Klement Tockner is director general of the Senckenberg Society for Nature Research and professor for ecosystem sciences at Goethe University, Frankfurt am Main. He was president of the Austrian Science Fund—FWF (2016–20), full professor for aquatic ecology at the Free University Berlin (2007–20), and director of the Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin (2007–16). He received a Ph.D. from the University of Vienna (1993) and a Titulary Professorship at ETH Zürich (2005).

Klement Tockner is an internationally leading freshwater scientist, in particular in the research domains biodiversity, ecosystem science, and environmental management. He has published about 250 scientific papers including 180 ISI papers. He was editor-in-chief of the journal *Aquatic Sciences* (2005–2014) and is subject editor of the journal *Ecosystems*. He has published about 250 scientific papers including 180 ISI papers. In 2009, he edited a comprehensive book on European Rivers (Rivers of Europe, Elsevier; 2nd Edition in 2021). He is elected member of the Austrian Academy of Sciences and the German Academy of Sciences, Leopoldina.

Thomas Mehner is vice director and senior researcher at the Leibniz Institute of Freshwater Ecology and Inland Fisheries in Berlin, Germany. He is limnologist and fisheries biologist by training, and has got his Diploma and Ph.D. at the University of Rostock (formerly East Germany) in 1992. In 1999, he had received his habilitation and venia legendi in limnology, which allowed him to start teaching as Privatdozent at universities. Since 1997, he has been working at IGB in several positions. He has published about 170 ISI papers, with primary focus on fish communities, lake food webs, and species interactions. However, his topical interests are broader, and he has authored and co-authored several publications on freshwater fisheries management, fish population genetics and evolutionary and behavioral ecology of aquatic organisms. He has been Handling Editor of the journals "*Aquatic Ecology*" and "*Freshwater Biology*" for several years, and he is currently member of the Editorial Boards of "Global Change Biology" and "Limnologica." Since spring 2018, he has been the president of the International Society of Limnology (SIL), the oldest and most international scientific society devoted to the study of inland waters. Thomas Mehner has taught M.Sc. courses at universities on limnology, fish ecology, fisheries management, and behavior and evolution. His one-week course on "Scientific Writing" for Ph.D. students has been run at 3 universities and in total 18 times, with >120 international students participating. He has trained many M.Sc. and Ph.D. students and supervised their theses, and he is actively mentoring undergraduates, graduates, and post-doc researchers.

EDITORIAL BOARD

Editorial Board Names and affiliations

SECTION EDITORS

Damien Bouffard is leader of the aquatic physics lab at Eawag (Switzerland). He holds a Ph.D. from EPFL (with Ulrich Lemmin). After his Ph.D. he worked in Canada with Leon Boegman (Queen's U.), Ram Yerubandi (Environment Canada), and Joe Ackerman (Guelph U.) before returning to Switzerland as first assistant at EPFL with Alfred (Johny) Wüest. He has published over 70 peer-reviewed papers in aquatic physics and serves as associate editor for JGLR, AS, and HESS. His program research is focused on two axes: (i) linking the small-scale turbulence to the large-scale forcing with today a special interest in convective processes in lakes and (ii) aquatic physics as a tool to understand lake ecosystems. The later includes the use of 1D and 3D operational hydrodynamic models such as simstrat.eawag.ch or meteolakes.ch. Bouffard is also involved in promoting multidisciplinary and high-tech research on lakes, notably as member of the steering committee of the LéXPLORE floating research platform in Lake Geneva and in promoting open science in limnology with the web platform Datalakes-eawag.ch.

Debbie Chapman as a graduate of the University of London, Deborah Chapman started her research career as limnologist at the Freshwater Biological Association in the English Lake District. She subsequently became interested in monitoring the impacts of disposal of sewage sludge on aquatic organism and the potential for human health impacts from aquatic pollution. In 1986 she joined the United Nations Environment Programme's (UNEP) Monitoring and Assessment Research Centre (MARC) in London, participating in the international monitoring and assessment activities of UNEP and the World Health Organization (WHO), and assisting in global environment assessment programs. In 1988 she became the deputy director of MARC and took responsibility for the developing country workshops and training program, and global environment data review and compilation. After moving to Ireland in 1990, she worked as a freelance Environmental Consultant engaged mostly on international and developing country projects for WHO, UNEP, and other international organizations. She has assisted with the compilation of State of the Environment reports and has contributed to, edited, and produced more than 20 books on water resources and environmental management, including the internationally successful *Water Quality Assessments: A guide to the use of biota, sediments and water in environmental monitoring.*

In 1998 she joined UCC becoming the first lecturer in Environmental Science and then Head of Environmental Science in 2013. In recent decades her research interests have focused on water resources management, especially recreational and amenity lakes and reservoirs, developments and current practice in design and implementation of water quality monitoring programs, and human health risk assessment in relation to the use of freshwater resources and wastewater disposal. Drawing on 30 years of international experience, in 2015 she established the UNEP Global Environment Monitoring System for Water (GEMS/Water) Capacity Development Centre at UCC. This center delivers capacity development activities in water quality monitoring and

assessment worldwide for UNEP, including support for the Sustainable Development Goal indicator for good ambient water quality. She retired as director of the center in June 2021 and now acts in an advisory role and as an independent consultant.

Kendra Spence Cheruvelil is professor of limnology and co-director of the Data-intensive Landscape Limnology Laboratory at Michigan State University (MSU) in the Department of Fisheries and Wildlife (https://www.canr.msu.edu/fw/). She is also serving as Interim Dean of the Lyman Briggs College, which is MSU's residential college for studying the sciences and maths within their societal and global contexts (www.lbc.msu.edu). Kendra co-established the discipline of landscape limnology (https://bigdatalimno.org/research-themes/landscape-limnology/) and co-leads the LAGOS research program that is creating the research infrastructure to conduct big-data research on U.S. lakes (https://lagoslakes.org/). This large, collaborative, and interdisciplinary research program has been funded by the U.S. National Science Foundation and seeks to understand how global changes such as climate change and land use intensification affect lakes across regions and continents and through time. Dr. Cheruvelil also pushes the boundaries of how to conduct limnology research by using data-intensive science, science of team science, and open science approaches, tools, and perspectives to answer complex scientific questions. She also has an active research program to advance diversity and inclusion in the sciences (https://ee-stem.weebly.com/) and serves as an associate editor for the journals *Limnology & Oceanography Letters* and *Frontiers in Ecology & the Environment*. Prior to joining MSU, Dr. Cheruvelil was a faculty member in the Purdue University system. She has a dual Ph.D. from MSU in Fisheries & Wildlife and Ecology, Evolution, & Behavior (2004).

Catherine Febria is a Tier 2 Canada Research Chair in Freshwater Restoration Ecology and assistant professor at the Great Lakes Institute for Environmental Research (GLIER) & Dept. of Integrative Biology at the University of Windsor. Her research focuses on the ecology and restoration of small streams and wetlands in human-impacted landscapes, and the role of small waterways in supporting good ecosystem health in the Laurentian Great Lakes. She launched her lab—the Healthy Headwaters Lab—in 2019 and also wears multiple hats as co-director of the GLIER Organic Analysis & Nutrients Laboratory (a central research facility), associate director of FishCAST (an NSERC CREATE graduate student training program in Canada), co-chair of the International Science Advisory Panel for New Zealand's Biological Heritage National Science Challenge, coordinating editor with the journal *Restoration Ecology* and alumni fellow and contributing author with the Intergovernmental science-policy Platform on Biodiversity and Ecosystem Services (IPBES). She previously held a postdoctoral role at the University of Maryland's Chesapeake Biological Laboratory (USA), the University of Canterbury (Aotearoa New Zealand). Her research has been published in the *Science*, *Nature Geoscience*, *Canadian Journal of Fisheries and Aquatic Sciences*, *Environmental Science & Technology*, and *Frontiers in Microbiology*, *Restoration Ecology*, *Proceedings of the Royal Society*, to name a few. She is co-founder of the Kindness in Science global initiative, and contributes actively to actions, scholarship and mentorship to advance justice, equity, diversity, and inclusion in academia.

Christian Griebler is full professor and head of the Limnology unit at the University of Vienna, Austria. He is a dedicated groundwater ecologist with core expertise in microbial ecology and biogeochemistry.

Kenneth Irvine has a broad range of multidisciplinary experience working on aquatic ecology, ecological assessment of surface waters, especially lakes and wetlands, and policy and related policies and management. After gaining a Ph. D. in 1987 at the University of East Anglia (U.K.) for a study on trophic ecology of shallow lakes, he worked for the U.K. Nature Conservancy Council, before moving to study ecosystem structure of Lake Malawi in Africa. He moved to Trinity College Dublin in 1994 Ireland. There, he continued work on the African Great Lakes, as well as building a research group working on ecological assessment in support of the EU Water Framework Directive. In 2011 he moved to IHE Delft Institute of Water Education, the Netherlands, as chair of Aquatic Ecosystems. Current work focusses on wetlands and capacity development in Sub-Sahara Africa. Recent work also includes a review of hydromorphology and links to policy. He currently sits on the Board of the Board of the *African Center for Aquatic Research and Education* (ACARE) and on the Scientific Advisory Board of the *Leibniz Institute of Freshwater Ecology and Inland Fisheries* (IGB), Berlin.

Wolfgang Junk was scientist of the Max-Planck-Institute for Limnology, Dep. Tropical Ecology, Plön during 1970–75.He was scientist of National Amazonian Research Institute, leader of the Dep. of Hydrobiology and Inland Fishery at Manaus, Brazil during 1976–79. and leader of the Working Group "Tropical Ecology" at the Max Planck Institute for Limnology in Ploen, Germany during 1980–2007.He is expertise in ecology and sustainable management of floodplains, land-water interactions, wetland classification. His main research areas arestudies on biomass, primary production, and decomposition of wetland plant communities; nutrient fluxes between land and water; adaptations of plant and animals to periodical drought and flooding; ecology of aquatic macrophytes and fish communities; biodiversity; conceptional considerations on river-floodplain systems, sustainable management of wetland resources and wetland protection with emphasis on the Amazon River floodplain and the Pantanal of Mato Grosso, Brazil. He supervised numerous M.Sc. and Ph.D. students and published more than 300 peer-reviewed publications, including several books and book chapters on Amazonian wetlands and the Pantanal of Mato Grosso. He received many honors, among them the Award of the Grande Cruz (the highest distinction of Brazil) for exceptional scientific performance, and the Cross of Merit First Class of the Federal Republic of Germany. He is corresponding member of the Academy of Sciences of Brazil.

Krantzberg is professor and lead for the engineering and public policy in the School of Engineering Practice and Technology at McMaster University offering Canada's first master's degree in engineering and public policy. Gail completed her M.Sc. and Ph.D. at the University of Toronto in environmental science and freshwaters. She worked for the Ontario Ministry of Environment from 1988 to 2001, as coordinator of Great Lakes Programs, and senior policy advisor on Great Lakes. Dr. Krantzberg was the director of the Great Lakes Regional Office of the International Joint Commission from 2001 to 2005. In 2007 she was appointed as an adjunct faculty member of the United Nations University Institute for Water and Environmental Health and participated in the twinning of the Laurentian and African Great Lakes (principally Lake Victoria). She has co-authored and edited 9 books and more than 200 scientific and policy articles on issues pertaining to ecosystem quality and sustainability and is a frequent speaker to media and the public. Her research interests include investigating Great Lakes governance capacity, analyzing interjurisdictional co-management arrangements internationally for application to the Great Lakes regime, and methods to better integrate science and engineering in policy formulation and decision-making.

Marie-Elodie Perga is associate professor of limnology at the University of Lausanne in Switzerland. Since receiving her Ph.D. from the University of Savoie-Mont Blanc (France), she has worked at the University of Victoria in Canada, and the French National Institute for Agronomy and Environment (France), before moving UNIL.

Because she is a Lindeman's groupie, her research lies at the interface of community ecology and biogeochemistry, through lake food webs and carbon processes. More recently, she added a pint of hydrodynamics with the intent to bridge physical and biogeochemical mechanisms, especially in alpine and high-altitude lakes. Her work covers centennial up to minute timescales through the combination of high-resolution paleo-records and high-frequency data from autonomous sensors.

She is also involved in promoting high-tech research on lakes, notably as a member of the steering committee of the LéXPLORE floating research platform in Lake Geneva, and in connecting science and management through a transdisciplinary network involving National Parks in France. She has published over 75 peer-reviewed papers and serves as associate editor for WIRES Water.

N. LeRoy Poff is professor of biology at Colorado State University and holds a partial appointment as distinguished professor at the University of Canberra, Australia. Since receiving his Ph.D. in 1989, his research has focused on understanding how natural and human-caused hydrologic variability regulates the interactions among species and the structure and function of riverine ecosystems. By developing techniques to quantify streamflow variability in ecologically meaningful terms and using species (functional) traits as generalized, mechanistic response variables, he has been a leader in advancing the field of hydroecology. Through his interdisciplinary and collaborative work, he has contributed fundamentally to the development of the field of "environmental flows," which aims to support sustainable management of streams and rivers at local to regional to global scales in the face of growing human water demands. His current interests are on developing better conceptual frameworks and decision support tools for science-based management of streams and rivers in our current period of rapid climate and ecological change.

Lars Rudstam is professor of fisheries and aquatic sciences in the Department of Natural Resources and the Environment, Cornell University (USA) and the director of the Cornell Biological Field Station. He has a master's degree from the Center for Limnology, University of Wisconsin-Madison and a Ph.D. from Stockholm University, Sweden. Rudstam has published over 250 papers ranging from lake physics to phytoplankton, zooplankton, mussels, mysids, fish, birds, and anglers, mostly about processes associated with food web interactions and ecosystem dynamics. He has worked in lakes in North America, Europe, and Asia as well as the Baltic Sea.

Stuart Warner works with the United Nations Environment Programme with a focus on helping countries to monitor and assess their freshwaters. He was born in England, he moved to Ireland in 2001 to work at University College Cork. Stuart has published in the areas of water quality monitoring and assessment and citizen science approaches to data collection. He has written reports on the capacity of countries to understand their freshwaters which highlight the challenges faced in different world regions. Recent efforts have focused on the development and implementation of a global water quality indicator, and the delivery of capacity development targeted at improving freshwater management. His professional interests include using both traditional and innovative approaches to understand and protect freshwater ecosystems.

Florian Wittmann is professor for physical geography and head of the Department of Wetland Ecology at the Karlsruhe Institute for Technology, Germany. He studied geography, geology, and botany at the Universities of Mannheim and Heidelberg, got his Ph.D. in physical geography at the University of Mannheim, and his lecturer qualification at the University of Bayreuth, Germany. He held post-doc positions at the Max Planck Institutes for Limnology and Chemistry, Germany, where he was working at the bilateral project between the Max Planck Society and the National Institute for Amazonian Research in Manaus, Brazil, for more than 15 years.

His research focuses on neotropical wetlands, with special interest in biogeography, plant species distribution, species diversity, forestry and sustainable management, remote sensing, biomass and primary productivity, and botany and vegetation ecology. Actually, he teaches at the Institute for Geography and Geoecology of the Karlsruhe Institute for Technology, Germany, and in the post-graduate program of Tropical Ecology—Botany at the National Institute for Amazon Research—INPA, Manaus, Brazil. He supervised numerous M.Sc. and Ph.D. students and published more than 150 peer-reviewed publications, including several books and book chapters on Amazonian wetlands.

Department of Thematic Studies—Environmental Change, Linköping University, Linköping, Sweden; Multiuser Unit of Environmental Analysis (UMAA/UFRJ), CCS, Ilha do Fundão, Cidade Universitária, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil

S Esterhuyse
Centre for Environmental Management, University of the Free state, Bloemfontein, South Africa

Thomas Evans
Leibniz Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany; Freie Universität Berlin, Berlin, Germany; Berlin-Brandenburg Institute of Advanced Biodiversity Research, Berlin, Germany

Michelle A Evans-White
Department of Biological Sciences, University of Arkansas, Fayetteville, AR, United States

Sherman Farhad
Department of Agricultural Economics, Universidad de Córdoba, Cordoba, Spain; Social and Participatory Action Research Group (GISAP), Universidad Pablo de Olavide, Seville, Spain

Andreas H Farnleitner
Karl Landsteiner University of Health Sciences, Department of Pharmacology, Physiology and Microbiology, Division Water Quality and Health, Krems, Austria; TU Wien, Institute of Chemical, Environmental and Bioscience Engineering, Vienna, Austria; ICC Water & Health, www.waterandhealth, Austria

P Fearnside
Instituto Nacional de Pesquisas da Amazônia (INPA), Manaus, Brazil

Catherine M Febria
Great Lakes Institute for Environmental Research and Department of Integrative Biology, University of Windsor, Windsor, ON, Canada

Sarah C Fell
School of Geography/water@leeds, University of Leeds, Leeds, United Kingdom

Owen Fenton
Teagasc, Environment Research Centre, Co. Wexford, Ireland

C Emi Fergus
Oak Ridge Institute of Science and Education, US Environmental Protection Agency, Corvallis, OR, United States

Camila R Ferrara
Wildlife Conservation Society—WCS, Manaus, Brazil

Bieito Fernández Castro
Ocean and Earth Science, University of Southampton, Southampton, United Kingdom

Lucas Fillinger
Department of Functional & Evolutionary Ecology, Division of Limnology, University of Vienna, Vienna, Austria

Kerri Finlay
Department of Biology, University of Regina, Regina, SK, Canada

CM Finlayson
School of Biological, Earth and Environmental Sciences, Faculty of Science, University of New South Wales, Sydney, NSW, Australia; IHE Delft, Institute for Water Education, Delft, Netherlands

Kathryn J Fiorella
Cornell University, Ithaca, NY, United States

Robert Fischer
WasserCluster Lunz, Lunz am See, Austria

Stewart Floyd
Agri-Food and Biosciences Institute, Belfast, United Kingdom

Megan Fork
Cary Institute of Ecosystem Studies, Millbrook, NY, United States; West Chester University, Department of Biology, West Chester, PA, USA

Jennifer A Fox
Department of Biology, Georgetown University, Washington, DC, United States

MJ Franca
Karlsruhe Institute of Technology, Karlsruhe, Germany

Fanny Frick-Trzebitzky
ISOE—Institute for Social-Ecological Research, Research Unit 'Water Resources and Land Use', Frankfurt am Main, Germany

Dafang Fu
Southeast University, Nanjing, China

Ian Fuller
Innovative River Solutions, School of Agriculture & Environment, Massey University, Palmerston North, New Zealand

Alenka Gaberščik
Department of Biology, University of Ljubljana, Ljubljana, Slovenia

U Gaedke
University of Potsdam, Potsdam, Germany

Shang Gao
School of Civil Engineering and Environmental Science, University of Oklahoma, Norman, OK, United States

Emili García-Berthou
GRECO, Institute of Aquatic Ecology, University of Girona, Girona, Spain;

Robert W Gastaldo
Department of Geology, Colby College, Waterville, ME, United States

Amrita Gautam
Technische Hochschule Köln, Köln, Germany; Institute of Engineering, Tribhuvan University, Kathmandu, Nepal

Peter Gege
German Aerospace Center (DLR), Remote Sensing Technology Institute, Wessling, Germany

Toby Gifford
AiMi, Melbourne, VIC, Australia

David Gilvear
School of Geography, Earth and Environmental Sciences, University of Plymouth, Plymouth, United Kingdom

Michail I Gladyshev
Institute of Biophysics of Federal Research Centre, Krasnoyarsk Science Centre of Siberian Branch of Russian Academy of Sciences, Krasnoyarsk, Russia; Siberian Federal University, Krasnoyarsk, Russia

Stephan Glatzel
Department of Geography and Regional Research, University of Vienna, Vienna, Austria

T Golemgeski
Lawrence University, Appleton, WI, United States

Dietrich Gotzek
National Museum of Natural History, Smithsonian Institution, Washington, DC, United States

Lynn Govaert
Department of Evolutionary Biology and Environmental Studies, University of Zurich, Zurich, Switzerland; Department of Aquatic Ecology, Eawag: Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland; URPP Global Change and Biodiversity, University of Zurich, Zurich, Switzerland

Emma Gray
Galway-Mayo Institute of Technology, Galway, Ireland

Stephen F Greb
Kentucky Geological Survey, University of Kentucky, Lexington, KY, United States

Franz Greimel
University of Natural Resources and Life Sciences, Department of Water, Atmosphere and Environment, Institute of Hydrobiology and Aquatic Ecosystem Management, Vienna, Austria

Christian Griebler
Department of Functional & Evolutionary Ecology, Division of Limnology, University of Vienna, Vienna, Austria

Hans-Peter Grossart
Dept. Experimental Limnology, Leibniz-Institute of Freshwater Ecology and Inland Fisheries (IGB), Stechlin, Germany; Potsdam University, Institute for Biochemistry and Biology, Potsdam, Germany

Erin MK Haacker
Department of Earth and Atmospheric Sciences, University of Nebraska-Lincoln, Lincoln, NE, United States

H Habersack
University of Natural Resources and Life Sciences, Institute of Water Management, Hydrology and Hydraulic Engineering, Christian Doppler Laboratory for Advanced Methods in River Monitoring, Modelling and Engineering, Vienna, Austria

Hans Jürgen Hahn
University Koblenz-Landau, Institute for Environmental Sciences, Landau, Germany; Institute for Groundwater Ecology IGÖ GmbH, University of Koblenz-Landau, Landau, Germany

Nelson G Hairston Jr.
Department of Ecology and Evolutionary Biology, Cornell University, Ithaca, NY, United States

Mehrdad Hajibabaei
Department of Integrative Biology & Centre for Biodiversity Genomics, University of Guelph, Guelph, ON, Canada

Spencer R Hall
Department of Biology, Indiana University-Bloomington, Bloomington, IN, United States

Halvor M Halvorson
Department of Biology, University of Central Arkansas, Conway, AR, United States

Stephen K Hamilton
W.K. Kellogg Biological Station, Michigan State University, Hickory Corners, MI, United States; Cary Institute of Ecosystem Studies, Millbrook, NY, United States

David M Hannah
School of Geography, Earth and Environmental Sciences, University of Birmingham, Birmingham, United Kingdom

Matthew P Hare
Department of Natural Resources and the Environment, Cornell University, Ithaca, NY, United States

Jerneja Harmel
ZaVita Consulting, Ljubljana, Slovenia

Andreas Hartmann
Institute of Groundwater Management, Technical University of Dresden, Dresden, Germany

Elhagag Ahmed Hassan
Department of Botany and Microbiology, Faculty of Science, Assiut University, Assiut, Egypt

István Gábor Hatvani
Institute for Geological and Geochemical Research, Research Centre for Astronomy and Earth Sciences, Eötvös Loránd Research Network (ELKH), Budapest, Hungary

Charles P Hawkins
Department of Watershed Sciences, National Aquatic Monitoring Center, and Ecology Center, Utah State University, Logan, UT, United States

Daniel S Hayes
University of Natural Resources and Life Sciences, Department of Water, Atmosphere and Environment, Institute of Hydrobiology and Aquatic Ecosystem Management, Vienna, Austria

Luke Hecht
Wild Animal Initiative, Washington, DC, United States; Durham University, Durham, United Kingdom;

Stephen M Henderson
School of the Environment, Washington State University, Vancouver, WA, United States

Nicole Herman-Mercer
U.S. Geological Survey, Reston, VA, United States

Virgilio Hermoso
Centre de Ciència i Tecnologia Forestal de Catalunya, Lleida, Spain

Martina Herrmann
Friedrich Schiller University Jena, Institute of Biodiversity, Aquatic Geomicrobiology, Jena, Germany; German Center for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, Leipzig, Germany

Sabine Hilt
Leibniz Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany

Timothy Hoellein
Loyola University Chicago, Chicago, IL, United States

Severin Hohensinner
University of Natural Resources and Life Sciences Vienna, Institute of Hydrobiology and Aquatic Ecosystem Management, Vienna, Austria

Yang Hong
School of Civil Engineering and Environmental Science, University of Oklahoma, Norman, OK, United States

Garrett W Hopper
Department of Biological Sciences, University of Alabama, Tuscaloosa, AL, United States

Martin Horstmann
Ruhr-Universität Bochum, Bochum, Germany

Grant C Hose
Department of Biological Sciences, Macquarie University, Sydney, NSW, Australia

