically within the same taxonomic group (e.g., algae, invertebrates, or fish).

Biological criterion Either a narrative description or a numerical value used to judge if a waterbody is biologically altered or legally impaired (i.e., not meeting its designated use).

Biological integrity The capability of supporting and maintaining a balanced, integrated, adaptive community of organisms having a composition and diversity comparable to that of the natural habitats of the region. This term is used in the United States and is similar in concept to the term ecological status used in the European Union.

Biotic index An index that measures the average tolerance of an assemblage to pollution or habitat degradation.

Causal analysis The process of identifying the stressor or stressors causing biological impairment.

Ecological status An expression of the quality of the structure and functioning of aquatic ecosystems. This term is used in the European Union and is similar in concept to the term biological integrity used in the United States.

Endpoint Either an ecological good or service that society seeks to protect (an assessment endpoint such as biodiversity) or the value of an index that is used to represent the assessment endpoint (a measurement endpoint such as taxa richness).

Harmonization The process of comparing and scaling different types of indices that may differ in what indicator groups are used, how raw data were collected, and how indices are calculated so that they produce similar assessments of ecological quality.

Index of biotic integrity (IBI) An additive multimetric index that incorporates several metrics selected on theoretical grounds that collectively are thought to characterize biological integrity.

Index of taxonomic completeness A ratio index (O/E) that measures the degree to which the taxonomic composition observed at an assessed site (O) matches the composition expected (E), via model prediction, to occur if the site were in reference condition.

Indicator A species, group of species, or functional property used to assess the ecological status of a waterbody.

Metric A numeric measure of some biological structural or functional attribute or trait typically derived from taxonomic counts obtained from a sample of a biological assemblage. Metrics may be in different units – e.g., richness, relative abundance of individuals, mean tolerance of species.

Multimetric index (MMI) An additive index that incorporates several different types of standardized biological metrics. MMIs are similar to IBIs but often differ from IBIs in that the selection of specific metrics is usually guided by how well individual metrics discriminate degraded sites from reference-quality sites rather than a priori selection based on ecological theory.
Reference condition The naturally occurring (i.e., pre-development) or desired condition used to judge the ecological quality of assessed sites.
RIVPACS River Invertebrate Prediction and Classification System – the original method developed in Great Britain to measure taxonomic completeness and other derived indices.
Typology Classification of waterbodies based on similarities in physiography. Typologies are used to control or adjust for naturally occurring differences in aquatic life that may otherwise confound biological assessments.
Water quality standard A regulation that may include specific numeric criteria used to protect designated uses (such as aquatic life) of waterbodies.

What is bioassessment

Most modern societies have laws or policies designed to protect the ecological wellbeing of water resources. Biological assessments include a variety of activities and analyses that provide water resource managers and policy makers with the information needed to infer if, and how, human activities are harming aquatic life. The type and amount of information produced by biological assessments has greatly evolved in response to both changing societal needs and improvements in our scientific understanding of the structure and function of aquatic ecosystems and the goods and services they provide. For example, over a hundred years ago aquatic biologists discovered that the presence and absence of specific aquatic species were often associated with pollution (Cairns and Pratt, 1993; Moog et al., 2018). Such indicator species provided information regarding the potential harm different waterbodies could cause to human health. Since then, scientists and policy makers have recognized that the goods and services provided by healthy aquatic ecosystems are also essential to the well-being of human societies and need to be protected. Laws and policies such as the 1972 United States Clean Water Act and the 2000 European Union's Water Framework Directive recognize both the intrinsic value of aquatic species and the need to maintain healthy, sustainable freshwater ecosystems that support human wellbeing. To meet these societal goals, aquatic scientists needed to develop more comprehensive ways to measure the status of aquatic life and the effects that human-caused stressors have on different levels of biological organization (Fig. 1). Not surprisingly, specialized language evolved to facilitate communication between specialists and managers, but which can often be confusing to non-specialists. We define some of these terms in the Glossary.

Legislatively mandated biological assessments often are conducted within an adaptive management framework (Fig. 2) in which aquatic life is monitored over time to determine if desired conditions within a waterbody are being achieved and maintained. In general, all biological assessments are conceptually straightforward in that they require (1) selection of one or more biological or ecological endpoints that represent valued aquatic resources of interest and (2) establishment of a benchmark or criterion by which to judge if a waterbody is biologically altered or legally impaired. In addition, if the assessment leads to the conclusion that aquatic life is impaired, further analyses may be needed to identify the factor(s) causing impairment. However, the specific measures used to

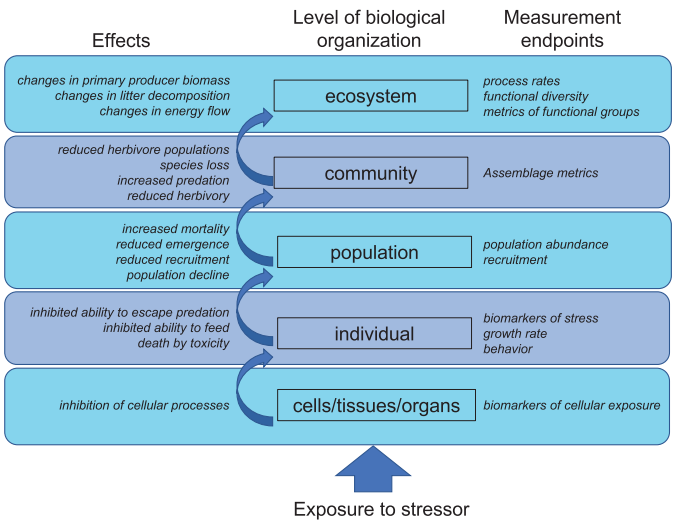

Fig. 1 Diagram illustrating how the effects of a stressor can cascade through different levels of biological organization and the types of measurement endpoints used to quantify its effects at each level.

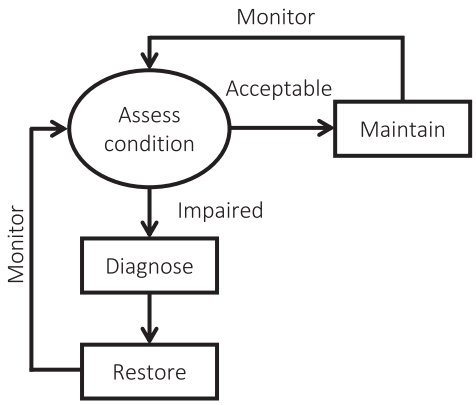

Fig. 2 Diagram illustrating how biological assessments are used within an adaptive management framework to protect and restore the ecological status of aquatic ecosystems.

quantify aquatic life, the approaches used to establish benchmarks or criteria and infer impairment, and the ways used to identify which factors – hereafter stressors – are causing biological impairment vary markedly among programs and practitioners. In this chapter, we summarize the ways aquatic scientists have addressed each of these core aspects of biological assessment as applied to natural water bodies and conclude by highlighting outstanding issues that are currently being addressed and could improve the performance of biological assessments in the future.

Quantifying the status of aquatic life - endpoints, indicators, and indices

Most people have a general, intuitive understanding of what aquatic life is and, perhaps, what biological integrity or ecological status means. Aquatic life includes the set of species (from microbes to vertebrates) that inhabit aquatic ecosystems, and the terms biological integrity and ecological status refer to the level of biological condition or health exhibited by aquatic life. In the United States, biological integrity was defined as "the capability of supporting and maintaining a balanced, integrated, adaptive community of organisms having a composition and diversity comparable to that of the natural habitats of the region" (Frey, 1977). The Water Framework Directive uses similar, although briefer and broader language to define ecological status as "an expression of the quality of the structure and functioning of aquatic ecosystems" (European Commission, 2000). The latter definition explicitly recognizes that functional processes are an important aspect of ecological status, whereas functional processes are implied but not specifically mentioned in the definition of biological integrity. Because the term ecological status is explicitly more inclusive than the term biological integrity, we will use ecological status in the rest of this chapter when referring to the overall condition, or health, of aquatic life and the ecological processes supported by aquatic life.

Aquatic scientists largely assumed the responsibility for mapping broad policy language to specific scientific concepts and deciding what to measure and how. Ecological status is a general assessment endpoint (i.e., the ecological goods and services that society seeks to protect) that is targeted by water resource legislation and policies. However, aquatic scientists have not agreed on a standard list of measurement endpoints (i.e., specific biological attributes or features) to use when characterizing ecological status, and decisions on what to measure have varied across national and state jurisdictional borders for many legal, historical, scientific, and practical reasons. The result has been a sometimes confusing mix of hundreds of combinations of indicators, sampling methods, indices (measurement endpoints), and analysis techniques (Friberg et al., 2011; Birk et al., 2012) that have made cross-program comparisons of ecological status difficult (Cao and Hawkins, 2011). Moreover, even if all aquatic scientists agreed on a common set of indicators and measurement endpoints, it is not clear how they should be weighted to produce an overall measure of ecological status. In addition, some measurement endpoints are much more difficult or expensive to quantify than others, which limits their practical application. Despite these challenges and lack of complete consensus, broad similarities have emerged in the specific types of measures that have been developed for use in biological assessments. Fish, macroinvertebrates, algae, and macrophytes have been frequently selected to serve as indicators of overall ecological status, but several ways of measuring or quantifying status (measurement endpoints such as an index) have been developed (Bonada et al., 2006).

Many bioassessment programs recognize that selection of the type of indicator used can influence institutional and public support. For example, aquatic vertebrates, specifically fish, are a conspicuous component of aquatic life that are generally valued by society because they provide both food and recreation. In contrast, the public is less aware of the importance and value of less conspicuous species (such as invertebrates, algae, and microbes) to human wellbeing. Consequently, fish are frequently used as an indicator to assess the broader endpoint of overall ecological status. However, fish abundance and diversity may be naturally too low or variable to serve as a good indicator of overall ecological status in some regions, so many bioassessment programs use macroinvertebrates as an indicator group because they are cosmopolitan in distribution and both locally and regionally diverse.

In general, bioassessment practitioners have tried to select taxa groups as indicators that have both public recognition and ecological attributes that make them good indicators. Research has shown, though, that no single taxa group adequately represents how all other groups respond to human-caused stress (Carlisle et al., 2008; Bae et al., 2014). More than one group of taxa must therefore be used collectively to provide a robust assessment of overall ecological status. Moreover, static measures of status based on assemblage structure and species composition may not provide much insight regarding how functional processes respond to stress (Friberg et al., 2011), although strong relationships have been observed in some studies (Wallace et al., 1996).

Indices

Regardless of the indicator group(s) used in assessments, managers need measurement endpoints that quantify ecological status. Several different methods have been developed to do so, the choice of which was driven by specific sociopolitical needs coupled with the current state of scientific understanding of aquatic ecosystem structure and function. Six broad approaches emerged over time: the use of indicator or sentinel species, diversity indices, biotic indices, multimetric indices, measures of taxa loss or shifts in taxa composition, and functional indices. Regardless of the measurement endpoint used, the assessment of ecological status is usually based on the degree to which index values observed at an assessed site deviate from values observed at one or more reference sites considered to be in high, or desirable, ecological condition (see the section on Benchmarks and baselines for details).

Indicator/sentinel species

Indicator or sentinel species are those species that are highly sensitive to environmental disturbance and are sometimes used in aquatic biological assessments to provide an early warning that more severe water quality conditions are likely to occur unless mitigation measures are taken. However, the response of single species cannot quantify overall ecological status because they occupy only a small part of the overall niche space represented by an entire ecological assemblage. As a consequence, bioassessment programs typically favor the use of indices that assess the overall condition of entire assemblages.

Diversity indices

The first of the assemblage-wide indices used in bioassessments were species diversity indices, such as the Shannon-Wiener index. With the emergence of theoretical ecology in the 1970s, aquatic scientists promoted the use of these indices, which measure aspects of alpha diversity (i.e., at a site) and whose values are jointly influenced by variation in both taxa richness and evenness. Two potential advantages of these indices are that they had a theoretical foundation and did not require specific identification of taxa (just the ability to assign individuals into unique taxa – e.g., morphospecies). High diversity values were interpreted as implying better ecological status than lower diversity values. However, use of these indices as a sole basis for quantifying ecological status was soon abandoned both because natural systems vary substantially in both of the key diversity components of richness and evenness and because little consensus emerged regarding the broader ecological significance of observed differences in diversity values. Recent studies have questioned the extent to which diversity indices like the Shannon-Wiener index can be interpreted and compared (e.g., Jost, 2010) and suggest that they may obscure signals based on simple measures of taxa richness and evenness (Cao and Hawkins, 2019). Despite difficulties in their interpretation, diversity indices are still frequently included as one of several metrics incorporated in more contemporary multimetric indices (MMIs). There is evidence, though, that simple measures of taxa richness, after adjusting for the effects of natural environmental setting, may be an effective index of ecological condition (Bailey et al., 1998).

Biotic indices

Biotic indices quantify assemblage-wide tolerance to organic pollution. The original biotic indices were based on tolerance of species to reduced oxygen associated with organic pollution (Chutter, 1972; Hilsenhoff, 2017). Biotic index values can represent either the simple or weighted average of tolerance values assigned to species. Tolerance values were often assigned based on expert knowledge derived from observations of species distributions across known organic pollution gradients, and low tolerance values were assigned to sensitive species and high values were assigned to tolerant species. This approach assumes that waterbodies with lower biotic index scores (i.e., relatively more sensitive species) are in better ecological status than waterbodies with higher biotic index scores (i.e., relatively fewer sensitive species). However, aquatic scientists soon pointed out that species tolerances can vary markedly across natural environmental gradients and that values calculated from appropriate sites in reference condition were needed to avoid misinterpretation of ecological status. Moreover, biotic indices measure just one aspect of ecological condition and may therefore be less robust than desired.

Multimetric indices

Multimetric indices are additive indices in which several aspects of assemblage structure (e.g., trophic structure, taxa composition, tolerance, richness/diversity) are first standardized to a common scale and then summed to represent a more ecologically comprehensive measure of ecological status than any single metric provides. The first multimetric index, an *Index of biological*

integrity (*sensu* Karr, 1981), was specifically designed to include measures that spanned the types of community attributes mentioned in the definition of biological integrity. However, the selection of the individual metrics used in more recently developed multimetric indices have been driven more by their ability to discriminate reference-quality waterbodies from those believed to be degraded or stressed (e.g., Hering et al., 2006; Stoddard et al., 2008), thus MMIs have lost some degree of connection to the original concept of biological integrity that stimulated their development and use. However, MMIs are widely used and much progress has been made in improving their performance (Ruaro et al., 2020).

The use of biological traits that describe species autecology beyond the standard metrics used in many MMIs has been proposed for use as metrics in MMI-type indices (Dolédec and Statzner, 2010; den Brink et al., 2011). A theoretical advantage of using biological traits as metrics is that variation in biological traits should be more independent of geography than variation in taxa. Theoretically, indices based on biological traits should also lead to more direct mechanistic interpretation of the causes of biological degradation than is possible from taxonomic-based indices (Poff et al., 2006; Culp et al., 2011). Trait-based indices should also be more comparable across regions than taxa-based indices because convergent evolution has led to species possessing the same types of traits globally.

Indices of taxonomic completeness

The last major approach to assessing ecological status focuses on quantifying species loss or shifts in taxonomic composition. In this approach, the taxonomic composition observed at an assessed site is compared with that expected to occur in the absence of human-caused environmental alteration. Two main approaches have emerged in their use: a numerical expression of the degree of departure of assemblage composition from reference conditions, and a graphical approach. In the prior case, originally developed in the United Kingdom as RIVPACS (River Invertebrate Prediction and Classification System) (Moss et al., 1987), the proportion of the specific taxa predicted (expected, E) to occur at an assessed site that are observed (O) provides a quantitative measure of the loss of endemic taxa (O/E). O/E theoretically scales from 0 to 1. In contrast, the graphical approach shows the position of an assessed site in taxa-defined ordination space relative to the distribution of reference sites in that ordination space (Reynoldson et al., 1995). In the latter case, the degree of impairment is based on a more general measure of differences in compositional similarity between an assessed site and a set of appropriate reference sites. Both the assessed site and the reference sites are plotted in taxa-defined ordination space, and confidence ellipses around the reference sites are used to assign the degree of departure by the assessed site. The modeling to adjust E for the effects of natural environmental gradients and the standardization of assessment values as a ratio (O/E) means this approach can potentially be used to directly compare ecological status across regions without the extensive intercalibration and harmonization needed when comparing different MMIs and other types of indices (Furse et al., 2009). In addition, because the modeling modules within RIVPACS approaches are essentially multitaxon distribution models, the main model outputs (probabilities of capture) can be used to estimate which taxa have increased and decreased within regions in response to land use and waterway alteration (Hawkins and Yuan, 2016).

Conceptual and practical differences between MMI and O/E approaches

The MMI and O/E approaches are the most frequently used indices globally, and they differ in three major ways that have produced scientific debates regarding their use and interpretation. First, they differ in what assemblage-level attribute(s) are used to characterize biological status as described above. Second, they differ in how biological reference conditions are determined as described below. Third, they differ in how indices are calibrated. MMIs are calibrated by selecting metrics that best discriminate between reference sites and sites considered to be physically or chemically degraded, hence their performance is potentially dependent on the specific stressor conditions occurring at the degraded sites used in calibration as well as sampling variability and the degree to which typologies or models account for natural variability across reference sites. In contrast, O/E indices do not use degraded sites for calibration, and their performance and interpretation are influenced by those factors that affect model predictive accuracy and precision – e.g., sampling variability, the predictor variables used, the type of model used, and the inherent variability of the reference state.

Indices of ecosystem function

Indices based on snapshots of assemblage composition provide no direct assessment of the ecological processes that provide goods and services. Some traits or metrics have been used to characterize trophic roles of species (e.g., functional feeding groups), which theoretically should indicate shifts in the relative importance of different food resources available to consumers and the relative magnitude of different processes involved in energy flow and material transformations (e.g., shredding of leaf litter, consumption and regulation of algal standing crops, filtering of seston). However, few MMIs include functional feeding group metrics, primarily because they seldom discriminate between reference and degraded sites as strongly as other metrics, which implies that functional feeding group assignments may be too coarse or inaccurate to adequately reflect differences in ecosystem processes. Direct estimates of ecosystem processes are therefore needed. The rate of leaf litter processing has been suggested as one useful ecosystem function index (Wallace et al., 1996; Gessner and Chauvet, 2002; Gulis et al., 2006; Young et al., 2008). Differences in processing rates have been detected associated with changes in nutrient inputs, sedimentation, and the presence of contaminants, but such measures have yet to be routinely incorporated into large-scale biomonitoring programs, probably because they can be either too expensive or time consuming.

Benchmarks and baselines

Modern biological assessments measure ecological status as the magnitude of departure of the value of an index of choice from a baseline value. Ideally this baseline (or reference) value would describe the range of natural variation expected at each individual waterbody (Stoddard et al., 2006; Hawkins et al., 2010). Historical data collected over many years at sites prior to human-caused alteration would provide the best estimates of reference condition. However, such data are rarely available, although past assemblages have been reconstructed from fossil organisms observed in sediment cores from lake bottoms. Furthermore, this approach is largely limited to standing waters and may not be practical for routine bioassessments. Instead, the biota expected to occur under natural or desirable conditions are usually estimated via some type of control-impact design or a space for time substitution. The control-impact design requires that one or more reference sites be selected for each assessed site and both the reference and assessed site must be sampled over the same time period. Control-impact designs, though, are expensive, susceptible to serious statistical limitations, and most applicable to targeted assessments of individual sites rather than regional surveys. Some type of space-for-time substitution is used in most regional surveys, but they also have limitations as described below.

The more common approach that can be used in both targeted assessments and regional surveys is to select a large number of high-quality (natural condition or reflective of desirable condition) reference sites within a region of interest. The spatial variation in aquatic life observed across these high-quality sites is then used to estimate natural spatial variation in aquatic life. In the MMI approach, reference condition was originally estimated directly as the variation among reference sites within a homogeneous landscape – e.g., an eco- or bioregion or within a geomorphic or hydrologic type of waterbody, and no attempt was made to specifically estimate temporal variability at individual sites (Hughes et al., 1986). If the index value observed at an assessed site fell outside of a specified range of values observed at the reference sites (e.g., 10th and 90th percentiles), that site was considered to be in non-reference condition and likely to be biologically impaired. Effects of natural environmental gradients within a region or waterbody type were often implicitly ignored, except for stream size in some cases. In the O/E index approach, the relationship between species composition and naturally occurring environmental gradients is modeled in an attempt to more accurately and precisely estimate the reference condition that best matches each individual assessed site (Moss et al., 1987; Bailey et al., 2004; Hawkins et al., 2010). In this approach, model residuals estimate the range of natural variability expected at each site in the region (i.e., a space-for-time substitution), although these residuals also include unexplained variation in E associated with sampling variation and model error. This approach has also been used to adjust simple measures of taxa richness for the effects of natural environmental variation (Bailey et al., 1998). More recently, modeled MMIs and biotic indices have been developed in which either each individual metric of an MMI is modeled (Cao et al., 2007; Vander Laan and Hawkins, 2014) or the MMI or biotic index as a whole is modeled (e.g., Hawkins, 2006) as a function of natural gradients to better parse the effects of stressors and natural environmental features on index values. The primary limitation of this approach is that the quality and number of reference sites can vary across regions, and without post hoc adjustments for reference site quality, assessed sites in some regions can be held to a higher or lower standard than sites in other regions. This issue is not as problematic, though, if reference sites in a region are mainly used to establish an anchor or benchmark that can be used to assess if sites are improving or not over time. An active area of research focuses on how to predict reference conditions in the absence of (high-quality) reference sites – i.e., in regions that are generally degraded or altered by human activities (Chessman and Royal, 2004; Paulsen et al., 2008).

Establishing physical/chemical water quality standards protective of aquatic life

The protection of ecological status generally requires regulatory policies that set limits to physical and chemical conditions beyond which aquatic organisms are harmed. Water-quality standards are regulations that may include specific numeric criteria used to protect designated uses of water bodies – such as the maintenance of aquatic life. In theory, numeric criteria are the concentrations of pollutants (or the degree of habitat degradation) in water bodies beyond which substantive or unacceptable ecological harm occurs, and they are therefore considered allowable limits for regulatory purposes. Traditionally, these criteria were established by conducting bioassays that expose a standardized set of species to different concentrations of a pollutant in a highly controlled laboratory setting for a standardized period of time (e.g., 96 h). Biological responses to pollutant exposure are then measured, which may be either acute or chronic, lethal or sub-lethal. The resulting dose-response relationship is then modeled and used to estimate the pollutant concentration at which a measurable biological response is initiated (e.g., Lowest Observed Effect Concentration, or LOEC). For practical reasons, bioassays are often limited to acute, single-species exposures, and the resulting LOEC is divided by a safety factor to better protect against chronic exposures. If LOECs are available for many different experimental organisms, the LOEC protective of 95% of species, or some other agreed-upon number, could be estimated and used as the water quality criterion—an approach known as species-sensitivity distributions (Posthuma et al., 2001). A common criticism of bioassays is that they lack realism, largely because they are derived from a set of species that are conducive to laboratory rearing rather than representative of the species native to the waterbodies of interest. Moreover, controlled testing is not representative of exposures and responses under natural conditions over the full life-cycle of most species (Clements and Kotalik, 2016). However, large-scale survey data are being increasingly used to either construct field-based species-sensitivity distributions or describe how the values of indices of choice (e.g., MMIs or O/Es) vary across gradients of specific stressors. These relationships coupled with laboratory data and information produced during stressor identification (see below) can be used to better estimate criteria that more fully protect

aquatic life. Indeed, some studies that integrate more realistic experimental exposures – such as on multi-species assemblages within microcosms – with field data have shown that water-quality criteria based on bioassays alone are not sufficiently protective of natural systems (Miller et al., 2020).