J Ethan Householder
Wetland Ecology, Institute for Geography and Geoecology, Karlsruhe Institute for Technology, Karlsruhe, Germany; Botanical Research Institute of Texas, Fort Worth, TX, United States

Robert W Howarth
Cornell University, Ithaca, NY, United States

William F Humphreys
School of Biological Sciences, University of Western Australia, Crawley, WA, Australia; Collections and Research Centre, Western Australian Museum, Welshpool, WA, Australia

Peter Hunter
Biological and Environmental Sciences, University of Stirling, Stirling, United Kingdom

Andreas Hussner
Leibniz Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany

Bastiaan Ibelings
Department F.-A. Forel for Environmental and Aquatic Sciences and Institute for Environmental Sciences, University of Geneva, Geneva, Switzerland

Corina Iţcu
National Institute of Research and Development for Biological Sciences, Bucharest, Romania; Romanian Young Academy, University of Bucharest, 90 Panduri Street, Sector 5, Bucharest, Romania

Kenneth Irvine
IHE Delft, Institute of Water Education, Delft, The Netherlands; Aquatic Ecology and Water Quality Management, University of Wageningen, Wageningen, The Netherlands

Anne Jäger
University Koblenz-Landau, Institute for Environmental Sciences, Landau, Germany

Sonja C Jähnig
Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin, Germany; Geography Department, Humboldt-Universität zu Berlin, Berlin, Germany

R Jan Stevenson
Department of Integrative Biology, Michigan State University, East Lansing, MI, United States

Alexandra RJ Jansen
School of Biological, Earth and Environmental Sciences, University College Cork, Cork City, Ireland; Environmental Research Institute, University College Cork, Cork City, Ireland

Marcel AK Jansen
School of Biological, Earth and Environmental Sciences, University College Cork, Cork City, Ireland; Environmental Research Institute, University College Cork, Cork City, Ireland

Tim Jardine
School of Environment and Sustainability, University of Saskatchewan, Saskatoon, SK, Canada

Amanda L Jeanson
Fish Ecology and Conservation Physiology Laboratory, Carleton University, Ottawa, ON, Canada

Eleanor Jennings
Centre for Freshwater and Environmental Studies, Dundalk Institute of Technology, Dundalk, Ireland

Jonathan M Jeschke
Leibniz Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany; Freie Universität Berlin, Berlin, Germany; Berlin-Brandenburg Institute of Advanced Biodiversity Research, Berlin, Germany

Carolyn Johns
Department of Politics and Public Administration, Ryerson University, Toronto, ON, Canada

Sönke Johnsen
Department of Biology, Duke University, Durham, NC, United States

Ian D Jones
Biological and Environmental Sciences, University of Stirling, Stirling, United Kingdom

Stuart E Jones
Department of Biological Sciences, University of Notre Dame, Notre Dame, IN, United States

C Juez
Department of Geoenvironmental Processes, Instituto Pirenaico de Ecología, Consejo Superior de Investigaciones Científicas (IPE-CSIC), Zaragoza, Spain

Hermann F Jungkunst
iES Landau, Institute for Environmental Sciences, University of Koblenz-Landau, Landau, Germany

Wolfgang J Junk
Former Working Group Tropical Ecology of the Max-Planck-Institute for Limnology, Plön, Germany; National Institute of Science and Technology in Wetlands (INCT-INAU), Federal University of Mato Grosso, Cuiabá, Brazil

Igor L Kaefer
Departamento de Biologia, Instituto de Ciências Biológicas, Universidade Federal do Amazonas, Manaus, Brazil

Maiko Kagami
Faculty of Environment and Information Sciences, Yokohama National University, Yokohama, Kanagawa, Japan

Gerhard Kammerer
University of Natural Resources and Life Sciences, Vienna, Department of Water, Atmosphere and Environment, Institute for Soil Physics and Rural Water Management, Vienna, Austria

Külli Kangur
Centre for Limnology, Institute of Agricultural and Environmental Sciences, Estonian University of Life Sciences, Tartu, Estonia

Clemens Karwautz
Department of Functional & Evolutionary Ecology, Division of Limnology, University of Vienna, Vienna, Austria

Herbert Kasozi
Department of Fisheries and Wildlife, Michigan State University, East Lansing, Michigan, United States

Leon Katona
Department of Biological Sciences, Wright State University, Dayton, OH, United States

B Kaunda-Arara
Department of Fisheries and Aquatic Science, University of Eldoret, Eldoret, Kenya

Ravinder Kaur
Water Technology Center (WTC), Indian Agricultural Research Institute, New Delhi, India

Reuben P Keller
School of Environmental Sustainability, Loyola University Chicago, Chicago, IL, United States

Fiona L Kelly
Inland Fisheries Ireland, Dublin, Ireland

John J Kelly
Loyola University Chicago, Chicago, IL, United States

Martyn Kelly
Department of Water Resources and Ecosystems, IHE Delft Institute for Water Education, Delft, The Netherlands; Bowburn Consultancy, Bowburn, United Kingdom

Seán Kelly
Inland Fisheries Ireland, Dublin, Ireland

Joanna Lynn Kemp
Norwegian Institute for Water Research (NIVA), Oslo, Norway

Kieran Khamis
School of Geography, Earth and Environmental Sciences, University of Birmingham, Birmingham, United Kingdom

Alison J King
Centre for Freshwater Ecosystems, La Trobe University, Wodonga, VIC, Australia

R Kipfer
Swiss Federal Institute of Environmental Science and Technology (Eawag), Swiss Federal Institute of Technology (ETH), Ueberlandstr, Duebendorf, Switzerland

Georgiy Kirillin
Leibniz-Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin, Germany

INTRODUCTION TO ENCYCLOPEDIA OF INLAND WATERS, 2ND EDITION

The surface of the earth is dominated by water. Water is fundamentally critical for the life forms we know. Not surprisingly, humans have always settled near the shores of oceans, rivers, and lakes. However, the amount of potentially drinkable, non-salty water on earth is much more limited, and hence inland waters are of particular focus to humans. Whereas lakes and rivers constitute the largely visible part of inland waters, wetlands and groundwater are less visible, and hence are often neglected in consideration of inland water systems. However, all inland water types constitute the centrally important resource for future life, and hence understanding the structure, functions, and interdependencies of inland waters is paramount for a sustainable development of the human population.

The science of inland waters is limnology, also called the queen of sciences because of its multidisciplinary nature, including aspects of biology, ecology, physics, chemistry, hydrology, and geology. Given the strong interactions between humans and inland waters, this set of disciplines has to be expanded toward medical sciences, toward technological disciplines such as engineering and construction, and toward social sciences, like sociology, psychology, and history. Ultimately, covering the full bandwidth of scientific disciplines related to inland waters requires a comprehensive approach.

It can be discussed whether a comprehensive topical coverage of the science of inland waters in the form of a printed Encyclopedia is still an approach worthwhile to be completed. In contrast to a classical lexicon, which addresses the meaning of key terms and definitions, an Encyclopedia bundles articles related to structures, processes, and concepts. If ideally structured, the reader of an Encyclopedia article will understand both details and the complexity of topics, and this knowledge may support informing others, whether in school and university teaching, or may be applicable to public discussion and information.

We are convinced that an edited volume such as this *Encyclopedia of Inland Waters* can still serve as a reference output for a discipline. The strong interactions between authors, section editors, and us, the editors-in-chief, were the foundation for generating a volume that reliably reflects scientific quality and correctness, in contrast to several web-based text compilations that are exposed to less rigorous quality controls. Nevertheless, the chosen structure of the Encyclopedia keeps the contributions by researchers or researcher groups, and hence perpetuates the flavor of individual perspectives on topics. By this approach, the *Encyclopedia of Inland Waters* does not rival, but complements several textbooks on limnology and aquatic ecology.

When discussing a second edition of the successful *Encyclopedia of Inland Waters* whose first edition was printed in 2009, the process has got its own dynamics. While the initial idea was primarily related to updating the chapters from the first edition, and adding a few fresh chapters on emerging topics, the intense consideration of what we think is relevant to understand inland waters has enforced a full re-structuring of the volume. The inclusion of sections on lakes and rivers was obvious, but the addition of sections on wetlands and groundwater became necessary to address the full set of forms in which inland waters are present on earth. When considering the strong interactions between humans and inland waters, a section on pressures on, and management of, freshwater systems became evidently necessary, and the addition of a section on social values of inland waters reflects the tight linkages between water and human beings. We complemented these six sections by a general section, in which structures and processes are outlined that are not specific to only one type of inland waters. And ultimately, we added a section on emerging topics; themes in research and methodology that are not yet fully fledged and hence often not properly covered in textbooks, but for which we think that they will become standard in future limnological research.

Inevitably, the outcome of such an endeavor is not perfect. Despite having enthusiastic section editors, finding and selecting authors or author groups for the more than 250 originally planned topics was more complicated than initially anticipated. Despite all efforts, we could not secure contributions to all topics, and hence we have to accept that there are thematic gaps also in the second edition of the Encyclopedia. Furthermore, we tried to apply a consistent chapter structure at least for all chapters that were freshly produced for the second edition. Yet, this structure could not be harmonized for the chapters we reproduced from the first edition. Finally, drafting, revising, editing, and producing a volume of this dimension under the conditions of the Covid-19 pandemic was an extra challenge. We appreciate the motivation, diligence, and patience of all contributors in these complicated times. The volume finally available is a wonderful piece of work that can emerge if professional expertise, creativity, and enthusiasm are combined via a shared vision.

Ultimately, we wish to thank Gene Likens for his original idea to create the *Encyclopedia of Inland Waters*. We followed his intentions and hope that the second edition of this book is a dignified continuation of his first collection of articles. In summer 2022, the International Society of Limnology (SIL) celebrates its centennial year of foundation. In 1922, August Thienemann and Einar Naumann founded an international society devoted to the study of inland waters, named Societas Internationalis Limnologiae Theoreticae et Applicatae. Now, 100 years later, we, the editors-in-chief of the second edition of the *Encyclopedia of Inland Waters*, offer this volume as a contribution to theoretical research and practical management of inland waters, in the sense of Thienemann and Naumann. We hope that it will be well received.

FUNDAMENTAL CONCEPTS AND THEORIES

Section introduction: Fundamental Concepts and Theories of Inland Waters

Lars G Rudstam, Department of Natural Resources and the Environment, Cornell University, Ithaca, NY, United States

Introduction

Earth is a water planet, life originated in water, and all life on this planet (and everywhere else in the universe as far as we know) depend on water. Clearly, the study of inland waters—limnology—is critically important to humanity. Even though water is the most abundant liquid on Earth, most of the water is in oceans. Freshwater is a valuable resource that needs careful management both when it is in short supply and when there is too much of it causing floods. Inland waters contribute to our food supply, to our enjoyment through boating, swimming, wildlife watching, hunting and fishing, and to the beauty of the landscape. To me, limnology is also intellectually stimulating because its multidisciplinary nature. To understand how inland waters function, limnologists use concepts and theories from physics, chemistry, biology, ecology, geology, and their subdisciplines. In his introductory chapter, Gene Likens calls limnology the Queen of Sciences, as limnology includes aspects of so many natural science fields. It was therefore difficult to decide which fundamental concepts and theories to include in this section of the Encyclopedia of Inland Waters. Working with Thomas Mehner, I consulted the first edition of this encyclopedia (Likens, 2009), canvassed colleagues, and read limnology textbooks. The resulting 36 chapters by world-renowned experts range from an introduction to limnology by Gene Likens and how the science of limnology is organized by Jonathan Cole and Michael Pace, to the physical, chemical and biological concepts and theories that I consider fundamental to the field. Some chapters are updates of the chapters in the 1st edition, other chapters are completely new. Together these 36 chapters present the fundamental concepts and theories a reader interested in limnology and inland waters should know about. Note though, that fundamental concepts and theories are also discussed in other encyclopedia sections. I have organized the chapters below in subheadings of water budgets and flows, physical properties, chemical properties, ecological concepts, population interactions, and ecosystem processes. But sorting chapters with often multidisciplinary content are somewhat arbitrary. In particular, many chapters include effects on the whole system, an indication of the whole system thinking that permeates the science of limnology.

Water budgets and flows

Water is constantly evaporating from the surface of the oceans into the atmosphere, transported with winds, deposited on land as rain and snow and then flow back to the ocean. Without this hydrologic cycle, there would be no inland waters. Dale Robertson and Howard Perlman describe this cycle and the water budget, concepts requiring information on evaporation, precipitation, and water movement. Water travel back to the oceans in streams and rivers, and the nature of flowing water affect all organisms living in it. Turbulent and laminar flows as well as the theory of turbulent flows are described in the chapter by Alexander Sukhodolov, Oleksandra Shumilova and Bruce Roads. Water also accumulates in land depressions forming lakes and ponds, and how long time water remain in such waterbodies—the residence time—depends on the hydrology of the watershed and morphometry of the lake basin. Isabella Olesky and colleagues describe the relationship between hydrology and residence time, and how these attributes of lakes affect ecosystem processes, such as lake metabolism and biogeochemistry. Hydrology and residence time are clearly fundamental concepts for our understanding of inland waters.

Physical properties of water

Water is a different medium than air. It is 800 times more dense, 50 times more viscous, can dissolve chemicals, and has lower oxygen content, higher heat conductivity, higher light absorbance, and higher sound speed. Even though life originated in water, humans are terrestrial animals and do not have an intuitive understanding of living in water. Limnologists still need to understand the basic properties of this medium. Kenton Stewart and Joseph Atkinson describe the physical properties of water, including density, heat capacity, phase shifts (ice-water-vapor), sublimation, surface tension, viscosity, and colligative properties. Pressure received its own chapter by Atkinson, as it is central to currents, seiches, buoyancy, and solubility of gasses. Because of the differences between water and air, more energy is required to move through water than through air, especially when moving fast. On the other hand less energy needs to be invested in structural parts like skeletons and wood due to the buoyancy of water. Another difference is that it is harder to insulate body temperature from the surrounding water temperature due to the higher heat conductivity of water. The bioenergetics of aquatic organisms therefore includes functions for temperature and swimming speed in addition to the allometry of size, as described in the chapter on bioenergetics by Steve Chipps, David Deslauriers and Charles Madenjian. Temperature affects most ecological processes making inland water sensitive to climate change. Bart DeStasio and colleagues describes how temperature is a driving force in aquatic ecosystems affecting seasonality, growth rates, distribution and ecological interactions. The physical properties of water also affect light absorbance, light color at depth, and light scattering. Three chapters describe light in inland waters. Patrick Neale, Craig Williamson and Donald Morris describe these optical properties of water, with UV light receiving a more in-depth treatment by Williamson and Neale because of its potential harmful effects on organisms. How organisms are adapted to different light regimes and how they perceive light is described in the chapter on light as an ecological resource by Dina Leech and Sönke Johnsen.

Chemical properties of water

The chemical reactions occurring in water are fundamental to limnology. The chemical properties of water include concepts such as the structure of the water molecule itself, water's ability to dissolve various substances from ions and gasses to complex organic molecules, and the inclusion of H_2O in chemical reactions. Joseph Aldstadt III, Harvey Bootsma and Jessica Ammerman discussed these and other chemical properties of water in their chapter. Photochemical reactions break down organic matter as well as pollutants and are a major component of the carbon cycling and ability of inland waters to "self-depollution" as described by Anssi Vähätalo, Luca Carena and Davide Vione. Many other chemical reactions are mediated by organisms, including photosynthesis, chemosynthesis, methanogenesis, and nitrogen fixation. The chemistry of inland waters is the result of an integrated system of biological and chemical processes that build up and break down organic molecules and recycle nutrients. In his chapter on nitrogen—one of the most important nutrients in inland waters, Robert Howarth discusses the nitrogen cycle and the effect of excess nitrogen from human activities. The chapter by Roxanne Marino and Howarth goes into more detail on one part of the nitrogen cycle, nitrogen fixation, particularly by cyanobacteria. Chapters on the other important nutrients, like phosphorus, are in the sections specific to lakes and rivers. Chemosynthesis refer to the synthesis of complex organic compounds—the building blocks of life—from simple one-carbon molecules using energy from oxidation of a number of inorganic compounds. Alex Enrich-Prast and colleagues describe this process and the highly diverse group of bacteria and archaea involved. Methane received its own chapter by David Bastviken given its importance as a greenhouse gas and the complex processes leading to methane production. Carbon cycles, including the breakdown of organic compound and carbon dioxide production, are discussed in other sections of the encyclopedia. Photosynthesis uses energy from light to synthesize complex organic molecules. Organisms that have the ability to do photosynthesis include cyanobacteria and various phytoplankton and higher plants. The distribution of photosynthesis in inland waters is described by Martin Dokulil and Katrin Teubner. The details of the photosynthesis process are described by Dokulil as part of the lake section of this encyclopedia.

Ecological concepts and theories

Fundamental concepts describing how we organize the biology of inland waters include the individual, species, population, meta-population, food webs, and ecosystems. The chapter on biodiversity by Alan Covich stresses the importance of species in inland waters and describes the various groups present, their species richness, and some fascinating natural history. Populations are defined as collections of individuals of the same species that either interact evolutionarily through gene flow or can be considered to be affected by the same demographic processes like birth, death and harvest rates. The distinction between a genetic based and a demographic based definition of a population is described in the chapter by Matthew Hare and myself. When the dynamics of a population requires consideration of migrations from surrounding populations, we have meta-population dynamics. A meta-population is a collection of interacting populations, and the theory of meta-populations is described in the chapter by Kasey Pregler, Emily Chen and Stephanie Carlson. Populations exist within food webs, and the food web and its trophic structure are explained by Ursula Gaedke using Lake Constance as an example. Finally, the ecosystem concept is defined by William Lewis from a lake perspective as including both biotic and abiotic components and their interactions.

Interactions between populations

The processes that govern interactions between populations include competition, predation, commensalism and mutualism as well as the indirect interactions that emerge, such as apparent competition and buffering by alternate prey. For this encyclopedia, I selected concepts and theories with special relevance to inland waters. Each organism is using a subset of the environment, its niche. The niche is defined by William Lewis based on the multidimensional niche concept (Hutchinson, 1957), stressing the differences between the fundamental niche and the realized niche and the importance of niche overlap for competition between species. Predation is a major source of mortality and driving force in many aquatic ecosystems, and is the topic of the chapter by Jonathan Jeschke and colleagues. That chapter highlights the predation cycle and describes how predation is affected by prey defenses, swarming, prey offenses, and functional responses. When an animal feeds on another without killing it, such as parasites and disease organisms, the effects and dynamics are different. Spencer Hall shows how parasites and diseases affect populations and how these effects can (and should) be incorporated in food web models. Both predators and parasites have to meet their prey/host to interact making the distribution of animals in both space and time a critical part of these interactions. In many inland waters, vertical migrations are ubiquitous as animals react to changing light and food resources to optimize their growth and survival rates. This concept and the theories explaining diel vertical migration are described in the chapter by Luc De Meester, Thomas Mehner and Anne Scofield. More general predictions of the distribution of organisms requires understanding the decision rules that drive organisms to use certain habitat at certain times. Several approaches have been used to predict distributions, and these theories are explained in the chapter on spatial models by Milan Říha and Marie Prchalová. Interactions between organisms drive evolutionary changes, including arms races between predators and prey. It is now clear that such evolutionary changes can occur rapidly and affect ecological interactions, which in turn can drive further evolutionary changes. Such eco-evo dynamics is fundamental to the interactions between species and the topic of the chapter by Lynn Govaert and colleagues. Populations are also buffered by the presence of resting stages, both evolutionary and demographically. The "egg bank" allows genotypes to survive periods of adverse conditions. If conditions become more favorable in the future, delayed hatching of dormant eggs can "resurrect" past genotypes adapted to those conditions. The description and implications of dormancy are explained in the chapter by Nelson Hairston Jr. and Jennifer Fox.

Ecosystem processes

The last section on fundamental concepts and theories involves processes operating on the ecosystem scale, and how to study and understand them. Perhaps because the system boundaries of waterbodies consist of an air-water interface and is therefore easy to define, a whole systems approach was introduced early to the study of lakes by S.A. Forbes in 1887 in "A lake as a microcosm" and in the monographs on Lake Geneva introducing limnology as a science by Francois Alphonse Forel (the first volume published in 1892). Lakes were also the inspiration for Raymond Lindeman's (1942) classic study introducing trophic dynamics and quantitative ecosystem science. The field of ecosystem ecology in inland waters has advanced substantially since then and continues to generate new ecological concepts such as alternate stable states, regime shifts, resilience and tipping points (Scheffer and Carpenter, 2003). Tipping points and regime shifts describe how a system may relatively suddenly shift into a different state, perhaps an alternative stable state that is resilient to further change (a new regime). Small changes past a tipping point will cause large ecosystem changes due to non-linear dynamics and feedback loops. These are important concepts in inland waters as well as in science in general and are described in the chapter by Sarian Kosten, Annelies Veraart and Vasilis Dakos. Another way ecosystems can change dramatically implying a regime shift is by the arrival of new invasive species, a change that is typically irreversible. Biological invasions are reviewed by Reuben Keller and David Lodge. Further, ecosystems are affected by ecosystem engineers, a concept explained by Christine Mayer. Ecosystem engineers alter their physical habitat by their activities and by their physical presence, such as dam building beavers or reef building molluscs. Nutrient cycling is integral to ecosystem dynamics, and is affected not only by the chemistry of the water and the organisms present, but also by the ratio of nutrients within organisms—their ecological stoichiometry. This concept and its implications for organism growth and food web interactions are described in the chapter by Robert Sterner. The biomass size spectrum is a concept based on large organisms consuming smaller organisms and the allometric relationships inherent in body size. Biomass size spectra theory originated in biological oceanography and may be a particularly useful concept for aquatic systems. This theory is explained in the chapter by Gary Sprules. Note also that several chapters introduced earlier consider ecosystem processes, including the chapter by Olesky and colleagues on ecosystem consequences of residence time, by DeStasio and colleagues on the ecosystem effects of temperature, by Gaedke on food webs and by Lewis on ecosystems.

Many of these concepts and theories benefit from studies on long time scales and large spatial scales. Long term data are needed for assessing slowly changing systems, effects of long-lived organisms, and changes associated with human use, biological invasions and climate change. Long-term ecological data series of half a century or more do exist in some inland waters of the world (e.g., Magnuson et al., 2006; Jeppesen et al., 2012; Rudstam et al., 2016), but such data series are rare. There is an increasing number of large-scale, world-wide analyzes of limnological concepts and theories, partly shepherded through organizations like the Global Lakes Ecological Network (Hanson et al., 2016), the ability to collaborate world-wide through the internet, and the science of Big Data (e.g., Soranno et al., 2017). These large-scale syntheses are powerful, especially when available long-term data series can be combined and compared over large spatial scales (e.g., O'Reilly et al., 2015; Solomon et al., 2013). Paleolimnology can

provide longer data series. In the final chapter of this section, John Smol describes how paleolimnology has provided insights into the structure and function of pre-industrial ecosystem that helps us better understand the current state of our ecosystems and inland waters.

Acknowledgments

I like to thank the Editors-in-Chief, Thomas Mehner and Klement Tockner, for taking on this massive and important task and recruiting me to work on the fundamental concepts and theories section. I learned a lot and hope the readers will as well. A big thank you to all the contributing authors who stayed with the project during the time of a pandemic, and to our managing editor Paula Davies. The importance of understanding inland waters is increasing in this era of environmental change, and together we have contributed to an encyclopedia that will be useful to students and scientists of inland waters around the world.

Glossary

Ecosystem An ecosystem is a spatially explicit unit of Earth that includes all of the organisms, along with all components of the abiotic environment, interacting together as a system, within its boundaries.
Inland waters Waters on or in the terrestrial portion of the Earth.
Limnology The scientific study of inland waters.
Saline Salty; approximating or exceeding the salt content of sea water.

Inland waters

All life on Earth is dependent in some way on water for providing a vital habitat, the milieu for biochemical reactions, electrochemical transformations, reproduction, food production, transportation, climate regulation, and for many other ecosystem services to biota. Some 75% of the Earth's surface is covered by water and ice, but most of this area (71%) contains water that is salty and is found primarily in oceans and seas. Inland waters are distributed among polar ice and glaciers, actively exchanged groundwater, freshwater lakes, and human-made impoundments (farm ponds and reservoirs), saline lakes, soil water, marshes/wetlands, and rivers and streams, in order of decreasing volume (Table 1). Although the areal extent and volume of freshwater lakes and rivers are relatively small, their interest and value to humans is huge as a source of drinking water, for transportation, food, recreation, and esthetics (Figs. 1–6). Recently, their importance as a significant source of carbon dioxide and methane flux to the atmosphere, as well as carbon storage in sediments, has become apparent from scientific study because of increased interest in the flux and balance of carbon for the Earth as related to the climate crisis.