Stressor identification

Knowledge of ecological impairment is fundamental in identifying waterbodies in need of restoration, but that knowledge by itself provides insufficient information to guide the specific management actions needed to achieve restoration goals. Therefore, a critical next step is to identify the stressor(s) causing impairment of ecological status – often described as diagnosis or causal analysis (Norton et al., 2009). Diagnosis typically occurs on a site-specific basis because sites (e.g., river segments) are usually the management unit of concern. But insight into potential stressors can also be gained by analysis of survey data across many sites and stressor gradients (Vander Laan et al., 2013).

Diagnostic approaches to stressor identification can be based solely on biological data, on empirical relationships between biological data and measured stressors, or combinations of both. The most common approach, however, is limited to the use of the biological data collected at monitored sites, largely because many stressors simply cannot be adequately characterized with a single discrete sample—as is typically employed in large-scale bioassessment programs. For example, characterizing the modification of hydrologic or thermal regimes or episodic exposure to pesticides requires continuous monitoring over many months, which presents major logistical and economic constraints. Diagnostic approaches that rely on biological data typically include the computation of metrics based on external information, such as species sensitivities to specific stressors from bioassays, or species traits derived from life-history studies. Both approaches assume that patterns observed in impaired biological communities provide clues about potential causative factors.

Diagnostics based on known species sensitivities consider the extirpation of sensitive species as diagnostic evidence. Indeed, this is the premise for some biotic indices that are computed from assemblage data based on relative sensitivities of taxa to specific stressors. In theory, these indices respond to changes in assemblage composition driven by declines in taxa that are sensitive to a specific stressor and increases in taxa that are tolerant of that stressor (e.g., salinity). This specificity in response is an important assumption in the use of these diagnostic indices. This approach has promise, but many taxonomic groups appear to be sensitive or tolerant to multiple types of stressors. For example, experimental evidence shows that the mayfly family Heptageniidae is among the most sensitive aquatic insect group to heavy metal exposure (Clements et al., 2002). However, reductions in the diversity or abundance of this group at a monitored site does not reliably indicate the presence of heavy metals because many species in this family are also sensitive to sedimentation or the modification of hydrological and thermal regimes (Carlisle et al., 2011).

Diagnoses can also be based on trait signatures such as shifts in body morphology, phenology, desiccation resistance, or dispersal abilities (den Brink et al., 2011; Culp et al., 2011) as discussed earlier. The assumption is that changes in trait signatures at ecologically impaired sites are indicative of exposure to specific types of stressors. For example, if the relative abundance of desiccation-resistant species is higher than expected at an ecologically impaired site, then dewatering could be considered a potential cause. Researchers are evaluating the potential utility of extracting causes of degradation from overall trait profiles (e.g., Culp et al., 2011) as well as developing stressor-specific indices for causal diagnosis (e.g., Murphy et al., 2015). These approaches show promise, but major limitations of trait-based approaches are (1) the limited autecological and natural history information available for many species and (2) the coarseness at which many trait categories are described (e.g., cold, cool, and warm water taxa). Traits for fish are better known than for other taxonomic groups, except for the European insect fauna (Schmera et al., 2015). Another limitation is that the environment often acts on groups of interrelated traits (adaptive syndromes), many of which are also linked to phylogenic history. The assumption of specificity, as described above, also applies to trait-based approaches. In summary, trait-based, diagnostic indices have intuitive appeal as they are based on ecological theory, but more research is needed to demonstrate their diagnostic power.

Integrated approaches may be more reliable in diagnosing stressors given the limitations of individual stressor-specific indices. For example, the SPEAR (SPEecies At Risk) index developed in Europe uses information on relative sensitivities of taxa to organic chemicals obtained from bioassays, combined with information on estimates of relative risk of exposure based on life histories (e.g., timing of emergence relative to season of pesticide applications). Such integrated indicators are promising (Bray et al., 2021), but their reliability at diagnosing causes of ecological impairment has yet to be widely established.

Diagnostic evidence from indices derived from sensitivities or traits can be substantially enhanced where stressors have also been reliably characterized at monitoring sites. However, measures of stressors require context to be useful for stressor diagnosis. Potential stressors that also occur naturally, such as sediment deposition, streamflow alteration, temperature modification, and nutrient concentrations, need to be placed in context of the natural range of conditions at the assessed site. Even potential stressors that are entirely anthropogenic, such as many pesticides, need to be viewed in the context of how variation in natural factors influence responses to novel stressors. Moreover, responses need to be interpreted in context of whether acute or chronic lethal concentrations have been estimated and, if so, how. Benchmarks for many stressors do not exist, but those for some well-known stressors, such as salinity and maximum water temperature, may be inferred from existing water-quality criteria, although they have known limitations (see previous section). Despite the challenges of characterizing stressors, integrated analyses that include the use of stressor-specific indices can provide strong diagnostic evidence. For example, consider again the site with a higher-than-expected

frequency of species with desiccation-resistant traits. If measured daily flow data indicated that the duration and magnitude of low-flow periods are outside the bounds of natural variation for that site, both lines of evidence lead to a stronger case for flow modification being the stressor causing ecological impairment (Carlisle et al., 2011).

In general, the strongest diagnostic evidence emerges when multiple lines of evidence are obtained through integrated analyses of biological, physical, and chemical survey data, as well as information from follow-up monitoring and investigations (Clements et al., 2002). Integrated analyses as describe above can lead to hypotheses regarding the causative factors responsible for observed biological impairment, which can be subsequently tested with new survey data or more intensive stressor monitoring at a site. In addition, integrated data analyses from region-wide surveys may provide additional evidence regarding the stressors that are most likely influencing an individual site. In addition to multiple lines of empirical evidence, the diagnostic process requires critical thinking about the direct and indirect effects of stressors on biological assemblages—often obtained via conceptual models—as well as thorough reviews of relevant literature.

Outstanding issues and challenges

Fully characterizing aquatic life

Biological assessments of waterbody condition rely on estimates of what species occur in a specific waterbody. Ideally, we would detect all species present in a waterbody, but practical constraints require that we sample (rather than census) the species that are present. Sampling seldom captures all species present, especially for small, diverse taxa such as algae and invertebrates of which we collect a very small fraction of the total individuals present. Moreover, some taxonomic groups (e.g., microbes, protozoans, microcrustaceans) are not typically used in bioassessments because of the expense and time it would take to determine what taxa occur at a site. Even for those taxa frequently used in bioassessments, imperfect detection associated with the use of small sample counts can lead to distorted estimates of taxa richness and other metrics and endpoints. Fortunately, the use of either DNA extracted from benthic samples or environmental DNA (DNA shed by species and suspended in the water column) samples holds great promise in improving the detection of species in all taxonomic groups while simultaneously reducing the time and expense to produce usable data (species counts) from raw samples and the costs of sample processing (Elbrecht and Leese, 2017; Macher et al., 2018). The use of DNA in bioassessments is a very active area of current research (see Baird et al., 2022).

Expand the types of aquatic ecosystems that can be reliably assessed

Another vexing issue is the absence of reliable methods for bioassessment of non-perennial systems such as temporally intermittent streams and ephemeral wetlands (Mazor et al., 2014; Soria et al., 2020). Non-perennial streams represent a significant portion of the headwaters of stream networks in mesic regions, but they constitute the majority of the networks in arid and semi-arid regions. Ephemeral wetlands are critical reproductive habitat for many invertebrates and vertebrates. However, most state and federal programs are unable to assess the ecological status of these important ecosystems because bioassessment methods have not yet been fully developed and evaluated for these aquatic systems. Active research has started in arid and semi-arid regions of the world (see Compson et al., 2022), but much more is needed, especially given that these systems appear to be much more dynamic and unpredictable than their perennial counterparts (see next section). In addition to non-perennial water bodies, perennial ponds, small lakes, and bogs also are often overlooked in regional bioassessment programs.

More thorough incorporation of ecological theory in index development and interpretation

Reference condition approaches to biological assessment require that practitioners predict the biological condition that would be expected at a waterbody if it was in reference condition. Both classification (typologies) and continuous modeling approaches to predicting biological reference conditions essentially assume biota-environment relationships are deterministic and that taxa or their traits are inherently predictable as long as the classification is correct or the appropriate environmental predictors have been measured. The increasing availability of refined environmental data (e.g., stream temperatures, hydrologic regimes, background water chemistry) and sophisticated statistical tools (e.g., random forest and other machine learning predictors) have improved the accuracy and precision of predictions to some extent, but considerable prediction error still occurs, especially in highly dynamic landscapes that experience frequent natural disturbance. Aquatic scientists now recognize that ecological communities vary in the extent to which they are predictable because the relative importance of niche processes (deterministic biota-environment relationships), dispersal-driven processes, and stochastic colonization and establishment can vary considerably across regions. The development of metapopulation and metacommunity theory (Leibold et al., 2004) has provided the bioassessment community with great insight regarding how to use this understanding to potentially improve assessments (Brown et al., 2011; Heino, 2013; Cid et al., 2020; Brown et al., 2022). For example, depending on the environmental setting, niche processes can vary in their strength with strong niche effects expected in relatively stable environments and weak niche effects occurring in frequently disturbed systems. Variation in dispersal strength can also affect predictability. For example, the mass effects associated with high dispersal pressure can cause environmentally different waterbodies to harbor assemblages that are more similar to one another than would arise from niche sorting, whereas weak dispersal between environmentally similar, but isolated, waterbodies can cause assemblages to be less similar than expected from niche sorting. Incorporating these processes into biological indices may help improve their performance,

but if the predictability of either species or their traits is fundamentally limited by high, naturally occurring environmental variability, additional predictor variables or new modeling techniques will not likely improve index precision. However, simply recognizing that ecosystems naturally vary in how dynamic and predictable they are can help managers set more appropriate index thresholds for regulatory purposes. For example, knowledge of regional variability in the predictability of assemblages is required to set regionally-specific impairment thresholds from the frequency distributions of reference-site index values observed in different regions.

Other research has focused on the evaluation of different measurement endpoints than those currently represented by the six types of indices discusses earlier. For example, a few researchers have proposed biological indices based on phylogenetic diversity (Keck et al., 2016; Weglarz et al., 2021). They argue that phylogenetic indices can more fully assess the completeness of the functional diversity expected at a site or in a region. Maintaining phylogenetic diversity is a goal of many conservation programs. Such new ideas need to be fully evaluated both in terms of their overall ability to detect biological impairment and with respect to how well the assessment and measurement endpoints match to and address specific policy and management directives.

Moving beyond site-specific assessments

Some biological assessment programs are also starting to recognize the need to move beyond site-specific assessments. Site-specific assessments will continue to be a central focus of most programs because most management activities occur at the site level. However, society also needs to know the spatial extent of biological degradation and if certain types of landscape settings are either more or less sensitive or resistant to human-caused stressors, including climate and other global environmental changes. Answering questions about the status and trends at regional to global scales requires that programs adopt statistically valid survey designs that can estimate regional conditions with known certainty (Paulsen et al., 2008). These designs require that programs assess sites other than those known or expected to be impaired. From these designs, site-specific assessments can simply be scaled up to express mean conditions and the likely distribution of different assessment classes across a region of interest. When biological, chemical, and physical sampling occurs, information from such programs can also be used to identify likely stressors of regional importance as mentioned above. However, other, more regional-specific measures of biological condition can provide additional insight. For example, the predictive models used in O/E assessments can be used to quantify what taxa are decreasing and increasing in frequency of occurrence (Hawkins and Yuan, 2016). This information can help us understand what individual taxa may be most susceptible or responsive to human activities in general. Both sensitive, native taxa as well as tolerant, invasive taxa may require specific conservation actions. Information on the taxa composition at multiple sites can also be used to estimate aspects of regional beta diversity – i.e., how similar or different sites are in taxonomic (or functional) composition. Such measures may be especially useful in assessing the degree to which individual sites within a region may be becoming more or less homogenous in response to human-caused alteration of waterways and their surrounding landscapes (Bini et al., 2014; Hawkins et al., 2015).

Cross-regional comparisons of ecological status are often required to support both national and international policies and legislation. Such comparisons assume that the indices used are either the same or that they can be compared in a straightforward and valid way. Unfortunately, these comparisons are a particularly vexing issue for many programs. For example, the US Clean Water Act requires individual states and tribal nations to assess and monitor the status of their surface waters, but individual states and tribes can choose which scoring tools they use. A similar situation exists across countries in the European Union. Index harmonization efforts have met with limited success, which emphasizes the likely need for states and nations to eventually adopt standard approaches to biological assessments.

Better characterization of stressors

A long-standing issue in bioassessments is the incomplete characterization of stressors, which severely limits the ability to understand causes of ecological degradation. In general, stressors that require continuous or frequent sampling are either inadequately characterized with a single sample, or simply not measured. For example, insecticides are designed to be toxic to invertebrates and are ubiquitous in freshwater ecosystems, but they are almost never characterized in bioassessment programs. Similarly, water temperature is a controlling factor of many ecological processes, but it is typically only measured once during site visits, which provides little information about overall thermal conditions. Fortunately, technological advances and innovative research is starting to provide useful and economical tools for characterizing stressors. For example, the recent development of passive samplers has streamlined the collection and characterization of organic compounds such as pesticides. These devices are essentially containers of media that accumulate organic contaminants through time and were designed to be a standardized way to evaluate bioavailability. Samplers are deployed in a water body for several weeks, such as a period of expected pesticide use in the watershed, and therefore require only two site visits and a single laboratory analysis. Pesticide concentrations extracted from passive samplers were strongly associated with indices of ecological status and more representative of exposure than multiple discrete samples (Waite et al., 2021). A variety of cost-effective methods have also been evaluated for characterizing streamflow. Although it is unlikely that technology will replace the need to deploy and retrieve monitoring devices, which requires at least two site visits, better characterization of stressors is necessary to improve bioassessment programs.

The critical need for effective science communication

The main challenges to effective water resources protection and restoration are social, political, and economic rather than scientific. Aquatic scientists can enhance the development and application of successful bioassessment programs by developing effective ways of engaging and communicating with nonscientists. Doing so requires that scientists clearly communicate their knowledge (and its relevance) to stakeholders and decision makers – a process recently termed translational ecology (Enquist et al., 2017). In many respects, biological assessment programs are the poster children of translational ecology in that regulatory agencies have convened meetings between scientists, stakeholders, and regulators to improve the scientific foundations of biological assessment programs for many years (Adler, 2020). However, the success of any translational ecology approach depends heavily on how well different constituents communicate with one another, and a chief impediment to communication in the past has been the inability, or reluctance, of scientists to explain in simple, direct terms both the need for biological assessments and how to use and interpret the tools they develop. Many scientists increasingly recognize the need to improve their communication skills and are seeking training (Brunson and Baker, 2016). Aquatic scientists are also learning at an earlier career stage that science is just one piece of the information ultimately used by decision makers to develop water resources policy and management goals. That understanding, coupled with an ability to more effectively communicate their knowledge, should allow aquatic scientists to be better advocates for the protection and restoration of the planet's critical aquatic ecosystems and the species that depend on them – including humans.

Glossary

eDNA An abbreviation of the term 'environmental DNA.' eDNA is the DNA that can be extracted from an environmental sample, such as from bulk sediment, filtered water, or mixed communities actively or passively collected (e.g., kick-net sampling and periphyton scraping), as opposed to DNA that is extracted from one individual at a time.

DNA metabarcoding A method to support species-level identification of organisms from bulk or mixed environmental samples via marker gene sequences, without the need to isolate individual specimens.

DNA barcoding The use of DNA sequences from a signature region of the genome to make species-level identifications.

Operational taxonomic unit (OTU) A cluster of similar sequence variants for a marker gene, usually defined by some measure of sequence similarity (e.g., 97%) or dissimilarity (e.g., 3%). OTUs are sometimes used as a proxy for 'species' even though thresholds needed to group sequences from a taxonomically defined species may vary across taxonomic groups and genomic markers. OTUs are usually represented by a single centroid sequence. A synonym is molecular operational taxonomic unit (MOTU).

Exact sequence variant (ESV) Similar to an OTU that is defined by 100% sequence similarity, but ESVs are generated by a denoising algorithm. Denoising methods commonly attempt to remove or correct errors generated during PCR and/or sequencing, remove artefactual chimeric sequences generated during PCR, and remove other artefactual sequences commonly found in rare sequence clusters. Synonyms include amplicon sequence variant (ASV) or zero-radius OTU (ZOTU).

Bioinformatics An interdisciplinary field that integrates aspects of biology, computer science, statistics, and mathematics to automate the analysis, modeling, and visualization of biological data in "pipelines" of software algorithms.

Polymerase chain reaction (PCR) A process used to amplify millions to billions of copies of a DNA fragment via thermal cycling (i.e., repeated cycles of heating and cooling).

Quantitative polymerase chain reaction (qPCR; also called "real-time" PCR) A laboratory technique akin to PCR, but one that involves the monitoring of the DNA amplification during the PCR (i.e., in real time). qPCR involves either fluorescent dyes or DNA probes to detect the amplified DNA fragment.

Droplet digital PCR (ddPCR) A method used for performing digital PCR that is based on water-oil emulsion droplet technology. Samples containing DNA to be amplified are fractionated into 20,000 droplets, and PCR amplification of the DNA occurs in each individual droplet.

High-throughput sequencing A term referring to DNA/RNA sequencing platforms that are capable of sequencing DNA/RNA in parallel, processing up to millions of sequences simultaneously.

DNA sequence capture An approach that targets enrichment of specific regions of a genome. Coupled with NGS, sequence capture technology enables high-throughput screening of genomic regions of interest.

*Joint last authors.

Introduction

Since the advent of the Industrial Revolution, anthropogenic activities, such as agriculture, mining, and rapid urbanization have severely degraded the world's rivers (Echols et al., 2009). As rivers play a critical role in global biogeochemical cycling (e.g., carbon, nitrogen, and phosphorus cycles) and provide essential ecosystem services for society, significant alterations to either the physical and/or biological components of these important habitats are an omnipresent cause of concern, requiring increased understanding of their scale and potential consequences (Limburg, 2009; Norris and Barbour, 2009). The first step in addressing degradation of rivers is to assess the nature and extent of the damage through an understanding of the current state of the ecosystem. In an attempt to reduce and ultimately reverse decades of river degradation, bioassessment programs have been launched in many countries to evaluate the biological condition of aquatic ecosystems (e.g., US Clean Water Act and the European Water Framework Directive) (Buss et al., 2015; Norris and Barbour, 2009). Such bioassessment programs observe the state of river ecosystems through biological surveys (Bailey et al., 2014; Buss et al., 2015) or other direct measures (e.g., field experiments) of the biological elements of the ecosystem (Norris and Barbour, 2009). For example, fish, algae, plants, and most commonly, benthic macroinvertebrates are targeted as units of bioassessment in rivers (Buss et al., 2015).

River macroinvertebrate organisms are sensitive to environmental stressors and have been routinely used as biological indicators of river and stream health (Buss et al., 2015). Yet, current bioassessment programs often rely on microscopy methods based on morphological characters of mature specimens for identification (Elbrecht and Leese, 2017; Emilson et al., 2017). This can be a laborious practice, slowing the delivery of timely results to bioassessment programs. Moreover, misidentifications of closely related taxa with differing tolerances to environmental stressors could have consequences for bioassessment, introducing error and potentially compromising study conclusions (Macher et al., 2016). Thus, there is an unmet need to produce rapid, robust bioassessment data to improve river management.

With the advent of high-throughput gene sequencing technologies, coupled with a maturing program to build reference libraries of marker gene sequences that can facilitate accurate species identification, we can now harvest biodiversity information from environmental samples rapidly and cost-effectively by analyzing their constituent DNA. This extracted DNA is termed environmental DNA, or eDNA. The accessibility of eDNA in traditional bioassessment samples presents a major new opportunity to increase the efficiency and accuracy of bioassessment programs supporting river ecosystem policy development and management (Baird and Hajibabaei, 2012; Deiner et al., 2017). In this chapter, we present an overview of the current state of the science concerning observation of riverine biodiversity using eDNA, and how current and future bioassessment programs could profit by employing this new approach.

eDNA and bioassessment

Although various definitions of eDNA exist in the literature (e.g., Deiner et al., 2017; Pawlowski et al., 2020; Taberlet et al., 2018, 2012a, b), here we define eDNA as all of the DNA that can be extracted from an environmental sample, such as from bulk sediment, filtered water, or mixed communities actively or passively collected (e.g., kick-net sampling and periphyton scraping), as opposed to DNA that is extracted from one individual at a time (Fig. 1). DNA extracted from environmental samples includes both the intra- and extracellular DNA of living, decaying, or dormant cells, including cells that are shed by organisms, gut contents, and excrement (Deiner et al., 2017; Pawlowski et al., 2020). Once eDNA has been extracted from the river environmental sample, signature DNA sequences from target species (e.g., invasive species, pathogens), target assemblages (e.g., Ephemeroptera, Plecoptera, Trichoptera), or whole communities (e.g., plants, macroinvertebrates, bacteria, fungi, diatoms—see Deiner et al., 2017; Hajibabaei, 2012; Kelly et al., 2020) can be enriched for DNA gene sequence analysis for bioassessment of rivers. While the detection of a species from eDNA does not necessarily indicate the presence of a living organism at a sampling site, it does provide a biological signal for an organism in the broader study area. In essence, the assessment of eDNA in rivers can provide a snapshot, within a relatively narrow time window, of a target species, assemblage, or community that can be used for bioassessment.

The Environmental Protection Agency (EPA) defines bioassessment as, "the process of evaluating the biological condition of a body of water using biological surveys (i.e., biosurveys) and other direct measurements of the resident biota, and those organisms living in the surface water, including fish, insects, algae, and plants." Traditional means of generating biodiversity data for bioassessment, such as morphology-based identification of freshwater benthic macroinvertebrates, were established decades prior to the implementation of eDNA methods. While DNA-based methods are often advantageous over traditional methods for generating biodiversity data for bioassessment (e.g., detection of rare, cryptic, or low- density taxa and identification to genus or species level; Ruppert et al., 2019), there are also instances where eDNA approaches fall short of traditional methods for detection (e.g., for semi-aquatic snakes; Rose et al., 2019), and there are benefits in combining these approaches. Bioassessments for freshwater health have been enhanced through the application of eDNA due to the ability to identify a greater number of bioindicator taxa to lower taxonomic ranks (i.e., to genus and species level). Likewise, morphological approaches enable direct abundance and body size measures of identified taxa and assessment of life history characteristics (e.g., whether it is a larval, pupal, or adult form), and thus these approaches provide valuable information for biobanking of biodiversity data (Sheth and Thaker, 2017).

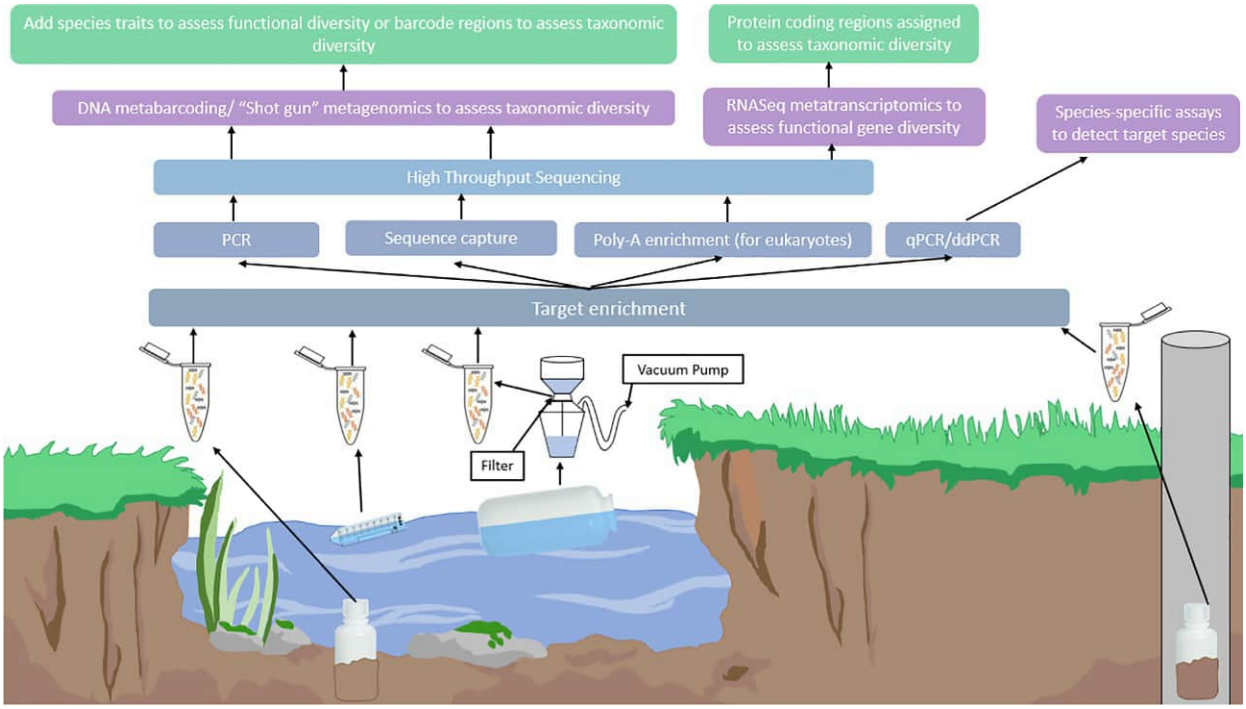

Fig. 1 eDNA workflows for bioassessment in freshwater ecosystems to assess taxonomic or functional diversity.

Observing river biodiversity with eDNA

DNA barcoding and DNA metabarcoding of eDNA has revolutionized the way we observe biodiversity and detect biological change in river ecosystems. The term 'DNA barcoding' refers to the use of DNA sequences from a signature region of the genome to make species-level identifications (Hebert et al., 2003). The process involves the use of reference sequence libraries from individual specimens identified by experts. Collection information, referred to as metadata, is deposited into a database that houses barcode sequences from such specimens along with the trace file of the sequence itself (Ratnasingham and Hebert, 2007). The Barcode of Life Database (BOLD) can be accessed from https://www.boldsystems.org/ and holds about a million DNA sequences representing freshwater biomonitoring taxa of interest (Porter and Hajibabaei, 2018b). DNA barcode sequences from taxonomically identified specimens. DNA barcodes, when linked to confirmed specimen identifications, can form the basis of a reference database for the species-level identification of marker gene sequences that are generated from bulk or mixed environmental samples, i.e., without the need to isolate individual specimens. This has been termed DNA metabarcoding (Hajibabaei et al., 2011; Hajibabaei, 2012; Taberlet et al., 2012b).

For animals, the official barcode region is ~658 base pairs (bp) of the cytochrome *c* oxidase subunit I (COI) gene found in the mitochondrial DNA; other signature DNA regions may be more appropriate for other organisms (Table 1). For example, other suitable DNA regions include: the internal transcribed spacer (ITS) rRNA for fungi; the ribulose-bisphosphate carboxylase (rbcL) and maturase K (matK) region for plants, and 16S rRNA for prokaryotes. While these are the most commonly targeted genes for a vast array of organisms, 5.8S rRNA, 18S rRNA, and large subunit rRNA (LSU rRNA) have been used for other microbial-eukaryotic groups, and 18S rRNA for other eukaryotes. There are also other genomic markers, such as small and large subunit rRNA as well as a suite of "housekeeping" genes, which have been useful for fungal species and even strain-level identification (Taylor and Fisher, 2003). For plants, there are a number of genomic regions that have been used for phylogenetic studies, and these have in turn been used as targets for marker gene studies (Hollingsworth et al., 2011). The current consensus is that rbcL and matK cpDNA together may provide species-level resolution for plants; however, it has also been suggested that ITS rDNA may be needed as well to be able to make species-level identifications (Hollingsworth, 2011).

Albeit both DNA barcoding and metabarcoding are procedures to detect and identify organisms, DNA metabarcoding is more feasible for bioassessment, as this approach can process 96 taxonomically diverse environmental samples (96-well plate) at a time, as opposed to separating and sorting 96 individual organisms for downstream DNA sequencing (Hajibabaei et al., 2011). Environmental samples often contain a plethora of phylogenetically diverse organisms, and this can be inconvenient for sorting and separating organisms quickly. Because many bioassessment programs need to repeat biological monitoring regimes over large-scales and frequent time intervals (Hajibabaei et al., 2011), a DNA metabarcoding approach for multi-species bioassessment

can overcome bottlenecks for routine biomonitoring in times of when biodiversity information is urgently needed. However, for single-species approaches and/or for adding to library reference databases, DNA barcoding and other technologies, such as quantitative PCR (qPCR) and droplet digital PCR (ddPCR), may be applicable for river bioassessment.

Environmental DNA workflow

In Table 2, we outline several bioassessment targets and illustrate appropriate eDNA methods by 'use cases,' and in Fig. 1, we provide a schematic for eDNA workflows for bioassessment in freshwater ecosystems. The detection and identification of organisms from eDNA typically involves 5 procedures (Fig. 1): (1) environmental sample collection; (2) extracting DNA from environmental samples; (3) performing polymerase chain reaction (PCR) to amplify the DNA in the sample(s); (4) DNA/RNA sequencing; and (5) bioinformatic analysis. For collecting eDNA from water, samples are typically either collected in small volumes (i.e., $\sim$ 15 mL) and precipitated in ethanol (Ficetola et al., 2008), or collected in larger volumes (i.e., $>$ 250 mL) and filtered (Tsuji et al., 2019). A range of different filter styles and sizes have previously been applied to eDNA sample collection (e.g., see Majaneva et al., 2018). Bulk-benthos or river sediment samples can be collected via direct surface sediment collection (e.g., Turner et al., 2015), sediment coring (e.g., Shaw et al., 2016) or via benthic kick-net sampling (Hajibabaei et al., 2011). After environmental samples are collected, DNA is extracted from these samples using a DNA extraction kit. Several DNA extraction kits exist but can differ in quality, DNA yield, and cost. Moreover, studies have shown that the type of environmental sample from a river (e.g., water vs benthic sample) is known to yield differing concentrations of DNA and should be taken into consideration for bioassessment programs, as this can influence the number of taxa detected in a sample type (Macher et al., 2018; Hajibabaei et al., 2019a).

Once eDNA has been extracted from the environmental sample, the DNA is amplified via PCR to produce millions of copies of this DNA. To target different taxonomic hierarchies with PCR, gene regions (i.e. DNA 'barcodes') specific to these hierarchies are achieved using a 'universal' primer set (e.g., see Folmer et al., 1994). However, universal primer sets are not without their limitations and no single universal primer set is, in fact, universal. Using species-specific primer sets may be warranted in bioassessment studies in order to analyze species distributions and dispersal mechanisms (Elbrecht et al., 2018) (Table 2). Moreover, for single-species bioassessments (as opposed to a broad suite of taxa) other technologies could provide a useful approach.

Followed by DNA amplification of specific gene regions for target taxa via PCR, DNA is then sequenced using high-throughput gene sequencing technologies. The most commonly used platforms include Illumina, Ion Torrent, Pacific Biosciences, and Oxford Nanopore platforms (Reuter et al., 2015). These technologies typically involve DNA sequencing-by-synthesis in parallel to read DNA fragments ranging from 200 to 400 bp in length. Due to the limitations of current high-throughput sequencing platforms, it is common for DNA metabarcodes to range from $\sim$200–400 bp – only a fraction of the barcode region for most primers, including COI. Where the sequencing platform permits, and where the environmental sample makes this feasible, longer DNA metabarcodes could result in more reliable taxonomic assignments (Porter and Hajibabaei, 2018a, b). The recent development of new sequencing technologies, such as LoopSeq (compatible with Illumina platforms) and circular consensus sequencing (PacBio), may facilitate the generation of DNA metabarcodes that are at least as long as the standard DNA barcode region and that have the potential to sequence even longer regions (Heeger et al., 2018; Tedersoo et al., 2018).

Table 2 Major use cases for the application of eDNA in river bioassessment.

Use case	*eDNA/RNA method*	*Challenge*	*References*
Assessing overall sample diversity	DNA metabarcoding using PCR primers that target the barcoding region of interest. If the community is 'known' and detections only need to be counted, microarray methods would be appropriate.	Taxon detection may vary depending on DNA extraction method, primers chosen, technical replicates, sequencing depth	Majaneva et al. (2018), Baird and Hajibabaei (2012), Taberlet et al. (2012b), Hajibabaei et al. (2019a, b)
Assessing presence of indicator groups (e.g. EPT)	DNA metabarcoding or ddPCR using primers that target the 'barcoding' region for the target taxonomic group(s). Ex. For EPT target the COI region using primers that target arthropods	Working with eDNA extracted from bulk benthos may recover greater diversity than from water samples. Detections from water samples can be improved by using taxon specific primers that exclude detections from non-target taxa. Taxonomic detections will only be as complete as the underlying reference sequence databases.	Hajibabaei et al. (2019a, b) and Leese et al. (2020)
Identifying the presence of single target species	Quantitative PCR (qPCR)	Need to develop species-specific primers. Abundance after qPCR/ddPCR reflects abundance in DNA template which may or may not correlate with species abundance/density	Hernandez et al. (2020)
Analyzing species distribution and dispersal	DNA metabarcoding with species specific primers.	Extra care needs to be taken to ensure sequence quality and removal of artefactual sequences (denoising) to avoid haplotype inflation.	Elbrecht et al. (2018)
Estimating the abundance or biomass of target species.	Quantitative PCR can be used to estimate relative abundance of the same species across samples. In some systems, read abundance has been shown to be correlated with species abundance.	Primer binding efficiency to different DNA templates in a mixture may result in skewed template to product ratios after PCR. This may be less of a problem for quantitative PCR where primers are designed to be species-specific or digital droplet PCR where the PCR reactions occur in their own individual droplets. In eDNA from water, water temperature has been shown to affect release rates of eDNA. The quantitative use of DNA counts/relative read abundance may not be appropriate for macroinvertebrates that may vary by orders of magnitude but may be appropriate for taxa with a smaller range of sizes/DNA release rate such as diatoms or fish.	Polz and Cavanaugh (1998), Elbrecht and Leese (2015), Di Muri et al. (2020)
Assessing functional composition of a target community	This can be done by: (1) identifying functional genes; (2) assigning functional traits. DNA metagenomics targets environmental DNA and can be used to assess whole community genomic content directly from environmental samples. Metatranscriptomics targets environmental RNA, and can be used to assess whole community gene expression. Quantitative PCR can be used to assess or verify gene functions present in environmental samples one gene or species at a time. DNA metabarcoding can be used to identify taxonomic diversity, then traits/function can be mapped from public databases such as EPA Freshwater biological traits database (USA), freshwaterecology.info (Europe), or the primary literature.	Taxonomic identification from non-barcode genes/regions may be difficult as database representation for taxa tends to be most diverse for barcoding markers. Gene function from metagenomic or metatranscriptome sequences may be possible using public databases. Ecological traits can be mapped onto taxonomically identified metabarcodes, but databases are not necessarily complete and some databases are not formatted for easy parsing.	U.S. Environmental Protection Agency (2012)
Assessing ecological interactions	DNA metabarcoding coupled with trait-matching and probabilistic methods to infer species interactions	Incomplete trait databases/co-occurrence does not always mean taxa interact	Reviewed in Compson et al. (2020), Makiola et al. (2020), and Blanchet et al. (2020)

Identification of biodiversity from eDNA

DNA from many organisms is present in mixed community or bulk samples, and individual species are identified using computational algorithms that compare the 'anonymous' DNA sequences from signature DNA regions to a reference sequence database of known DNA 'barcodes.' This process is referred to as taxonomic assignment, and there are a variety of methods and tools available for this purpose that vary in ease of use, accuracy, and speed (Table 3). Some of these methods (e.g., using Bayesian classifiers—see, Lan et al., 2012; Wang et al., 2007) can produce a measure of confidence for a taxonomic assignment, thus reducing the risk of false positive assignments. However, not all methods used to identify DNA metabarcodes are equally effective, and some methods have difficulty assigning identity with confidence for short query sequences. For example, sequence similarity-based methods such as the, 'top BLAST hit' approach (e.g., see Table 3) is susceptible to short, spurious matches that can lead to false positive assignments, but this can be minimized by employing high query coverage and sequence similarity cutoffs to filter out spurious matches. For COI, the consensus is that metabarcodes at least 200 bp in length can be reliably assigned to species (Porter and Hajibabaei, 2018a). Even without species-level assignments to reference databases, DNA metabarcoding can produce statistically defined sequence clusters, e.g., operational taxonomic units (OTUs) or exact sequence variants (ESVs), that can be used to assess richness and beta diversity in ecological studies (Porter and Hajibabaei, 2018a, b, 2020). Nevertheless, the scalability of bulk sample processing, as well as the speed and statistical confidence of taxonomic assignments based on DNA sequence analysis, addresses some key bottlenecks in conventional biomonitoring studies (Porter and Hajibabaei, 2018a).

The phylogenetic breadth of marker sequences and their reference databases is important so that target taxa can be identified. Existing reference sequence database coverage is highest for small subunit (SSU) ribosomal RNA (rRNA) prokaryotes, as microbial ecologists have been using marker gene sequencing for phylogenetic and specimen identification for decades (Pace, 1997). Many SSU rRNA sequences can be found in the International Nucleotide Sequence Database Coalition (INSDC), which links the National Center for Biotechnology Information (NCBI), DNA Data Bank of Japan (DDBJ), and the European Bioinformatics Institute (EMBL-EBI). There are numerous community-led efforts to build curated prokaryote SSU reference sets, each with their own criteria for sequence inclusion and underlying taxonomy, such as the Ribosomal Database Project (RDP), GreenGenes, and SILVA. For fungi, reference sequence databases have especially high coverage for the internal transcribed spacer (ITS) region of rRNA, as this region has been used for to study fungal molecular ecology and to identify unknown specimens for decades (Bruns et al., 1991). These sequences can be found in the INSDC, and curated reference sets are also available (Kõljalg et al., 2019; Ankenbrand et al., 2015).

The freshwater invertebrates, including water quality indicators (i.e., Ephemeroptera, Plecoptera, and Trichoptera (EPT), chironomids, and Odonata) are typically targeted using the COI mtDNA marker, which has the largest curated reference set available and has been growing since the advent of 'DNA barcoding' for sequence-based, species-level identification (Hebert et al., 2003; Porter and Hajibabaei, 2018b). These sequences are available from the NCBI, but the largest highly curated repository is available from the BOLD database (Ratnasingham and Hebert, 2007). Gap analyses have been conducted for North American freshwater invertebrates (Curry et al., 2018), European aquatic biota (Weigand et al., 2019), and for biomonitoring in general (McGee et al., 2019). Generally speaking, existing databases are heavily biased toward sample records collected in Canada and the USA (Curry et al., 2018), but work is also ongoing in Europe (Weigand et al., 2019) and Australia. Biodiversity research involving rivers and lake benthos on the other hand, is disproportionately focused on polar or tropical regions (McGee et al., 2019). The consequence is that many endemic species, or rare species in tropical or polar regions will lack a reference sequence to permit species-level identification. In these instances, the importance of geographically-expanded reference library building is crucial (Wilson, 2017).

Specific applications: Single-species and multispecies bioassessment

Experimental approaches can vary from single-species assays to multiplexed assays for a handful of target species to approaches using multiple non-specific primers for DNA sequence generation of broad taxonomic groups, such as macroinvertebrates or diatoms (e.g., Ficetola et al., 2008; Hajibabaei et al., 2011; Kelly et al., 2020). DNA metabarcoding approaches, by contrast, are employed to target phylogenetically diverse taxon assemblages, which can be used to study freshwater community ecology, to create

Table 3 Commonly used methods for identifying DNA metabarcodes.

Method	*Examples*
Sequence similarity	The top BLAST hit approach is one of the most widely used methods to identify unknown sequences. A query is compared with a reference database by aligning their sequences and adopting the taxonomic assignment from the top hit with the best alignment metrics such as sequence similarity, query coverage, bit score, e-value.
K-mers	The naive Bayesian classifier is an example of a k-mer based taxonomic assignment method (Wang et al., 2007). Confidence in an assignment is assessed using a bootstrapping procedure.
Phylogeny	Phylogenetic based methods involve assigning taxonomy based on the evolutionary relatedness of a query sequence with reference sequences. Confidence in an assignment is based on statistical support at the nodes obtained from a bootstrapping or posterior probabilities.

food web networks, and to conduct bioassessments (Compson et al., 2020). In Fig. 1, we provide a schematic representation of these methods. Single-species approaches are typically employed for routine monitoring of a particular species of interest, such as conservation monitoring for rare species, environmental screening for newly introduced aquatic invasive species, or assessing the successful eradication of invasive species (Ruppert et al., 2019).

EPT macroinvertebrates comprise the orders Ephemeroptera (mayflies), Trichoptera (caddisflies) and Plecoptera (stoneflies). These taxa groups are generally highly sensitive bioindicator orders in river systems. Presence of these orders at high family/genus/species richness in eDNA samples can indicate that the local freshwater system is "healthy" (Bush et al., 2019). Conversely, high prevalence of particular families from Diptera that are tolerant to low oxygen levels and larvae of Odonata often indicate the degradation of freshwater wetland systems (Kutcher and Bried, 2014), through poor water quality (Fierro et al., 2017). Certain diatom species within the genera *Navicula*, *Epithemia*, and *Achnanthidium* are classed as highly sensitive to changes in aquatic systems, and they are a focus of bioassessment for freshwater health studies worldwide. There are certain orders and genera of diatoms and macroinvertebrates that are either highly tolerant or highly sensitive to low water quality and poor aquatic conditions, and these specific groups are used as biological indicators for freshwater health bioassessments (Apothéloz-Perret-Gentil et al., 2020; Bush et al., 2019).

eDNA bioassessment metrics

To disentangle natural biodiversity variation and anthropogenic-induced biodiversity assemblage fluctuations, long-term (i.e., 10+ years) datasets are required, which are often lacking from DNA-derived data due to the recent introduction of these methods (Jourdan et al., 2018). In addition, creating policies and implementing management decisions based on freshwater biodiversity data requires robust and established datasets (Jourdan et al., 2018). Embracing the combined efforts of traditional and DNA-based methods overcomes the shortcomings of each standalone approach and facilitates integration of new DNA data with long-term morphological datasets (Porter and Hajibabaei, 2018a; Sheth and Thaker, 2017). One such example is the Canadian Aquatic Biomonitoring Network (CABIN), which has been generating biodiversity data for freshwater health bioassessments since 2006 through community-based water biomonitoring. Previously, CABIN solely employed morphological analyses for identifying invertebrates to (mostly) family or genus level; however, CABIN has begun to integrate DNA sample collection methods for downstream DNA metabarcoding as part of a new pan-Canadian biomonitoring project, STREAM (Sequencing The Rivers for Environmental Assessment and Monitoring; Fig. 2). Established in 2018, STREAM seeks to generate data on benthic macroinvertebrates in watersheds across Canada to address data-deficiencies and to create a better understanding of freshwater health (Robinson et al., 2021). The STREAM project involves DNA metabarcoding of river benthos, following the standardized CABIN kick-net sample collection method (Environment and Climate Change Canada, 2012). Combining traditional taxonomic identification and DNA-based sample processing enables resulting data to form the baseline for bioassessment models such as the River Invertebrate Prediction and Classification System (RIVPACS) (Armanini et al., 2013), which facilitates bioassessment comparisons within and between watersheds.

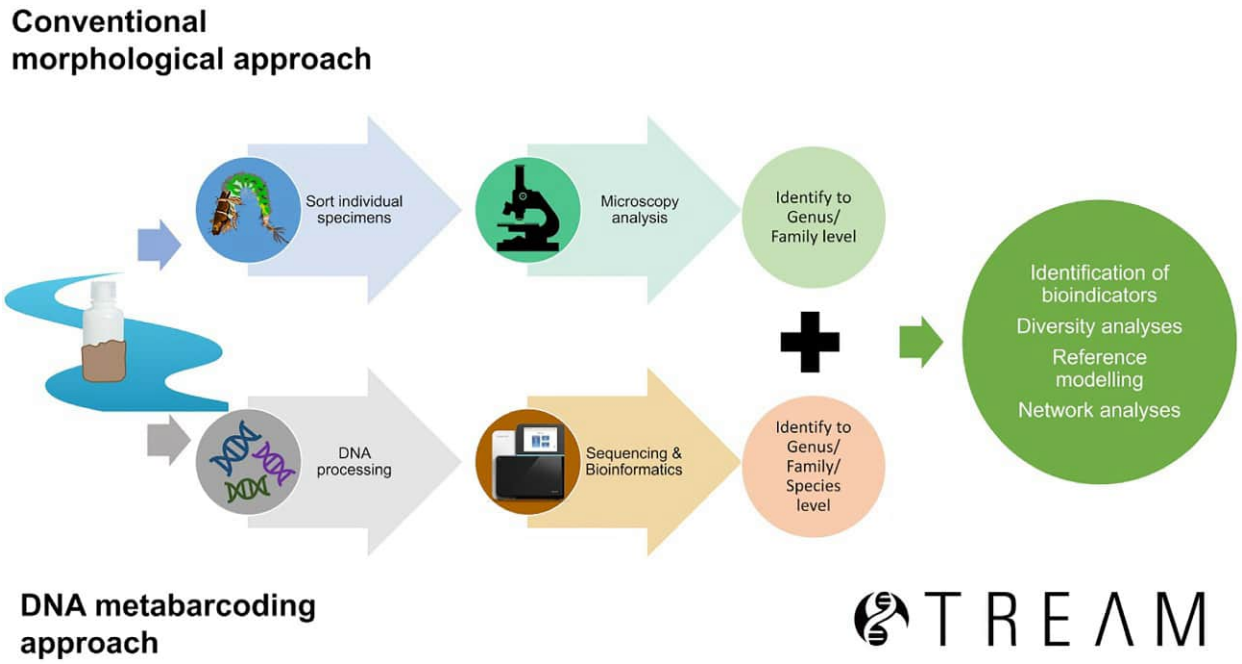

Fig. 2 Workflow of the integration of conventional morphological and DNA metabarcoding approaches for Sequencing the Rivers for Environmental Assessment and Monitoring (STREAM).

The unique properties of DNA mean that there are many opportunities for development of novel bioindicators for environmental disturbance. Traditionally, morphological approaches have relied on relatively simple metrics (e.g., the EPT Index, Indices of Biotic Integrity, Miller et al., 1988), which depict the presence or prevalence of taxa known to be sensitive or tolerant to particular environmental disturbances. The most common application for many of these metrics, however, is by resource managers and scientists who use them to generally classify a system as "healthy" or "impaired" without a real sense of whether a single or multiple stressor–or what particular stressors–are influencing the presence, absence, or prevalence of the indicator taxa. The information embedded in DNA code holds the potential for deeper assessment from eDNA samples, including phylogenetic and functional gene analysis (e.g., Beermann et al., 2021; Compson et al., 2020; Makiola et al., 2020). It is worth noting, however, that at this time the lack of a quantitative signal from metabarcoding data places a significant obstacle in its immediate application in routine bioassessment programs, as many metrics require not only information on composition, but also measures of taxon relative abundance. Some progress has been made in this area for macroinvertebrates (e.g., Elbrecht and Leese, 2015) and also for freshwater diatoms (Kelly et al., 2020).