Estimates of the worldwide dimensions of inland waters are changing as a result of the use of new technology, such as satellite observation of the Earth and increased computer power to deal with large and more complicated data sets. Scientists have estimated that freshwater lakes and impoundments (engineered dams and farm ponds) occupy a much larger proportion of the Earth's surface than previously thought (Table 2), overall comprising ~3% of the terrestrial surface of the Earth. Most inland waters in lakes, reservoirs, and rivers are shallow (less than a few tens of meters in depth), but a few are very deep. Lakes Baikal in Russia (Fig. 5) and Tanganyika in Africa are more than 1000 m deep. Lake Baikal with a maximum depth of 1620 m contains about 23,000 km^3 or 18% of the Earth's surface freshwater in its basin and is one of the oldest fresh water basins (formed >20 Mya). The five Laurentian Great Lakes (Superior, Michigan, Huron, Erie, and Ontario) in North America contain another 20% or so of the Earth's surface fresh water in their basins. A very large (possibly the largest) lake, Lake Vostok, exists below the ice in Antarctica, but relatively little is known about this lake. Antarctica contains some 70% of the Earth's freshwater, but most of it is locked up as ice. Because of glacial, tectonic, and volcanic activity, many areas have numerous basins now filled with water, thus forming "lake districts." Examples include the Patagonian region of South America, northern England, the upper midwestern and St. Lawrence regions of North America, and the Rift Valley of Africa. Many inland waters, such as the Dead Sea in Israel, are highly saline. The Black Sea and Caspian Sea in Eastern Europe, Great Salt Lake in United States, and Lake Corangamite in Australia are saline and very large. Some inland bodies of water, such as the Black Sea, Aral Sea and Caspian Sea, represent areas recently isolated geologically from the ocean. In many respects, including their name, they are much more like oceans than lakes. Recent human activities, for example water withdrawal, have greatly reduced the volume and areal extent of the Dead Sea, and particularly the Aral Sea.

☆*Change History:* November 2021. GE Likens made all of the updates. Photos and tables have been updated.

Table 1 Estimated volume of water on the Earth (thousands of km^3).[a,b]

	Volume (1000 of km^3)	*Percent of total water*	*Percent of total fresh water*
Oceans	1335040[a]	96.95	–
Glaciers, permanent groundwater	26350[a]	1.91	62.9
Groundwater	15300[a]	1.11	36.6
Ground ice, permafrost	22[a]	<0.01	0.1
Lakes and river impoundments	178[a]	0.01	0.4
Marshes, wetlands	11.5[b]	<0.01	<0.1
Saline lakes	85[b]	0.01	–
Incorporated in biota	1.12[b]	<0.01	<0.1
Total water on Earth	1377000[a]	100	–
Total fresh water on Earth	41,860	3.04	100

Percentages don't sum to 100 because of rounding.

Unfortunately, there are no good estimates for the total area of small rivers and streams, yet the huge interface between these inland waters and their adjacent terrestrial drainage areas is one of the exciting and important subject areas in limnology. This interface is often occupied by lacustrine and riverine wetlands consisting of herbaceous-dominated marshes and forest- or shrub-dominated swamps. These wetlands often occupy much larger surface areas than do lakes and rivers. In addition to these transitional wetlands, wetlands also occur in depressions, seepages on hill slopes, and on poorly drained flat lands not adjacent to lakes and streams.

Fig. 4 Chandalar Lake, Alaska. Photo by G.E. Likens.

Fig. 5 Lake Baikal, Russia. Photo by L.G. Rudstam.

The so-called lentic or standing, inland waters include lakes, ponds, pools, reservoirs, inland saline systems, and wetlands (swamps, marshes, bogs, fens). Lakes, ponds, and reservoirs are transient features of the landscape because as their basins fill with water, they immediately start to disappear as the basin fills with sediment. Of the 83,115 lakes with names in the conterminous US,

Table 2 Areas of water on the Earth (thousands of km^2).[a]

	Area (thousands of km^2)	*Percent of total*
World (total)	510,230	100
Land area	148,925	29
Oceans	361,305	71
Polar ice caps and glaciers	17,871	3.5
Fresh and saline lakes	4200	0.82
Inland seas	699	0.14
Rivers	360	0.071
Impoundments	335	0.066

[a]Compiled from Nace (1960), Wetzel (2001), Lehner and Döll (2004), Downing et al. (2006), and other sources.

897 are named "Mud" (Mud Lake, Mud Pond), the most common name (Soranno et al., 2020). Nevertheless, lakes esthetically represent some of the most beautiful "gems" of the landscape, e.g., Lake Tahoe, CA, United States; Lago Grey, Chile; Crater Lake, OR, United States; Lake Atitlan, Guatemala; Lake Pukaki, New Zealand; Lake Baikal, Russia. Lotic or running inland waters are referred to by different names (e.g., stream, brook, rivulet, river, headwaters, run, fork, creek [crick], kill, chalk stream, tributary) in English depending on the size and regional or cultural background. Obviously, water flows downslope by gravity, coalescing in networks from headwaters, into large rivers and eventually to the ocean. These networks of channels with flowing water may be simple or complicated, but flowing waters are challenging to study because the water is constantly moving, often in numerous channels (braided), and below ground.

A brief history of limnology

Limnology (from the Greek: limné = pool or pond; logos = discourse or study), the study of inland waters, is the scientific discipline focused on all inland waters of the Earth. These days, the term, limnology, may be replaced by or subsumed under other terms of scientific inquiry such as aquatic ecology, hydrobiology, or even hydrology. Initially, limnology lagged behind oceanography as a scientific discipline, as F. A. Forel in 1892, in his book (first volume) on Lac Léman (Lake Geneva, Switzerland/France), defined limnology as the oceanography of lakes.

Because successful limnological studies depend upon an understanding of the interactions of physics, chemistry, biology, meteorology, and hydrology for aquatic ecosystems, such as lakes, ponds, reservoirs, rivers, streams, and wetlands, limnological investigations often draw rather uniquely on a team of scientists with diverse interests and expertise. To do limnological research well, studies must incorporate biology, physics, chemistry, hydrology, geology, etc. into an holistic approach in order to make sense of the function, structure, and temporal change of a lake, pond, river, stream, or wetland. Such studies, focused on a systems approach, provide limnologists with a powerful and successful framework for addressing complicated environmental issues such as eutrophication and anthropogenic acidification. This integrative approach to the study of inland waters as complicated systems renders it the status as "queen" among the natural sciences.

The success and vitality of any endeavor is the product of its historical underpinnings. Limnology is no exception. The first work explicitly introducing limnology was Forel's three volumes on Lac Léman published in 1892, 1895 and 1904. In Eurasia, academic limnology has a long history with early, major centers of activity in Sweden (E. Naumann, S. Ekman, W. Rodhe), Germany (A. Thienemann, H. Elster, W. Einsele, W. Numann, W. Ohle, H. Sioli, D. Uhlmann), Denmark (K. Berg, C. Wesenberg-Lund, P. Jónasson), Norway (K. Strom), France (F.A. Forel, A. Delebeque, B. Dussart), Switzerland (L. Minder, E.A. Thomas), Spain

(R. Margalef), Austria (A. Ruttner-Kolisko, F. Ruttner, I. Findenegg), England (T.T. Macan, W.H. Pearsall, C.H. Mortimer, E.M. Wedderburn, J. Talling, J. Lund, W. Tutin), Japan (S. Yoshimura, S. Horie), Poland (A. Hillbrecht-Ilkowska), Russia (Yu. I. Sorokin; G.G. Winberg), and Italy (E. Baldi, V. Tonolli, L. Tonolli). This is a non-exhaustive listing of locations of major limnological centers and pioneers in the field. Austrian Professor F. Ruttner's early textbook (*Fundamentals of Limnology*, 1940) (Ruttner, 1940) had been a standard for years in Europe and in North America. He offered a course in hydrobiology (limnology) at Lunz, Austria in 1908, possibly the first such course in Europe.

In North America, Dr. J.G. Needham, who was appointed Assistant Professor of Limnology at Cornell University in Ithaca, New York in 1907, offered the first course on limnology in the United States in 1908 (Hairston and Likens, 2009). In 1911, he authored with J.T. Lloyd the first textbook on limnology—*Life of Inland Waters*. Although the book is broad in disciplinary coverage as expected for limnology, its focus was biological. Another major center for limnological studies was the University of Wisconsin-Madison, often referred to as the "birthplace of limnology in North America" because of the leadership and proficiency of E. A. Birge and C. Juday. Drs. Birge and Juday championed the systematic analysis of inland waters (Beckel, 1987). Courses in limnology and plankton were taught at the University of Wisconsin-Madison in 1909 by Chancey Juday. Other early pioneers in limnological studies in the United States and Canada included A.D. Hasler (Wisconsin), J. Reighard, F.E. Eggleton, P. Welch, H.B. Ward (Michigan), D.S. Jordan, D.G. Frey, S. Gerking, C.A. Kafoid, S.A. Forbes (Indiana), R. Patrick (Pennsylvania), L. Agassiz, G.C. Whipple, G.E. Hutchinson (New England), and F.R. Hayes, H.B.N. Hynes, F.E.J. Fry, D.S. Rawson, F. Rigler, J.R. Vallentyne (Canada). Again, this list is not exhaustive.

Some 39 professional limnological organizations exist in countries throughout the world. The International Association for Theoretical and Applied Limnology (Societas Internationalis Limnologiae) was founded in 1922 by E. Naumann and A. Thienemann and represents the international organization for limnology and limnologists (www.limnology.org). The name was changed in 2007 to the International Society of Limnology. Its mission "to... work worldwide, to understand inland aquatic ecosystems and to use knowledge, gained from research, to manage them," and its Congresses, now occurring every 2–3 years in different countries, attract limnologists from throughout the world. Other limnological professional societies, such as the Association for the Sciences of Limnology and Oceanography and the Asociación Española de Limnología, although originally more national/regional in origin and scope, are working to expand international memberships and activities. Dozens of limnological journals and periodicals are being published, including *Limnology and Oceanography*, *Journal of Paleolimnology*, *Journal of Crustacean Biology*, *Chinese Journal of Oceanography and Limnology*, and *Japanese Journal of Limnology*, on diverse topics and in many different languages.

The future of limnology

Historically, inland waters have been attractive to humans as a place to live, providing a convenient source of water, food, recreation, and transportation. Unfortunately, inland waters have also been a "convenient" receptacle for wastes. Flowing waters have been used especially for waste disposal by humans following the old adage, "out of sight, out of mind," and with little regard for other organisms, including humans, living downstream. Currently, freshwater ecosystems are much threatened and degraded because of pollution, human occupation and development of shorelines, and increased sediment loading and sedimentation. This degradation results from human activity such as agriculture, urbanization, and industrial activity, affecting the airshed or the catchment of these inland waters.

Water shortages for human use are common in many areas of Australia, the Middle East, Africa, Asia, and even in areas of eastern North America, long perceived to have abundant water. Serious water-quality problems are now occurring because of the pollution of surface waters by sediments, excess nutrients such as phosphate and nitrate, acids, mercury, pharmaceuticals, toxic algal/cyanobacterial blooms, human parasites, e.g., *Cryptosporidium* spp. and *Giardia* spp., and invasive alien species. Excess nutrient loading to inland waters has led to eutrophication (nutrient enrichment) of standing and flowing waters worldwide with resultant degradation (changes in species composition and diminishment of dissolved oxygen). Anthropogenic acidification from acid rain deposited on geologic areas with low buffering capacity has resulted in widespread degradation of lakes and rivers. Government action during the past few decades to lower emissions of sulfur dioxide and nitrogen oxides, the primary precursors to acid rain, have reduced this pollutant impact. Pollution of lakes and streams from atmospheric deposition of mercury, originating largely from combustion of fossil fuels and incineration of municipal waste, has resulted in health advisories for the consumption of fish throughout North America and Europe.

Inland waters are spatially explicit ecosystems that include all the organisms along with all components of the abiotic environment, interacting together as a system. The inland waters of the Earth result from the balance between precipitation, evapotranspiration, and runoff (Table 3; Clausen, 2017). The chemistry of inland waters is the result of how the chemistry of precipitation is transformed along hydrologic flow paths, by hydrologic factors (dilution or concentration such as by evaporation), biotic factors (such as plant uptake, storage and release, and microbial storage and transformation) and geologic factors (geochemical reactions). Clearly, all aspects of limnology as a science have to be considered. Using the ecosystem approach, the boundaries of a lake, pond, or river are ostensibly clear because the shorelines would appear to make quantitative, mass-balance calculations easier, but it has become apparent that there is a critical need to look "beyond the shoreline," that is, to the airshed and to the watershed or catchment, for evaluating human impacts on a body of inland water. Moreover, it is mostly impossible to judge the "health," condition, or value of an aquatic ecosystem from a causal observation from the shoreline. It is necessary to get inside the boundaries of the system to learn about these characteristics. Humanity needs water, and understanding the ecosystems of inland waters is vital to our future.

Table 3 Water balance for the Earth.

Fluxes	*Volume (km^3/year $\times$ 10^3)*	*Percent of total*
Evaporation from ocean	413	100
Precipitation to ocean	373	90.3
Water vapor transport from ocean to land	40	9.7
Precipitation to land	113	100
Evapotranspiration from vegetation	73	64.6
Runoff from land	40	35.4

The Discipline of Limnology☆

Jonathan J Cole[a] and ML Pace[b], [a]Cary Institute of Ecosystem Studies, State University of New York, Millbrook, NY, United States; [b]Department of Environmental Sciences, University of Virginia, Charlottesville, VA, United States

This is an update of J.J. Cole, Limnology as a Discipline, In Encyclopedia of Inland Waters, Edited by: Gene E. Likens, Academic Press, 2009, https://doi.org/10.1016/B978-012370626-3.00002-8.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor, Lars Rudstam.

Glossary

Colloidal organic matter Very large molecules or aggregates that have properties intermediate between particles and truly dissolved substances.
Dispersion The spatial mixing of a solute in water or the spatial mixing of more than one water mass.
Eutrophication Nutrient enrichment that leads to increased autotrophic growth.
Food-web An assemblage of organisms that interact by consuming each other.
Piscivorous A predator that eats fish.
Secondary production The growth of consumer organisms.

Limnology—An integrative, multidisciplinary science

The objective of limnology is a comprehensive, integrated, scientific understanding of inland waters. As Gene Likens points out in this Encyclopedia, limnology can be viewed as the Queen of Science because of its inherent interdisciplinary nature. As the scientific study of inland waters, limnology incorporates knowledge of geological, physical, chemical, and biological processes at a range of spatial and temporal scales. Although some limnology textbooks greatly emphasize lakes, the inland waters within the purview of modern limnology include lakes, streams, rivers, ground water, and often wetlands. Like oceanography, limnology is a highly integrative and interdisciplinary science and frequently adopts an ecosystem perspective to approach research questions or applied problems. This need for integration to understand the dynamic processes of inland waters has been evident since the beginnings of limnology as a formal discipline in the late 19th century, and in this regard there is a striking parallel between the fields of limnology and oceanography. With one important caveat, it is instructive to think of limnology as "freshwater oceanography." Forel was a little too narrow for modern limnology when he referred to it in 1892 as the "oceanography of lakes." Nevertheless, both limnology and oceanography are focused on types of environment (as are atmospheric science or forestry) and both are integrative sciences constructed from the strengths of the traditional scientific disciplines. If we wear jackets or tee-shirts with the word "limnology" emblazoned on the back and someone asks what it is, this definition as "freshwater oceanography" seems to be the one that best conveys limnology to the general public or scientists from diverse fields. The important caveat is that many inland waters are saline. So, one has to be careful here with the analogy. In some ways it is unfortunate that Francois- Alphonse Forel (1841–1912), the first to use the term limnology, was both conversant with ancient Greek, and unwilling to compromise linguistic purism by combining perhaps a more widely recognized Latin word for inland water with the Greek "-logos" (the study of). The Greek, "limni" (λίμνη) can be translated as lake, pool, lagoon, or lough. Even if most people knew Ancient Greek, "limni" does not represent limnology well because limnologists study both flowing and standing waters, and a host of systems that are neither lakes, nor lagoons, nor loughs. More problematic is that, for the few non-Greek speakers among us, there is no familiar everyday cognate for "limni." Thus, we have a scientific endeavor that studies a resource that is critically important to human welfare but exists under a rubric that is not recognized by the general public. Many practicing limnologists, and some entire universities, have chosen to drop the term

☆*Change History:* October 2020. JJ Cole and ML Pace.

limnology and describe the discipline other ways, such as "water science," "aquatic science," "aquatic ecology," "freshwater ecology," or by a sub discipline (e.g., "freshwater microbiology"). None of these are perfect. Both aquatic and water could just refer to the ocean as well as to inland waters, and in most definitions, ecology is too biological to represent the full spectrum of science in limnology (but see Likens, 1992). Sometimes the term "hydrology" is used in place of limnology. While etymologically reasonable, hydrology, especially in North America, as a discipline is well entrenched as the study of the water cycle and the movement of water. Limnology and hydrology are related sciences, but are not synonyms. Certainly other disciplines with otherwise obscure Greek names have caught the imagination of the public. Is "astronomy" well recognized because of its cognates, or are we aware of "astro-" because the space program, and some of its more visible proponents, made sure of it?

Limnology—Integration and sub disciplines

Although the science of limnology is by definition integrative and comprehensive, limnology is built upon its interacting sub disciplines. We can recognize four or five major sub disciplines. Physical limnology is focused on water movement at all spatial scales (from large-scale water balances to turbulence); heat and gas transfers; the optical properties of water, and often, the effects of physical properties on chemical reactions or organism function, and vice versa. Geological limnology is concerned with the formation and morphology of lake basins and river networks, the record of past events recorded in sediments (paleolimnology) and the distribution of aquatic environments over the landscape (which could also be called geographical limnology). Chemical limnology attempts to understand (a) the distribution of chemical constituents in water bodies, (b) the transport and retention of these constituents, (c) the chemical and biological reactions that control the forms of these constituents. Because of the strong direct and indirect roles that organisms, and especially microbial organisms, have on many chemical constituents much of chemical limnology would be classified as biogeochemical limnology. Biological limnology is concerned with the numbers and kinds of organisms that inhabit inland waters; their evolutionary adaptations, genetic relationships, and autoecology; their trophic and behavioral interactions with other organisms; food webs; and the effects of organisms on ecosystem-level processes such as whole-system metabolism and the effects of organisms on major biogeochemical cycles. Because of its rapid growth and high visibility, paleolimnology should probably be treated as a subdiscipline separate from geology. Paleolimnologists use the geological, chemical, or organismal records preserved in sediments to reconstruct conditions in the aquatic system itself (usually lakes), in the watershed, or more broadly as a record of paleoclimatic conditions.

The teaching of limnology

Although limnology, as "freshwater oceanography," is a broad and interdisciplinary topic in theory and origin, the teaching of limnology has progressed mainly in university departments that are most closely associated with biology and ecology. Even the historic and famous Center for Limnology at the University of Wisconsin at Madison is part of the larger Department of Integrative Biology (formerly Zoology). Thus, the teaching of limnology at most institutions tends to emphasize biological aspects. Basic physics, chemistry, and geology are covered, but not in the depth to which biology is. Where there is a clear distinction in oceanography between Marine Biology (the study of marine organisms and their interaction with the marine environment) and Biological Oceanography (how organisms effect the biogeochemical cycles in the ocean and vice versa), these distinction are usually blurred in the modern teaching of limnology. Many courses in limnology are really courses in freshwater biology, with physics and chemistry playing a supporting role. Many students are able to take a course in limnology (under whatever name) without a strong background or prerequisite courses in either chemistry or physics. While limnologists sometime complain about either a decline in the field of limnology or lack of recognition (see Jumars, 1990), an internet search in Google during May 2020 (with no date restrictions) reveals there are 965,000 hits for the parameters "limnology and course." Adding the names "freshwater biology" and "aquatic science" brings the total to about 62 million hits. This value is comparable and a bit larger to the results of a search for "oceanography and course," which recovers 11.2 million hits and quite a bit less than the 159 million for "ecology and course." Thus the teaching of limnology continues to have adherents and visibility, but not nearly what it should have because of the importance and relevance of the topic. The basic principles of limnology are also covered in other course work. Frequently, high-school students will have had a section on limnology in a basic course in either Earth Science or Environmental Science, as will university students who follow a course of study in areas like Natural Resources, Ecology, or Conservation Biology.

Principal limnological text books

The material covered in principal texts used to teach limnology is generally broad but as suggested above tends to be more focused on biology as a discipline and lakes as an environment. These texts contrast with the broader integrative science aspirations of the field. G.E. Hutchinson's classic four-volume Treatise on Limnology devoted one volume to geography, physics, and chemistry with the other three covering biological topics: Volume 2—Introduction to Lake Biology and the Limnoplankton; Volume 3—Limnological Botany; and Volume 4—Zoobenthos (coauthored with Yvette Edmondson). Though wide ranging in the topics covered, the Treatise, nevertheless, is nearly entirely devoted to lakes. One of the founding textbooks is Ruttner's 1953 Fundamentals of

Limnology, which devoted about half its length to biology, and thus more to chemistry, physics, and geology, and does give a single chapter on flowing waters.

Table 1 lists some of the more popular English-language texts published since 2000. We do include several texts focused exclusively on streams and rivers such as Stream Ecology: Structure and Function of Running Waters by Allen and Castillo (2007) or Stream Ecosystems in a Changing Environment by Jones and Stanley (2016). Students may want to consults these texts for more detailed analysis of flowing water.

The most comprehensive of the modern textbooks are Wetzel's 2001 Limnology: Lake and River Ecosystems and Dodds and Whiles, 2019 Freshwater Ecology. Both texts explicitly include flowing waters, and both devote multiple chapters to physical and chemical topics. The Dodds and Whiles text gives a comprehensive definition of limnology as, "The study of continental waters." Interestingly, though the scope of Wetzel's text does cover the full field of limnology, Wetzel inexplicably defines limnology (p. 4) as ". . . the study of the structural and functional interrelationships of organisms of inland waters as they are affected by their dynamic physical, chemical and biotic environments." Kalff's 2002 Limnology, also covers both flowing and standing waters and defines limnology more simply as (p. 1) ". . . the study of lakes, rivers, and wetlands as systems . . ." Kalff goes on to suggest that limnology is the most successful of the ecological sciences. Dodson's (2005) Introduction to Limnology is structured differently than the other modern texts in several ways. It is the only text to provide a specific manual for teachers of limnology. The text is also hierarchical and ecological, moving from the diversity of organisms to populations, communities, and ecosystems, a design that is shared with some ecology texts. This text pays little attention to physics or chemistry but strongly includes the interaction of humans with aquatic environments. Similar to Dodson the text of Lampert and Sommer is ecological and one of the few limnology texts that covers evolution. Cole and Weihe (2016) provide a recent update to a text that has been through many editions (with Cole as the sole author of prior versions). This text is less biological than others with more emphasis on aquatic habitat types as well as physical and chemical topics. The first edition of The Encyclopedia of Inland Water. Oxford-Elsevier, edited by G.E. Likens and published in 2009, and the precedent of this volume, has become an important go-to text. The coverage is very comprehensive and the short chapters are useful as a way to start to investigate a particular topic. Two more textbooks, likely to come out in the near future are noteworthy. An update of a long-standing text by Moss will be published posthumously in 2020. Moss provides an ecologically oriented text with light coverage of physical and chemical topics based on review of the pre-publication table of contents. Finally, although R.G. Wetzel died in 2005, an update of his famous text book is in the works at present, with John Smol and Ian Jones as editors. Unlike Wetzel's original text, this new one is an edited book with different authors for the individual chapters.

Scientific journals—The publication of limnological research

Exciting limnological research competes for space in the top, broad scientific journals such as Science, Nature, Nature Geoscience, Bioscience, Proceedings of the National Academy of Science, and so on. Limnology competes reasonably well for this space but not under its own name. There are 33 papers in these journals that come up in a Web of Science search (1975 through 2020) using the keyword "limnology" and its linguistic expansions (e.g., limnological etc.). However, if we put in a search that includes limnology

Table 1 Some of the more widely used English language text books of limnology published since 2000. For texts with multiple editions the most recent version is listed and subtitles are included with main title.

Author	*Date*	*Title*	*Scope*	*Comment*
Wetzel	2001	Limnology: Lake and River Ecosystems	Comprehensive, geography, geology, physics, chemistry, biology	Strong summary of field at the time of publication
Kalff	2002	Limnology: Inland Water Ecosystems	Comprehensive with more strength in ecology and biogeochemistry than physics or chemistry	Extensive comparative analyses
Dodson	2005	Introduction to Limnology	Mostly biology	Structured like an ecology text
Lampert and Sommer	2007	Limnoecology: The Ecology of Lakes and Streams	Mainly biology, includes flowing waters	Includes evolution and adaptation, ecological research methods and approaches
Likens (editor)	2009	The Encyclopedia of Inland Water. Oxford-Elsevier Volume 1	Comprehensive, encyclopedia, includes flowing waters	Short chapters with multiple authors
Cole and Weihe	2016	Textbook of Limnology	Comprehensive, less biology than most texts, includes chapters on streams and wetlands	Organization moves from biology to physical and chemical topics
Brönmark and Hansson	2018	The Biology of Lakes and Ponds	Focuses on biology and standing waters	Integrates ecology, evolutionary biology with limnology
Dodds and Whiles	2019	Freshwater Ecology: Concepts and Environmental Applications of Limnology (Aquatic Ecology)	An ecologically oriented text but also includes considerable coverage of physics and chemistry	Coverage of flowing waters, management applications
Moss	2020	Ecology of Freshwaters: Earth's Bloodstream	Ecologically oriented text with some chemistry and physics as well as coverage of major aquatic environments	Publication planned for late 2020

(and its expansions) plus we add "aquatic ecology" or lake or river, there are many more papers. For these journals combined from 1975 to 2020 in Web of Science there are 3009 entries. A similar search using oceanography (and its expansions) or "marine ecology" or estuary or sea, we get almost threefold this, 9784 hits. This is about the same as a search for ecology (with expansions) in the same set of journals (5211). Using "ecology" and expansions to include "ecosystem" and "ecological" the search yields 8777 hits. So limnology holds it own in these very high impact journals but not quite as well as do ecology and oceanography.

Most limnological research is published in journals dedicated to limnology itself (some including oceanography) or to fisheries or more generally, ecology. Taking just the journals of the Ecological Society of America, for example Ecology, Ecological Applications, Ecological Monographs, Frontiers in Ecology and Environment, Ecosphere, there are 2732 papers that cover limnological topics. This number is about 13% of the total content of these journals. Twenty eight percent of the papers in the journal Ecosystems from 1998 to 2020 cover inland aquatic environments.

There are 10 journals included by Web of Science with the word "limnology" (or a linguistic variant) in the title; 37 more with the word "aquatic"; and many others that come under different names, such as Hydrobiologia or Freshwater Biology, for a rough total of about 70 (Table 2). This number is comparable to the 29 journals with the word "oceanography" (or a variant) and 87 with the word "marine." As in most scientific disciplines, the citation rates or impact factors among these journals are highly variable reaching as high of 5.2 for Limnology and Oceanography Letters. These factors are based on the most recent data available for all journals in the limnology grouping as listed by the Institute for Scientific Information (ISI). The higher-impact limnological journals are on a par with higher-impact field-oriented journals such as Ecology, Geology, and so on.

Limnology—Multiple scientific approaches

As with other aspects of ecosystem science, limnology employs multiple approaches. These can be classified, albeit imperfectly, as: observational; comparative; experimental; and theoretical (including modeling; see Carpenter et al., 1997).

Observational approach. The observational approach consists of measurements over time of key parameters of interest, often in a single system, and has dominated limnology in the past. The observational approach is descriptive. That is, measured variables, their changes over time or space, and their apparent interrelations can be depicted quite quantitatively, but the backbone here is the description of a state or change in state.

While the observational approach can suffer from being narrowly site-specific in some single-system studies, it forms the background of what we know about aquatic systems and how they vary over time. Further when such observations are sustained over time (long-term studies), or extended to include multiple systems, the observational approach becomes particularly powerful at detecting changes or long-term trends. Sometimes this approach can identify the factors that cause the observed changes, and this is often useful to management or policy about these resources.

Table 2 Leading limnological journals, ranked by Journal Impact Factor (JIF).

Rank	*Journal Title*	*Journal Impact Factor*
1	Limnology and Oceanography Letters	5.2
2	Water Resources Research	4.3
3	Limnology and Oceanography	3.8
4	Freshwater Biology	3.4
5	Canadian Journal Fish & Aq. Sci.	2.9
6	Limnology And Oceanography-Methods	2.5
7	Aquatic Sciences	2.4
8	Hydrobiologia	2.4
9	Freshwater Science	2.3
10	Journal of Great Lakes Research	2.2
11	Limnologica	1.8
12	Journal of Paleolimnology	1.6
13	Limnology	1.6
14	Inland Waters	1.5
15	Marine and Freshwater Research	1.5
16	Aquatic Ecology	1.4
17	Water and Environment Journal	1.4
18	Journal of Limnology	1.3
19	Journal of Freshwater Ecology	1.2
20	Water Environment Research	1.1

The JIF is the number of times an article was cited during a 2-year period, divided by the total number of articles published in that journal during that same period. Data are the most recent available from Journal Citation Reports Science Edition (Clarivate Analytics, 2020). Note than JIF varies over time and can change year to year.

Comparative approach. In the comparative approach researchers often choose to sample a wide variety and number of related aquatic systems and then formulate a relationship between aspects of these systems (e.g., lake size, river discharge rate, slope, pH, wind stress) and the objective of the study (phytoplankton biomass, bacterial secondary production, diversity of fishes, net gas flux rates). When these relationships are strong and based on reasonable connections between driver and observation, they can be used to predict conditions in a system that has not yet been sampled. When the relationships also have strong mechanistic underpinnings, they can be used in management as well. Examples include: the relationships between the loading or concentration of total phosphorus, and algal biomass (as chlorophyll-a) in lakes: the rate of phosphorus release from sediments over a gradient of sulfate concentrations (Caraco et al., 1989); how food chain length is related to lake size (Post et al., 2000): or how the fraction of dissolved and particulate organic matter derived from terrestrial organic matter relates to lake size, trophic richness and other variables (Wilkinson et al., 2013).

Experiments. Limnologists use experiments at many time and space scales ranging from short term manipulations of water in bottles or sediment cores, to more complex mesocosms, or artificial stream channels, to entire ecosystems. Experiments in bottles or mesocosms offer replicability but can be criticized for a lack of realism. Nevertheless, work on limiting nutrients for algal primary production; food preferences of zooplankton, the uptake and releases of chemicals from sediments, have been greatly advanced by work at these small and replicable scales. An interesting example is that of Howarth et al. (1993) who manipulated turbulence in large mesocosms to investigate its effects on cyanobacterial blooms. Because aquatic systems are discrete with observable boundaries, limnology has always been a leader in whole-ecosystem experiments, especially in smaller lakes and in streams. Whole-ecosystem experiments also suffer the limitation of being site specific, and from lack of strict controls, but can be used to look directly at a system's response to a perturbation and can be very useful from a management point of view. Manipulative experiments are designed to change the properties of a system (add nutrients; alter the food web; decrease available light; (Carpenter et al., 2005). Tracer experiments do not alter the system per se, but are designed to follow a process by adding a purposeful tracer (C or N isotope to follow the food web Wilkinson et al., 2014.); inert gas to measure gas exchange rates (Cole and Caraco, 1998); or an exotic or non-reactive solute to trace water movement or residence time (Peterson et al., 2001). Whole system experiments are difficult to replicate and require special care in their interpretations but can be very powerful. As demonstrations, especially to the general public, whole-system manipulations can be particularly convincing and evocative. For example, the addition of phosphorus and nitrogen to a lake without significant algal blooms almost always results in these blooms (Schindler 1977; Carpenter et al., 1997, 2001).

Modeling and theory. Modeling and theory are widely used, often in conjunction with data from comparative or long term studies, to test the theory of interest. Theoretical approaches are able to look at essentially any spatial or temporal scale and integrate knowledge across these scales. In fact, most data analysis contains some type of modeling. Some limnological models are designed to represent the physics of systems and the user can input local data (Imberger and Ivey, 1991), or to calculate primary production from continuous oxygen data in a stream or river (Holtgrieve et al., 2000). Others are designed for a specific use in a particular analysis (Carpenter and Brock, 2011).

The four basic approaches are used unevenly in the major subdisciplines of limnology (Fig. 1). In modern limnology some of the best studies combine aspects from the four basic approaches. A few examples are noteworthy. Combining long-term observations

	Geological	Physical	Chemical	Biological	Paleolimnology
Observational	XXX	XXX	XXX	XXX	XXX
Comparative	XXX	X	XX	XXX	XX
Experimental	?	X	X	X	?
Model/theory	X	XXX	XX	X	?

Fig. 1 Approaches used in the major subdisciplines of limnology. More X's means more commonly used. Thus, the observational approach (measurements over time in a single system) is widely used in all subdisciplines whereas whole-system experiments are rarely if ever attempted in paleolimnology or geology.

carried out in multiple lakes (observational plus comparative), Magnuson et al. (2000) used historical records of ice duration data on lakes to document a warming climate in the Northern Hemisphere over the past 150 years. Combining physical theory and experimental approaches, a number of researchers have added purposeful tracers to lakes, rivers and streams to estimate the physical basis of gas exchange and the factors that regulate it. In the work that led to the modern understanding of the causes of cultural eutrophication in lakes, we have all four legs of the table in play at various times. The comparative work of R.A. Vollenweider and colleagues showed the initial correlation between total phosphorus (TP) and chlorophyll-a levels among lakes. Further comparative work has revealed numerous factors such as lake depth, zooplankton community structure that modify the basic TP-chlorophyll relationships. Whole lake nitrogen and phosphorus additions revealed that phosphorus was necessary to stimulate large algal blooms. Again further experimental work that followed showed that the effect of a given level of TP loading could be modified by the presence or absence of piscivorous fishes. Models from the simple empirical type to more refined models that included the effects of hydraulic residence time were added and aided managers to predict the effects of a given increase or decrease in nutrient loads. A number of studies have followed the time course of eutrophication (Smith, 1997). An important example is the long-term work at Lake Washington, which was studied both before and after a large-scale sewage-nutrient diversion (Edmonson, 1991). The work on acid rain and its effects on aquatic ecosystems is a second excellent example of a topic that used all four legs of the table. The work included specific experiments on acid sensitivity of key organisms, following over long-term the changes in acidity, organisms and organism health in systems, comparative studies, direct, whole system experiments in lakes and streams, and rich modeling data that simulated acid from its deposition, through the watershed and into water bodies. Another research area that is richly developed in combining theory with both experimental and comparative approaches is the Lotic Intersite Nitrogen Experiment (LINX) which consists of a large network of stream sites all performing N-isotope addition experiments, linked to a common model to examine nitrogen retention and transformations (Peterson et al., 2001). The exciting work on regime shifts in shallow lakes is particularly strong in combining theory, experiments and long-term observation. This body of work endeavors to explain the factors that cause the observed sudden shifts from macrophyte to phytoplankton dominance in shallow systems. The advent of reliable instruments which can make high-quality continuous measurements of variables such as temperature, dissolved oxygen, pH, chlorophyll etc., has opened up a new approach. Persistent high-frequency measurements are being used to measure whole system primary production and respiration in lakes and in flowing waters and are beginning to be used to reveal the factors that regulate this metabolism. Some limnologists are exploring the value and challenges of a global network of persistent high frequency measurements. For example, the Global Lake Ecological Observatory Network is a grass-root, international collaboration organized around using these sensors in lake and reservoirs of the world (www.gleon.org).

Current and emerging themes in limnological research

Several consensus documents (Lewis et al., 1995; Wurtsbaugh et al., 2003) have attempted to summarize the key unifying and emerging themes in modern limnology. These are useful compilations because both are the results of workshops, sponsored by the scientific societies and funding agencies, and thus, have the consensus of more than a few individuals. Neither workshop attempted to be comprehensive; the list here, derived from both sources, is meant only to be illustrative of selected important themes with a few examples. The further reading lists a few studies under each topic where the reader can gain more information. More detailed information on some of these topics appears elsewhere in this Encyclopedia.

Principles governing aquatic food webs. This topic covers the role of consumers in determining the biomass, species composition and production of prey items and primary producers. How changes in piscivorous fish, by removal due to over fishing or addition by stocking, affect the rest of the food web and both algal and macrophytes communities. Fish manipulations have been used as a tool in managing freshwater ecosystems.

The origin, structure and roles of organic matter in natural waters. Organic matter affects the optical properties of water as well as pH and, through chelation, the degree of toxicity of certain metals. The amount of organic matter in a given system is governed by its production from within the system, the rate of input from the watershed and losses due to degradation by light and microbes. Researchers have also been interested in the role of terrestrial subsidies and how terrestrial organic matter does or does not enter the aquatic food web. In addition to the roles of organic matter, other researchers have been advancing our understanding of the chemical make up of dissolved and colloidal organic matter to achieve a molecular understanding of its macro-properties.

Hydrodynamics and fluid mechanics. There have been stunning achievements in recent years in understanding water movement and fluid dynamics in all aquatic ecosystems, largely as the result of improved instrumentation such as acoustic Doppler current profilers (ADCP). Interacting with the better measurements has improved theory for modeling thermal structure, advection, dispersion and turbulence. In streams, the ability to do tracer experiments has led to a much better understanding of temporary storage and mixing in eddies. The work on fluid dynamics extends to the effects on biological and chemical processes.

Biogeochemistry of aquatic ecosystems. The transport, retention and transformation of key elements such as carbon, nitrogen, phosphorus and more recently mercury, has been an important component in limnology for some time. Balancing input-output budgets often requires the identification of sources and sinks that were not known or realized to be important or biogeochemical reactions that were thought not to occur like the anaerobic oxidation of ammonia. As new toxic materials become of concern, their biogeochemistry becomes relevant and interesting, sometimes in surprising ways. For example, the creation of new, large hydro-electric reservoirs in Canada, Brazil and China has caused an enormous release of mercury, which is highly toxic.

Energetics of aquatic ecosystems. The study of energy as a basic currency in ecosystems is a pervasive theme in all types of ecosystems and particularly well developed in limnology and has a long history of study. An interesting modern extension has been the

expanded use of ecological stoichiometry which links the ratios of key elements in organisms (N, P, Si, C) to food webs and ultimately to energetic constraints (Sterner and Elser, 2002).

Land-water and atmosphere-water interactions. A key area in limnology is to explore the relationship of the conditions within an aquatic system (chemical constituents, biological productivity, etc.) to the system's links with its watershed or airshed. This endeavor includes the responses of an aquatic system to changes in land cover or land use. With climate change as a potential driver of new land use or land cover patterns, this area of research has become critically important as well as the system's geographical and hydrogeographical position in the landscape. Atmosphere-water interactions include the mechanisms, magnitudes, and of materials that enter and leave aquatic systems at the air water interface. The exchange processes include aeolian transport of particles, and the exchange of gases.

Ecosystem services. Aquatic environments provide many services to humans such as drinking water, fisheries, recreation, cooling water for power plants. These services are the result of natural processes such as the food webs that produce fish and the aggregated flows that provide power plant cooling waters. Disruption of these services can be costly and research is addressing the value of ecosystem services, the consequences of losing services, and resilience of services to various types of disturbance (e.g., storms, land use change).

Conservation of biodiversity. Inland waters support a rich diversity of flora and fauna and many species are imperiled due to pollution, loss of habitat, overharvesting, invasions of exotic species, and flow modifications. Sustaining and restoring endangered species requires understanding both population processes and the ecosystem dynamics that support species. Examples of successful conservation programs are often founded on sustaining or restoring habitats and particularly in flowing waters this requires attention to hydrology (e.g., minimizing low flow condition in a river). Despite examples of success, inland water biodiversity is declining as water resources are continually subjected to greater human pressures and development (e.g., dams).

Global limnology. Limnologists are increasingly interested in the global status of aquatic resources. Seemingly simple but nonetheless technically challenging problems are amenable to analysis using remote sensing and modeling. These include questions like how many lakes are there in the world, how are the number of volume of reservoirs changing globally, what is the total length and discharge of rivers globally and how are these properties changing. Answers to these questions open others such as what are the emissions of greenhouse gases from inland waters and how much carbon is stored in their sediments. Limnological research is achieving global scope with value for understanding the earth system and managing aquatic resources and regional and global scales.

The future of limnology as a discipline

There is no doubt that the comprehensive, integrative scientific understanding of inland waters (e.g., limnology) is critical to our understanding of the larger terrestrial matrix in which these aquatic systems are embedded. It is becoming increasingly clear the aquatic systems are often biogeochemical "hot spots" which regulate chemical cycles to a much greater extent than their small size would suggest. Certainly, inland waters are critically important habitats and resources for wildlife and humans alike. While the scientific study of these inland waters will continue, it is not clear to what extent that limnology will either maintain its independent identity, or be subsumed into ecology or earth science in the future.

Glossary

Component Specific pool of water in the hydrological cycle.
Evaporation Process where a substance in a liquid state changes to a gaseous state.
Evapotranspiration Process where water is transferred from the land to the atmosphere by evaporation from water and soil, and transpiration from plants.
Flux Flowing of water or a constituent per unit time.
Groundwater Water that exists in saturated zones beneath the land surface.
Hydrological cycle Also known as the water cycle, describes the continuous movement of water on, above, and below the surface of the earth.
Runoff Flow of water over the land surface to the stream network.
Soil-zone water Water retained in the unsaturated zone (zone between the land surface and the water table).
Storage Amount of water contained in a specific component of the water budget.
Surface water Any body of water above ground, including streams, wetlands, rivers, lakes, reservoirs.
Unsaturated zone Zone between the land surface and the water table.
Water budget An accounting of the rates of water movement and the change in water storage in all parts of the atmosphere, land surface, and subsurface.

*Deceased.

Introduction

The earth's geology, atmosphere, and life itself have been profoundly affected by water and the movement of water. The movement of water is the result of the hydrological cycle, which is a continuous exchange of water above, on, and in the earth. The hydrological cycle is characterized by the circulation of an almost insignificant fraction, about 0.01%, of the total water existing on the earth. Almost all biological creatures on land require freshwater for sustenance. Yet, remarkably, they have evolved and proliferated, depending on the repeated reuse of this small fraction of available water. The partitioning of water among the components of the hydrological cycle at a given location over a given time period constitutes a water budget. Water-budget evaluations are important to understand the geological and biological evolution of the earth and of practical value in environmental and natural-resource management on various scales. The purpose of this chapter is to describe the important components (often referred to as pools) of the hydrological cycle and water budgets relevant to inland waters and aquatic ecosystems.

Hydrological cycle

The hydrological cycle (National Oceanographic and Atmospheric Administration, 2020) is a continuous cycle with no beginning or end point, but the atmosphere is a good place to start (Fig. 1; Perlman and Evans, 2019). Atmospheric water vapor condenses and precipitates as rain or snow. Part of this precipitation is intercepted by vegetation canopies prior to reaching the ground. What precipitation does reach the ground either evaporates, percolates into the soil, or flows immediately (or after snow melting) over land as surface water and moves toward inland depressions, streams, rivers, and ultimately the oceans. Much of the surface water is intercepted along the way by wetlands, lakes, and reservoirs. The water that percolates into the soil either replenishes the soil-water zone, where it is available for uptake by plants, or continues downward to replenish aquifers and deeper groundwater reserves. Depending on soil characteristics, the water reaching aquifers (groundwater) flows relatively slowly from areas high in the landscape to areas lower in the landscape. Because of variability of the layers of soil and rock, the rate of downward movement of water can vary. Groundwater is transported horizontally and discharged in springs, streams, wetlands, ponds, lakes, or the ocean itself. At the land and water surface, surface water is subject to evaporation by solar radiation and to transpiration by plants as they consume water for photosynthesis. Collectively referred to as evapotranspiration, this transfer of water back to the atmosphere completes the hydrological cycle.

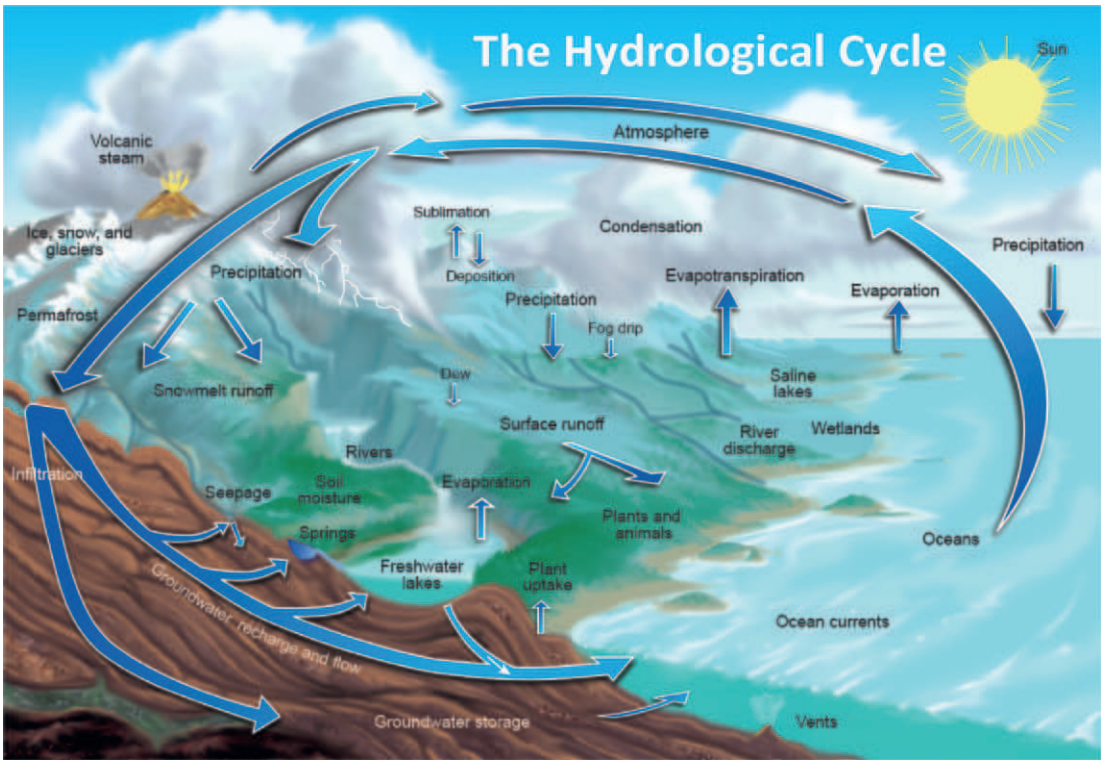

Fig. 1 Schematic of the hydrological cycle. Modified from Perlman H and Evans J (2019) *U.S. Geological Cycle*, *The Water Cycle*, https://www.usgs.gov/special-topic/water-science-school/science/water-cycle?

Table 1 Components or pools of water in the hydrological cycle, with their respective spatial and temporal scales.