Another approach to bioindicator metric development is to use the rich taxonomic information revealed by eDNA metabarcoding for ecological network analysis (e.g., food webs). Food web networks can be generated using co-occurrence data from DNA metabarcoding surveys. While this approach can be done with any dataset that has co-occurrence data at many sites, DNA metabarcoding again provides much higher taxonomic resolution (Gibson et al., 2015) with more complete coverage of species present, allowing more complex networks to be created. While co-occurrence networks do not definitively identify what taxa are interacting in a sampled community (e.g., Blanchet et al., 2020), the topological structures of these networks can provide useful information about those communities, and this can be strengthened by linking to other lines of evidence, such as stable isotopes (e.g., Compson et al., 2019).

One way of improving ecological network analysis based on co-occurrence data is to refine the set of possible interactions to a subset of more probable interactions, enabling more accurate food web descriptions. Methods for refining these networks range from empirical approaches that infer true interactions among taxa from information in empirical interaction databases (e.g., Global Biotic Interactions (GLOBI): https://www.globalbioticinteractions.org/) or interactions documented in the literature (e.g., Gray et al., 2014, 2015) to theoretical methods that infer interactions through probabilistic modeling (e.g., Morales-Castilla et al., 2015). Other information, such as species traits (e.g., trophic habit, functional feeding guild, body size) or abundance measures, can be used to further refine interactions (e.g., by calculating probabilities of interaction) to predict actual food web connections. This hybrid approach has been used to create heuristic food webs from DNA metabarcoding observations (e.g., Compson et al., 2018, 2019), and these models have been used to predict properties of real food webs, such as the trophic position of consumers and maximum trophic position of the food web (Compson et al., 2019). Since these heuristic models rely on real observations, they offer potential to develop novel, sensitive metrics for trophic interactions, food web dynamics, and ecosystem health and function (reviewed in Makiola et al., 2020).

Considerations for using eDNA

eDNA is essentially ubiquitous in nature, and standard methods of field sampling (see previously described above), will yield varying quantities of eDNA, itself of variable quality, potentially affecting the likelihood of detecting taxa in bulk environmental samples. For example, 3 L of water is more likely to contain eDNA of target taxa than 15 mL of water, depending on target taxa, due to the likelihood of a greater number of DNA copies in the system. However, collecting and filtering large volumes of water is more time-consuming and requires more handling (i.e., switching out DNA filters once full), which may result in higher chances of reduced sample integrity (e.g., via accidental contamination) as compared to direct extraction of DNA from a small volume (Muha et al., 2019). With eDNA research, there are trade-offs between sample effort, risk of contamination, and likelihood of detecting target taxa; the optimal sampling method is likely to differ depending on the research question and desired downstream DNA processing method (i.e., qPCR, ddPCR, or DNA metabarcoding). Different yields of eDNA in the environment can also arise from both the habits of target taxa and associated environmental and ecological factors. Details of taxa life cycles (e.g., mating, molting, emergence, migration) create seasonal changes that can result in eDNA 'boom-bust' cycles and influence likelihood of detection (de Souza et al., 2016). In addition, determining the exact geographic source of eDNA and whether DNA is derived from a living or recently deceased individual is difficult (e.g., Shogren et al., 2017). Abiotic factors, including light, temperature, oxygen saturation, pH, salinity, and existing substrates influence the rate of DNA degradation (Shogren et al., 2017).

For freshwater macroinvertebrates, several studies have shown that a variety of biological and technical factors affect the template for reading numbers and proportions of sequence reads after sequencing, such as water temperature, primer-bias, DNA polymerase mixes, template GC content, specimen biomass, and larval stage (Elbrecht and Leese, 2015; Fonseca, 2018; Hajibabaei et al., 2011). This is in line with the microbial and fungal literature that identified a suite of technical and biological issues potentially affecting accurate quantification using marker gene sequencing: primer bias, PCR cycle number, annealing temperature, DNA template concentration, and nuclear ribosomal repeat number (Bellemain et al., 2010; Polz and Cavanaugh, 1998). In nematodes, the number of ribosomal repeats can have up to 6-fold variation and this could affect quantification of metabarcoding reads if not accounted for (Bik et al., 2013). Depending on the target organism, it is debated whether DNA metabarcoding can provide insights beyond detecting presence/absence to generate a quantitative signal of biomass or abundance. For example, read counts have previously been shown to correlate with fish abundance and biomass (Di Muri et al., 2020) but have produced equivocal results for other organisms such as macroinvertebrates (Elbrecht and Leese, 2015) or fungi (Amend et al., 2010). In ecological studies, species

richness, distribution, and abundance are key biodiversity measures. Species richness is often used as a simple metric of ecosystem health; however, this simple measure is not straight-forward to calculate using DNA metabarcoding. By only employing the sequences that can be assigned taxonomically using existing sequence databases, we risk underestimating true richness, simply because current databases are incomplete. In the literature, clusters of similar sequences are sometimes used as a proxy for species; for example, clustering DNA sequences with 97% similarity could in theory emulate a 'species' unit based on phenotypic identification. Yet, this is only an estimate of species richness, as the phylogenetically-defined species concept was not conceptualized to support the use of COI sequence diversity for taxonomic discrimination. Generally, metabarcoding results in the detection of many more rare species than typically encountered using conventional methods, so it yields higher richness estimates, and thus may detect species not detected using conventional methods. For this reason, the method adds value to conventional methods (Deiner et al., 2017). For example, in a study of stream chironomids collected from leaf litter and assessed from sequences using COI metabarcoding, specimens were identified to the family rank using conventional methods (Chironomidae), yet 183 metabarcoding sequence clusters were detected and responded to a greater number of response patterns, revealing higher explanatory power using metabarcoding data (Beermann et al., 2021). For macroinvertebrates in water samples, primers should be designed to target species of interest, while excluding non-target taxa (Leese et al., 2020).

Conclusion

River bioassessment has struggled to move beyond binary 'pass/fail' assessments toward a more nuanced interpretation of risk prioritization that acknowledges the presence of multiple stressors derived from a range of anthropogenic pressures simultaneously affecting the ecological condition of rivers, all in the context of accelerating climate warming. Species detection methods using eDNA that are capable of being applied at scale, and allow consistent observation of the existing biological community can support bioassessment outcomes. Moreover, they provide important additional information, enabling insight into the distribution of rare species, supporting the early detection of invasive species or those of public health concern. The recent rapid adoption of eDNA as a biodiversity detection tool has resulted in many well-documented use cases which can be applied to all aspects of riverine aquatic (and riparian) life - from microbes to mammals (Compson et al., 2020). We are at the early stages of a scientific revolution in bioassessment practice, as new biodiversity insights offered by this tool open up new possibilities in the design and application of indicators and metrics that were not previously practicable for routine application outside highly-specialized research laboratories. What is also clear is that the need for such a tool has never been more pressing, but its potential as a game changer in our search for nature-based solutions to reverse decades of river habitat destruction is illustrated by its rapid and widespread uptake by bioassessment practitioners across the globe.

Knowledge gaps

- Significant gaps still exist in reference sequence databases for major taxa groups. To fill these gaps will require 'boots on the ground' to collect and identify local taxa to improve the representation of reference sequence databases when using DNA sequence based taxonomic-assignment methods
- More effort is required to understand the fate and degradation of eDNA in specific systems, keeping in mind that individual studies in this area will not likely be definitive, due to variation in factors determining DNA decay (e.g., microbial action, temperature) across diverse habitats and ecosystems.
- As our understanding of the behavior of eDNA in varying habitats and ecosystems improves, this should inform new designs for field studies in terms of the required spatio-temporal aspects of sampling in relation to habitat heterogeneity.
- eDNA offers exciting opportunities to provide more complete measures of taxonomic and functional diversity in sampled habitats, which in turn can greatly improve species coverage and accessibility of functional trait databases (e.g., EPA Biological Traits Database, freshwaterecology.info, Global Biotic Interactions).
- Although it is clear that DNA metabarcoding is not yet suitable for generation of quantitative observations of biomass or abundance of species for many groups, the application of machine learning algorithms to large datasets of matched DNA sequence and traditional observational data could yield valuable insights as data accumulate (Di Muri et al., 2020; Elbrecht and Leese, 2015).
- eDNA has an important role to play in the area of metapopulation theory and dynamics, supporting alternate methods of quantification based on probability of species detection/non-detection, which can be facilitated by recent advancements in Bayesian-based multi-species occupancy models.
- There are still many questions of how to incorporate biodiversity-rich eDNA data into ecological network and food web analysis. While these types of approaches work with any biodiversity data, the high-resolution taxonomic data the DNA metabarcoding approach affords provides opportunities to model (e.g., through trait-based food webs) or measure (e.g., through metabarcoding consumer stomach contents) food web dynamics in unprecedented detail, and the utility of these approaches for estimating and measuring these topological and trophic processes has not been fully realized. Important ways forward in these areas include (1) expansion of trait and trophic linkage databases (e.g., Global Biotic Interactions database), (2) exploration of new methods for predicting trophic linkages, including using machine learning to extract graph embeddings to predict linkages in real food

webs and using Bayesian approaches to improve probabilistic modeling of linkages, (3) development of novel, taxonomy-free bioassessment metrics from network or food web models that can be more sensitive measures of community change to disturbances and better indicate changes in ecosystem functions (e.g., trophic position, trophic vulnerability, degree of omnivory), and (4) a better understanding of DNA persistence in the guts of consumers and how this affects our measures of trophic linkages in studies that use metabarcoding to illuminate consumer stomach contents.

- Perhaps the greatest challenge of all is the incorporation of these transformative new techniques within highly conservative government bioassessment programs in the areas of biomonitoring, toxic substance monitoring, and impact assessment. This will require open minds to support development and adoption of protocols that will quickly evolve with the rapid pace of change exhibited in molecular technology and techniques. This will include new bioinformatic pipelines, sequencing platforms, and processing algorithms used to 'denoise' and estimate error, as well as taxonomic assignment methods.

Acknowledgments

This Chapter is a joint effort of the Baird and Hajibabaei labs. DJB, TP and KM wish to acknowledge funding support from Environment and Climate Change Canada through the Government of Canada Genomics Research and Development Initiative 'Ecobiomics' Project, and an NSERC Discovery Grant to DJB. MH would like to acknowledge funding by the Government of Canada through Genome Canada, Ontario Genomics and Environment and Climate Change Canada.

Glossary

Best Management Practices Standard land management approaches that help to mitigate impacts on stream ecosystems from land uses such as agriculture and urban development.

Ecosystem Goods Food, drinking water, wood materials and other products provided by river and riparian ecosystems.

Ecosystem Services Processes provided by river ecosystems that are valued by humans, such as filtering of pollutants from water by aquatic biota and riparian vegetation.

Eutrophication Degradation of aquatic ecosystems caused by excess inputs of nutrients that typically lead to algal blooms, increased turbidity, reduced dissolved oxygen availability, and often loss of biodiversity.

Process-based restoration An approach to river restoration that attempts to recover river and watershed processes necessary to promote river self-sustainability.

River and watershed processes The physical, chemical, and biotic forces, fluxes, and reactions that shape and modify river ecosystem features and properties. Examples of important processes include infiltration of precipitation into the soil, erosion of sediment from hillslopes, surface runoff of precipitation to streams and rivers, river flooding, uptake and transformation of nutrients by aquatic biota, migrations of aquatic organisms, and morphodynamic processes of sediment transport and deposition by flowing water that alter the morphology of river channels.

River restoration The assisted recovery of the biophysical processes that support river self-sustainability.

River self-sustainability The ability of a river to adjust, without human intervention, to disturbances and variability in environmental conditions without compromising natural river processes.

Socio-environmental systems Ecosystems influenced by both natural processes and human activities. Nearly all river ecosystems are socio-environmental systems and river restoration must account not only for natural processes, but also the needs, values, and constraints of human systems.

State-based restoration Restoration that focuses on recovering particular features of river systems, such as habitat heterogeneity, channel morphology, desired water quality levels, or esthetic features.

Stormwater management A watershed-based river restoration approach to deal with increased runoff from urban developed areas. It typically involves construction of features such as ponds, wetlands, rain gardens, bioswales, and other features around impervious surface cover in order to capture runoff from precipitation and allow the water to slowly infiltrate into soil instead of running directly into streams. Stormwater management is designed to reduce the intensity of floods in urban rivers and allow water to be purified naturally by filtering through soil and groundwater.

Watershed management An approach to managing aquatic resources that uses whole watersheds as the unit of management. Aquatic resources are managed in a watershed approach by looking not just at river and stream channels, but also all upland land area within the watershed boundaries.

Introduction

Ecological restoration of rivers and the science supporting effective practices remain vitally important for meeting societal goals for sustainability in the 21st century (Brierley and Fryirs, 2008). People the world over rely on goods and services provided by natural river ecosystems including food, energy production, transportation, recreation, and clean freshwater supplies (NRC, 1992). Yet human activities have degraded many river systems worldwide to such an extent that they no longer function to provide goods and services valued by people, or at least not at historical levels. Water has frequently become undrinkable and incapable of supporting healthy biotic communities and the esthetic and recreation value of many rivers has declined or been lost completely. For example, the U.S. Environmental Protection Agency (2020) estimated that in 2014 only 30% of the nation's rivers and streams ranked as good condition for stream invertebrate communities, and 43% rated poor for nitrogen conditions. In Europe, only 40% of the rivers and streams are ranked good based on biotic assessments – the remainder are ranked moderate, poor, or bad (Büttner et al., 2020). Where desired goods and services have been lost or degraded, people often turn to river restoration to recover the ecological integrity of river ecosystems.

Global development and biodiversity conservation goals provide examples of the important roles river restoration and restoration science will play in securing sustainable freshwater resources in the coming decades. The United Nations (UN) sustainable development goal number six (SDG6) emphasizes the need for clean water and sets targets for improving water quality and protecting and restoring aquatic ecosystems. Drinking water and wastewater treatment can help improve water quality, but centralized treatment plants in urban areas require large amounts of energy, materials, and chemicals. Thus, in places where water quality has been degraded, restoration of natural processes that provide clean water will also be needed to ensure sustainable water security (Palaniappan et al., 2010). The UN Convention on Biological Diversity also defines conservation and recovery of biodiversity a global goal through the Aichi Biodiversity Targets. Rivers hold a disproportionate amount of diversity relative to their land area, and thus represent a key ecosystem for biodiversity conservation (Dudgeon et al., 2006). Restoration of many river systems will likely be needed to ensure sufficient ecological integrity to support sustainable populations of currently rare and threatened species. The UN has recognized the importance of restoration globally by declaring the 2020s as the decade of ecosystem restoration, and improving the health of rivers and streams is a priority (Palmer and Stewart, 2020).

The use of restoration to achieve defined development and biodiversity goals highlights the role of river restoration for sustainability and also the fact that the process of river restoration takes place within a socio-environmental system, meaning that people and the environment are inextricably linked. Decisions about when to undertake restoration, where, and for what reasons are ultimately societal decisions informed in part by science, but also by the knowledge, values, and needs of people. Human use of water resources, though often damaging to river ecosystems, benefits society in some way, and thus, restoration only becomes an option when some segment of society decides that environmental degradation outweighs the benefits provided from human resource use. In some cases, national or international laws mandate restoration, but laws would not be enacted unless people valued river ecosystems or the goods and services provided by river ecosystems. Local citizens also often have important knowledge of river ecosystems including historic conditions and how conditions have changed over time (Szałkiewicz et al., 2020). For this reason, people besides scientists must be involved in any river restoration project, including local citizens, decision-makers, and resource managers (Brierley and Fryirs, 2008; Naiman, 2013; Schmutz and Sendzimir, 2018; Szałkiewicz et al., 2020). Ecological science and scientists play an important role in the restoration process, by providing knowledge of the extent of degradation, the causes of degradation, and how to recover biophysical processes that support valued goods and services.

Restoration of impacts to rivers caused by hydroelectric dams provides a good example of how ecological science informs the restoration process. The decision to try and restore a river impacted by a dam, either by modifying dam operation practices or through dam removal, is ultimately made by political leaders, resource management professionals, or by citizens. Citizens may participate in decision making directly through voting or indirectly through pressure on local leaders and decision-makers. However, ecological science can inform the decision to restore by providing information on the impacts from the dam to aquatic resources such as fish populations, and the potential for recovery under different management or removal scenarios. Ecological science may also inform the details of restoration, such as what specific flow patterns would be needed to best support migration, reproduction, and survival of particular fish species. For example, ecological research in the Colorado River delta region of Mexico has provided recommendations for flow releases to accomplish specific restoration objectives, but providing flow releases requires bilateral cooperation between Mexico and the United States (Pitt et al., 2017; Schlatter et al., 2017; Shafroth et al., 2017).

The role of people in river restoration, and the reality that river restoration is not solely a scientific undertaking, is important to keep in mind. However, the focus of this chapter will be on the ecological science of river restoration and its role in the restoration process. There are several sources that discuss the role of people in aquatic ecosystems, including several chapters in this encyclopedia (Naiman, 2013; Roni and Beechie, 2013; Riley, 2016; Perini and Sabbion, 2017; Schmutz and Sendzimir, 2018; Szałkiewicz et al., 2020). In addition, river restoration science is inherently multidisciplinary, and fields including hydrology, geomorphology, and biogeochemistry are all vital for informing effective river restoration.

The aim of this chapter is to describe current ecological understanding of how best to restore river ecosystems toward self-sustainability and how ecological science is applied in practice. Self-sustainable rivers are able to recover from disturbance and respond to climatic and landscape changes while maintaining ecosystem goods and services. Self-sustainability is emphasized as a key target for river restoration from an ecological perspective (Hawley, 2018). Rivers that are not self-sustainable will require continual active management, and thus, cannot be considered fully restored to the equivalent of natural functioning ecosystems.

Achieving self-sustainability may not be possible for many rivers, yet the application of ecological principles can still improve them (Riley, 2016). In such cases, river restoration becomes one tool used in a watershed management approach rather than a goal itself. Nonetheless, we define river restoration as the assisted recovery of the biophysical processes that support river self-sustainability, because from the restoration ecology standpoint, self-sustainability represents the ultimate end goal of full river ecosystem recovery (Simon et al., 2011).

Process-based river restoration

A process-based restoration approach emphasizes the need to recover natural processes, because loss or alteration of natural processes is very often the cause of river degradation (Kondolf et al., 2006). To achieve continued success in the long-term, river restoration must mitigate or reverse causes of degradation, and this makes process-based restoration a necessary approach to recover river self-sustainability (Beechie et al., 2010). Another advantage of process-based river restoration is that it often addresses multiple causes of degradation simultaneously. To understand how process-based restoration is beneficial in these ways, it is helpful to first provide a definition of river processes and how they are impacted by human activities.

What are river processes?

A fundamental concept in restoration science is that recovery of natural processes is required to achieve ecosystem self-sustainability (Wohl et al., 2005, 2015; Roni and Beechie, 2013). Natural processes are the physical, chemical, and biotic forces and reactions that shape and modify ecosystem structures and properties. In their natural state, rivers are dynamic, with processes continually modifying river features such as channel shape and position on the landscape. Spatial and temporal variability in processes and their rates create further heterogeneity in river features (Kondolf et al., 2006). For example, the concentration of nutrients in a river, a property of concern for drinking water standards and potential downstream eutrophication, is determined by processes including the movement of water through soils and the uptake and transformation of nutrients by microbial communities in the river. Nutrient concentrations fluctuate naturally during precipitation events and in response to changes in stream biotic communities such as algal growth. The processes of hillslope erosion and sediment transport within river channels continuously shape and reshape river and riparian habitat.

How are processes impacted by human activity?

Human activities can degrade river ecosystems directly and by altering natural processes (Table 1). For example, direct discharge of untreated sewage or industrial wastewater to rivers will increase nutrient concentrations, and direct modification of river channels such as dredging, straightening, installation of levees, or even burial, has degraded river habitat in many regions. However, perhaps an even more pervasive cause of river degradation is alteration of watershed and river processes. One common example is urban land development, where impervious cover alters the process of runoff from substantial infiltration of precipitation into soils to primarily surface runoff directly into stream channels (Paul and Meyer, 2001). The shift in runoff from infiltration to surface runoff often causes greater flooding and erosion in stream channels, incising or widening stream channels and degrading physical habitat (Walsh et al., 2005b). Dams are another pervasive modifier of river processes, substantially changing the patterns of river flow, sediment movement, and downstream temperature fluctuations. Altered flow and sediment regimes in turn alter channel and riparian habitat and often cause loss of river and riparian species that depend on natural patterns of flow to complete their life histories (Collier et al., 1996; Nilsson and Berggren, 2000). Altered temperature regimes can disrupt organism lifecycles, including juvenile growth rates as well as cues for spawning and migration timing (Olden and Naiman, 2010).

Process vs. state-based restoration

A process-based restoration approach may be contrasted with a state-based approach (Fig. 1). A state-based approach focuses on directly restoring the degraded properties of a river system, whereas a process-based approach focuses on the processes that caused degradation. In settings where large dams have curtailed the processes of floodplain inundation and sediment deposition that sustain riparian vegetation species, direct planting of riparian species is an example of a state-based restoration approach. The approach may sometimes recover riparian vegetation temporarily but will require continued maintenance to persist over the long term. The process-based restoration approach would emphasize the need to modify dam operations or remove the dam entirely to help recover the processes of flooding and sediment deposition (Kondolf et al., 2006). Process-based restoration efforts like these, that initialize morphodynamic processes and result in enhanced spatial variability in flow velocities and depths, can help recovery of aquatic, as well as semi-aquatic and even terrestrial species (Muhar et al., 2016).

In addition to focusing on causes of degradation, a process-based approach can often help address multiple limiting factors preferentially or simultaneously, which is less often the case for state-based restoration. For example, if the restoration goal is to increase biotic diversity in a section of river, a state-based approach attempts to identify features of the river section that might be limiting for diversity. Where features are found to be modified compared to pre-disturbance conditions, restoration is implemented to try and recreate pre-disturbance conditions, such as installation of missing habitat features. Habitat restoration approaches such

Table 1 Examples of common anthropogenic activities that degrade river ecosystems, the societal benefits provided, and the direct impacts and processes that are altered by each.