Water source	*Water volume, in cubic kilometers*	*Percent of freshwater*	*Percent of total water*	*Spatial scale*	*Residence time*
Oceans, Seas, and Bays	1,340,000	–	96.480	Km to thousands of km	Thousands of years
Ice caps, Glaciers, and Permanent Snow	25,800	96.116	1.858	Km to thousands of km	Tens of thousands of years
Groundwater	22,600	–	1.627	Tens of meters to hundreds of km	Days to millions of years
Renewable (young)	*630*	2.347	*0.045*	Tens of meters to hundreds of km	Days to millions of years
Nonrenewable (old)	*22,000*	–	*1.584*	Tens of meters to hundreds of km	Days to millions of years
Soil-zone water	54.1	0.202	0.004	Meters to tens of meters	Weeks to years
Ground Ice and Permafrost	207	0.771	0.015	Km to hundreds of km	Days to millions of years
Lakes	190	–	0.014	Meters to hundreds of km	Weeks to years
Fresh	*108*	0.402	*0.008*	Meters to hundreds of km	Weeks to years
Saline	*95*	–	*0.007*	Meters to hundreds of km	Weeks to years
Artificial Reservoirs	10.8	0.040	0.001	Km to hundreds of Km	Weeks to years
Rivers	1.90	0.007	0.000	Meters to hundreds of km	Days
Atmosphere	12.9	0.048	0.001	Km to thousands of km	Days
Wetlands	14.1	0.053	0.001	Meters to km	Weeks to years
Seasonal snowpack	2.90	0.011	0.000	Meters to hundreds of km	Weeks to years
Biological Water	0.94	0.004	0.000	Less than meters	Minutes to years

Modified from Abbott BW, Bishop K, Zarnetske JP, Minaudo C, Chapin FS, Krause S, Hannah DM, Conner L, Ellison D, Godsey SE, Plont S, Marcais J, Kolbe T, Huebner A, Frei RJ, Hampton T, Gu S, Buhman M, Sayedi SS, Ursache O, Chapin M, Henderson KD, and Pinay G (2019) Human domination of the global water cycle absent from depictions and perceptions. *Nature Geoscience*, 12: 533–540, https://doi.org/10.1038/s41561-019-0374-y.0374.

The components or pools of water of the hydrological cycle, namely, the oceans (the biggest pool and one often not considered in surface water), atmosphere, surface water, soil-zone water, and groundwater are intimately interlinked over a variety of spatial scales (meters to thousands of kilometers) and temporal scales (days to millions of years). Estimates of the volume of water stored in each component or pool of the hydrological cycle for the entire earth, and the relevant spatial and temporal scales are summarized in Table 1, which is based on a synthesis of 80 recent modeling and empirical studies (Abbott et al., 2019).

Water is essentially an incompressible liquid, with high specific heat capacity and latent heats of melting and evaporation. Water exists in solid, liquid, and gaseous phases within the range of temperatures over which life, as we know it, is sustained. The relation between temperature and water density of fresh water is nonlinear. As temperatures decline, the density of water increases until water reaches 4 °C, with further cooling its density decreases until it reaches 0 °C. At 0 °C, water forms into ice and its density abruptly decreases by about 10%. After freezing, the density of ice slowly increases with further cooling. Ice being much less dense than water is the reason ice forms on the surface of lakes rather than lakes freezing solid. The nonlinear decrease in density as water warms from 0 to 30 °C is one of the main reasons that lakes and ponds thermally stratify into specific layers during summer. The bipolar nature of water enables it to trap nonelectrolyte molecules as well as charged ions. For these reasons, water is an active chemical agent, efficient transporter of energy and heat, and a carrier of dissolved and suspended substances. These attributes render water to be an extraordinary geological and biological agent.

The hydrological cycle is driven mostly by solar energy and gravity, and to a minor extent by geothermal heat and underground pressure. The earth's erosional and geochemical cycles exist because of water's ability to do mechanical work associated with erosion, chemically interact with rocks and minerals, and transport dissolved and suspended materials. Collectively, the hydrological and geochemical cycles constitute the vital cycles that sustain life. The interrelationships among these vital cycles can be conveniently understood by examining the components of the hydrological cycle.

Specific components (pools) of the hydrological cycle

Oceans, glaciers, ice caps, and snow fields

The oceans, seas, and bays are the biggest pool of water, followed by the glaciers, ice caps, and permanent snow field pool. Both of these pools are at the land surface, but they are not typically considered in the surface-water pool.

Surface water

Once precipitation reaches the earth's surface, the water that does not percolate into the ground becomes surface water. Surface water chemically breaks down rocks through actions of microbes, plants, and animals and solar radiation and physically breaks down rocks through weathering and erosion during its transport. The products of weathering are transported as sediments

(bedloads and suspended loads) and dissolved chemicals. In addition, water transports leaf litter and other decaying vegetation and animal matter. Sediments and organic matter together contribute to the cycling of life-sustaining nutrients. Habitats for flora and fauna along the course of a river depend, in very complex ways, on the texture of sediments as well as on their chemical makeup. Most runoff and streamflow is intercepted along its movement to the oceans by wetlands, ponds, and lakes, where its temperature and chemical makeup can be greatly altered. In addition, reservoirs built for many purposes intercept the flow.

Soil-zone water

Once water percolates into the soil, it is either retained in the soil zone (zone between the land surface and the water table also called the unsaturated zone) or it seeps down to the water table. Water in this unsaturated zone is referred to as soil-zone water. In the soil zone, water and air coexist. Soil-zone water, which is held in the pores by capillary forces, is not amenable for easy extraction by humans. However, plants can overcome the capillary forces and extract soil-zone water. With abundant availability of oxygen and carbon dioxide in this zone, the soil is an active chemical reactor, with microbially mediated aqueous reactions. In the soil zone, water movement is mainly vertical, with downward directed gravity flow and upward evaporative movement. Water moving down by gravity reaches the water table to recharge the groundwater pool.

Groundwater

Throughout the watershed, water enters the groundwater pool via infiltration, and driven by gravity or pressure from the soil and rocks above moves vertically down in areas of groundwater recharge. Depending on topographic relief and the distribution of permeable and impermeable layers, the vertical downward movement is resisted sooner or later, and the movement becomes more horizontal, and is discharged into streams or lakes. The journey of water from the time it enters the groundwater pool to the time it emerges back at the land surface is referred to as regional groundwater flow (Fig. 2; Carter, 1996). Regional groundwater flow constitutes a convenient framework for understanding the formation of sedimentary rocks and minerals, and the areal distribution of soils and aquatic ecosystems on land. Groundwater discharge typically occurs in perennial stream channels, wetlands, springs, low lying areas, and lakes. In these discharge areas, surface water and groundwater directly interact with each other, with important geological and biological consequences. For example, the spectacular tufa towers of Mono Lake in California represent precipitates of calcium carbonate resulting from a mixing of subaqueous thermal springs with the lake water. Areas where groundwater discharge occurs are referred to as hyporheic zones, which play an important role in stream ecology.

Regional groundwater flow provides a framework to interpret patterns of chemical processes in the subsurface. Water in recharge areas is generally rich in oxygen and carbon dioxide and can chemically break down minerals through corrosive oxidation reactions. However, available oxygen is consumed as water chemically interacts with the minerals along the flow path, and the oxidation potential of groundwater progressively decreases along the flow path. In swamps and wetlands of discharge areas, water typically has strong reducing (anaerobic) conditions. Between these two extremes, ambient conditions of acidity (pH) and redox state (Eh) govern the chemical makeup of water and the types of minerals and microbial populations that are compatible with ambient water

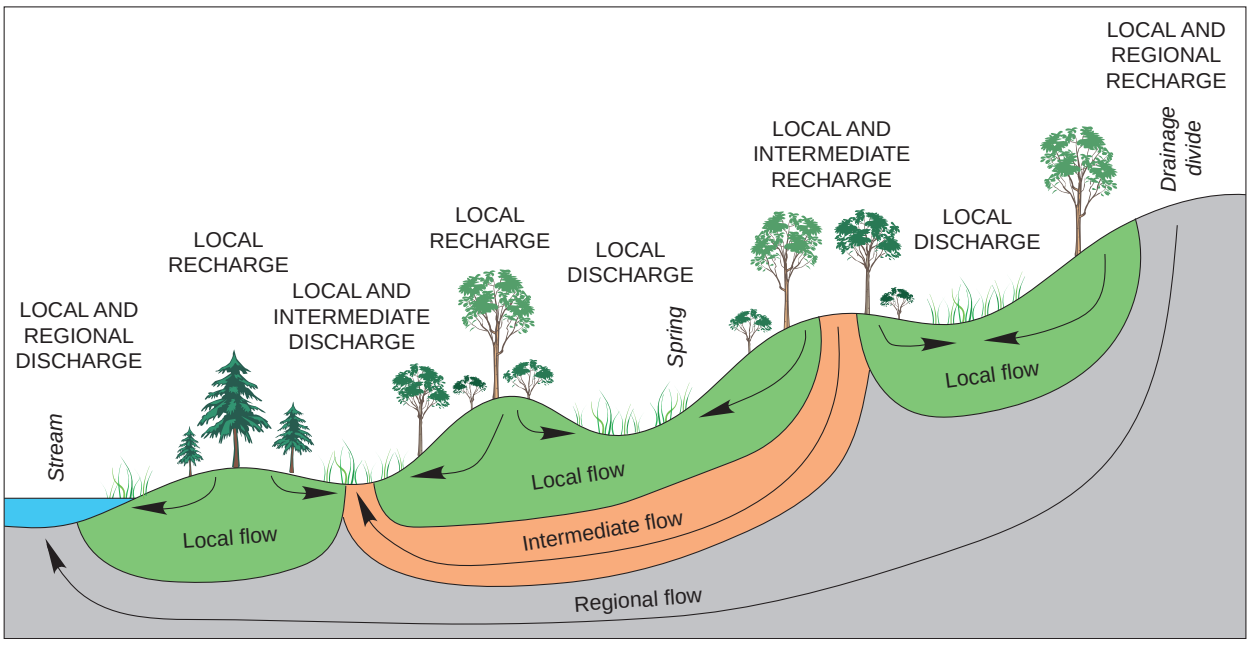

Fig. 2 Regional groundwater flow demonstrating local, intermediate, and regional flow patterns. Modified from Carter V (1996) Technical aspects of wetlands: Wetland hydrology, water quality and associated functions. In: *U.S. Geological Survey. National Water Summary on Wetland Resources. U.S. Geological Survey Water-Supply Paper 2425*. pp. 35–48.

chemistry. In general, the cation content of groundwater reflects the chemical makeup of the rocks encountered along the flow path, and the anion content is indicative of the progress of chemical reactions.

Nutrient cycling

The hydrological cycle is important to the transport and cycling of nutrients. A glimpse into connections to nutrient cycling can be gained by examining the role of water in the cycling of carbon, sulfur, and phosphorus. Almost all biological carbon originates from atmospheric carbon dioxide through photosynthesis by plants and phytoplankton. Water, essential for photosynthesis, is transferred by terrestrial plants from the soil via leaves to the atmosphere (transpiration). Water plays a dominant role in the decomposition and mineralization of organic carbon on diverse time scales, ultimately producing carbon dioxide or methane to be returned to the atmosphere.

Sulfur is a redox-controlled chemical element that plays an important role in metabolic reactions of plants. Under reducing conditions, sulfur is insoluble in water. Sulfate, in its most oxidized form, is water soluble, and is the form that sulfur usually enters plant roots. Sulfide minerals are oxidized in the presence of bacteria to sulfate and become available for uptake by plants. In plants, sulfur is fixed in a reduced form. Thus, sulfur from dead organic matter is mobilized by oxidizing waters to sulfate to sustain the sulfur cycle.

Phosphorus plays several important roles in the biological processes of plants and animals and often limits productivity in lakes. Phosphorus is water soluble only under narrow ranges of redox and pH. Because phosphorus does not readily form gaseous compounds, phosphorus is almost entirely transported with the movement of surface water and to a much lesser extent with the movement of groundwater. Because of the importance of phosphorus to the productivity in lakes and rivers, management actions are often taken to limit its transport, especially in runoff and wastewater effluent.

Energy balance

A discussion of the hydrological cycle with respect to inland waters is incomplete without mentioning its connections to the solar energy balance. The hydrological cycle is driven largely by solar energy. Just like water, solar energy is also subject to cyclic behavior. On the land surface, the energy received as incoming solar radiation (insolation used to heat streams and lakes) is balanced partly by outgoing longwave radiation, partly as sensible heat by convecting air columns, and partly as latent heat transferred by water from the land to the atmosphere during evaporation. Of the total solar radiation received from the sun, about 45% of the energy is returned to the atmosphere by water, a major fraction. Any significant perturbation to this natural cycle could influence global climate.

Summary

The concept of the hydrological cycle is quite simple. But, its importance to life on earth is profound. The hydrological cycle plays an overarching role in the cycling of solar energy, sediments, and chemical elements vital for life. Although it is clear that contemporary ecosystems reflect an evolutionary adaptation to the delicate linkages that exist among the various components of the hydrological cycle, it is also apparent that evolving life has affected the evolution of the hydrological cycle over geological time. Life, it appears, is simultaneously a product of the hydrological cycle and a factor causing changes in the cycle.

Water budgets

Humans, like plants and animals, have had to adapt to natural variability in weather and climate and now will have to continue to adapt to a changing climate. However, many individual components of the hydrological cycle (surface water, soil-zone water, and groundwater) lie within reach of human control and can be managed for human benefit. In this context, the concept of water budgets (Healy et al., 2007) becomes relevant.

Given a specific area with well-defined boundaries, constructing a water budget consists of quantifying the amount and relationships among inflow, outflow, and change in storage within a defined area (i.e., the transport or flux of water between each pool). This simple concept is as valid over the entire earth, over a river basin, or over a small rural community. In a world of stressed water resources, water budgets are becoming more important as a framework for wise and equitable water management.

Water is always in motion, and its budget is governed by the simple notion that the sum of inflows must equal sum of outflows plus a change in storage. Symbolically, this may be stated as:

$$PPT = R_{SW} + Q_{GW} + ET + \Delta SW + \Delta SoilW + \Delta GW + D_H \quad (1)$$

where PPT is precipitation, R_{SW} is runoff from surface water, Q_{GW} is groundwater flow, ET is evapotranspiration, SW is water in surface waters, SoilW is soil-zone water, GW is the water in groundwater storage, D_H is diversion out of the area being considered (diversions into the area would be negative), and Δ denotes change in storage. If the time interval of interest is smaller than a year, the terms involving change in storage cannot be neglected because the system is usually under transient conditions. If, however, the

time interval of interest is a year or several years, seasonal increases and decreases in storage typically cancel out, except for areas with large reservoirs, and the water budget equation reduces to a steady-state balancing of inflow and outflow:

$$PPT = R_{SW} + Q_{GW} + ET + D_H \quad (2)$$

Implicit here is the assumption that precipitation and diversions into the defined area constitute the only inflows, which is reasonable if one considers a watershed is enclosed by both surface-water and groundwater divides. However, the groundwater divide is not necessarily the same as the surface-water divide, especially for small areas. Also implicit is the assumption that there are no long-term changes in weather (i.e., climate changes) causing changes in the surface- and groundwater pools. If the area of interest is defined by open boundaries, additional terms representing water import and export must be added to the equations. The simplicity of the above equations belies the difficulties inherent in assessing the different components involved.

Specific flux components of water budgets

Precipitation

Perhaps the most widely measured quantity or flux in water budgets is precipitation. Precipitation represents a combination of rainfall and snowfall. In general, precipitation data obtained from aerially distributed rain-gaging stations are integrated over space to arrive at the total volume of water falling over an area during a period of interest.

Surface-water runoff

Surface-water runoff, estimated at a given location in a stream with flow meters or river-stage data supplemented by rating curves, represents outflow from the watershed upstream from that location. To help determine the water budget of a defined area, it is helpful to have a streamgage at the outlet of that basin.

Groundwater flow

The movement of groundwater in the subsurface is quantified with Darcy's Law, according to which the volume of water flowing through a given cross-sectional area per unit time is equal to the product of the hydraulic conductivity of the formation, the gradient of hydraulic head, and the cross-sectional area (Freeze and Cherry, 1979). In the field, hydraulic gradients can be obtained from water-table maps. These maps, in conjunction with the known hydraulic conductivity of the geological formations can be used to estimate groundwater flow. Groundwater flow is often defined using groundwater flow models or from surface-water streamgages using baseflow-separation techniques. Often groundwater movement is not constrained to surface-water basins making it difficult to quantify.

Evapotranspiration

Evapotranspiration includes evaporation from water surfaces and water transpired by plants. Evapotranspiration constitutes a significant percentage of the precipitation over the land surface. Yet, quantification of evapotranspiration is a difficult task. A gravimetric lysimeter provides a way of estimating evapotranspiration from a soil mass over the scale of a few cubic meters. For watersheds and river basins, it is customary to use a combination of empirical and theoretical methods. In one such approach, the concept of potential evaporation plays a central role. Potential evaporation is understood to be the amount (for example, millimeters) of water that would be evaporated from a pan at a given location, assuming unlimited supply of water, as from a deep lake. If precipitation at the location exceeds potential evaporation, the soil is assumed to hold a maximum amount of water in excess of gravity drainage. If precipitation is less than potential evaporation, then the actual evapotranspiration will be limited to what precipitation can supply. In this case, empirical curves are used to estimate soil-moisture storage based on precipitation deficit and the maximum water-holding capacity of the soil. With the availability of instruments of increased sophistication, energy budget methods are increasingly sought after to estimate evapotranspiration from watershed scale to continental scale. In these methods, the goal is to carry out an energy budget and isolate the amount of energy that is transferred by water from the land surface to the atmosphere as latent heat. This estimate is then converted to evapotranspiration. To support this model, data are generated from detailed micrometeorological measurements such as short-wave and long-wave radiation, temperature, humidity, cloud cover, and wind velocity. Another method for estimating evapotranspiration is to carry out an atmospheric water balance in a vertical column overlying the area of interest. In this method, evapotranspiration is set equal to the sum of precipitation and change in water vapor content of the column, less the net flux of water laterally entering the column. Often hydrodynamic energy mass-balance models are used to estimate evaporation from the surface of lakes and reservoirs.

Soil-water storage

In the field, water content of soils can be profiled as a function of depth with the help of neutron logs or by time-domain reflectometry, both which measure the dielectric capacity of moist soil in situ (International Atomic Energy Agency, 2000). In principle, the change in soil-water storage can be empirically estimated by carrying out repeat measurements with these instruments. However, these methods are of limited value when estimates are to be made over large areas.

The concept of field-water capacity, used widely by soil scientists and agronomists, denotes the quantity of water remaining in a unit volume of an initially wet soil from which water has been allowed to drain by gravity over a day or two, or if the rate of drainage has become negligible. The water that remains is held by the soil entirely by capillary forces. Field capacity depends on soil structure, texture, and organic content and is commonly measured to help in scheduling irrigation. Empirical curves presented by Thornthwaite and Mather (1957) provide correlations among field-water capacity, water retained in soil, and the deficit of precipitation with reference to potential evaporation. These curves can be used to estimate change in soil-water storage.

Groundwater storage

Changes in groundwater storage occur because of two distinct physical processes. At the base of the soil zone, as the water table fluctuates, change in storage occurs through processes of saturation or desaturation of the pores. In this case, change in groundwater storage per unit area is equal to the product of the magnitude of the water-level fluctuation and the specific yield of the formation, a parameter that is approximately equal to porosity. In the case of formations far below the water table, water is taken into storage through slight changes in the porosity, depending on the compressibility of the formations. In this case, change in groundwater storage can be estimated from the product of water-level fluctuation and the storage coefficient of the formations. Typically, changes in soil-water storage and groundwater storage are neglected in developing water budgets for specific areas.

Anthropogenic modifications to water budgets and water balances

Water budgets, at all spatial scales, are determined by the interaction and movement of water between its different components. Today's hydrological cycle is different than the natural-water cycle of thousands or millions of years ago because of the effects of human activity on specific components of the water budget and the movement of water between the components. The ways humans affect water budgets can be classified into three categories: water appropriation, land and environmental disturbance, and indirect consequences.

Water appropriation

People have appropriated water for their own uses throughout history. With the population of the earth now in the billions, withdrawals from surface water and groundwater affect the amount of water in each pool. Water is withdrawn from surface water for drinking-water needs, domestic and public-supply uses, industrial and commercial uses, and most significantly for agricultural uses. The results of these appropriations can be seen in some areas as a reduction of flows in rivers, lower water levels in lakes and reservoirs, and lowering water tables in aquifers. Taking water from one pool affects not only that pool, but also water movements in other parts of the hydrological cycle and water budget. If groundwater is withdrawn from aquifers faster than natural rainfall replenishes them, then groundwater levels fall, sometimes precipitously, as in the central United States (for example, see McGuire, 2017). Because groundwater contributes to flow in nearby rivers, falling groundwater levels can directly reduce streamflow, which can have further repercussions on water availability, water quality, and ecosystems.

Land and environmental disturbance

Another way people have affected water budgets and water balances is by landscape and hydrosphere disturbance. As people changed from their nomadic ways and began to cultivate crops and domesticate animals, agricultural practices began to modify the landscape. Although a single farmer modifying a field for crop planting will not upset the global water balance, billions of people manipulating the landscape over time have altered where water exists on earth and how it moves through the hydrological cycle. Even before industrial-sized machinery was used to modify landscapes, towns and roads were built, and streams and rivers were redirected to serve community needs. This trend continues today at an exponential rate and with large effects on the hydrosphere. The need for water has resulted in damming of rivers to produce reservoirs, which affects all aspects of a regional hydrosphere, from water quantity to water availability to water quality (Collier et al., 2000). The effects of these disturbances have consequences both on surface water and groundwater, which plays a major role in supplying water for the needs of people, especially the agricultural sector. Withdrawing groundwater faster than it can be replenished not only affect water budgets and water balances, but also affects the local area used by people. These effects can even alter the landscape, as is seen by the formation of sinkholes and land subsidence over large areas, such as in California (Poland, 1984).

Indirect consequences

On a global scale, the indirect consequences of human activities on the hydrosphere are perhaps the most significant, but also the most difficult to quantify and understand. These consequences have become increasingly apparent and people have begun to question what effects human activities will have on not only themselves but on all life on earth. These indirect consequences are often slow to develop, but they may take the most time and resources to alleviate. The most obvious causes of worldwide water-budget and water-balance changes are global warming and climate change and variability. People continue to engage in

activities that cause climate change and increased variability in weather, which may potentially lead to extreme changes to many aspects of the hydrosphere (Seneviratne et al., 2012). Climate change is contributing to rising sea levels (Thead, 2016), which affect the global water balance. The increased melting of icecaps and glaciers contribute additional freshwater to the oceans, possibly affecting ocean currents along with ocean ecosystems. Reduction of snow cover directly affects people that rely on consistent annual snowmelts for agriculture and daily water needs. Climate change is affecting weather and precipitation patterns worldwide, resulting in more variability in the occurrence and increased intensity of precipitation (Seneviratne et al., 2012), which in turn affect the hydrologic cycle. Lack of rainfall leading to droughts, and excessive and more intense rainfall leading to floods are having negative effects on the ability to supply food and water, the most basic of human needs. Perhaps the most precarious aspects of climate change are the likely changes in the hydrologic cycle that could affect food production. It is currently unknown how these changes will affect the earth's ecosystems and their ability to support human life.

Although we can quantify how human activities affect water budgets and water balances, it is difficult to interpret these changes and to predict how they will affect human, animal, and plant life in the future. Still, it is important to understand that significant effects have occurred and will continue to occur, possibly at an accelerated rate.

Two examples of water balances

Global water balance and fluxes

For the earth as a whole, precipitation and evapotranspiration (including evaporation from the oceans) are the two most dominant hydrologic fluxes, which on average balance one another. Based on a synthesis of studies by Abbott et al. (2019), precipitation and evapotranspiration for the earth are each about 490,000 km^3/yr; however, an imbalance exists between precipitation and evapotranspiration, if land and the oceans are considered separately. Over land, average annual precipitation is about 111,000 km^3/yr. Of this, evapotranspiration constitutes about 69,000 km^3/yr and runoff and groundwater flow to the oceans constitutes about 41,000 km^3/yr (36,000 km^3/yr from surface and subsurface flows and 5000 km^3/yr from groundwater), indicating a surplus of precipitation in comparison to evapotranspiration. Over the oceans, the average annual precipitation is about 381,000 km^3/yr, while evaporation is about 421,000 km^3/yr. The excess of evaporation over precipitation on the oceans is about equal to the runoff and groundwater flow from the land to the oceans.

Mercer Lake

Typically, water balances for inland waters are constructed over much smaller areas and used to assist in guiding specific management actions. An example of this is a water mass balance constructed for the drainage basin upstream from Mercer Lake, which is a small lake (72 ha) in northern Wisconsin. Because productivity in Mercer Lake is limited by phosphorus, decreasing phosphorus input is expected to reduce phosphorus concentrations in the lake and thus improve its water quality. Almost all phosphorus entering the lake is transported by water inputs; therefore, to quantify phosphorus inputs, it was necessary to first quantify the water inputs (Robertson et al., 2012). The gaged inlet to the lake was the largest source of water to the lake, supplying about 67% of its total input of water. Other sources were groundwater (16.9%, estimated with a groundwater model), precipitation (7.0%, measured at nearby meteorological stations), and the near-lake drainage (9.2%, estimated from nearshore gages). To determine the accuracy of the water inputs, monthly water balances were constructed by quantifying outflows from the lake (gaged stream), groundwater outputs (estimated with a groundwater model), and evaporation from the lake (estimated from nearby evaporation pans). These net inputs were compared with the change in the volume of the lake (change in storage, estimated from a lake morphometric map and measured water levels). Over a 2-year period, the average absolute monthly error was less than 5% of the total measured outflow from the lake. With the fluxes of water and their corresponding phosphorus concentrations for each source, water and phosphorus budgets were constructed for the lake and used to guide where management actions could be taken to reduce phosphorus input to the lake.

Concluding remarks

Modern science has shown that the observed behavior of the hydrological cycle can be understood and explained in terms of the laws of mechanics and thermodynamics. However, the ability of modern science to describe the hydrological cycle in precise detail and to predict the future behavior of its individual components with confidence is severely limited. The limitation arises from the many spatial and temporal scales in which the components interact, the complexity of processes, difficulties of access to observations, and sparsity of data, not to mention the role of living beings that defy quantification. Yet, our goal should be to draw upon our best science to use the world's limited supplies of freshwater wisely and equitably. This goal will be best achieved if we recognize the limitations of science, moderate our social and economic aspirations, and use science to help us adapt to the constraints imposed by the hydrological cycle.

Glossary

See also glossary in Dokulil (2021) Phytoplankton productivity. Bioc(*o*)enosis (ecological community, life assemblage) Interacting organisms living together in a biotope.
Biotope Area that supports its own distinctive community.
Community respiration (CR) Total respiration produced by organisms in a given community.
Ecosystem Complex of living organisms, their physical and chemical? environment, and all their interrelationships in a particular unit of space.
Gross accrual rate Gross biomass changes over time.
Gross primary productivity (GPP) Total amount of energy fixed by photosynthesis.
Habitat Type of natural environment in which a particular species lives. Habitat and biotope are related terms which interact (*biotope* and *habitat* are like *city* and *place of residence*).
Helophyte Any perennial marsh plant overwintering in the mud.
Net accrual rate Net biomass changes over time.
Net primary productivity (NPP) Amount of energy fixed less that respired.
Pleustohelophyte Plant free-floating on the water surface (e.g., *Eichhornia* or *Pistia*).
Standing crop Total above-ground biomass.

Introduction

Inland water bodies are an infinite variety of freshwater and saline lakes, ponds, man-made reservoirs, rivers, streams, swamps, and marshes (Downing, 2010; Downing et al., 2006, 2012). Total production of these lentic and lotic ecosystems comprises many photoautotrophic assemblages which inhabit a variety of habitats. Aquatic systems are conceptually divided into pelagic

☆*Change History:* August 2021. MT Dokulil and K Teubner prepared the update. All sections, figures and tables were updated.

(free-water), profundal (bottom), and littoral (shore) biotopes, as well as aquatic-terrestrial ecotones. Organisms range from microscopic forms, such as planktonic and benthic algae, via macroscopic visible life forms, such as filamentous algae and charophytes, to submersed and emergent macrophytes.

Primary production can be compared:

- between different components within the same freshwater ecosystem.
- between types of freshwater ecosystems.
- between climatic regions.
- in relation to other ecosystem types, such as semi-aquatic or terrestrial ecosystems.

Concepts

Comparison of primary productivity between ecosystems and compartments is based on different varieties of the *aquatic ecosystem concept* (Reynolds, 1997; Minshell et al., 1985) and the *biofilm concept* (Romaní et al., 2016). The river continuum and flood pulse concept are relevant for streams and rivers (Vannote et al., 1980; Junk et al., 1989; Tockner et al., 2000).

Estimation of productivity and production

In principle, the same or a similar terminology as outlined in Phytoplankton productivity (Dokulil, 2021) applies to the organisms considered here. Tracer techniques have been recently augmented by fluorescence methods. Corresponding to the variety of habitats and life forms, many different techniques and methods exist.

Modifications of conventional techniques are used to assess photosynthetic rates of microscopic and macroscopic algal assemblages. Productivity on substrates however is often estimated from algal accumulation as either area-specific (dN/dt, e.g., cells cm^{-2} d^{-1}) or biomass-specific rates (dB/dt, e.g., biomass cm^{-2} d^{-1}). The term *accrual rate* is also used for area-specific accumulation rates. Gross accrual and net accrual rates might be appropriate for biomass changes (biomass cm^{-2} d^{-1}) that do or do not respectively take gains and losses into account. Many procedures are used to estimate benthic algal biomass. Besides cell-counting methods, several inexpensive techniques are used to obtain estimates of biomass such as chlorophyll-a, algal group-specific pigments (marker pigments), dry mass, ash-free dry mass, C, N, or P content of the cells, all expressed usually per cm^2. These different measurements have their advantages and disadvantages. Inter-comparison of data is often difficult due to the multitude of units used.

Production of macroscopic algae and, especially, macrophytes is often deduced from *standing crop* census at times of maximum biomass development. Again, as outlined above, several different estimators of biomass are in use, making comparison of results difficult. Production of higher plants (macrophytes) is usually expressed as dry mass per unit area. It must be emphasized however, that standing crop estimates in macrophytes commonly refer to above ground biomass only, and do not take losses into account or assume them negligible.

Assessments of primary productivity in rivers often use an integrative approach. Total area-specific net production may be calculated for a river segment from diurnal changes in O_2 of the open water (Demars et al., 2015; Grace et al., 2015). Newly developed optodes for CO_2 concentration measurements (Atamanchuk et al., 2014) allow estimation of diel changes in CO_2.

Components of freshwater ecosystems

Benthic algae

Benthos refers to all organisms living on the bottom or associated with substrata. Terms largely synonymous with benthic algae are *Periphyton* and *Aufwuchs*, broad terms that apply to microbiota living on any substratum. *Biofilm* is another synonymous term frequently used in engineering applications. The nature of the habitat in which these organisms are found depends on the habitats present and on the size of the organisms. Macroalgae on substrata are in very different habitats than microalgae on the same substrate type, because they extend further into the surrounding water. However, one common criterion for habitats is the type of substrate:

- *Epipelic* algae live on inorganic or organic sediment. Characteristically, these are large motile diatoms, motile filamentous cyanobacteria, or large motile flagellates.
- *Epipsammic* algae live attached to grains in sandy sediments
- *Epilithic* algae live on hard, relatively inert substrata (gravel, pebble, cobble, stone surfaces).
- *Epiphytic* algae live on plants and larger algae
- *Epizooic* algae live on surfaces of animals.
- *Metaphyton* refers to algae of the photic zone not directly attached to substrata. Usually these are clouds of filamentous green algae.

Table 1 Summary of biomass and carbon fixation rates for algal components in wetlands.

Algal type	*Wetland*	*Chl-a [mg m^{-2}]*	*Dry weight [mg cm^{-2}]*	*C-fixation rate [g m^{-2} year^{-1}]*
Epipelon	Freshwater marsh	0.4–435		<0.1–29
	Salt marsh	20–231		28–341
	Tundra ponds			4–10
Epiphyton	Freshwater marsh	1–650		2–548
	Peat bog	2–238		
Metaphyton	Freshwater marsh		0.5–80	12–1120
	Shallow fish ponds		1–49	
	Peat bog		0–6	
	Cypress swamp		1–3	
Phytoplankton	Freshwater marsh	3–104		1–381
	Cypress swamp		0.34	
	Tundra ponds			0.6–0.9
	Salt marsh			100

Modified from Goldsborough LG and Robinson GC (1996) Pattern in wetlands. In Stevenson RJ, Bothwell ML and Lowe RL (eds.) *Algal Ecology. Freshwater Benthic Ecosystems*. pp. 77–117, San Diego: Academic Press. ISBN 9780080526942, Table II.

For a more detailed categorization of benthic algae refer to Poulíčkova et al. (2008). Attached algal assemblages in freshwaters are dominated by the three divisions (phyla) Cyanobacteria, green algae (Chlorophyta), and diatoms (Bacillariophyta). These attached groups can dominate whole-lake primary production in small oligotrophic lakes and dominate littoral zone primary production in clear lakes of all sizes (Vadeboncoeur and Power, 2017).

As primary producers, algae are fundamental for wetland ecosystems and their food web. Production estimations are summarized in Table 1 for a variety of algal and wetland types. Evidently, highest biomass and carbon fixation rates are attained by all components in freshwater marshlands but vary considerably. In tundra ponds, annual carbon uptake rates of the epipelon can be 10× higher than those of the phytoplankton.

Epipelic assemblages

Maximum photosynthetic rates of periphyton (epipelic microphytobenthic biofilm) ranged from 125 mg C m^{-2} d^{-1} to 425 mg C m^{-2} d^{-1} in the upper epilimnion of five United States lakes. Average littoral zone primary production did not depend on lake size or water column P concentration (Devlin et al., 2016). In an extremely turbid shallow lake, Neusiedler See, Austria, daily epipelic production ranged from 0.4–275 mg C m^{-2} d^{-1} with highest rates in winter under the ice (Khondker and Dokulil, 1988). Observations of epipelic microalgal production in an oxbow lake of the River Danube near Vienna varied from 7.6 to 223.5 mg C m^{-2} d^{-1} (average 107.35 mg C m^{-2} d^{-1}) with higher values in winter (Dokulil and Schiel, 2000).

Liboriussen and Jeppesen (2003) compared epipelic production in two contrasting shallow lakes, one turbid and P-rich, the other clear and low in phosphorus. Total annual production of phytoplankton plus epipelon was 190 g C m^{-2} year^{-1} in the turbid lake, 34% greater than the 141 g C m^{-2} year^{-1} in the clearwater lake. Phytoplankton accounted for 96% of the annual production in the turbid lake. Epipelic microalgal production dominated in the clear lake with 77%. Epiphytic production on reeds was low and did not vary significantly between the two lakes. In contrast to the clearwater lake where epipelon contribution varied little over the year, epipelic algal share to total production was 11–25% in winter but only 0.7–1.7% during summer due to changes in turbidity.

Epilithic and metaphytic assemblages

Epilithic primary production of *Cladophora*-dominated rocky substrata in western Lake Ontario was highest in spring (2.39 mg C g Dry Mass^{-1} h^{-1}), had negative specific photosynthetic rates by early summer (−0.76 mg C g DM^{-1} h^{-1}), and showed regrowth in late summer (1.98 mg C g DM^{-1} h^{-1}). Mean areal net epilithic production at the depth of peak biomass (2 m) was 405 mg C m^{-2} d^{-1}, averaged over the growing season from May to August. Net epilithic production exceeded planktonic primary production (Fig. 1) from the shoreline to the 12 m depth contour (Malkin et al., 2010).

An excellent example of the primary production by metaphytic species was provided for Lake Thingvallavatn, Iceland by Jónsson (1992). GPP, NPP and community respiration (CR) of epilithic *Ulothrix*, *Cladophora* and *Nostoc* communities is indicated in Fig. 2. Maximum production occurred in all cases in July when irradiance and temperatures were high. Annual net production per square meter was calculated as 127 g O_2 year^{-1} at 0.4 m depth, 177 g O_2 at 1 m depth, and 122 g and 82 g at 2 m and 6 m respectively.

Macrophyte (hydrophyte) communities

Investigations on macrophyte biomass and production are numerous. The most productive communities in the world are generally emergent macrophytes which are most common in lentic ecotones. In temperate zones they attain an annual production of 30–45 Mt. ha^{-1}, and in tropical regions 65–85 Mt. ha^{-1}. Submerged plants are less productive (Table 2). Maximum standing crop data for different species and climatic regions are summarized in Table 3 extracted from Kvet and Westlake (1998). Extended information on the structuring role of macrophytes is included in Jeppesen et al. (1998).

Modified from Kvet J and Westlake DF (1998) Primary production in wetlands. In Westlake DF, Kvet J and Szczepanski A (eds.) *The Production Ecology of Wetlands*. Cambridge: University Press, https://doi.org/10.1017/CBO9780511549687.

Pelagic versus benthic production

The increases in water clarity associated with the declines in phytoplankton biomass during oligotrophication in the Laurentian Great Lakes had positive effects on benthic primary production. Phytoplankton production declined by 5–45% from the 1970s to 2000s but was compensated by benthic primary production, which increased by up to 190%. Autotrophic productive capacity of large aquatic ecosystems seems to be relatively resilient to shifts in trophic status, due to a redirection of production to the benthic zone. The autotrophic structure of large lakes can shift like the regime shifts in shallow lakes (Brothers et al., 2016).

The relation of benthic to planktonic primary production explored in 13 hemiboreal lakes indicates that one lake was clearly dominated by benthic production. Autotrophic structure of all other lakes was dominated by phytoplankton production possibly switching to benthic dominance from time to time. The benthic fraction varied from 0.01 to 0.94 in these lakes (Cremona et al., 2016).

The clear-water state in shallow lakes without macrophytes was largely maintained by benthic production, benthic-pelagic coupling and the capacity of periphyton to buffer impacts such as increased P-loading or fish removal as demonstrated by Genkai-Kato et al. (2012). Blanco et al. (2016) refined these findings for shallow lakes in Spain using biomass as an estimator. The response of epiphyton biomass to increasing phosphorus levels was unimodal, phytoplankton developed exponentially and submerged aquatic plant coverage decreased. Phytoplankton began to dominate when TP levels were greater than 30 μg P L^{-1}, a threshold for the turbid state.

Littoral primary production may dominate whole-lake autotrophic production in small lakes (Vesterinen et al., 2016). Periphyton production shifted a humic boreal lake towards net autotrophy with production exceeding destruction processes (Fig. 3). How important littoral production can be for higher trophic levels such as fish has been demonstrated by Vander Zanden et al. (2011) using data from 75 lakes (Fig. 4). Contribution of benthic primary production to total lake production varied between 0.1 and 1.0 with an average of 0.36 ± 0.24 in these 75 lakes (Fig. 4A). The contribution of benthic carbon to fish body carbon was higher than expected in most of the lakes (Fig. 4B).

Photophysiology of communities

There is considerable variation in the photosynthesis-irradiance relationship measured for benthic algae from wetlands (Table 4). Differences reflect the physiological state of organisms collected from diverse habitats but may also reflect differences in analytical methodology. Part of the variability in epiphytic assemblages with discrete three-dimensional physiognomy can be attributed to accumulated biomass because photosynthetic efficiency and biomass estimated as chlorophyll-a are inversely related (Fig. 5, Goldsborough and Robinson, 1996). Based on the few studies conducted, generalizations on the photosynthetic behavior of various algal assemblages are difficult to make since ranges of all three parameters are wide. Maximum chlorophyll-specific carbon

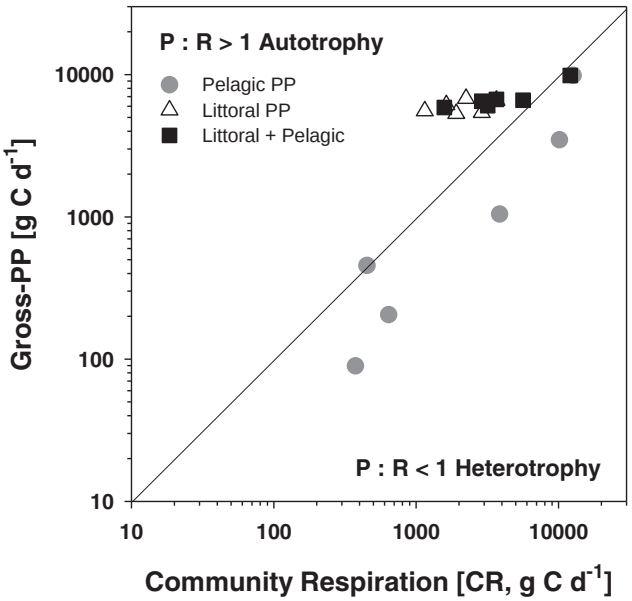

Fig. 3 Comparison of whole-lake gross primary production (GPP) and community respiration (CR) from pelagic and littoral habitats, both separately and in combination on a log-log scale. The line represents a GPP:CR ratio of 1. Data from a Finnish boreal lake modified from Vesterinen J, Devlin S, Syväranta J and Jones R (2016) Accounting for littoral primary production by periphyton shifts a highly humic boreal lake towards net autotrophy. *Freshwater Biology* 61(3): 265–276. doi: https://doi.org/10.1111/fwb.12700, Fig. 5.

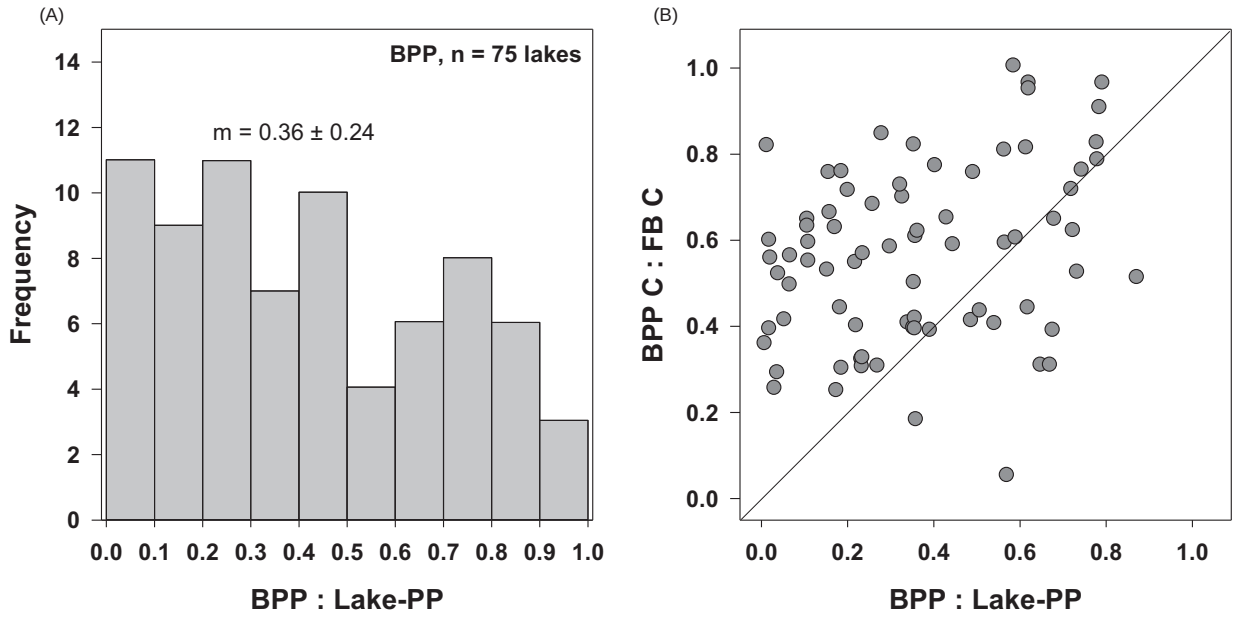

Fig. 4 Frequency of benthic algal contribution (BPP) to whole-lake primary production (Lake-PP) in (A). Benthic algal contribution (BPP) to whole-lake primary production (Lake-PP) related to mean benthic carbon contribution (BPP C) to fish body carbon (FB C) in (B). Data from 75 North American lakes. Modified from Vander Zanden MJ, Vadeboncoeur Y and Chandra S (2011) Fish reliance on littoral–benthic resources and the distribution of primary production in lakes. *Ecosystems* 14: 894–903. https://doi.org/10.1007/s10021-011-9454-6.

Table 4 Ranges of parameters derived from photosynthesis-irradiance curves (PE curves) for wetland algae.

Algal type	α [μg C μg Chl-a^{-1} h^{-1} (μE m^{-2} s^{-1})$^{-1}$]	E_K [μE m^{-2} s^{-1}]	P^*_{max} [μg C μg Chl-a^{-1} h^{-1}]
Epipelon	0.002–0.006	237–834	0.8–4
Epiphyton	0.008–0.016	198–659	0.5–21
Metaphyton	0.003–0.007	36–400	0.2–2
Phytoplankton	0.025–0.092	235–446	2–79

Examples of PE curves are in Fig. 6.

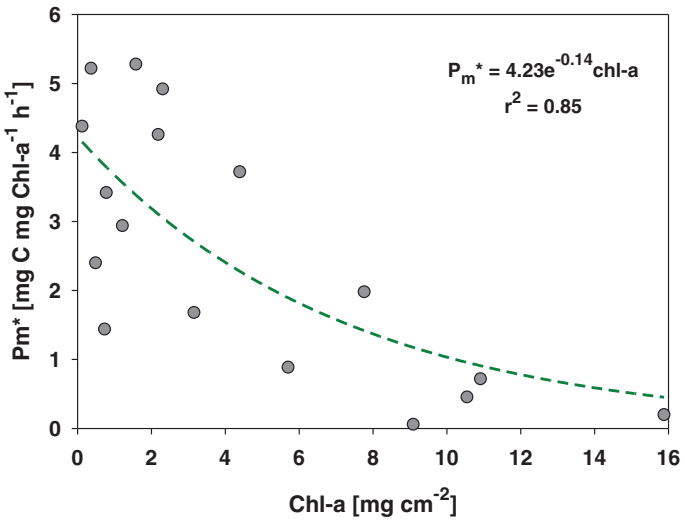

Fig. 5 Relationship between maximum chlorophyll-specific photosynthetic carbon uptake and biomass as chlorophyll-a of epiphytic algae. Modified from Goldsborough LG and Robinson GC (1996) Pattern in wetlands. In Stevenson RJ, Bothwell ML and Lowe RL (eds.) *Algal Ecology. Freshwater Benthic Ecosystems.* pp. 77–117, San Diego: Academic Press. ISBN 9780080526942, Fig. 1.

uptake of the metaphyton however, is comparatively small and light saturation (E_K) occurs at low light intensities. In turbid waters and under a macrophyte canopy irradiance can fall well below E_K (e.g., <5 μmol photons m^{-2} s^{-1} below a dense mat of *L. minor*). Evidence of photoinhibition in surface waters has been reported from only a few investigations.

Although many benthic habitats are characterized by extremely low light levels, shade acclimation is little documented in freshwater benthic algae. It is, however, a common response of phytoplankton and macrophytes in habitats characterized by low ambient irradiances. It is usually manifest in increased photosynthetic efficiency at low irradiances (increased α), lower photosynthetic rates at saturating irradiances (lower P_{max}), and decreased saturation parameters (E_K or E_{max}) as shown in Dokulil (2021, Fig. 1).. These functional changes typically reflect increased quantities of antenna pigments and decreased quantities of dark reaction enzymes. Shade acclimation theoretically buffers the photosynthesis-limiting effects of low irradiances. If respiratory losses are not too high, it will have a positive effect for production. One of the best documented shade acclimations by benthic algae originates from a study on a stream (Hill, 1996)—see below and Fig. 6. A comparison of P_{max} and α for epilithic algae and phytoplankton in Lake Huron indicate lower P_{max} values but higher α values for epilithic algae. These differences may be related to light adaptation and the lower in situ light levels found for epilithic algae (Fahnenstiel et al., 2003).

Freshwater ecosystems

The pelagic zone is reviewed in Dokulil (2021) Phytoplankton productivity.

Rivers

Organic carbon in rivers is either autochthonous or allochthonous. Autochthonous carbon derives from primary production within the river itself, while allochthonous carbon is based on decomposed products of terrestrial origin.

An inter-biome comparison of first to third order streams in North America (Mulholland et al., 2001) using open-water diurnal oxygen changes revealed three general patterns of whole ecosystem production:

(1) high gross primary production (GPP) with positive net ecosystem production (NEP)
(2) moderate GPP during daylight but negative NEP at all times.
(3) little or no GPP during daylight and negative NEP over the entire day.

In these streams, GPP ranged from <0.1–15 g O_2 m^{-2} d^{-1}. Variation of respiration was substantially lower, ranging from 2.4 to 11 g O_2 m^{-2} d^{-1}. The NEP was negative for all streams except one. Most of the streams were strongly heterotrophic with P:R ratios <0.25.