Common Anthropogenic Activities	
Dams	
Benefits	Hydroelectricity
	Flood protection
	Water storage
Direct Impacts	Replacement of river habitat with reservoir
	Blocks migration of aquatic organisms
Impacts to natural processes	Upstream to downstream connectivity disrupted
	Altered patterns of flow downstream
	Traps sediment, disrupting delivery and transport of sediment downstream
	Altered temperature regimes below some dams
Water abstraction	
Benefits	Water use for agriculture, municipalities, and industrial activities
Direct Impacts	Organisms can become stranded in canals
Impacts to natural processes	Altered patterns of flow downstream, including river drying
	Increased concentration of pollutants and nutrients due to reduced dilution
Agriculture	
Benefits	Production of food and natural products
Direct Impacts	Riparian vegetation may be cleared in some cases
	Some aquatic ecosystems such as wetlands may be filled
Impacts to natural processes	Altered patterns of interception, infiltration, and runoff
	Increased runoff of sediment and nutrients
Urbanization	
Benefits	Housing
	Transportation
	Economic and cultural amenities
	Industrial production
Direct Impacts	Channel burial, straightening, and hardening
	Riparian vegetation removal in some areas
	Direct inputs of waste and pollutants
Impacts to natural processes	Decreased infiltration and increased surface runoff
	Increased erosion during the construction phase or urban growth
	Increased temperature of runoff
	Increased delivery of pollutants through runoff

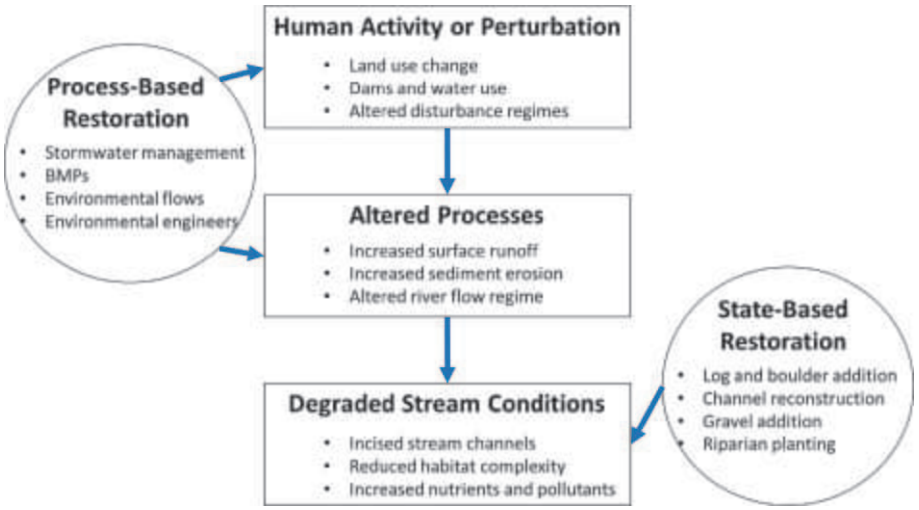

Fig. 1 Diagram comparing process and state-based restoration approaches. Human activities alter watershed and river processes that degrade river and stream conditions. Bullet points in each box and circle give examples. Process-based restoration attempts to restore stream conditions indirectly by recovering natural process rates, whereas state-based restoration attempts to directly modify stream conditions. Process-based restoration will usually be necessary to recover river self-sustainability, but both approaches may be useful in many watersheds where socio-environmental systems pose constraints to full recovery of natural processes. BMPs = best management practices.

as placement of logs or boulders, installation of hydraulic features such as weirs or riffle-pool sequences, and full construction of a new channel with desired features has, despite some failures, improved habitat diversity in many cases (Roni et al., 2008). However, invertebrate and fish diversity often does not increase even with structural habitat improvements (Lorenz et al., 2018). Research has found that other limiting factors, such as water quality, or availability of source populations to serve as a colonization source, often prevent biotic recovery (Palmer et al., 2014) – in other words, watershed scale degradation can override the effectiveness of reach-scale habitat restoration (Leps et al., 2016).

Restoration of natural processes often improves several features of river ecosystems simultaneously because multiple issues often have the same cause of degradation. For example, a common cause of habitat degradation is land use change, such as forest clearing or urban or agricultural development that leads to excessive runoff and erosion of stream channels, large inputs of fine sediments and nutrients, and often loss of wood inputs to streams (Allan, 2004). A process-based approach to habitat restoration would attempt to recover processes such as infiltration in the watershed, hydraulic retention and filtering in a recovering floodplain, and soil stabilization through upland vegetation recovery (Beechie et al., 2010). This approach better addresses watershed-scale impacts and would help recover not only degraded habitat, but degraded water quality as well and thus would be more likely to recover biotic diversity in the long-term (Palmer et al., 2014).

Application of process-based river restoration

Example applications of process-based restoration have been steadily increasing. Four common activities that have developed from process-based approaches to restoration include environmental flow programs, stormwater management in urban areas, agricultural best management practices (BMPs), and assisted recovery of environmental engineer species. Environmental flow programs are often developed to help rehabilitate degraded river systems below large dams. An environmental flow program is a recommended set of flows that can be released from dams to recreate or mimic at least some important elements of the historic natural flow regime (see chapter on environmental flows by Arthington, 2022). Flows often targeted include some minimum flow level to maintain key habitat elements, for example during droughts, and floodplain inundation flows to help maintain riparian vegetation communities and allow for completion of life history events for flood-dependent species. Flood releases from Glen Canyon Dam for the Colorado River in Grand Canyon National Park are a good example of an experimental flows program. Several times over the past 25 years, flow release gates on the dam have been opened to mimic flood occurrences. The flow releases do not fully replicate historic flooding, but are experimental in nature, designed to study how aspects of the river ecosystem, such as non-native fish species and sand bar habitat respond to flooding (Melis, 2011).

Stormwater management in urban landscapes, also referred to as green and blue infrastructure, attempts to recover natural runoff processes that are altered when natural ground cover is converted to impervious cover (Perini and Sabbion, 2017). Altered flowpaths caused by increasing impervious cover in urban areas can contribute to both increased nutrients and degraded habitat by bypassing the natural hydrologic retention and filtering processes that occur when precipitation infiltrates into soils and water makes its way slowly to the stream via belowground pathways (Paul and Meyer, 2001; Walsh et al., 2005b). Examples of stormwater management devices include bioswales, bioretention basins, rain gardens, cisterns, and pervious pavement (Fig. 2). Each of these devices is designed to intercept runoff from impervious surfaces during precipitation events, increase hydraulic retention, and direct the water into soils through increased infiltration, rather than having the runoff flow directly to the stream channel (Walsh et al., 2005a). In many of these devices, a special mix of soil, sand, and organic matter is added and vegetation is planted to help filter nutrients and pollutants out of the stormwater as it infiltrates into soils. By reducing surface runoff from impervious surfaces and restoring more natural flow patterns, stormwater management can help address multiple issues including degraded habitat and water quality, though full recovery to pre-urbanization conditions may be difficult to achieve on a watershed scale, especially in highly urbanized watersheds (Walsh et al., 2005a).

Agricultural best management practices (BMPs) are similar to urban stormwater management approaches, in that they are applied to mitigate the impacts of agricultural land use development on river and stream ecosystems. Conversion of naturally vegetated landscapes to agricultural land use often increases runoff, hillslope erosion, and delivery of sediments to streams, due to soil compaction and reduction in vegetation that would otherwise intercept rainfall and promote infiltration into soils. In addition, delivery of nutrients and other contaminants to stream channels usually increases due to application of fertilizers and other chemicals such as pesticides. Increased runoff, erosion, and nutrient delivery frequently degrades stream ecosystems by reducing habitat heterogeneity and promoting eutrophication (Allan, 2004). Typical examples of agricultural BMPs include cover cropping during fallow periods, no-till farming, crop rotation, multi-cropping, and contour plowing, all of which are designed to help keep vegetation and soil structure intact and reduce runoff and erosion. Crop rotation and multi-cropping can also help reduce applications of fertilizers and pesticides by improving soil nutrient content and reducing damage by pests and weeds (Liebman and Dyck, 1993; Lötjönen and Ollikainen, 2017) Another important BMP applied in agricultural and urban watersheds is the preservation or restoration of a vegetated riparian buffer zone along the length of stream channels, which provides multiple benefits including interception of nutrients and sediments from runoff, shading to help keep stream temperatures lower, and provision of wood material for habitat. The common purpose of all BMPs is to help recover natural rates of processes such as runoff and erosion by mitigating impacts to these processes caused by agricultural land use.

Assisted recovery of environmental engineer species has been used for multiple decades, but has become increasing popular recently as a restoration strategy. Assisted recovery of North American beaver (*Castor canadensis*) and Eurasian beaver (*Castor fiber*) in

Fig. 2 Examples of a bioretention basin (top left) and cisterns (top right), two types of stormwater management features. The cisterns capture runoff from rooftops and the bioretention basin captures storm runoff from the urban landscape, allowing the water to filter through a sand filter media before flowing downstream. Stormwater management is intended to improve water quality and reduce runoff volume from stormwater events, such as seen in the bottom image.

North American and European rivers is one well-researched example (Pollock et al., 2014; Brown et al., 2018). Beavers substantially modify small stream and river systems through the process of dam-building. Dam-building provides unique habitat for aquatic species and increases local groundwater levels, which can in turn expand riparian habitat and enhance riparian vegetation growth. Dams also trap sediment and have been observed to raise streambed elevations, restore floodplain connectivity, and improve fish habitat in incised channels. In many regions in North America, beaver populations were severely reduced in the late 1800s during the fur trade. *Re*-establishment of beaver may be as simple as reintroducing beaver to streams where they were previously extirpated, but in incised channels, structures may be needed to help beavers maintain dams through high-energy flood events. The installation of structures has been successful in at least one incised stream at restoring channel-floodplain connectivity and increasing available habitat for fish (Bouwes et al., 2016). Re-establishment of beaver in rivers and streams represents a self-sustaining restoration, because the beavers will continue to modify stream and river channels without further human intervention (Pollock et al., 2014). It should be noted, however, that beavers are not always an appropriate restoration strategy, and beaver removal is a restoration strategy where beaver are non-native, such as South American river systems (Jusim et al., 2020). Ecological engineer species are found worldwide, ranging from the very large, such as hippopotamus in Africa (Mosepele et al., 2009), to the very small, including microbial biofilms that stabilize sediment (Battin et al., 2003), but with the exception of beavers, riparian vegetation, and some anadromous fish species, relatively little research has been conducted on their use in river restoration.

Restoration in a watershed management context

In the ideal ecological situation, river restoration would remove all human impacts on the river ecosystem and fully recover natural self-sustaining processes. However, rivers are part of complex socio-environmental systems, with often long histories of human use, which often pose justified constraints to full recovery of self-sustainability (Naiman, 2013; Wohl et al., 2015; Brown et al., 2018). In rare cases, full recovery of natural processes, or at least near-full recovery, may be achievable. One example is restoration of the Elwha River on the western coast of the U.S., where complete removal of the only two large dams on the river was completed in

2011–2012. The Elwha River watershed is located primarily within the boundaries of the protected Olympic National Park. Dam removal, coupled with the protection of natural hydrologic and biotic processes through most of the watershed, has allowed the river to transport sediment downstream and alter river, floodplain, and estuarine habitat (East et al., 2015; Foley et al., 2017). Native vegetation communities have reestablished on former reservoir sediment (Prach et al., 2019), and salmon have resumed spawning activities in river sections upstream of the former dams (Tonra et al., 2015). In most cases, river restoration requires a compromise between full recovery of natural processes and preserving human use of river ecosystems for societal benefit. Thus, in most cases, restoration should be viewed as one tool in a program of active watershed management (Wohl et al., 2005).

In watershed management, rivers and streams are managed as components of the overall landscape within watershed boundaries (Schmutz and Sendzimir, 2018). The focus is not just on rivers and streams but on the suite of processes and landscape patterns that influence the movement of water, sediments, chemicals, and organisms from upland areas to and through river channels. Under a watershed approach, land management, such as preservation of forested areas in an unimpacted tributary, become important tools for protecting and restoring river ecosystems. Other tools in watershed management may include controlling hillslope erosion, managing disturbances such as fire and other upland-associated activities, in addition to active stream channel restoration. In this context, river restoration is not applied as a standalone management activity but is instead part of a suite of activities applied at a broad scale to manage the natural processes that create and maintain healthy aquatic ecosystems (Wohl et al., 2005). Such approaches to restoration usually require changes to policies and regulations and can be quite successful ecologically (Viswanathan and Schirmer, 2015). For example, one effective way to limit impacts of further land use development is through altered zoning and other regulations. This illustrates the socio-environmental nature of river restoration – in many cases human actions that caused river degradation can best be reversed with changes in policy or economic incentives.

Whether watershed management incorporates active river restoration, upland land management, or changes in policy, the goals should still target protection or recovery of processes. For example, reforestation efforts on degraded landscapes can be successful at improving stream habitat and water quality conditions, because they recover natural watershed hydrologic processes, thus helping to reduce delivery of solutes and sediments to stream channels (e.g., Paudyal et al., 2017). While most restoration goals require actions outside of the channel, for some, direct manipulation of river channels or riparian zones may be necessary, at least in the short term. Installation of required habitat for an aquatic species with restricted range to prevent imminent extinction during an extreme event, such as a severe drought, is one example of a situation where direct manipulation may be required (Hammer et al., 2013). In such cases, the restoration activity can be viewed as a type of emergency intervention, where immediate actions are needed to save a population or species. In addition, approaches that work within constraints are often more easily implemented from a political, economic, and feasibility standpoint, at least in the short-term. For example, adding gravel to a river below a hydroelectric dam to recover fish spawning habitat lost by sediment retention above the dam is often more expedient than efforts to fully recover flow and sediment transport processes, such as full dam removal (Wheaton et al., 2004). Although such manipulations may provide essential habitat for threatened species in the short-term, they should not be viewed as a substitute for recovering the processes needed to self-sustainably create and maintain required habitat.

In many watershed management cases, ecological or social constraints make it necessary to couple active river manipulation and process-based restoration in some capacity. For example, active manipulation may be necessary in some rivers to maintain appropriate water temperatures for particular aquatic organisms under climate change. One way to maintain cold water as air temperatures rise is to maintain flow releases from large dams, because the water at the bottom of large reservoirs is much colder compared to surface water and incoming river water (Null et al., 2013). Sometimes, continual active management may be needed to ensure conditions are appropriate to take full advantage of natural processes when they occur or are restored. For example, in the Colorado River delta region, the natural flow regime has been altered to such an extent that former lush marshland completely dried up. A recent dam release flow in the region attempted to mimic, albeit on a much smaller scale than natural, historic floods that occurred in the region (Shafroth et al., 2017). Recruitment of native vegetation such as cottonwood trees did occur in response to the flood, but was facilitated by more active restoration measures in the highly modified ecosystem, including maintenance of seed-source trees by irrigation and nonnative vegetation removal (Schlatter et al., 2017). While this flow release was a one-time event, commitments to revisit the 1922 Colorado River Compact are under way, with a 2026 deadline. In addition to the potential for redistribution or further regulation of water rights, some have goals of keeping more water in the river, with the hope of restoring ecosystems including the Colorado River delta (Pitt et al., 2017).

In other cases, active manipulation may be needed initially to assist recovery of natural processes that could eventually become self-sustaining. Installation of structures to assist recovery of dam-building activity by beaver, as described above, is one example. As another example, restoration of small headwater streams can help recover processes that maintain healthy rivers downstream. Attempts to restore Coastal Plain rivers and streams on the eastern coast of the U.S. with poor water quality and low biodiversity have involved converting small tributaries to wetland-stream complexes. Wetlands can provide watershed-wide water quality benefits, particularly by reducing the flux of nutrients to downstream waters (Golden et al., 2019). So while the small channels must be reconfigured, stabilized, and then replanted, if established properly the wetlands should persist, and there is hope the downstream benefits exceed the ecosystem service losses of converting small streams to wetland complexes. To date, these practices have had mixed results and suggest that appropriate siting of the projects is critical, such as placing them in physiographic settings that allow for increased infiltration and water storage in the wetland (Williams et al., 2017).

Whether applied as part of watershed management or relatively independently, a formal process of planning, implementation, and monitoring should be followed for any river restoration project (Fig. 3). One key step in restoration planning, as highlighted in the above example about converting streams to wetland complexes, is to prioritize where on the landscape restoration activities will

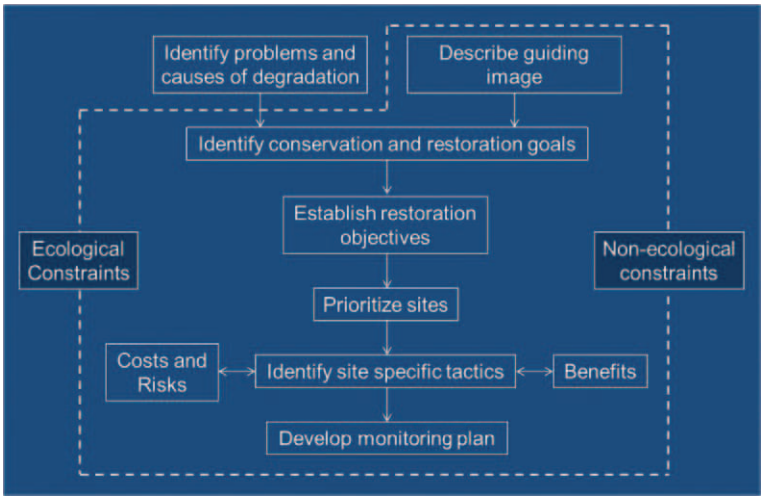

Fig. 3 Flowchart depicting key steps in the restoration planning process. Unless resources, time, and space are nearly unlimited, all restoration projects will have to occur within socio-environmental constraints, such as non-native species, changing climate, and human land and water use. Although not shown here, this process is iterative, with monitoring data feeding back to reconsider goals, objectives, site prioritization, and tactics.

have the most benefit and to prioritize the order of any restoration actions. Prioritization is not necessarily needed in small watersheds or in cases where funding and personnel resources are not limiting. But in large watersheds where resources are limiting, identifying locations and activities that will have the greatest improvement in desired conditions is useful. An example where spatial prioritization is obviously useful is a case where multiple dams or other barriers could potentially be removed or modified to increase connectivity within a watershed or other hydrologically connected region. Removing the furthest upstream dam is likely to have little benefit to downstream river sections if other dams still regulate flow and sediment delivery downstream and block upstream-migrating fish. On the other hand, if the downstream dam is blocking colonization of upstream river sections by a non-native species, leaving the downstream dam in place and removing the upstream dam may provide some benefit to native species while preventing spread of the non-native species (Fig. 4). Prioritizing the order of restoration actions can also be important. Keeping with the same example, removing the non-native fish population first would allow dam removal to proceed without the risk of further expansion of the non-native population.

The complexity of addressing aquatic resource management issues at the watershed scale make an adaptive management approach useful for many river restoration projects. A key part of adaptive management is engaging stakeholders and monitoring the outcome of restoration activities over time to determine if the restoration project achieved the goals and objectives. The plan can be revised repeatedly with stakeholders if it needs adjusting. Ecological effectiveness monitoring must be planned carefully, because evaluation of restoration success can be difficult in practice for several reasons (Table 2), and effectiveness monitoring is still an area of important research in river restoration ecology. Depending on the goals for restoration, other types of monitoring information besides ecological effectiveness may also be important. For example, if restoration goals are to improve the esthetic appeal of a river

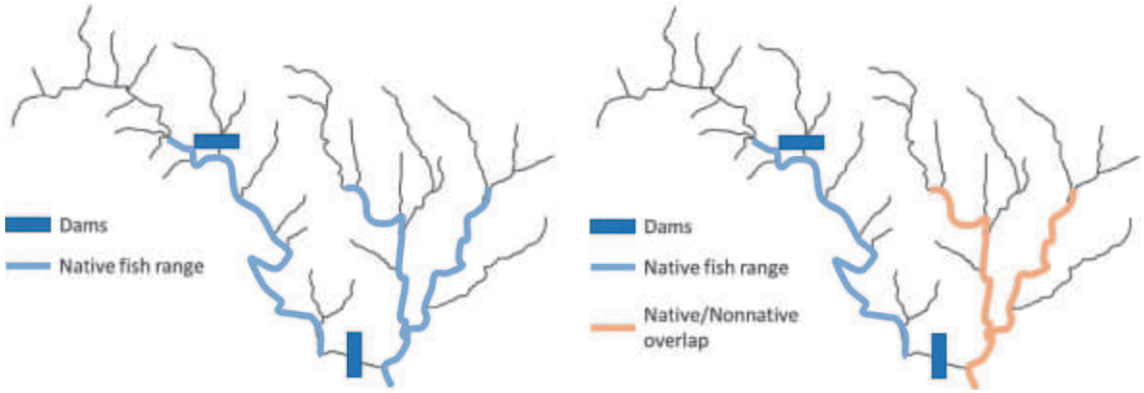

Fig. 4 A hypothetical example showing the importance of prioritizing dam removal. In both cases (left and right), the goal is to improve the conservation status of a native fish population, but there are only enough resources to remove one of the two dams in the watershed. The dams completely block upstream fish passage. In the left panel, removing the lower dam would likely be prioritized, because this would increase connectivity between the two ranges of the population by allowing upstream fish passage. In the right panel, removing the upper dam might be prioritized instead, because it allows access to some new habitat and prevents a non-native species from colonizing the full range of the native species.

Table 2 Potential pitfalls when evaluating restoration effectiveness and some best practices for avoiding pitfalls.

Pitfall	*Pitfall description*	*Best practices*	*Best practices explanation*
Lack of comparison for post-restoration outcomes	Post-restoration monitoring alone does not indicate whether a restoration project changed ecological processes or conditions	Collect pre-restoration data for multiple years on both the restored river and several similar rivers not undergoing restoration	Rivers are highly variable in time and space, thus to determine conclusively that restoration was effective, the amount of change caused by restoration and whether changes were greater than natural variability must be determined
Lack of data on how processes respond	Ideally, post-restoration monitoring will provide information on how processes respond, but monitoring processes can be more difficult than monitoring conditions	Collect pre-restoration data and develop a guiding conceptual or mathematical model of the system that captures important processes and how they will be restored	Process monitoring must be tailored to the restoration project, and having a clear set of objectives and expected outcomes regarding processes can help guide development of needed information. Technological improvements are making process monitoring more feasible, but research on standards for process monitoring is still ongoing.
Monitoring data collected at too small a spatial or temporal scale	Monitoring of individual restoration activities may not translate to effectiveness at the watershed scale. Effects of restoration may not be noticeable for multiple years after implementation, or effects may be short-lived.	Incorporate monitoring into watershed management	Watershed management is a continual process in most locations, thus if monitoring is incorporated as part of the management process, appropriate monitoring to determine watershed-scale and long-term impact of any watershed management activity, including restoration, is more likely to be in place. Increasing availability of remote-sensing data is helping to improve large-scale and long-term monitoring.
Lack of non-ecological monitoring data	Because restoration occurs in a socio-environmental system, monitoring of human systems is also usually important to determine restoration impacts and effectiveness.	Collaboration with social scientists and other non-environmental fields.	Evaluating whether restoration goals such as user experience or recreational value will require monitoring of human systems that interact with rivers, and social scientists have developed tools to evaluate these elements.

in an urban environment, surveys of river users and the surrounding neighborhoods would be appropriate. Matching monitoring to the identified goals is important, because success in one objective does not imply success in all objectives. For example, people's experience recreating in a river corridor could improve without any improvement in stream biodiversity.

If river restoration goals are not achieved, properly-designed monitoring can be used to help identify the reasons for failure and adjust restoration practices in the future. Of particular importance is to monitor the targeted natural process of restoration – if it is moving in the right direction but the ultimate goal (e.g., increase biodiversity) is not yet achieved, this may indicate that not enough time has passed. In this way, restoration projects can be seen as experimental manipulations that help provide understanding about river ecosystems and about how to better manage river ecosystems. Even the best planned restoration project faces uncertain outcomes due to the variability and complexity inherent to socio-environmental systems (Darby and Sear, 2008), and there are many reasons, both ecological and non-ecological, that restoration projects can fail to accomplish goals. For example, a program to address urban impacts on a river through installation of stormwater management practices may be an appropriate restoration approach for addressing altered processes, but it could fail to improve river conditions if stormwater features are not installed properly, or if climate changes alter precipitation patterns and overwhelm any benefits provided by installed stormwater features (Barbosa et al., 2012). In these cases, if monitoring is conducted and the reasons for failure identified, the project can still be considered a learning success even though ecological goals were not accomplished.

Synthesis

To consider a river fully restored from an ecological standpoint, natural river and watershed processes that create and continually alter the physical, chemical, and biotic conditions of river ecosystems must be recovered. Undertaking such a process-based restoration of river systems is the only way to ensure self-sustainability of river ecosystems over the long term. However, river

ecosystems are components in complex socio-environmental systems that often pose constraints to full recovery of natural processes. Thus, in practice, river restoration is best approached as one tool in an overall process of managing whole watersheds for sustainability. In watershed management, human use of river and watershed resources may still continue, and natural watershed processes are preserved or restored to the extent possible, but some forms of active river restoration may be included. Improving river restoration in the context of watershed management will require monitoring and learning from implemented projects, so that restoration approaches can be adapted to help achieve sustainability goals in these complex socio-environmental systems.