Photosynthetic active radiation (PAR) and soluble reactive phosphorus (SRP) explained 90% of the variation in GPP while NEP was correlated only with PAR ($r^2 = 0.53$). The rate of ecosystem respiration was poorly correlated with GPP, but SRP and the size of the transient storage zone explained 73% of the variation. In essence, stream metabolism is controlled by light, nutrient limitation and channel hydraulics across large geographic areas.

Rivers and streams often provide a mosaic of open sites exposed to full irradiance and sites shaded by patches of e.g., trees and bushes. Stream benthic algae have to cope and acclimate to such situations. An example of shade acclimation in stream benthic

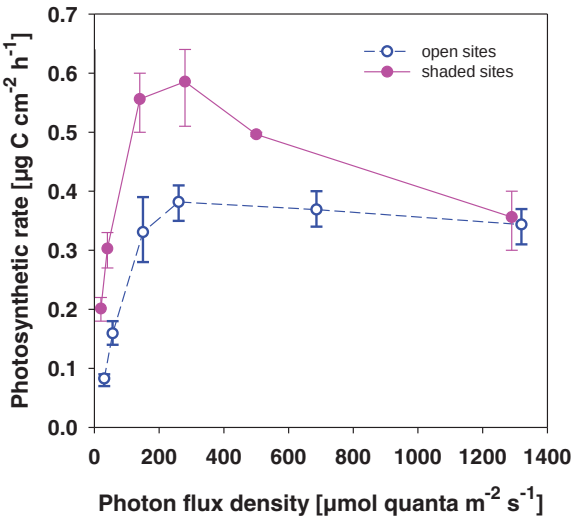

Fig. 6 Photosynthesis—irradiance (PE) response by stream periphyton at open sites and at sites shaded by vegetation. Data from North American streams. Modified from Hill W (1996) Effects of light. In Stevenson RJ, Bothwell ML and Lowe RL (eds.) *Algal Ecology. Freshwater Benthic Ecosystems.* pp. 121–148, San Diego: Academic Press. ISBN 9780080526942, Fig. 2.

algae is shown as photosynthesis–light energy (PE) curves in Fig. 6. At low light intensities, photosynthesis from the shaded sites (average light intensity 50 μmol m^{-2} s^{-1}) was twice that from the open sites (average intensity 1100 μmol m^{-2} s^{-1}). In these laboratory experiments, efficiency α is two times higher in the shaded assemblages. Shade acclimated communities saturate at lower intensities, have the highest P_{max}, and show clear evidence of photoinhibition not indicated in the results from the open site. Üveges and Padisák (2012) demonstrated that epilithic stream production strongly depends on canopy presence or absence. In an African watershed around Lake Tanganyika, stream productivity by benthic algae increase in regions of anthropogenic disturbance, mainly deforestation.

Temperature appears to be of secondary importance in determining seasonal changes in primary productivity of epilithon in streams. Little changes in net primary production are documented when temperature increases, suggesting that respiration increases at the same rate. Temperature however may interact with changes of other factors. The degree of photoinhibition can for instance be inversely correlated with water temperature. Temperature certainly sets an upper limit to areal primary productivity. As can be seen from Fig. 7 (DeNicola, 1996), maximum areal net primary productivity not corrected for biomass increases exponentially for temperatures <30 °C. The Q_{10} value (the relative increase associated with a temperature increase of 10 °C) for the regression in Fig. 7 is 2.9, like relations obtained for phytoplankton growth rates.

Algal biomass is used as an indicator of primary productivity in Table 5 to characterize different stream quality. Chalk streams and hypertrophic streams attain highest biomass and chlorophyll-a concentrations whereas acidic soft water streams are among the most unproductive (Hall et al., 2007; Janauer and Dokulil, 2006).

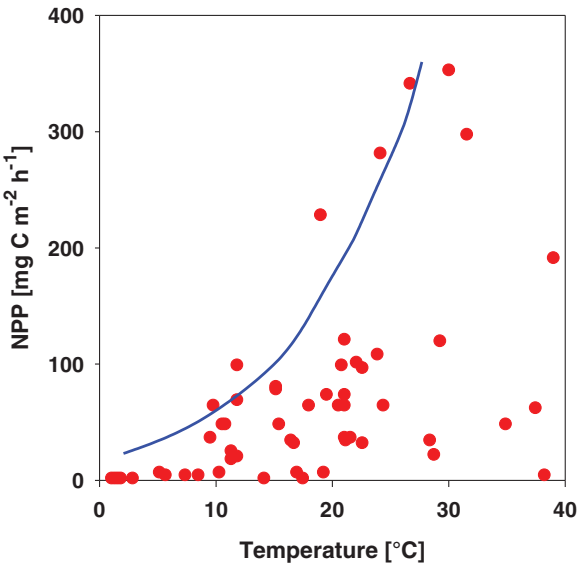

Fig. 7 Relation of areal net primary production in lotic epilithon assemblages with temperature. Curve determined by regression of maximum rates versus temperature, $r = 0.96$. River type	*NO_3-N mg L^{-1}*	*PO_3-P mg L^{-1}*	*Biomass range minimum g m^{-2}*	*Chl-a maximum mg m^{-2}*
Soft water pH 4–5	0.06–0.35	<1	26	92
Soft water pH 6–7	0.5	1–2	40	178
Headwater chalk stream	4–5	10–30	50	200
Chalk stream	4–5	30–50	15–25	150–300
Hyper-eutrophic stream	5–15	1000–3000	25–50	150–250

River type	*PP mean g C m^{-2} d^{-1}*	*PP range g C m^{-2} d^{-1}*
Small stream—forested	0.2	0–0.7
Open-canopy streams	0.5	0.08–1.3
Spring/desert streams	4.1	1.5–7.4

In general, attached algal and cyanobacterial productivity and biomass development is moderate in mid-order streams (3–5) and in backwater areas but low in light-restricted, canopied or high-velocity portions of low-order streams and in more turbid large rivers. In the highly dynamic large rivers of the tropics, such as the Amazon and Paraná river ecosystems, productivity of different vegetation components becomes much more complicated.

Littoral of lakes

Although the productivity in the littoral of lakes is relatively high, their contribution to the overall lake production largely depends on the morphometry of the system. The pelagic/littoral ratio (P/L) permits an estimate of the importance of the littoral in relation to the pelagic zone. Since most of the lakes of the world are small, their P/L ratios are low. On a global basis, the littoral zone is clearly dominant over the pelagic among most standing-water and river ecosystems. Addition of wetland components results in low P/L ratios for nearly all inland water ecosystems.

Emergent plants are the most productive macrophytes in the littoral (Table 6). Floating leaved plants are intermediate and submersed macrophytes are the least productive macrophytes among the higher plants in the littoral. In oligotrophic lakes, the algal class of the Charophytes (stoneworts) often is more productive than the submersed vegetation. Littoral productivity increases 3–5 times when lakes become eutrophic. Since macrophyte biomass in the littoral is high and turnover slow (P/B <1) nutrients are less readily available in the littoral region. Macrophyte beds buffer the pelagic zone. In general, the littoral is more defined by biomass than turnover.

Effects of temperature on the productivity of lenthic periphyton indicate an increase with temperature mainly due to increased biomass since assimilation efficiency is usually lower at heated sites.

Reservoirs

Reservoirs range from small ponds to huge impoundments. Classification is mainly based on morphological and hydrological features. One important criterion is retention time reaching from through-flow (e.g., river-run dams) to very long residence times (e.g., storage reservoirs).

On a large scale, lakes and reservoirs are distinctly different in behavior and operation. At the small spatial and temporal scales at which algae operate they are generally similar in both habitats. Broadly, the same type of algae occurs. Responses to fluctuations in resource availability and the severity of processing constraints are similar in both types of waters (Naselli-Flores, 2013). The development of biomass and the rate of productivity is therefore like those commonly observed in lakes. Elongated or highly dendritic reservoirs, however, develop longitudinal gradients as a result of variable input from the tributaries, retention time and sedimentation of particles. Moreover, clay and other suspended solids can reduce under-water light availability to an extent that primary production is suppressed through light limitation even in reservoirs with high nutrient load. For example, the high average volume-based production of the south arm of the Barra Bonito Reservoir, Brazil is constrained to a shallow photic zone by the high clay load. The water column in the north arm with adequate nutrients and less clay-turbidity produces almost twice as much. Even the lacustrine region with less nutrients and low clay turbidity produces more than the nutrient rich but clay-loaded south arm (Oliveira, 1997).

Canyon shaped reservoirs develop distinct longitudinal gradients (Fig. 8). Chlorophyll-a concentration, low near the inflow, increases rapidly further down the reservoir. Plankton production is also low near the river mouth, reaching maximum values in the middle section of the reservoir declining thereafter towards the dam region (Rychtecký and Znachor, 2011).

The high and variable turbidity and the water-level fluctuations in many reservoirs preclude the development of moderately stable and diverse substrate habitats. Limited habitat, substrata, and light therefore often restrict development and productivity of attached algae. Turbidity, basin shape and retention time are the key variables controlling phytoplankton primary production in reservoirs.

Table 6 Annual net primary productivity in the littoral of lakes modified and combined from Wetzel RG (2001) Limnology. In: *Lake and River Ecosystems*. 3rd edn, San Diego: Academic Press. ISBN: 9780080574394, several Tables.

Type	*Climatic region or Trophic level*	*NPP g C m^{-2} $year^{-1}$*

	Eutrophic	~1000

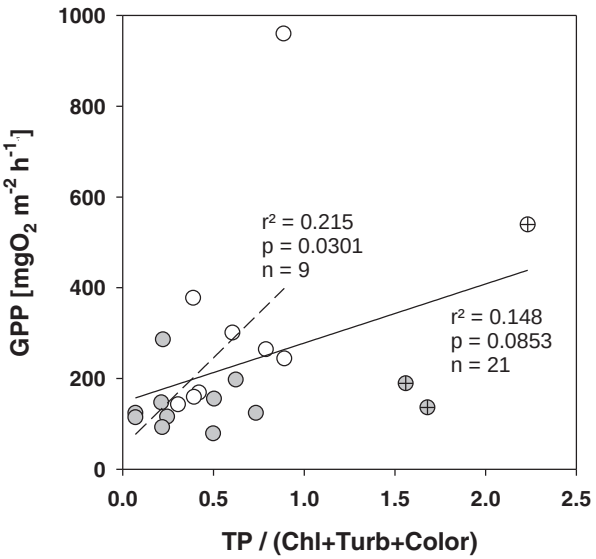

Fig. 8 The relationship of mean epilithic gross primary production (GPP) and a ratio of total-P (TP) to an index of water clarity (phytoplankton chlorophyll-a (Chl) + turbidity (TURB) + watercolor) in 21 lakes. Open circles represent lakes in limestone regions, closed circles are lakes in non-limestone basins. Regression lines are shown for all data and if hypereutrophic lakes are removed (⊕) from regression (———). Modified from DeNicola DM, de Eyto E, Wemaere A and Irvine K (2003) Production and respiration of epilithic algal communities in Irish lakes of different trophic status. *Archiv Hydrobiologie* 157: 67–87. https://doi.org/10.1127/0003-9136/2003/0157-0067, Fig. 5C.

Estimation of total lake production

Estimations of all components of lake primary production allowing calculation of production for the whole lake are not common. Two examples are given from Löffler (1979) and Nõges et al. (2010) in Table 7. Average total carbon uptake amounts to 3310 mg C per square meter and day in the shallow Neusiedler See, Austria bordering Hungary. With 83%, reed (*P. australis*) is the largest contributor, followed by *Utricularia* and phytoplankton (7% each). All other components are of minor importance. In Lakes Peipsi

Table 7 Estimation of total lake production from measurements of individual components Three examples from Austria and Estonia.

Neusiedlersee, Austria Component	*Annual Average [mg C m^{-2} d^{-1}]*	*%*
Phytoplankton (pelagial, open lake)	235	7.10
Phytoplankton (littoral, within reed belt)	20	0.60
Epiphytic algae (on *Phragmites*)	11.6	0.35
Epipelic algae (on the sediment surface)	50	1.52
Submersed macrophytes	12	0.36
Pleustophytes (*Utricularia* spp.)	242	7.32
Helophytes (*P. australis*)	2740	82.75

Phytoplankton	5.04	41.9
Epiphytes	0.01	0.10
Macrophytes	6.97	58.00
Total	12.02	

Comment to Neusiedlersee: 1.3 m mean depth, area ~320 km^2 (about 60% covered by a *Phragmites* reed belt).
Extracted from several authors in Löffler H (ed.) (1979) *Neusiedlersee: The Limnology of a Shallow Lake in Central Europe*. The Hague: Dr. W. Junk Publisher. 10.1007/978-94-009-9168-2; Nõges T, Luup H and Feldmann T (2010) Primary production of aquatic macrophytes and their epiphytes in two shallow lakes (Peipsi and Võrtsjärv) in Estonia. *Aquatic Ecology* 44(1): 83–92. https://doi.org/10.1007/s10452-009-9249-4.

and Võrtsärv, Estonia, macrophytes dominate littoral primary production in both lakes (*P. perfoliatus* in Lake Peipsi and *P. perfoliatus* and *Myriophyllum spicatum* in Lake Võrtsärv) (Table 7). Vadeboncoeur and Steinman (2002), (Table 4) proved that periphyton can contribute between 1% and 92% of whole-lake primary productivity in a range of lakes world-wide, depending on surface area, mean depth, trophic state and phosphorus gradient (Vadeboncoeur et al., 2003, 2008).

In the littoral zone of Lake Mikolajskie, Poland, attached algae contributed 41% to annual primary production per m^2, submersed macrophytes 28%, metaphyton 21%, and phytoplankton 10%. In a littoral zone overgrown with emergent vegetation, the contribution was almost twice as high from macrophytes (57%) and phytoplankton (20%), the share from attached algae decreased to 23% and metaphyton dropped to a negligible amount of only 0.1% (Pieczyńska, 1970).

Production of attached algae is usually higher in eutrophic shallow lakes when compared to oligotrophic deep lakes. Average annual production of epiphytic algae in Priddy Pool, a shallow lake in England, was estimated to 63.9 mg C m^{-2} h^{-1} which is 95% of the total amount (67.2 mg C m^{-2} h^{-1}). The remaining 3.3 mg C m^{-2} h^{-1} are almost equally shared by epipelic algae and phytoplankton. In contrast, attached algae contributed 28%, epipelic algae 29% and phytoplankton 42% to the average total production of 12.6 mg C m^{-2} h^{-1} in the deep oligotrophic Lake Pääjärvi in Finland. Total production in eutrophic lakes is much higher (in this case five times) and shifted towards attached algae (Wetzel, 2001, Table 19–11).

Benthic algal production in a gradient of lake size proved to be a function of light saturated photosynthesis (BP_{max}) and light availability (Vadeboncoeur et al., 2008). The maximum possible contribution of benthic algae to total lake production was largely determined by the depth ratio (DR $\hat{z}/z_{max}$) and light attenuation while light quality has no significant effect. In addition, periphyton productivity is a function of total phosphorus concentration ($BP_{max} = 28.1 * TP + 0.24$). Similarly, epipsammic algal production contributed 75–95% to total production at 0.5 m depth but decreased to less than 15% below 3 m in a shallow lake (Üveges et al., 2011). Estimates of net production for shallow epilithic algal communities in 21 lakes of different depth and trophic status in Ireland range from 51 to 958 mg O_2 m^{-2} h^{-1} (circa 16–319 mg C m^{-2} h^{-1}). Although overall GPP did not significantly depend on chl-a, lakes in limestone areas differed from those in non-limestone areas (Fig. 9). Alkalinity and turbidity significantly explained GPP and NPP while colour and turbidity were related to respiration (DeNicola et al., 2003).

Besides all these environmental constraints, water-level changes can severely affect total lake production through effects on the littoral vegetation as exemplified in Table 8 using data from a wetland on the shores of Lake Manitoba. Epiphytic and particularly metaphytic algae totally dominated the littoral algal productivity. Production rates declined markedly as mean water level raised by half a meter.

It is difficult to generalize the quantitative contribution of the types of algal assemblages to gross primary production in wetlands. Few studies have been sufficiently inclusive to measure all potential producers. In constructed wetlands in Illinois, United States, epiphytes contributed 1–65% to total primary production. Annual primary production by epipelon was estimated to be 4–10 g C m^{-2} $year^{-1}$, as compared to 1 g C m^{-2} $year^{-1}$ for phytoplankton and >15 g C m^{-2} $year^{-1}$ for the emergent macrophyte *C. aquatilis* in an Alaskan tundra pond (Miller, 2013). In a dystrophic wetland of South Carolina, contribution by littoral algae, including all possible types, was estimated to over one-third of net primary production, whereas macrophytes made up the remainder (Schalles and Shure, 1989). In a shallow clear-water lake, micro-phytobenthos contributed more than 70% (5.4 g C m^{-2} $year^{-1}$) to total production on an aerial basis while phytoplankton contributed less than 30% (2.2 g C m^{-2} $year^{-1}$) as stated in Goldsborough and Robinson (1996).

Climatic regions

There is no obvious correlation between standing crop data for species of wetland vegetation and climate (Table 3). High standing crop of around 4 kg m^{-2} are found from tropical to boreal regions. Values below 0.2 kg m^{-2} are equally widespread. Obviously, biomass development of emergent vegetation in wetlands is generally affected by local factors such as species composition, micro-climate, soil and grazing more than by climate.

Summarized across larger climatic regions however, large differences in the production of organic matter appear (Table 9). Production of submersed macrophytes triples on average in the tropics while production from emergent vegetation doubles compared to temperate regions.

In an early analysis based on data collected during the world-wide International Biological Program (IBP), latitude and altitude alone explained 49% of the variance of phytoplankton production; chlorophyll, as a substitute for biomass, and latitude explained 79%. Thus it appears that the geographical position on the globe and biomass are largely responsible for the productivity of freshwater ecosystems. Moreover, biomass and productivity reflect the nutrient levels of freshwater systems. Both are therefore dependent on the trophic level.

Comparison to other ecosystems

The best current estimate of global net primary production (NPP) is 104.9×10^{15} g of C $year^{-1}$ (104.9 Pg C y^{-1}) which is about 200×10^{9} tons dry weight per year, assuming 50% carbon in dry weight. The oceans contribute 46%, while production on land, including freshwaters, contributes 54%. A more detailed break-down of NPP for various ecosystem types is presented based on Lieth (1975) and Roehm (2005) in Table 10. All freshwater systems, lakes, streams, swamps and marshes contribute 3.9% to total continental NPP, and about 2.5% to total global NPP. Almost half of NPP on land is produced by tropical forests, while tundra, alpine and desert ecosystems together contribute only 2.4%. Cultivated land produces about 8% of NPP on land. However, per unit area, the range of wetland production is equal or higher than the production of cultivated plants or forests (see Table 2).

A clear latitudinal gradient of increasing productivity from boreal through temperate to tropical conditions has been established for lakes by Field et al. (1998). Similar trends are observed in grassland, tundra, and cultivated crops. Global NPP peaks on either side of the equator with a wide shoulder of higher productivity between 30 degrees and 60 degrees north, and a smaller peak between 30 degrees and 45 degrees south (Fig. 10).

Table 9 Annual primary production of aquatic communities.

Type of ecosystem	*Average net organic dry production [Mt ha^{-1} yr^{-1}]*	*Range of production [Mt ha^{-1} yr^{-1}]*

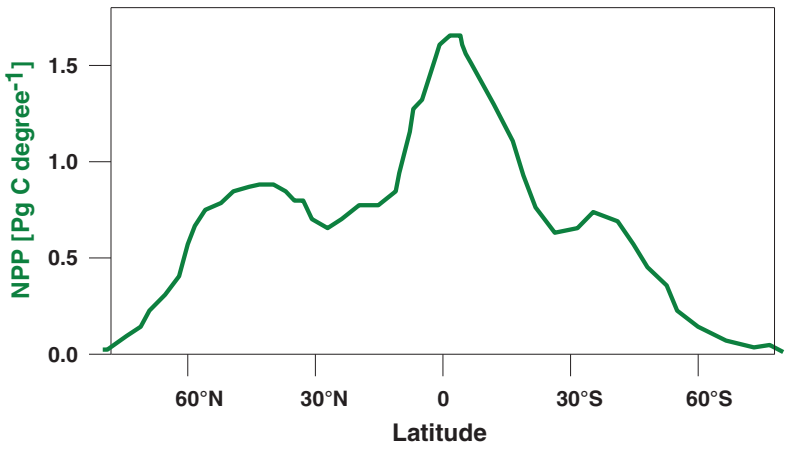

Fig. 10 Latitudinal distribution of the global net primary production. Modified from Field CB, Behrenfeld MJ, Randerson JT and Falkowski P (1998) Primary production of the biosphere: Integrating terrestrial and oceanic components. *Science* 281: 237–240. https://doi.org/10.1126/science.281.5374.237.

Average values of productivity are broadly related to biomass for the ecosystem types in Table 10. For a given NPP value however, biomass varies widely. Thus production-biomass (P/B) ratios (e.g., kg produced per year per kg biomass) are 17 for aquatic communities, 1–2 for helophytes, 0.29 for terrestrial systems, and 0.042 for forests. Differences are mainly due to size of the producers, as smaller organisms such as algae have much higher turnover rates and produce more per unit biomass. In contrast, forests are slow growing and accumulate large portions of biomass in supporting tissue or dead material.

More productivity data from various ecosystems as well as global production can be found in Dokulil (2019) and Dokulil and Qian (2021).

Conclusions

Comparative primary productivity of autotrophic freshwater organisms was attempted for different habitats, biotopes and ecosystems. Results indicate that contribution of distinct communities (biocenoses) to overall production vary greatly depending on the type and size of the ecosystem, the trophic status and the relative importance of the littoral or benthic zone. Although knowledge of various assemblages has generally advanced, several questions remain including the coupling between benthic and pelagic production, the relative importance of different primary producers along morphometric and productivity gradients, the importance of littoral vegetation to overall primary production, and how primary producers will be affected by climate change.

Knowledge gaps

- The function of various freshwater assemblages across a spectrum of ecosystems varying in morphometry and trophic conditions.
- Evaluation of further details of benthic-pelagic interactions.
- Contribution and importance of organisms and communities to food web structure.
- Importance of littoral vegetation, both micro- and macrophytes, for the overall production of freshwater ecosystem types.
- Significance of components in freshwater ecosystem during progressive climatic change.

Physical Properties of Water☆

KM Stewart and JF Atkinson, State University of New York at Buffalo, Buffalo, NY, United States

This is an update of K.M. Stewart, Physical Properties of Water, in Encyclopedia of Inland Waters, edited by Gene Likens Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00007-7
This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor, Lars Rudstam.

Glossary

Buoyancy Net gravitational force acting on a submerged object.
Colligative properties Properties that change when a solute is added to water.
Compressibility Tendency for a substance to change volume due to an applied pressure.
Density Amount of mass of a substance contained in a unit volume.
Heat capacity Energy required to raise 1 g of a material 1 °C.
Heat of fusion (melting) Heat released (added) for a phase change between solid and liquid.
Heat of vaporization (evaporation) Heat released (added) for a phase change between liquid and gas.
Surface tension Tensile or "pulling" force per unit length of a line on the interface between two materials that do not intermix (i.e., at an air/water interface or at a boundary between a liquid and a solid).
Viscosity A measure of the internal friction or resistance exerted on one substance (gas, liquid, or solid) as that substance tries to flow or move through the same or another liquid; defined in terms of the relationship between shear stress and rate of strain.

Introduction

Water is an indispensable and remarkable substance that makes all forms of life possible. Speculation about possible past or present life on other planets within our solar system, or on any extraterrestrial body somewhere within the universe, is conditioned on the evidence for or against the existence of past or present water or ice. Humans can and did survive and evolve without petroleum products (gas and oil), but cannot survive without water. Water is the most important natural resource on Earth.

Liquid water can be formed through hydrogen bonding and electrostatic attraction of two slightly positively charged atoms of the gaseous hydrogen (H) and one slightly negatively charged atom of the gaseous oxygen (O) to form one molecule of water (H_2O). Fig. 1 provides two views of that polar molecule. Figs. 1A and B show the somewhat lopsided or asymmetrical arrangement of two smaller hydrogen atoms, separated by an angle of approximately 105°, and a larger oxygen atom. Fig. 1A is a simple 'ball and spoke' representation and Fig. 1B shows the shared electron orbits, positive (+) and negative (−) poles, and the number (eight each) of protons and neutrons in the nucleus of the oxygen atom.