Knowledge gaps

- How much habitat or natural area is needed to ensure a sufficient level of processes to sustain desired features or services?
- What are optimal restoration strategies for ensuring resilience to future disturbances such as climate change?
- How do restoration actions impact ecosystem functions?
- What role do feedbacks between restoration and societal goals and values play in the design and application of restoration projects through time?
- Does restoring habitat complexity improve ecosystem functions?
- How long does it take for different components of river ecosystems to recover following restoration?
- How can ecosystem engineer species most effectively be incorporated in river restoration, especially outside of North America?
- What are the unique challenges associated with restoration of intermittent and ephemeral rivers and streams?

Environmental Flows: Ecological Effects of Hydrologic Alterations, Assessment Methods for Rivers, Challenges and Global Uptake

Angela H Arthington, Australian River Institute, Griffith University, Nathan, QLD, Australia

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor LeRoy Poff.

Introduction

Human activities have modified the natural hydrologic and ecological processes of catchments, wetlands, rivers, floodplains and estuaries for thousands of years. Early Mesopotamian civilizations constructed dikes, levee banks and barriers made of earth, rocks and logs to redirect water for flood control, and to capture water for irrigation (Arthington, 2012). Dam construction to impound water flows followed and eventually became a fundamental global water management technology. Dams store, regulate and deliver water collected during wet cycles for use during dry cycles. They are constructed and managed to provide water for agricultural production, industry and urban development, to generate electricity, for flood control, to store mine tailings, to foster fish and wildlife populations, and for recreation. Whist the contributions of dams to human development have been enormous, their effects on biodiversity and the ecological goods and services of freshwater ecosystems, such as clean water, fisheries and wildlife, are of global concern. Today most of the world's major river systems, including the 20 largest and the eight with highest biological diversity—the Amazon, Orinoco, Ganges, Brahmaputra, Zambezi, Amur, Yenisei and Indus—are impounded by dams. Moreover, growing energy demands, and a Rio + 20 commitment to the use of Kyoto-compliant energy resources, have triggered a new era of dam construction, with over 3700 proposed or under construction (Zarfl et al., 2015). Globally, impoundments are estimated to have a cumulative storage capacity somewhere between 7000 and 10,000 km^3, the equivalent of five times the total volume of the world's rivers (Vörösmarty et al., 2013). The effects of dams on river basin flow patterns and hydrological connectivity are catastrophic. Only 37% of rivers >1000 km in length remain free-flowing over their entire length, and a mere 23% flow uninterrupted to the sea (Grill et al., 2015).

Flow regime alterations resulting from these major hydrological disturbances have impacted the biodiversity and ecological functioning of rivers, floodplains, wetlands and estuaries worldwide (Vörösmarty et al., 2010). For example, a systematic review by Poff and Zimmerman (2010) reported ecological effects associated with flow regime alterations in 92% of studies. Negative responses to flow regime alteration were recorded in terms of population or community change of riparian vegetation, aquatic primary producers, macroinvertebrates, fishes, birds, and amphibians, primarily in terms of flow magnitude. The remainder reported an increased value for ecological response metrics, such as an increase in non-native species or non-woody plant cover on dewatered floodplains.

The deteriorating condition of freshwater ecosystems and loss of freshwater biodiversity from dam construction, barrier effects and altered flow regimes has led to the science and management of water for the environment (Tharme, 2003; Poff and Matthews, 2013). Originally termed in-stream flows, water allocations that maintain the biophysical and ecosystem processes of rivers and estuaries are now known almost universally as environmental flows (e-flows). A recent definition gaining traction forms part of the 2018 Brisbane Declaration and Global Action Agenda on Environmental Flows (Arthington et al., 2018a) which states: "Environmental flows describe the quantity, timing, and quality of freshwater flows and levels necessary to sustain aquatic ecosystems which, in turn, support human cultures, economies, sustainable livelihoods, and well-being."

This definition recognizes that sustaining water regimes, freshwater ecosystem health and resilience is the foundation for achieving human water security and flourishing livelihoods, for all societies in all regions and across all economic realms (Vörösmarty et al., 2013; United Nations (UN), 2015). Including "freshwater flows and levels" in the 2018 definition is intended to embrace the water requirements of all aquatic ecosystems that experience natural spatial and seasonal patterns in water-level fluctuations, wetting and drying, and connections with groundwater (Arthington, 2012; Kath et al., 2018).

The ecological effects of flow regime alterations and the water requirements of rivers are the main themes of this chapter. It traces the history of environmental flow assessment methods, the emergence of holistic ecosystem level environmental flow frameworks, the framing of two of these (DRIFT and ELOHA), and examples of recent developments. The chapter continues with a discussion of emerging issues for the future of environmental flows under shifting climatic and other regimes, when new scientific knowledge and different perspectives on planning and managing environmental water will often be needed (Capon et al., 2018). The chapter ends with recent efforts to increase the global profile and social-ecological relevance of the environmental flows enterprise. It presents the 2018 Brisbane Declaration and Global Action Agenda on Environmental Flows and examples of the uptake of e-flows within global spheres of influence, such as achievement of the Sustainable Development Goals (United Nations (UN), 2015), and planning for the Post-2020 Global Biodiversity Framework.

Ecological effects of flow regime alterations

Liquid fresh water covers less than 1% of the Earth's surface, constituting only 0.03% of the world's water. This tiny fraction of global water is absolutely vital for human life support and the provision of many ecosystem services—clean water, food organisms, fuels, pharmaceuticals, flood regulation, recreation and spiritual health. Flowing freshwater habitats range from headwater springs and streams to rivers, vast floodplains, and estuaries, all connected through space and time by the dynamics of water. Taken together, flowing and standing freshwater ecosystems support an extraordinary diversity of aquatic life forms—at least 126,000 species out of approximately 1.8 million described globally (Strayer and Dudgeon, 2010).

The dependence of freshwater biota on surface and linked groundwater habitats makes them vulnerable to natural and man-made changes in the availability of water and other drivers of aquatic habitat loss and change. River impoundment (dams, weirs), off-stream farm dams, surface water diversions, groundwater extraction, and modification to natural drainage networks for flood protection have some of the most destructive effects on flow regimes, aquatic habitats and ecosystems (Stewardson et al., 2017). Land clearance, afforestation and urbanization also alter patterns of catchment runoff and hence stream flow regimes.

Ecologists have long conceptualized and documented relationships between prominent features of river flow regimes, their ecological roles, and the effects of flow regime alterations. In 1997, a seminal publication captured the importance of river flows in the "Natural Flow Regime Paradigm" (Poff et al., 1997). This paper shows that the structure and functions of riverine ecosystems, and many adaptations of aquatic biota, are dictated by temporal patterns of river flow and disturbance regimes. Papers by Richter and colleagues contributed to the identification of important "facets" (often termed "components") of river flow regimes, and set out statistical methods to estimate alterations to 64 metrics using the Range of Variability Approach or RVA (Richter et al., 1996).

Understanding of the ecological consequence of alterations to river flow regimes burgeoned. Building on examples from Poff et al. (1997) and other literature, Bunn and Arthington (2002) developed four fundamental principles to summarize the importance of river flows to the maintenance of aquatic biodiversity, and then explored ecological consequences of alterations to natural flow regimes (Fig. 1). Informative summaries of quantitative relationships between particular flow facets, alterations to them and consequent negative ecological effects soon followed (e.g., Lytle and Poff, 2004; Poff and Zimmerman, 2010).

Ecological impacts from alterations to river flow regimes involve a range of mechanisms driven by the functional ecological roles of water in river networks. These roles include water as a habitat and source of food, a vector for transport of materials and organisms, a medium for active movement along connectivity pathways, and an agent of disturbance and geomorphic change. The effects of flow regime alterations span a broad range of taxa, including algae and biofilms, aquatic and riparian plants, zooplankton, invertebrates, fishes, amphibians, reptiles, waterbirds and mammals. Adverse effects have been recorded at individual, population, community and ecosystem levels of ecological organization (Poff and Zimmerman, 2010).

Rolls and Bond (2017) review common types of flow regime alteration linked to ecological consequences for riverine species and ecosystems (Table 1).

While a focus on the effects of alterations to individual components of flow regimes is useful, flows are rarely impacted in complete isolation from one another. For example, dam construction and flow management can produce syndromes of flow alteration involving changes in flow magnitude (e.g., reduced flood peaks, less frequent floods) combined with dramatic changes in the seasonal timing of high and low flows coupled with elevated, more stable baseflows (e.g., Fig. 2).

Stewardson et al. (2017) present a useful guide to how land and water management activities combined with climate change can alter flood regimes, channel flows, baseflows and flow variability. They caution that there can be great variation in the magnitude of these impacts and even the direction of change, resulting from variation in the climatic and hydrological setting, the type and size of water management infrastructure, and policies that guide water management operations. Accordingly, ecosystem responses to flow regime alterations tend to reflect the particular suite of circumstances, historical flow patterns and individual flow events. This particularity adds to the complexity of understanding and quantifying flow-ecology response relationships for use in river management (Stewart-Koster et al., 2014). Multivariate analysis of relationships between facets of flow regime alteration and ecological patterns and processes can reveal interactions as well as dominant responses, and help to unravel the mechanisms underlying syndromes of impact (e.g., Kennard et al., 2007; McManamay et al., 2013).

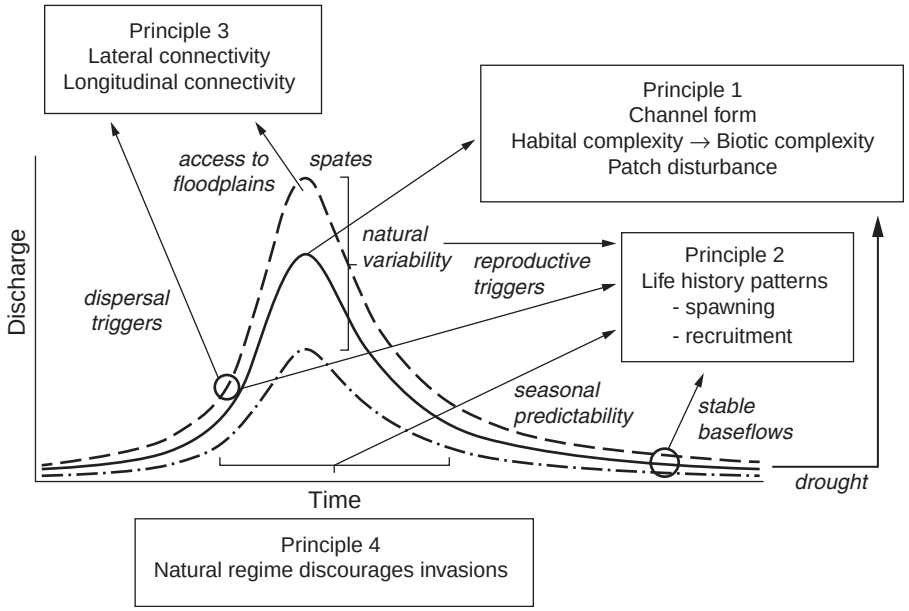

Fig. 1 The natural flow regime of a river influences aquatic biodiversity via several interrelated mechanisms that operate over different spatial and temporal scales. The relationship between biodiversity and the physical nature of the aquatic habitat is likely to be driven primarily by large events that influence channel form and shape (**Principle 1**). However, droughts and low-flow events are also likely to play a role by limiting overall habitat availability. Many features of the flow regime influence life history patterns, especially the seasonality and predictability of the overall pattern, but also the timing of particular flow events (**Principle 2**). Some flow events trigger longitudinal dispersal of migratory aquatic organisms and other large events allow access to otherwise disconnected floodplain habitats (**Principle 3**). The native biota have evolved in response to the overall flow regime. Catchment land-use change and associated water resource development inevitably lead to changes in one or more aspects of the flow regime resulting in declines in aquatic biodiversity via these mechanisms. Invasions by introduced or exotic species are more likely to succeed at the expense of native biota if the former are adapted to the modified flow regime (**Principle 4**). Redrawn from Fig. 1 in Bunn SE and Arthington AH (2002) Basic principles and ecological consequences of altered flow regimes for aquatic biodiversity, *Environmental Management*, 30: 492–507, with permission from Springer-Verlag; reproduced with permission from University of California Press, publisher of the text *Arthington AH (2012) Environmental Flows: Saving Rivers in the Third Millennium. Berkeley: University of California Press.*

Table 1 Summary of common alterations to specific components of river flow regimes, linked to ecological mechanisms underlying ecological consequences for riverine species and ecosystems.

Alterations to components of flow regimes	*Ecological mechanisms*	*Ecological consequences*
Reduced base flow magnitude	Reduced or complete loss of fast-flowing, turbulent habitats (riffles) and run habitat	Decline in density and aquatic species richness, or local extinction of species (Kupferberg et al. 2012).
	Reduced wetted habitat area	Encroachment of terrestrial organisms into the riparian and channel zone (Stromberg et al., 2007).
	Loss of longitudinal aquatic connectivity	Flow regulation and fragmentation imperil riverine fishes (Dudley and Platania, 2007)
Reduced flood size and frequency	Decline in life-history cues stimulating reproduction	Decline in richness and functional diversity of birds, aquatic plants, and microfauna (Nielsen et al., 2013)
	Reduced disturbance frequency and severity	Increased biomass and reduced diversity of aquatic macrophytes (Mackay et al., 2003)
	Loss of nutrient inputs and productivity from floodplains	Lower ecosystem productivity such as fisheries yields (Gillson et al., 2009)
Reduced floodplain inundation	Loss of flood pulse advantage	Reduced density of floodplain-dependent organisms, e.g., fish (Welcomme et al., 2006)
	Decline in flooded wetland area used for feeding, reproduction and rearing	Lower species richness of waterbirds (Kingsford and Thomas, 1995)
Increased base flow - artificial perennialization	Absence of non-flowing and low-flowing habitats	Altered species composition reflecting permanently flowing habitat (Rolls and Arthington, 2014)
	Loss of drying events	Increase metabolic activity of biofilms and productivity of chlorophyll *a* which in turn can increase density and biomass of consumers such as macroinvertebrates (Miserendino, 2009)
- anti-droughts		

(*Continued*)

Table 1 (Continued)

Alterations to components of flow regimes	*Ecological mechanisms*	*Ecological consequences*
Increased discharge variability, e.g., hydropeaking	Frequent drying and flooding of stream channel act as disturbances	Population declines due to increased mortality of eggs, larvae, and adults (Casas-Mulet et al., 2015) Reduced species richness and altered species composition (Perkin and Bonner, 2011)
Reduced discharge variability	Reduced flow velocity and flooding disturbances	Promotes invasion of some non-native vegetation (Stromberg et al., 2007) and fish (Rolls and Arthington, 2014)

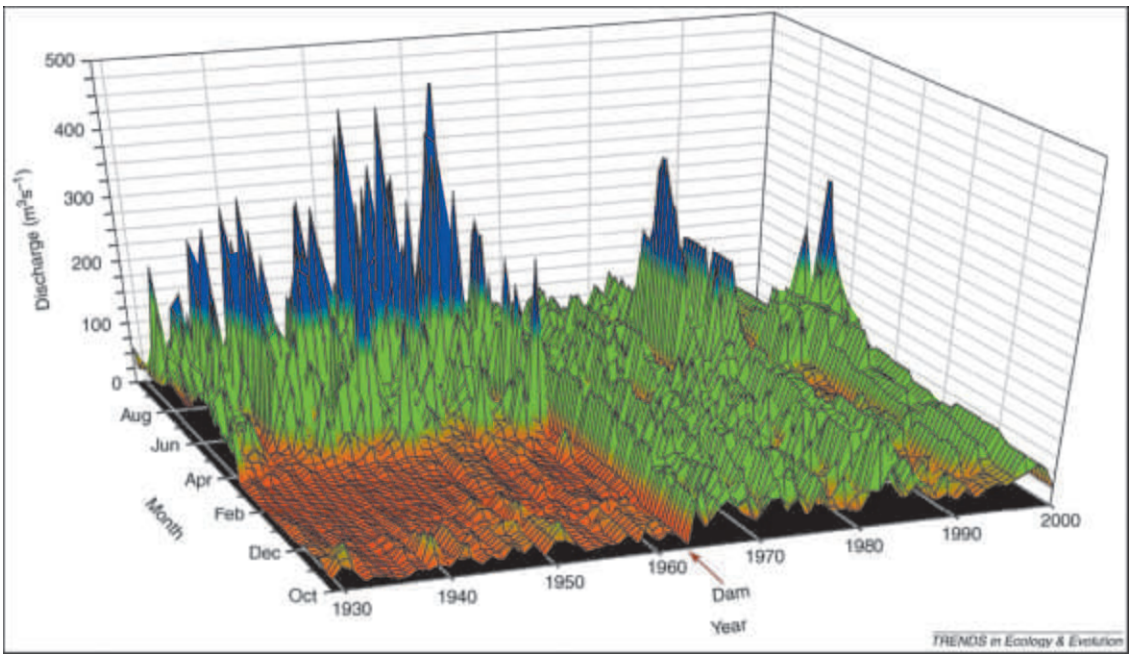

Fig. 2 Hydrograph of the Green River, Utah, United States from 1929 to 2000. Before the Flaming Gorge Dam was completed in 1963 (arrow), the river experienced floods from spring snowmelt and droughts during autumn and winter. Damming has caused both floods and droughts to become less frequent and smaller in magnitude. Lack of spring snowmelt floods in rivers of the western USA has halted recruitment of riparian cottonwoods, which had evolved to depend on these predictable seasonal events. Data from US Geological Survey. Reproduced from Fig. 1 in Lytle DA and Poff NL (2004) Adaptation to natural flow regimes. *Trends in Ecology & Evolution* 19: 94–100, with permission from Elsevier.

Environmental flow assessment methods

Assessments of environmental flow requirements began in the late 1940s in snow-melt streams and rivers of the western United States, initially to protect valuable cold-water fishes, especially salmonids. As the need to manage water flows in streams and rivers grew in prominence, many methods were devised. They are described in a comprehensive global review (Tharme, 2003), in numerous journal publications, two academic books (Arthington, 2012; Horne et al., 2017), and a recent book chapter (Poff et al., 2017). Fig. 3 captures the timeline of critical developments in the evolution of the environmental flow enterprise, beginning in the 1990s and followed by periods of consolidation, expansion, and global uptake (Poff and Matthews, 2013). This framing has helped to shape the present account, with slight adjustments in Fig. 3 to capture recent dimensions of global developments.

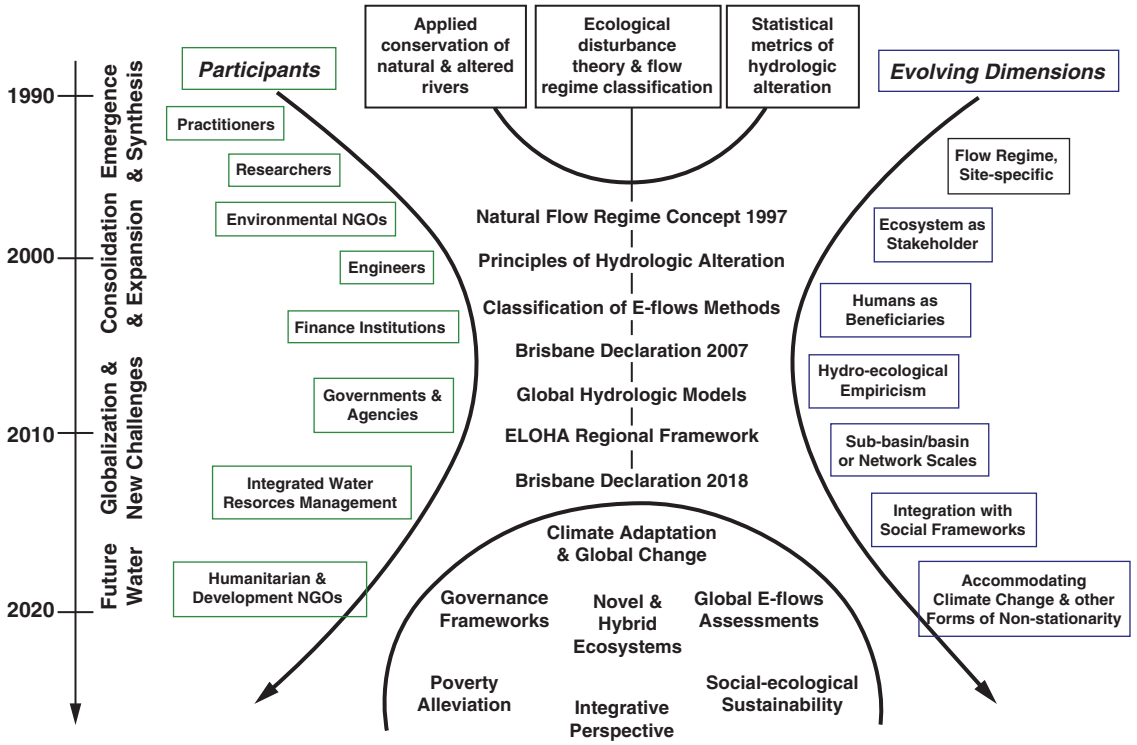

Fig. 3 Historical timeline for "modern" environmental flows (e-flows), showing emerging directions in the principles and concepts that underpin the science, and the growth in number and diversity of engaged institutions and practitioners. Timelines fall into relatively discrete periods of types of activities. The flow chart shows participants engaged in e-flows over time, benchmark achievements (central column), and evolving dimensions of e-flows. NGO—Non-Governmental Organization, ELOHA—Ecological Limits of Hydrologic Alteration. Adapted from Fig. 1 in Poff NL and Matthews JH (2013) Environmental flows in the Anthropocence: Past progress and future prospects, *Current Opinion in Environmental Sustainability* 5: 667–675, with permission from Elsevier.

Four main categories of environmental flow assessment methods were recognized by Tharme (2003) and this typology is still relevant today (Table 2).

The majority (70%) of methods provide simple flow rules founded on the characteristics of the surface water flow regime (e.g., the Montana Method of Tennant 1976), or quantify the discharge needed to maintain hydraulic habitat for selected species, usually fish of commercial or recreational value. PHABSIM, the Physical Habitat Simulation module of IFIM (In-stream Flow Incremental Methodology) is the prime example of these hydraulic habitat methods (e.g., Anderson et al., 2006). Often the flow recommended to support habitat was, and still is, termed a "minimum flow"—the lowest discharge that could maintain a wetted channel and provide opportunities for local movement and maintenance feeding for fish.

As the foundation of environmental flow assessments, these early habitat methods, and improvements in two and three-dimensional habitat modeling linked to habitat preference models, have proved immensely useful in protecting aquatic habitats and species (Poff et al., 2017). Recent advances offer more sophisticated applications at scales larger than river reaches, and encourage greater integration of physical and eco-hydrological models (e.g., Lamouroux et al., 2017; Curry et al., 2020).

Suitable wetted habitat is only one dimension of the needs of aquatic species and the ecosystem processes that support them, leading to the demand for methods that apply flow-ecology principles (e.g., Poff et al., 1997; Bunn and Arthington, 2002) and applications to a wider range of riverine and riparian taxa. A riverine ecosystem perspective on the assessment of environmental flows began to take shape in the 1990s, particularly in Australia and South Africa (Arthington et al., 1992; King and Louw, 1998). New directions in geomorphological theory contributed to these developments (Newson and Newson, 2000). Ecosystem frameworks proliferated rapidly such that after a decade of trial and error they represented around 8% of global methods (Tharme, 2003).

Table 2 Comparison of the four main types of methods and frameworks used worldwide to estimate environmental flows (e-flows) for rivers from site to regional levels.

Method type	*River ecosystem attributes/components addressed*	*Knowledge and expertise required*	*Resource Intensity*	*Resolution of output (environmental flow)*	*Appropriate level(s) of application*
Hydrological	Whole system, river or reach condition/ health, or non-specific	Primarily desktop, with modest data needs (e.g., virgin/naturalized (or other reference state) historical flow records (daily, monthly, or annual) Single flow indices or multiple ecologically relevant flow metrics characterizing flow regime Some use hydraulic habitat or ecological data, or meta-analysis of results of multiple e-flows assessments to derive rules	Low time, cost, and technical capacity	Mostly simple flow targets for maintaining river health, based on estimates of the percentage of annual, seasonal or monthly volume that should be left in a river to maintain acceptable habitat and river condition Often expressed as % of monthly or annual flow (median or mean); or as limits to change in vital flow parameters, commonly low flow indices Variable resolution, complexity and confidence	Reconnaissance/planning level of water resource developments Unsuitable for high profile, negotiated cases, or where flow regime dynamics are critical As a tool within habitat simulation or holistic methods For highly data deficient systems with limited ecological information Regionalization potential for different river ecotypes
	Used widely in many developed and developing countries/basins. Simple single index, rule-of-thumb and look-up table approaches (e.g., Tennant, 1976*) becoming less common. Shifting towards ecologically relevant flow metrics addressing multiple aspects of hydrological regime* (*e.g.,* Richter et al., 1996)				
Hydraulic rating	Aquatic (in-stream) physical habitat for target species or assemblages	Modest data needs, desktop or field surveys Historical flow records linked to single or multiple hydraulic variables at single river cross-section/transect Limited to moderate expertise	Mostly low, sometimes moderate time, cost, and technical capacity	Hydraulic variables (e.g., wetted perimeter) used as surrogate for habitat-flow relationships/models for target species or assemblages Low, sometimes moderate resolution, complexity, flexibility and confidence	Water resource developments where little negotiation is involved As a tool within habitat simulation or holistic methods
	Used widely historically, mostly in developed countries (see Tharme, 2003*), but nowadays largely superseded or used as one of several integrated habitat modeling tools in habitat simulation or holistic methods*				
Habitat simulation	Primarily in-stream physical habitat for target species, guilds or assemblages Some consider channel form, sediment transport, water quality, riparian vegetation, wildlife, recreation and esthetics	Moderate-high data needs, desktop, and field surveys Historical flow records, typically average daily discharge Few to many hydraulic variables are modeled at a range of discharges at multiple river cross-sections. Physical habitat availability, utilization and preference data, or similar models, for target biota	High to sometimes moderate time, cost, and technical capacity	Output in form of Weighted Useable Area (WUA) or similar habitat metrics for target biota (fish, invertebrates, plants) Often includes comparative analyzes of time-series of habitat availability, use and duration Moderate to high resolution, complexity, and confidence, moderate flexibility	Water resource developments, often large-scale, involving rivers of moderate to high strategic importance, often with complex, negotiated tradeoffs among users Commonly used as a method within holistic approaches and frameworks. Useful to examine a variety of alternative environmental flow scenarios for several species/life stages/assemblages
	*Move away from single species focus to increasing use for species, guilds and assemblages (*Tharme, 2003*). Primarily applied in developed countries, using increasingly sophisticated and multi-dimensional (eco)hydraulic habitat modeling*				

Holistic (ecosystem) methods and frameworks *Site level*	Entire ecosystem, river or several reaches, all or several ecological components Most consider in-stream and riparian components, some also consider groundwater, floodplain and other wetlands, deltas, estuaries and lagoons A few consider ecological functions/ processes (e.g., sediment flows, nutrient dynamics) Several explicitly address social and economic dependencies (e.g., livelihoods of rural subsistence users, health) on species, and ecosystem services (e.g., fisheries)	Typically moderate to high knowledge and expertise, but several used in data poor contexts Desktop and often field studies (seasonal, or more intensive), or mix of data. Expert judgment and traditional knowledge Use virgin/naturalized historical flow records, or rainfall records/other data for ungauged sites Several use hydraulic habitat variables from multiple cross-sections Biological data on flow-ecology relationships for lifecycle stages of aquatic and riparian species, assemblages and ecological processes	Moderate-high time, cost, and technical capacity	Recommended hydrological regime linked to explicit quantitative or qualitative ecological, geomorphological, and sometimes, social and economic responses and consequences Some address modified e-flow regimes for dry or wet years Moderate-high complexity and confidence Typically, high resolution and flexibility Several with potential to generate outputs for multiple scenarios (past, future) Some explicitly address probabilities, interaction effects, risk and/or uncertainty A few incorporate climate change	Water resource developments, typically large-scale, involving rivers of high conservation and/or strategic importance, and/or with complex, negotiated tradeoffs among stakeholders Simpler approaches (e.g., expert panels) often used in basin contexts where flow-ecology knowledge is limited, limited tradeoffs exist among users, and/or time and capacity constraints exist Potential for use in very modified or novel ecosystems, with focus on flow regime to deliver specific objectives
Regional level	As for other holistic methods, but for whole system(s)	Designed to use existing data sets and knowledge In some cases, includes collection of new data, or modeling for system locations of interest for which hydrological and/or ecological data are absent	As for other holistic methods	Quantified e-flow rules or standards for rivers of contrasting hydrological type or ecotype and points of management interest, at user-defined regional scale(s) Flow alteration-ecological/social response relationships by river type	As for other holistic methods Large systems/basins or aggregations of smaller ones, regions, entire states, or multiple projects May be integrated with water management systems

*Increasingly common in developing and developed countries. Recent attention in developed regions focused on in-depth analysis of ecosystem components and, less commonly, functions/processes. Used regularly in developing countries, including for capacity development, and in complex basins with development pressures and, in many cases, communities with clear dependencies on aquatic systems (*e.g., Arthington et al., 2003; King et al., 2003; King and Brown, 2010, 2018*). At regional scale, most applications are adaptations of a single framework, the* Ecological Limits of Hydrologic Alteration (ELOHA, Poff et al., 2010*) or derived approaches (*e.g., Kendy et al., 2012; Arthington et al., 2012; McManamay et al., 2013)

Current practice is summarized below each method type, with selected application examples from various world regions (references are provided within the body of the text).

Adapted from Tharme RE (2003) A global perspective on environmental flow assessment: Emerging trends in the development and application of environmental flow methodologies for rivers. *River Research and Applications* 19: 397–441, and Poff NL, Tharme RE and Arthington AH (2017) "Chapter 11: Evolution of environmental flows assessment science, principles, and methodologies," in *Water for the Environment: From Policy and Science to Implementation and Management*. Cambridge, MA: Elsevier.

Ecosystem frameworks for environmental flow assessment in rivers

Environmental flows can be assessed in two major contexts—flow regimes to support conservation of minimally impaired rivers, and flow regimes to guide restoration of regulated rivers. Two environmental flow frameworks, DRIFT and ELOHA, have been particularly effective in addressing these contrasting circumstances. Both are derivatives of early ecosystem approaches and flow-ecology principles.

DRIFT (Downstream Response to Imposed Flow Transformation)

King et al. (2003) developed the DRIFT framework during environmental impact studies in the montane rivers of the Kingdom of Lesotho, South Africa. Details of the original framework, such as the fish component, can be found in Arthington et al. (2003) and a fuller account of DRIFT applications is available in King and Brown (2010). DRIFT is comprised of four modules: (1) a biophysical module used to describe present ecosystem condition, and to predict how biophysical river components will change under a range of flow alterations; (2) a sociological module designed to identify subsistence users of river resources and to quantify the uses of river goods and services, including river-dependent health profiles; (3) a scenario development module which links the first two modules and generates ecological and social outcomes of specified flow alteration scenarios; and (4) an economic module to generate the costs of mitigation and compensation for each scenario.

Building on the Lesotho Highlands project, DRIFT has become a robust collection of field and desktop procedures, database systems and decision support tools for proactive planning of environmental flow provisions for rivers and estuaries. It now provides a platform for Integrated Basin Flow Assessment (IBFA), which can illustrate, for any future development option, potential changes in a wide range of river characteristics (e.g., channel configuration; bank erosion; water chemistry; riparian forests; river, estuarine and near-coastal fisheries; rare and pest species), and river-related human health and well-being (e.g., King et al., 2014). Most recently, King and Brown (2018) have promoted basin-wide environmental flow assessments of planned new hydropower developments, at a time of great concern for rivers and biodiversity threatened by new hydropower dams (Zarfl et al., 2015). DRIFT can be used to evaluate the biodiversity and ecosystem service consequences of different permutations of dam numbers, locations, designs, operations and power generation. "Such information is invaluable in helping guide decisions on whether or not to build, the design of meaningful mitigation measures, the fine-tuning of dam operation and, in some cases, identification and design of biodiversity offsets" (King and Brown, 2018).

ELOHA (Ecological Limits of Hydrologic Alteration)

The ELOHA framework (Poff et al., 2010) also aims to set limits on levels of ecological change in rivers as a consequence of flow regime alterations, and its outcomes can be applied in river flow restoration as well as protection of valued rivers and assets. A central concept is that eco-hydrological relationships can be developed for a selection of rivers with distinctive flow regime characteristics (distinguished by classification procedures) and transferred to other rivers of the same hydrological type, rather than managing for the "uniqueness" of each river's flow regime (Poff et al., 2010). The framework provides a multi-step process: (1) building a hydrologic foundation (including modeled hydrographs for ungauged stream segments), (2) classification of river segments into ecologically relevant types based on selected flow metrics, a further geomorphic sub-stratification (if necessary), (3) assigning flow-altered streams to pre-impact "reference" (unregulated) stream types, (4) and testing hypotheses (preferably mechanistic or process-based) about the likely ecological responses to flow alterations for each river type (Fig. 4).

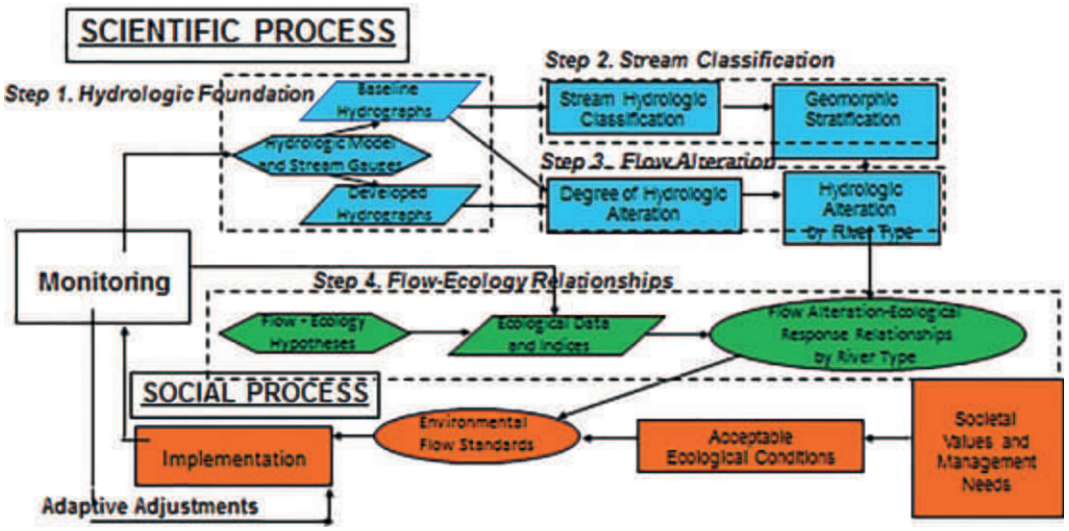

Fig. 4 The ELOHA framework comprises a scientific and a social process. Hydrological analysis and classification (blue) are developed in parallel with flow alteration–ecological response relationships (green), which provide scientific input into a social process (orange) that balances this information with societal values and goals to set environmental flow standards. Redrawn from Fig. 1 in Poff NL, Richter BD, Arthington AH, Bunn SE, Naiman RJ, Kendy E, Acreman M, Apse C, Bledsoe BP, Freeman MC, Henriksen J, Jacobson RB, Kennen JG, Merritt DM, O'Keeffe JH, Olden JD, Rogers K, Tharme RE and Warner A (2010) The ecological limits of hydrologic alteration (ELOHA): A new framework for developing regional environmental flow standards. *Freshwater Biology*, 55: 147–170, with permission from John Wiley & Sons Inc.; reproduced with permission from University of California Press, publisher of the text *Arthington AH (2012) Environmental Flows: Saving Rivers in the Third Millennium. Berkeley: University of California Press.*

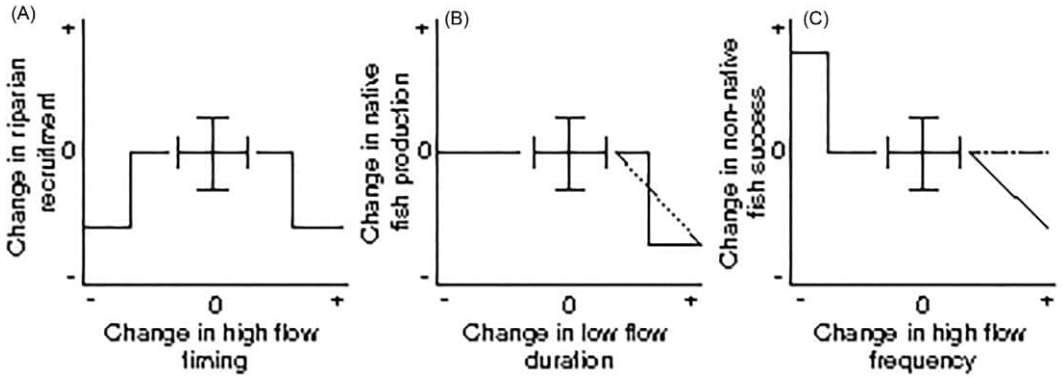

Fig. 5 Flow alteration–ecological response relationships for three river types: snowmelt (A), groundwater-fed (B) and flashy (C). Change in the flow metric (X-axis) ranges from negative to positive with no change representing the reference condition. The response of the ecological variable (Y-axis) to the flow alteration measured across a number of altered sites ranges from low to high. The bracketed space in the center of the graph represents the natural range of variation in the flow variable and ecological variable at the reference sites. Redrawn from Fig. 1 in Poff NL, Richter BD, Arthington AH, Bunn SE, Naiman RJ, Kendy E, Acreman M, Apse C, Bledsoe BP, Freeman MC, Henriksen J, Jacobson RB, Kennen JG, Merritt DM, O'Keeffe JH, Olden JD, Rogers K, Tharme RE and Warner A (2010) The ecological limits of hydrologic alteration (ELOHA): A new framework for developing regional environmental flow standards. *Freshwater Biology*, 55: 147–170, with permission from John Wiley & Sons Inc.; reproduced with permission from University of California Press, publisher of the text *Arthington AH (2012) Environmental Flows: Saving Rivers in the Third Millennium. Berkeley: University of California Press.*

When eco-hydrological relationships from ELOHA studies are expressed graphically, they provide information that can be used to set 'threshold' levels of change in flow alteration and species response in rivers of contrasting hydrological character (Fig. 5). In the final stages of an ELOHA application, a social process balances scientific information and impact risk assessments with societal values and goals, thus enabling environmental flow standards or "rules" to be negotiated for each distinctive river type.

Development of the hydrologic foundation has dominated applications of the ELOHA framework (e.g., Belmar et al., 2011; Kennard et al., 2010; Zhang et al., 2012) and prompted new approaches to accurately simulate flows and estimate flow metrics at many ungauged locations across broad geographical areas. Further developments have incorporated geomorphic features (e.g., Reidy Liermann et al., 2012) and water temperature (St-Hilaire et al., 2021) into river classification schemes. The framework has been applied in six US states and three interstate river basins to determine environmental flow needs at the regional scale (Kendy et al., 2012). It has been tested in Australian sub-tropical rivers to inform the possible development of new headwater dams to augment domestic water supplies (Arthington et al., 2012). McManamay et al. (2013) used flow-ecology relationships from an ELOHA study to predict fish and riparian responses to flow restoration in the regulated Cheoah River, Tennessee. This application demonstrated that recommended increases in flow magnitude reduced riparian encroachment 4 years after flow restoration, as predicted.

Like DRIFT, the ELOHA framework can be used in differing societal, governance and management contexts (Pahl-Wostl et al., 2013). ELOHA is being piloted for a collection of small coastal basins in Chiapas State, southern Mexico, and foundational studies are underway in China (Zhang et al., 2012). A further development has enhanced the social process within ELOHA by addressing indigenous people's beliefs, knowledge and socio-cultural relationships to water and rivers (Finn and Jackson, 2011). This long overdue recognition of indigenous values, knowledge and needs, initiated in the Lesotho DRIFT study, is becoming the norm in several countries (Anderson et al., 2019).

Future challenges for environmental flows

A founding principle of environmental flows assessment methods and implementation in river management is that the maintenance of critical features of the historical natural flow regime will sustain or restore associated ecological features and processes (Poff and Matthews, 2013). However, it is now clear that the hydrologic baselines and flow regimes of past eras are changing in many locations experiencing climate shifts (e.g., Laize et al., 2014). The implications of "non-stationary" climate regimes (Milly et al., 2008) are likely to be severe for many freshwater ecosystems. For example, Pound et al. (2020) forecast potentially devastating impacts of climate change on U.S. stream ecosystems, "with the restructuring of diatom, insect and fish communities, diminished distributions of functionally important taxa and widespread expansion of warm-water taxa, giving rise to biotic homogenization." Furthermore, natural ecological communities have been gravely impaired by the spread of non-native species (Bunn and Arthington, 2002; Rahel and Olden, 2008) and other forms of river and catchment degradation (Tickner et al., 2020).

A consensus is emerging that aiming to maintain or restore the historical patterns of flow variability, biodiversity and ecosystem structure in highly altered river systems that are also under duress from climatic shifts is typically unrealistic, even undesirable (Acreman et al., 2014; Poff et al., 2017). Scientists and managers are now faced with difficult social-ecological choices, trade-offs and decisions around the kinds of ecosystems (and e-flow regimes) that may be desirable, and manageable, now and in changing climatic futures (e.g., Poff et al., 2016).

In this context, should environmental flows be "designed" to sustain or improve particular features, such as fish catches of high value, as demonstrated for vital fisheries of the Mekong River Basin (Sabo et al., 2017)? This study found that a statistically optimized seasonally timed "designer flow regime" would lead to a two- to fourfold increase in fisheries catch compared with the historical (pre-dam) natural flow regime. Capon et al. (2018) comment that environmental flows can be designed to enhance ecological functions beyond their historical limits, such as the creation of new aquatic refuges or migration corridors where climate change has negatively impacted historical patterns of habitat, connectivity and organismal movement.

Given the potential for expansion of the "designer" environmental flow concept, river scientists urge caution and careful evaluation of the consequences of selective designs for broader freshwater biodiversity. Efforts to promote particular outcomes, such as sustainable fisheries, or to rescue and protect particular threatened species, may compromise other taxa, communities, even ecosystem processes. Tonkin et al. (2020) assert that "designing flows for the benefit of entire ecosystems requires long-term perspectives that embrace hydrologic dynamism involving critical flow events that occur at multiple temporal frequencies. While returning to the historical natural flow regime is an increasingly distant option in highly managed rivers in a non-stationary world, environmental flows must remain founded on the principles of the natural flow regime paradigm."

A capacity to predict possible future river ecosystem states and processes under changing climatic regimes is now demanded of river scientists and environmental flow managers. Yet the dynamic processes that underlie the assembly of ecosystem states are typically ignored in environmental water science and assessment (Poff et al., 2017). Envisioning the next developments in environmental flow science, Poff (2018) recommends several major areas of research: (1) shifting from static, regime-based flow metrics to dynamic, time-varying flow characterisations; (2) expanding the ecological metrics (and space–time scales) used in e-flows from primary reliance on ecosystem states to include process (e.g., population) rates and species traits; (3) incorporating other "non-flow" environmental features (e.g., temperature, sediment) to guide prioritization of e-flows applications with a likelihood of success; (4) broadening the ecological foundation of e-flows to incorporate more ecological theory that will contribute to a more predictive river science. Tonkin et al. (2019) call for a fresh global campaign to gather data on the dynamic responses of freshwater species and biodiversity to changes in river flows, preferably creating process-based models. They envisage that targeted interventions to avoid population collapse during extreme flows will be a cornerstone of managing rivers for resilience in future. "Freshwater biodiversity is disappearing on our watch. As the crisis deepens, we must model and manage rivers to safeguard the services they provide."

Capon et al. (2018) take a broader view of the implications of challenges associated with climate change and shifting hydrological and ecological baselines. They propose three guiding principles as "critical to avoiding perverse outcomes of environmental water management (EWM)": (1) climate change highlights the imperative for EWM to extend its scope beyond conventionally narrow ecological objectives, to encompass "functional, social, economic and cultural aspects"; (2) the scale of, and uncertainties associated with, climate change effects require that EWM adopt both "a broader and more nuanced consideration of its spatial and temporal framing"; (3) effective adaptation of EWM, and ultimately its transformation, will depend on its "successful alignment and integration, with respect to both water management more broadly and other sectors such as agriculture and energy production." The next section of this chapter moves into this broader policy arena.

Globalization and social-ecological sustainability

Frameworks such as DRIFT and ELOHA have expanded the geographic, socio-economic and governance contexts of environmental flow assessments and water management (e.g., Arthington et al., 2018b; King and Brown, 2018). Their incorporation into other policy and management frameworks is already under way; for instance, Integrated Water Resources Management (Overton et al., 2014), systematic conservation planning (Nel et al., 2011), climate change adaptation strategies (Poff et al., 2016; Capon et al., 2018) and implementation of the United Nation's Sustainable Development Goals (SDGs).

In an effort to increase the visibility and social-ecological relevance of the environmental flows enterprise as a powerful scientific and policy platform, the influential 2007 Brisbane Declaration and Global Action Agenda (www.eflownet.org) has been refreshed and expanded as the 2018 Brisbane Declaration and Global Action Agenda on Environmental Flows (Arthington et al., 2018a, see Box 1). The refreshed Global Action Agenda presents 35 actionable recommendations to guide and support implementation of environmental flows through legislation and regulation, implementation and water management programs, and research. The Declaration gives particular emphasis to integrated partnership arrangements that ensure full and equal participation for people of all cultures, and respect for their rights, responsibilities and systems of governance in environmental water decisions (see Anderson et al., 2019). The intent is that the Declaration and its actionable recommendations will guide a new era of shared visions, research and innovation, collaborative implementation programs, and adaptive governance of environmental flows, suited to diverse social, economic and environmental contexts.

The renewed 2018 definition has been incorporated (with the omission of water quality) into the Food and Agricultural Organization (FAO) Guidelines for inclusion of environmental flows into the SDG "Water Stress" Indicator 6.4.2. As custodian UN agency for this SDG, the FAO is required to collect global data on water stress and environmental flow allocations annually or at least every 3 years, following an agreed protocol for estimation of country-wide environmental flow provisions. This high-level process could facilitate a global review of the methods currently applied by every country to estimate environmental water allocations at finer scales (e.g., regions, basins), as well as data on how and where rivers have benefited from environmental water management—a significant information gap in the global literature (Horne et al., 2017). Discussions are underway to address these opportunities.

Box 1 The 2018 Brisbane Declaration and Global Action Agenda on Environmental Flows.

The 2018 Brisbane Declaration and Global Action Agenda on Environmental Flows was developed and endorsed by an international network of environmental flow practitioners comprising civil society, indigenous peoples, the private sector, scientists, water users, businesses, non-government organizations, local, regional and national government agencies and international institutions. It was endorsed by delegates of the 20th *International Riversymposium and Environmental Flows Conference* (Brisbane, September 2017) and numerous colleagues.

Definition: Environmental flows describe the quantity, timing, and quality of freshwater flows and levels necessary to sustain aquatic ecosystems which, in turn, support human cultures, economies, sustainable livelihoods, and well-being.

The goal of environmental flow management is to protect and restore the socially valued benefits of healthy, resilient, biodiverse aquatic ecosystems and the vital ecological services, economies, sustainable livelihoods, and well-being they provide for all societies.

Aquatic ecosystems include in the e-flow enterprise include rivers, streams, springs, riparian, floodplain and other wetlands, lakes, near coastal water bodies, including lagoons and estuaries, and groundwater-dependent ecosystems (Arthington et al., 2018a).

Global Action Agenda on Environmental Flows (2018)

The Brisbane Declaration on Environmental Flows (2018) calls upon all governments, development banks, donors, water and energy associations, multilateral and bilateral institutions, community-based organizations, research institutions, indigenous groups and the private sector across the globe to commit to the following actions for protecting and restoring environmental flows as a central element of water resources management, and as a foundation for achievement of the water-related Sustainable Development Goals (SDGs).

Declaration Statements	Leadership & Governance	Management	Research
E-flows are essential to protect and restore biodiversity, aquatic ecosystems, and the ecosystem services they provide for all societies	Develop and implement government programs to support provision of e-flows to freshwater-dependent ecosystems, including Groundwater Dependent Ecosystems GDEs) Develop and implement government e-flow programs to support achievement of water-related Sustainable Development Goals (SDGs)	Develop and implement e-flow programs that integrate surface and groundwater processes into e-flow planning, assessment, monitoring and management Integrate e-flows into programs and projects designed to support achievement of water-related Sustainable Development Goals (SDGs)	Quantify flow-ecology relationships and ecosystem services for all aquatic ecosystems that depend on fresh water, including GDE Demonstrate ecological, economic and societal benefits of e-flows and healthy freshwater-dependent ecosystems in programs and projects that support water-related Sustainable Development Goals (SDGs)
E-flows are critical to protect and restore the world's cultural and natural heritage	Develop and implement government programs to generate awareness of cultural heritage values, knowledge and attachments to freshwater-dependent ecosystems	Integrate cultural heritage values, knowledge and attachments to freshwater-dependent ecosystems into e-flow assessment, implementation, monitoring and adaptive management	Improve understanding and quantify relationships between e-flows, healthy aquatic ecosystems and cultural heritage values, and attachments to freshwater-dependent ecosystems
E-flows have been compromised and today many aquatic systems around the world are at risk	Develop and implement government programs to protect and restore freshwater ecosystems Protect healthy freshwater-dependent ecosystems.as early as possible Establish programs to implement e-flows during the planning stage of new dams and other water infrastructure	Apply systematic planning tools to achieve cost-effective protection and restoration of healthy freshwater ecosystem Base protection and restoration of e-flows on scientific and local knowledge within an adaptive management framework that balances human and ecological water requirements	Identify obstacles to implementation of e-flows in different world settings Improve systematic planning tools and trade-off processes that can guide the location, design, and operation of new dams/other water infrastructure, for social-ecological benefit
Implementation of e-flows requires a complementary suite of policy, legislative, regulatory, financial, scientific and cultural norms and values to ensure effective delivery and beneficial outcomes	Develop and implement a legal basis for regulating water use, e-flows, water rights and licenses, including recognition of cultural heritage values, knowledge and customary relationships with water Develop and implement policies and programs to position e-flows as an integral component of water, food and energy security objectives and water-related SDGs Provide sustained funding to effectively plan, design, implement, monitor and adaptively manage e-flows Provide sustained funding for research and training to enhance understanding of aquatic ecosystem functioning, e-flow planning, assessment, implementation, monitoring and adaptive management	Establish environmental water allocation mechanisms appropriate to basin conditions and governance structures Establish a system to manage consumptive water uses at basin and local scales Utilize basin and system-scale infrastructure planning, design and operation to protect and enable e-flows even where dams and other types of water infrastructure are needed, as well as in cases of infrastructure retrofitting and decommissioning Ensure that water management professionals have sufficient technical capacity and knowledge to incorporate environmental flow approaches into water resource management plans, implementation, monitoring and adaptive management	Investigate existing, and propose new, mechanisms for integrating e-flows implementation in broader water and related resource management system Research effective design, monitoring and reporting of e-flow implementation projects and programs, treating them as experiments where feasible Research and identify appropriate indicators of ecological, cultural, and economic outcomes from environmental flows Establish centers of excellence for research and training to enhance understanding of aquatic ecosystem functioning, e-flow planning, assessment, implementation, monitoring and adaptive management

(*Continued*)

Box 1 (Continued)

Local knowledge and customary water management practices can strengthen e-flow planning, implementation, and sustainable outcomes	Develop and implement arrangements for full and equal participation, and respect for the rights, responsibilities and systems of governance of all cultures and stakeholders in e-flow planning, assessment, implementation, monitoring and adaptive management	Empower and ensure the full and equal participation, and respect for the rights, responsibilities and systems of governance, of all cultures and stakeholders in e-flow planning, assessment, implementation, monitoring and adaptive management	Co-develop best-practice models to ensure full and equal participation, and respect for the responsibilities, rights and systems of governance of all cultures and stakeholders in e-flow planning, assessment, implementation, monitoring and adaptive management
Climate change increases the risk of aquatic ecosystem degradation and intensifies the urgency for action to implement e-flows	Develop and implement flexible governance and management arrangements that enable consideration of climatic and other environmental regime change implications for e-flows and ecosystems Establish programs to implement adjustments to e-flows in aquatic ecosystems impacted by changing flow and other environmental regimes	Where climate change may further disrupt e-flows and social-ecological systems, adapt existing approaches to maintain/restore ecological resilience and societal benefits Monitor ecological and societal outcomes of e-flows in relation to changing flow and other environmental regimes, and adjust implementation plans accordingly	Conduct long-term studies of freshwater-dependent ecosystem adjustments and societal responses to changing flow and other environmental regimes in areas experiencing shifts in climate, human demographic patterns and demands for water Research new approaches to maintain/restore ecological resilience and societal benefits in such areas

The year 2021 is notable for visionary global activities to "Halt the loss of species, ecosystems and genetic diversity by 2030; restore and recover biodiversity to ensure a world of people "living in harmony with nature" by 2050" (Post-2020 Global Biodiversity Framework Mission, https://www.iucn.org/theme/global-policy/our-work/convention-biological-diversity-cbd/post-2020-global-biodiversity-framework). To this end, governments are reviewing international agreements relevant to biodiversity loss—the Convention on Biological Diversity (CBD), the Sustainable Development Goals (SDGs), and the UN Framework Convention on Climate Change (UNFCCC).

The 2018 Brisbane Declaration and Global Action Agenda forms part of a submission to the CBD (SBSTTA—Subsidiary Body on Scientific, Technical and Technological Advice) on actions needed to support the Global Biodiversity Framework). Signatories to this submission urged SBSTTA to consider an Emergency Recovery Plan to "bend the curve" of freshwater biodiversity loss (Fig. 6).

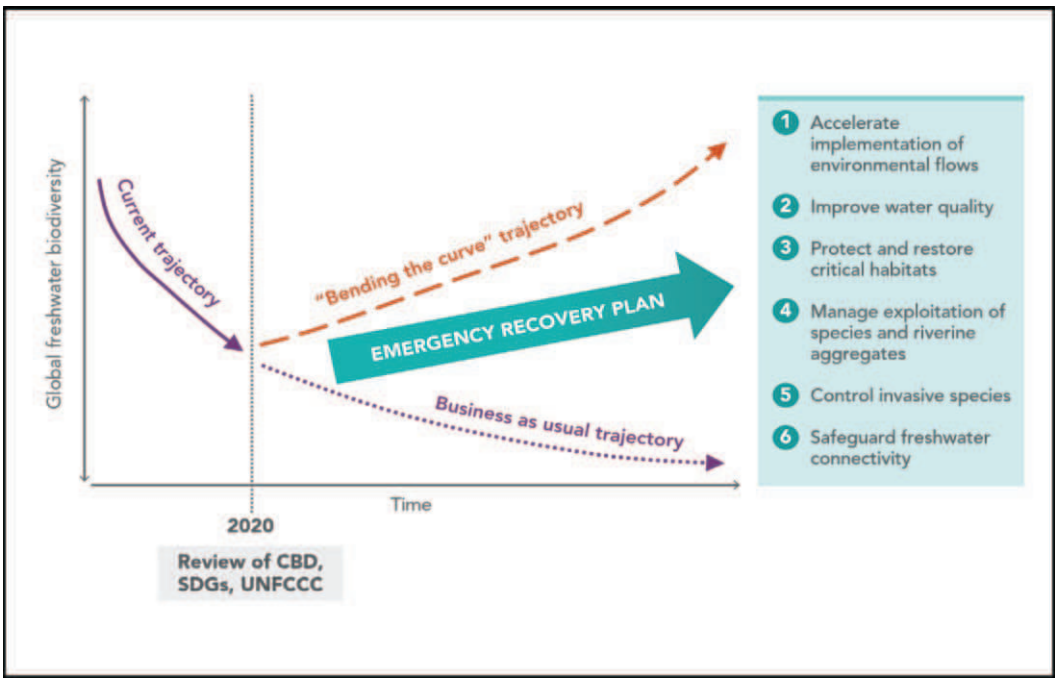

Fig. 6 The Emergency Recovery Plan for freshwater biodiversity: Six priority actions for global action to bend the curve of freshwater biodiversity loss that should be reflected in the post-2020 Global Biodiversity Framework. Threats to freshwater biodiversity are often synergistic so coherent planning of interacting priority actions to address such threats is necessary. Creative Commons License.

In this plan, six priorities for action start with the need to accelerate implementation of environmental flows globally (see Tickner et al., 2020). Other major actions to halt freshwater biodiversity decline include: improving water quality; protecting and restoring critical habitats; managing exploitation of freshwater species and riverine aggregates; preventing and controlling non-native species invasions; and safeguarding and restoring river connectivity.

In further support of the environmental flows aspects of the Emergency Recovery Plan, Tharme et al. (2020) published a BLOG to highlight the grave threat to freshwater biodiversity and river health from these multiple, interacting stressors (https://blog.oup.com/2020/09/bring-living-waters-back-to-our-planet). Its message is that Planet Earth "has shown unimaginable resilience, but at a cost we have not fully reckoned—precipitous declines in the health and biodiversity of freshwater ecosystems will undoubtedly push us beyond the bounds of sustainability. We have reached a pivotal moment when all of us, whether policymakers, indigenous and business leaders, resource managers, engineers, scientists, and the public, must re-evaluate priorities and mobilize to protect and recover our freshwater ecosystems for the long term. Meeting the imperative for accelerating implementation of environmental flows is central to that path and that potential."

Conclusion/Synthesis

The challenge of protecting or restoring the water regimes and biodiversity of rivers and other freshwater ecosystems is urgent and it is global. The evolution of the environmental flow enterprise has produced a remarkable array of methods, models, decision support tools and policy instruments to guide the management of environment water (Poff and Matthews, 2013; Horne et al., 2017). The development of ecosystem frameworks such as DRIFT and ELOHA has enabled quantification, evaluation and implementation of environmental flow regimes at reach, river, basin and regional scales. These framings and decision support tools can help to guide which aquatic ecosystems should be protected versus those that can be rehabilitated, re-engineered or even re-designed across diverse natural and developed landscapes (Poff et al., 2016; King and Brown, 2018; Tickner et al., 2020). Achieving a societally acceptable balance between the provision of environmental flows for wild and formally protected rivers and the return of flows to selected regulated rivers should be a major goal.

Shifting climatic regimes and associated effects on river hydrology, water temperature, water quality and ecological dynamics are creating new challenges across the full spectrum of river science and environmental water management (Capon et al., 2018; St-Hilaire et al., 2021). Predicting ecological configurations and outcomes from environmental flow allocations against a background of shifting climatic and other regimes, and diverse societal perspectives, is challenging but necessary. To this end, a more dynamic, process-based river science and new modeling techniques are emerging (Poff, 2018; Tonkin et al., 2019, 2020). The "designer environmental flow" concept may have merit in particular circumstances, but each application will require careful evaluation to ensure that freshwater biodiversity and valued ecosystem services are not compromised.

Continuing efforts to enhance and promote environmental flows science and implementation in diverse contexts, countries, systems of governance and policy arenas are essential. The 2018 Brisbane Declaration and Global Action Agenda on Environmental Flows and the 2020 Emergency Recovery Plan for Freshwater Biodiversity provide examples of what can be achieved by collaborative international teams speaking with one voice. The Post-2020 Global Biodiversity Framework offers a perfect window of opportunity to bring freshwater ecosystems to greater prominence in global policy arenas. Continued efforts will be needed to keep up the pressure on world governments and other sectors to ensure recovery of freshwater biodiversity and resilient ecosystems for the long-term benefit of people and nature.

Acknowledgments

The author acknowledges the many sources of information and examples cited throughout this chapter, which draws from the work of numerous colleagues and friends. Thanks are due to each and every individual for their dedication to research on rivers and environmental flows, and their commitment to sustaining healthy rivers for people and nature. I am especially grateful to Samantha Capon, who re-drew most of the figures from original sources for my book (Arthington, 2012) and to Paul Godfrey for his assistance with the preparation of figures for this chapter.

Glossary

Benthos Refers to the collective community of aquatic organisms that lives or forages at the bottom of an aquatic habitat like lakes, rivers, or the ocean.
Connectivity Represents the ability of water, organisms, and other materials to move among the main dimensions of a river, including longitudinally (upstream and downstream), laterally across the floodplain, and vertically through the interaction between surface water and ground water.
Dam removal mitigation A project, program, or structure designed to off-set the effects of dam removal, such as planting of vegetation, removal of exotic species, or installation of a water treatment facility.
Ecological memory The ability of past ecosystem states or events to influence present or future ecological condition.
Ecological response trajectory The path through time followed by an ecosystem or its fundamental properties after a major disturbance or restoration action.
Fish passage The modification or removal of barriers to allow fish and other aquatic organisms to swim and migrate unimpeded through a river system.
Instantaneous dam removal A dam removal project that proceeds following a relatively rapid drawdown (hours to days) of the impoundment.
Sedimentation The process of sediment transported in suspension by a river settling out once the water enters an impoundment, reservoir, or barrier.
Species turnover The change in taxonomic composition among habitats, time periods, or areas.
Staged dam removal A dam removal project that proceeds in stages, drawing out the reservoir drawdown by incrementally dismantling a dam.
Thermocline A relatively thin zone of stratification in a reservoir where layers contain markedly different water temperatures.

Introduction

We begin our discussion of dam removal by focusing on the importance of rivers. Rivers provide vital ecosystem services, largely through the provision of food, energy, and water. For millennia, humans have been attracted to rivers for these resources, settling near rivers and developing their floodplains. In the geologic record, signatures of human development on river systems date back to the earliest Mesopotamian civilizations of the 3rd millennium BCE, and elsewhere during the 1st and 2nd millennia BCE in Europe, Asia, and South America (Williams et al., 2014). Today, the intricate connections between societies and rivers occur across many socio-political boundaries and spatial scales. At the local scale (100s to 1000s of m^2) indigenous fishing communities harvest fish and use water for drinking and bathing; at continental scales, governments wrestle with river management—water scarcity, storage, irrigation, organic and inorganic pollution, eutrophication, disease, flood control, navigation, and sedimentation. Globally, rivers have sculpted the earth by weathering rock and mineral deposits, transporting sediment and nutrients to floodplains, river deltas, and oceans. They connect the atmosphere to the ocean via the water cycle and are a central geographic feature of many of the world's most populated cities.

Dams have become one of the most prevalent agents of change to the world's rivers. Early dam construction was largely driven by human needs for mechanical power, reliable water supplies, irrigation, and protection from floods, with little concern for the environmental consequences. As technology advanced in the modern industrial era, the form and magnitude of changes to rivers resulting from dam construction accelerated. The ability of human engineering to harness larger, more powerful rivers has advanced resulting in the damming of many of the world's rivers to maximize the provision of resources or infrastructure for providing flood protection, navigation, and recreational opportunities (Grill et al., 2019). Despite engineering feats that allow for the construction of mega-dams, the vast majority of the world's dams have heights of less than 10 m. Several national and global databases of larger dams exist (e.g., Mulligan et al., 2020), although the exact number of dams worldwide is unknown. Estimates using known databases of larger reservoirs and statistical projections of smaller reservoirs suggest that the number could exceed 16 million (Lehner et al., 2011). This number is expected to increase in the coming decades as developing countries build large dams on big rivers and small dams on tributaries for hydropower, irrigation, and water supply (Zarfl et al., 2015).

The different kinds of dams can be categorized into five groups (USSD, 2015). *Arch dams* are constructed of stone, brick, or concrete. They are curved in an upstream direction, which transmits the major part of force from the water load to the abutments (typically bedrock canyon walls or concrete). Arch dams facilitate a taller structure, which increases the reservoir storage capacity. A *buttress dam* is usually made of concrete, with a solid water-tight side upstream supported by concrete buttresses on the downstream side. A *gravity dam* depends upon its own weight for stability and can be constructed from concrete, stone masonry, timber cribs filled with rock, or roller-compacted concrete. An *embankment dam* is constructed of earth materials such as rock and soil, with an impervious core to control seepage. Finally, a *composite dam* consists of both embankment and concrete.

Effects of dams on rivers

Although dams produce societal benefits, they also impact the structure, function, and ecology of rivers and can have a range of impacts on indigenous communities both upstream and downstream of the dam structure. Dams instigate other potential socio-ecological impacts, such as population displacement, loss or inundation of agricultural lands, evaporative water loss, and greenhouse gas emissions. The ecological effects of dams occur both upstream and downstream of the structure; larger dams eliminate a free-flowing section of river by replacing it with a reservoir, while low-head dams may slow water velocities and create impoundments within the banks of the river channel. The magnitude of these effects depends upon the size of the dam and its impoundment, the operation and purpose of the dam, the geography and hydrology of the river system, and whether any additional drivers of change are present in the watershed, including other dams. Thus, each dam has a unique set of interacting factors contributing to the types and levels of impact on a river (Poff and Hart, 2002).

Immediately upstream of a dam, some of the free-flowing river is eliminated and replaced by an impoundment. The shallower and faster moving *lotic* habitat is replaced with deeper, slower moving *lentic* habitat. Although there may be some overlap, the organisms adapted to life in these two contrasting environments are different; therefore, creating an impoundment can cause a turnover in the assemblages of plant, invertebrate, and vertebrate species occurring in that segment of river. Reservoirs can also change the temperature regime of downstream waters. By absorbing more of the sun's heat and having a longer water residence time than an equivalent length of river, reservoirs can store heat. When water that passes through the dam originates from above the thermocline, the heated water can increase the temperature of waters downstream. In other cases, when the dam draws water from below the thermocline, a cooling effect can occur in downstream waters. In both cases, the change from the normal temperature regime can have consequences for downstream aquatic life. For dams without any provisions for fish passage past the dam (e.g., fish ladders, smolt bypass), migrating fish can no longer ascend or descend the river. This disruption of connectivity leads to loss of habitat availability, often extirpating upstream migratory fish and potentially leading to population declines across the whole river system.

Downstream of a dam, most of the changes to the river are driven by physical factors, which can indirectly affect organisms. A natural flow regime—defined by the magnitude of discharge, the timing and duration of peak flows, and the rate of change of flow events—determines the ecological character and integrity of a river (Poff et al., 1997). A river's natural flow regime is disrupted by dams when they are used to regulate discharge through water storage, withdrawals, and running turbines. Naturally occurring floods or pulses of seasonally high flows from snow melt, for example, that serve to reset the structure of gravel bars or create and transport large woody debris, may no longer occur with enough frequency or strength. Because many organisms are adapted to these habitat-forming processes and their timing, the effects on downstream organisms can cascade through freshwater food webs. In addition, the transport of sediment may be altered or eliminated, causing riverine habitat downstream to degrade and coarsen, which in turn affects the benthos and the ability of fish to spawn (Wohl et al., 2015).

A brief history of dam removal

As the effects of dams became more widely recognized and understood, the notion of deliberately removing them slowly emerged into the zeitgeist of river management and conservation. For much of human history, the removal of dams occurred unintentionally through failure during floods—whether due to old and degraded structures no longer able to withstand the forces of nature, or because new dams were improperly constructed or maintained. Such failures resulted in economic damage, environmental

degradation, and in some tragic cases the loss of human life. Despite modern safety standards and monitoring, structural and catastrophic failure of dams still occurs, sometimes with lethal consequences.

The advent of dam safety regulations has helped propel the recent increase in dam removal. In some countries, modern safety standards, policies, and laws require regular inspections of dams to assess risk, resulting in the identification of deficient dams and potential candidates for removal. Some states and municipalities have dedicated funding to remove obsolete, unsafe, or hazardous dams. In other cases, especially for privately-owned dams, economics may cause owners to remove some dams when the return on investment is inadequate to justify costly repairs, upgrades, or other mitigation measures to resolve environmental effects and legal mandates (e.g., fishways for adult fish, trap-and-haul structures for juveniles).

Increasingly, river restoration has spurred dam removal because the return of a natural flow regime and increasing connectivity have repeatedly resulted in restoration of river functions (O'Connor et al., 2015). Sedimentation has also led to dam removals in cases where reservoir water storage capacity has been lost due to the accumulation of sediment. Largely propelled by these factors, dam removals in the U.S. have steadily grown in number since the mid-1970s (Foley et al., 2017). A comprehensive list of U.S. dam removals shows that as of 2019 about 1700 dams have been removed (American Rivers, 2020), while Europe has documented over 4900 barrier removals, many of them dams and weirs (Dam Removal Europe, 2020).

A large share of dams removed in the U.S. are small, generally less than 10 m in height. Based on available data, the median height of dams removed in the U.S. was ~3 m (Bellmore et al., 2017). The skew toward small dams in the size distribution of dam removals is driven by a suite of factors. There are many more small dams in the world than larger dams and they are, on average, older than large dams. Thus, in addition to being structurally deficient, their purpose is often tailored to a bygone era. Such small dams are now less likely to generate significant economic benefits compared with larger dams that store water or produce hydroelectricity, increasing their likelihood for removal. In contrast, the bias against larger dam removals stems from there being fewer of them; moreover, they are, on average, younger and are more likely to provide economic and societal benefits, although many are older than 50 years (Perera et al., 2021). Additionally, it is generally more arduous, time consuming, fraught with socio-economic challenges, and expensive to remove large dams and in some cases, like flood protection, to replace their function.

Not all dam removal projects fit neatly into the categories described above. There are exceptions, for example, to the prevalent small- versus large-dam rules of thumb associated with the reasons and primary cost drivers for dam removal decisions. Some low-head dams can impound large volumes of water, making their operational footprint considerable. Although the potential risks for property damage and loss of life associated with catastrophic failure are generally greater with larger dams, fatalities at hydraulically dangerous low-head dams (to swimmers, boaters, and other river recreationists) are also a public safety issue.

Considerations for dam removal

Several factors must be considered when evaluating potential dam removal projects. These can include legal requirements such as obtaining the necessary federal and local permits. Other practical issues surrounding project management include obtaining funding, identifying and getting input from stakeholders, and determining whether mitigation projects are necessary or required to minimize dam removal effects. Technical difficulty, expense, and time horizon of a proposed dam removal project contribute to its feasibility. Additional factors include whether the dam is publicly or privately owned, the purpose and size of the dam, level of reservoir sedimentation, the status and ecology of the river and surrounding project lands, the infrastructure downstream of the dam, and any necessary environmental compliance mandates. These all contribute to the complexity and unique scope of each dam removal project.