The relative elemental simplicity of water is somewhat deceptive because of the great influence that some of the unusual properties of water have on the physics, chemistry, and biology of the world generally, and on the distribution of life specifically. The following discussion describes briefly some of these unusual properties and provides examples of how these properties may help us understand the world of inland waters. For more information on the chemical properties of water, see Aldstadt et al. (2021) in Further Reading.

☆*Change History*: October 2021. JF Atkinson updated the text and added several components, primarily in the density, viscosity, pressure, and isotope sections. Minor changes were made throughout text.

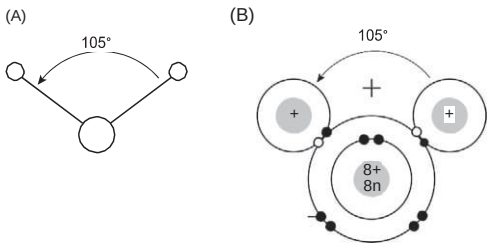

Fig. 1 Two schematic representations (A) and (B) of a water molecule. Modified from various sources.

Density and specific weight

Density may be defined simply as the amount of weight or mass contained in a specific volume. Typically, density is more often reported in units of mass per unit volume, while weight is the force of gravity acting on that mass. The nominal density of water at 4 °C is 1000 kg m^{-3} or 1 g cm^{-3}. Table 1 lists a few comparative densities (rounded to two decimal places) of two liquids (water and mercury) and several selected solids. The specific weight is found as the product of density and gravitational acceleration, i.e., $\gamma = \rho g$, where γ is the specific weight, ρ is density, and g is gravitational acceleration. The nominal specific weight of water is 9810 N m^{-3} (Newtons per cubic meter). Note that a mass of 1 g is equivalent to a weight of 9.8 N on Earth.

Density differences in inland waters may be caused by variations in the concentrations of dissolved salts, by changes in the water temperature, and by changes in pressure. However, the impact of pressure is small and generally ignored. Compressibility is a measure of the relative change in volume in response to an applied change in pressure. It is usually expressed in terms of a coefficient of compressibility, K, defined as

$$K = -\frac{1}{V}\frac{dV}{dp} = \frac{1}{\rho}\frac{d\rho}{dp} \tag{1}$$

where V is volume and dV is a change in volume resulting from a change in pressure dp. The negative sign accounts for the fact that V decreases under higher pressure, so that K is reported as a positive quantity. The second part of Eq. (1) is an alternative representation for K in terms of density. Since density changes inversely to volume, this expression does not have a negative sign. For water at 0 °C, K has a value of about 5×10^{-10} Pa^{-1}. Even at a depth of 2000 m (deeper than any inland water body), the relative change in density (or volume) is just under 1%. All liquids can be safely considered to be incompressible, that is, their volume or density does not change with applied pressure, but water is especially so. For a truly incompressible fluid, $K = 0$.

Fixed or uniform additions of salts tend to cause linear increases in the density of water. In contrast, fixed or uniform changes in the temperature (both below and above 4 °C) cause nonlinear changes in the density of water (see Table 2). The density of pure water is maximum at a temperature of 4 °C (3.98 °C to be precise). It is at this temperature that the interatomic and intermolecular motions and intermolecular distances of water molecules are least. One consequence of this reduction is that more molecules of H_2O can fit into a fixed space at 4 °C than at any other temperature. This compaction allows the most mass per unit volume and thus the greatest density. If salt is added, the temperature of maximum density drops slightly. It is especially noteworthy that the temperature at which water has the maximum density is above its freezing point. In fact, it is this property that allows life as we know it to exist in lakes. Imagine what would happen if water reached its maximum density just at the point where ice forms. In regions where ice forms in winter, it would sink and form a perpetual layer at the bottom, unless enough thermal energy was able

Table 1 Some comparative densities of water and other substances or elements.

Substance	*Density (g cm^{-3})*
Wood	
Seasoned balsa	0.11–0.14
Seasoned maple	0.62–0.75
Seasoned ebony	1.11–1.33
Water	1.00
Calcium	1.55
Aluminum	2.70
Iron	7.87
Lead	11.34
Mercury	13.55
Uranium	18.95
Platinum	21.5

Information from multiple sources.

Table 2 Comparative densities of average ocean water (salinity nominally 3.5% by weight, or 35 parts per thousand), freshwater ice, and pure distilled water at different temperatures.

Temperature (° C)	*Density (g cm^{-3})*
20	1.02760, ocean water (salinity 3.5%)
0.0	0.9168, freshwater (ice)
0.0	0.99987, pure water (from here on)
2.0	0.99997
3.98–4.00	1.00000
6.0	0.99997
8.0	0.99988
10.0	0.99973
12.0	0.99952
14.0	0.99927
16.0	0.99897
18.0	0.99862
20.0	0.99823
22.0	0.99780
24.0	0.99733
26.0	0.99681
28.0	0.99626
30.0	0.99568
32.0	0.99505

Values from Hutchinson (1957), Pinet (1992), and Weast and Astle (1979).

to reach the bottom to cause melting. Entire lakes and ponds could be completely frozen, thus eliminating habitat for aqueous biota. Our own ability to use water from lakes in cold regions would be severely compromised.

The primary reason we are interested in density is because mixing processes that control the fate and distribution of chemical and biological species are largely dependent on density stratification (the tendency for water layers of decreasing density to stack up on top of layers with higher density) and its resistance to wind induced mixing. For the vast majority of inland lakes, only vertical differences in salt concentrations and temperatures are of significant influence for mixing processes. Because the differences in densities, within a few degrees above and below 4 °C, are very slight, it takes relatively little wind energy to induce substantial vertical mixing when water temperatures are within those ranges. An example period, for those lakes that become covered with ice in the winter, would be shortly before an ice cover develops and shortly after the ice cover departs. Because energy is required to work against gravity forces, it takes much more energy to cause extensive mixing when density differences are high, such as is common between the usually warm upper waters and colder lower waters of temperate zone lakes during summer. The greater the top-to-bottom differences in temperature, the greater the top-to-bottom differences in density and, consequently, the greater is the energy required for wind-induced mixing.

There is an old, but still valid, cliché in the northern hemisphere that '... it is cold up north and warm down south.' Water temperatures in more northerly temperate zone lakes tend to average cooler than those of more southerly tropical lakes. Interestingly, although the upper-water summer temperatures in tropical lakes are somewhat higher than those of temperate lakes, the lower-water temperatures in tropical lakes are substantially higher than those ordinarily found in the lower waters of temperate zone lakes. It might therefore seem that there would be a relatively easy top-to-bottom mixing of the water in tropical lakes. Indeed, some shallow tropical lakes, with only slight top-to-bottom temperature differences, may experience this situation. However, because of the nonlinear increases in water density with temperature, tropical lakes can be surprisingly stable and resistant to much vertical mixing. Table 2 provides a listing of some comparative densities. Let us consider two hypothetical lakes with just a 2 °C spread between their lower and upper waters. For example, if a temperate zone lake in the spring, not long after the ice departed, had lower and upper waters of 4.0 °C and 6.0 °C, respectively, the density difference would be 1.00000–0.99997 = 0.00003 g cm^{-3}. In contrast, a warmer tropical lake whose lower and upper water temperatures may be 26.0 °C and 28.0 °C, respectively (i.e., with the same temperature difference), would have density differences that are much greater (0.99681–0.99626 = 0.00055 g cm^{-3}). Thus, the top-to-bottom ratio or density difference in these two lakes with a temperature difference of just 2 °C would be 55/3 or ~18 times greater in the tropical lake than in the temperate lake. This example is only hypothetical, but it shows the nonlinear influence of density changes with temperature, a property of water that influences the stratification and mixing of lakes around the world.

Pressure

Pressure p can be divided into hydrostatic pressure and dynamic pressure. Dynamic pressure is due to water movement and its full description is beyond the scope of this article (see Atkinson 2021 in Further Reading for further information on pressure). In addition, due to usually small velocities in lakes, consideration of hydrostatic pressure is often sufficient for most applications.

The (hydrostatic) pressure at any depth h is equal to the weight of water that sits above the point at which the pressure is calculated, per unit of horizontal surface area. Assuming density is constant, it is easily shown that pressure can be calculated simply as

$$p = \gamma\, h. \tag{2}$$

where $\gamma = \rho g$ is known as the specific weight and is calculated as the product of density ρ and gravity (g). Note that this calculation assumes $p = 0$ at the water surface. Using this datum, the pressure value is known as relative, or gauge pressure. Absolute pressure is equal to relative pressure plus the air pressure at the water surface. It is much more common to use gauge pressure readings.

Heat capacity/specific heat

Heat is a form of energy and, as such, we can measure changes in the temperature of a given volume of a substance and determine its heat capacity. Water is the common standard used and its heat capacity is defined as the amount of heat needed to increase the temperature of 1 g of water by 1 °C; this amount of heat defines a calorie. The number of calories needed to raise 1 g of a substance by 1 °C is termed its specific heat. For water, the value is 1 cal g^{-1} or 4.18 J g^{-1} (1 cal is equivalent to 4.18 J; Joule is the SI unit for heat). That quantity may not seem like much, but compared to other materials, the heat capacity, or specific heat of water (1.00 cal g^{-1}) is much greater than that of most other substances (Table 3).

Along with their ever changing and mesmerizing aesthetic qualities, inland waters are of immense importance in the storage and release of heat. In terms of freshwater lakes, the influence of their heat capacity can be seen most easily around very large lakes located in inland areas of temperate zone latitudes. It is in these areas that even larger swings in seasonal air temperature would ordinarily occur in the absence of those lakes. Parts of the immediate surrounding areas of Lake Baikal in Russia (this is actually the world's deepest freshwater lake as well as the one with the greatest volume of water, Kozhov, 1963) and the five Laurentian Great Lakes of North America are prime examples of the 'thermal buffering' these large lakes provide to their surroundings because of their large heat capacity.

For humans, this may result in some 'beneficial economic consequences' as portions of a lake's heat capacity are slowly released or 'shed' to down-wind regions as the fall and winter seasons progress. The immense thermal capacity of Lake Baikal, for example, is such that the lake and its immediate environments are roughly 10 °C warmer in December and January, and about 7 °C cooler in June and July, than in the cities of Irkutsk (about 50 km to the west of the southern half of Lake Baikal) and Ulan-Ude (about 70 km to the east of the lake). Several coastal and near-coastal regions of the Laurentian Great Lakes also provide impressive beneficial evidence of the influence of the Great Lakes' heat capacity. There may be reduced costs associated with home and business heating in some nearshore regions. An extended or milder autumnal period permits greater production in near-shore plantations of fruit trees and vineyards. Economic benefits also may accrue in some nearshore regions of higher terrain during winter, when enhanced snows permit additional winter skiing, snowmobiling, and other winter sports.

However, some influences of a lake's heat capacity have detrimental economic consequences. There are costs involved with snow removal, increased vehicular accidents (because of slippery roads), the corrosion of cars (attributable to higher use of road salts), and the potential long-term ecological changes associated with lake and stream salinization. There also are greater heating costs in spring as cooler water bodies extend their cooling influence inland. In addition, in late fall and winter (northern temperate zones), before an ice-cover develops, heavy snows may result when water vapor, being formed by evaporation off a relatively warm lake, is buoyed into much colder arctic air crossing the lake. Intense, 'lake-effect' snow storms tend to have their greatest impact at the downwind end of a lake after very cold arctic air has moved across the long axis of a lake and deposited its snows. These events may be part of broader synoptic patterns, but sometimes they are in very narrow bands of heavy snowfall that may bring auto traffic, schools, and businesses to a stop. In the Great Lakes region of North America, three of the better known areas for this phenomenon are (1) portions of the Upper Peninsula of Michigan on the southeastern shore of Lake Superior, (2) the southeasterly and easterly

Table 3 The specific heat of selected substances compared to that of ice, pure water, and ammonia.

Substance	*Specific heat (cal g^{-1})*
Aluminum	0.215
Copper	0.092
Gold	0.030
Lead	0.030
Silver	0.056
Zinc	0.092
Ethyl alcohol	0.60
Ice (at 0 °C)	0.51
Water	1.000
Ammonia	1.23

Information from multiple sources.

shores of Lake Ontario, especially the Tug Hill Plateau area of New York State, and (3) the easterly end of Lake Erie, around Buffalo, NY (Eichenlaub, 1979). Indeed, the Laurentian Great Lakes have been considered 'weather factories' capable of causing twists of climate found in few other parts of the world.

Heat of fusion/melting

This property is just the amount of heat exchanged during a phase shift from either liquid water to solid ice, or from solid ice to liquid water. One gram of water at 0.0 °C can be converted to ice at 0.0 °C if 80 cal (79.72 cal g^{-1}, to be precise) are released in the process. The same quantity, i.e., 80 cal, is required to melt that 1 g of ice back to 1 g of water. No further caloric additions or subtractions are needed to effect the phase shift. Because of the heat needed to melt ice, researchers might intuitively expect to see a brief but substantial drop in the mean or weighted lake-water temperature when the ice cover of a lake melts in the spring season. For example, consider a hypothetical northerly latitude and a 20-m deep lake in late winter (March), and that the lake is covered with 50 cm of ice at 0.0 °C. Furthermore, assume that the weighted mean temperature of the 1950 cm (essentially 1950 g) water column below the ice is 3.0 °C. The heat content of that water column would be 5850 cal (1950 g × 3 cal g^{-1} = 5850 cal). Assuming that there are no further gains or losses of heat to the lake, the amount of heat required to melt the ice would be 3680 cal (80 cal g^{-1} × 50 cm of ice x 0.92 g cm^{-1}, allowing for density of pure ice rounded to two decimals, it is about 3680 cal). If some of the caloric content of the water column could be used to melt all the ice, the total caloric content would drop to 2170 cal (5850 cal – 3680 cal = 2170 cal). If those 2170 cal were now equally distributed within a 1-cm^2 square and 20-m (2000 cm, essentially 2000 g) deep water column, the mean water temperature would need to drop from 3 to 1.08 °C (2170 cal/2000 cal = 1.08 °C). A drop of about 2 °C during the melting of ice would be large!

However, the temperature decline during ice-off is less as the ice generally melts over an extended period of time, from several days to several weeks, not suddenly. Half or more of the total ice thickness may be lost from the top of the ice by melting from warming air temperatures, not necessarily from waters that are just above freezing below the ice. Because of its *albedo* (percent of incoming solar radiation that is reflected back into space), dark or open water generally reflects only a small fraction of the incoming solar radiation, whereas white snow cover on a frozen lake can reflect a large fraction of incident radiation. Indeed, snow cover extending into the spring period can delay the date the ice disappears. However, with increasing amounts of solar radiation, rising air temperatures, melting snows, and darkening ice, the water below the ice may be gaining some heat from solar inputs at the same time it is losing heat in melting an overlying ice cover. Therefore, do not expect a big drop in mean water temperature as an ice cover melts on a lake.

Heat of vaporization/condensation

As was the case for 'Heat of Fusion/Melting,' the heat of vaporization/condensation also represents the amount of heat exchanged during a phase shift. For vaporization, it is the quantity of heat (540 cal g^{-1}) needed to convert 1 g of water to 1 g of water vapor. The same amount of heat is exchanged or released in the phase shift during the condensation of 1 g of water vapor to 1 g of water.

Aquatic scientists may be naturally impressed with the large amount of heat exchanged (80 cal g^{-1}) in the phase shift from water to ice, or from ice to water, but the amount of heat exchanged (540 cal g^{-1}) in the phase shift from water to water vapor, or water vapor to water is 6.75 times larger (540/80 = 6.75). Although the importance of this large amount of heat exchange via vaporization or condensation may be underappreciated by humans, it is huge. On a small but critical scale for life, water evaporating off perspiring warm-blooded animals, including humans, helps maintain body temperatures within narrow survivable limits. On a global scale, the seemingly endless phase shifts between liquid water and water vapor in the atmosphere are key determinants in the redistribution of water and heat within the hydrological cycle around the world.

Isotopes

An *isotope* is one of two or more forms of the same chemical element. Different isotopes of an element have the same number of protons in the nucleus, so they have the same atomic number, but a different number of neutrons giving each elemental isotope a different atomic weight. Isotopes of the same element have different physical properties (melting points, boiling points, etc.) and the nuclei of some isotopes are unstable and radioactive. For water (H_2O), the elements hydrogen (atomic number 1) and oxygen (atomic number 16) each have three isotopes: ^{1}H, ^{2}H, and ^{3}H for hydrogen; ^{16}O, ^{17}O, and ^{18}O for oxygen. In nature, the ^{1}H and ^{16}O isotopes are by far the most common (greater than 99.7% of oxygen is in the ^{16}O form). In water, the water molecule may be given as $^{1}H_2O$ or hydrogen oxide, $^{2}H_2O$ or deuterium oxide, and $^{3}H_2O$ or tritium oxide, which is the radioactive species. Both of the latter two are sometimes called heavy water because of their increased mass. However, the phrase 'heavy water' gained notoriety primarily because of the association of $^{2}H_2O$, or deuterium oxide, also called the deuterated form of water, in the development of nuclear weapons. Many elements have isotopes, but the isotopes of hydrogen and oxygen are of particular interest because fractionation occurs in vapor–liquid–solid phase changes. Heavier molecular species tend to be enriched in the condensation phase and lighter molecular species in the vapor phase.

This phase difference has been used in studies of paleoclimate changes by looking at the ratio of $^{18}O/^{16}O$ in ice or ocean sediment cores. Because of the greater tendency for ^{16}O to evaporate, seawater is slightly enriched in ^{18}O, relative to fresh water or polar ice, which is made up of the evaporated water. Thus, a higher $^{18}O/^{16}O$ ratio in an ice core indicates a warmer climate (less ice production). Similarly, analysis of sea shells in ocean sediment cores can help identify general climate variations, since shells are made of calcium carbonate, $CaCO_3$, which includes oxygen, and a higher $^{18}O/^{16}O$ value indicates a colder climate, since more ^{16}O would be frozen in ice and the sea water would be more enriched in ^{18}O.

Some isotopes also can be used to great advantage as tracers in understanding water movements and exchanges within atmospheric, oceanic, lake, stream, and ground water systems. For example, in a recent study Yeung et al. (2015) showed that photosynthetically produced O_2 is depleted in the heavier oxygen isotopes, and suggested that "Similar signatures may be widespread in nature, offering new tracers of biological and geochemical cycling." Other studies have shown that ^{18}O concentrations can be used as a tracer that is related to particular source conditions, including photosynthetic processes and the production of phosphate.

Sublimation

Water is said to be sublimated, sublimed, or undergo sublimation when it passes directly from a solid (ice) stage to a gas (vapor stage) without becoming a liquid in between. The latent heat of sublimation, i.e., the heat required to make the form of water change from ice to a water vapor, is 679 cal g^{-1}. This quantity is larger than the heat required to melt ice (80 cal g^{-1}) and vaporize water (540 cal g^{-1}), which combined is (80 + 540 = 620 cal g^{-1}). Because there may be multiple heat sources and sinks (e.g., the air above the ice and the water below the ice) associated with changing ice thickness on frozen Temperate Zone lakes, it is a challenge to assess the quantitative role that sublimation may play in those changes.

Some practical effects of sublimation may be visualized by observing a reduction in the volume of some dry ice (solid CO_2) or camphor. In another example, after several weeks of continuing subfreezing temperatures and deep frost, and assuming that no deicing salts were used, sublimation is most likely responsible for the slow disappearance of an ice sheet over the surface of a frozen sidewalk. Sublimation also is the main process by which wet clothes, which were hung out to dry in subfreezing temperatures, may actually dry. In the latter case, the water on the clothing quickly freezes to ice, but then slowly vaporizes through sublimation, and the clothes dry. In more recent years, freeze-dried vegetables, fruits, and other products (including instant coffee) provide other examples where the practical application of sublimation is utilized to both market and preserve food.

Surface tension and cohesiveness

Surface tension may be regarded as the resistance offered by liquid water to forces attempting to deform or break through the surface film of water. The interface between two immiscible fluids behaves like a stretched membrane, and surface tension comes from intermolecular attraction, or cohesion. At an interface between two fluids or between a fluid and a solid container, the fluid molecules try to pull the interface inward. The surface tension is then defined as the tensile force per unit length of the line at the interface. It is an interesting property and, for water, the surface tension, measured in force per unit length, e.g., Newtons per meter (N m^{-1}), is high and shows a slight increase as the temperature falls from 100 °C (0.0589 N m^{-1}) to 0 °C (0.0765 N m^{-1}).

An interesting application of surface tension is in calculating the size of raindrops. It can be shown that a simple mass balance for a spherical droplet may be written as

$$\sigma(2\pi R) = (p_1 - p_2)\ \pi R^2 \tag{3}$$

where σ is surface tension, R is the radius of the droplet, and p_1 and p_2 are the pressures inside and outside the droplet, respectively. If the pressures are known (depending on local meteorological conditions), then the radius of the droplet can be determined.

The properties of surface tension and cohesiveness also work together in shaping the small rounded water droplets seen on a table top or a car windshield. The primary force for restoring larger wind-generated surface and internal waves of lakes is gravity, but the primary force for restoring the much smaller capillary waves or ripples on a lake's surface is the surface tension of the water itself.

The surface tension of water is sometimes used to advantage in parlor games in which someone claims that he/she can float a more dense (than water) steel needle on less dense water. When the needle is lowered slowly and carefully with its long axis paralleling the surface of the water, it may be possible to 'float the needle' because the high surface tension of the water may prevent the needle from sinking. Do not try this by lowering one of the sharp ends of the needle first, because a point application of the needle will not provide enough length for the surface tension to work on, it will exceed the surface tension of the water film, and the needle will sink rapidly.

There is a specialized community of organisms, sometimes called neuston, associated with the surface film. For many observers of nature, it is always fascinating to see small insects such as pond skaters or water-striders (*Gerris* sp., within the insect order Hemiptera), and whirligig beetles (*Gyrinus* sp. and *Dineutes* sp., within the insect order Coleoptera), running around on the surface of ponds, sheltered lakes, and some streams. Because of padded ends on the long middle and hind feet of water striders, and the much shortened but paddle-like feet of the whirligig beetles, the high surface tension of the water is such that the insects may dimple, but not break through, the surface film.

Viscosity

This property may be thought of as the internal friction or resistance exerted on one substance (gas, liquid, or solid) as that substance tries to flow along or move through the same or another liquid. One way of visualizing the influence that liquids or semiliquids of progressively greater viscosities might exert is to take three glass marbles (same diameter and density) and drop one in each of three similarly sized glasses, one glass containing water, one light oil, and one honey, all at the same temperature. The marble would descend quite rapidly in water, more slowly in the light oil, and very much more slowly in the glass of honey. In this example, honey, with the highest viscosity, exerts the most friction or resistance to movement through it. Viscosity is usually measured in poises (P, defined as N s m^{-2}) or centipoises (cP =0.01 P). Water at 20 °C has a viscosity of 0.01002 P or 1.002 cP.

It should be noted that the rate of passive descent through a liquid reflects the density of the liquid itself as well as the surface area and density of the substance moving through it. Viscosity changes with water temperature in that viscosities decrease as water temperatures rise and increase as water temperatures fall. Most fish are sufficiently powerful, slippery from mucous on their skin, and shaped so they can 'slip through' water relatively easily. In contrast, tiny zooplankton, with multiple projections on their body, are ordinarily challenged as they attempt to move in any direction and particularly so when moving in cool waters.

An important application of viscosity is in calculating shear stress (an important property in the equations of motion for water). Water is known as a Newtonian fluid, in which the shear stress due to molecular cohesive forces is proportional to the rate of strain, also calculated as the velocity gradient, and the proportionality coefficient is the molecular viscosity, i.e.,

$$\tau = \mu \frac{du}{dy} \tag{4}$$

where τ is the shear stress (force acting on a plane of fluid parallel to the flow direction, per unit area), μ is viscosity, and du/dy is the velocity gradient normal to the plane on which τ is calculated. Note that this form of dependence between shear stress and strain differentiates fluids from solids, for which it is much more common to assume a linear dependence of shear stress on strain (not rate of strain). In many situations flow is often turbulent, in which case the shear stress is more dependent on flow properties and not the fluid properties.

Colligative properties

There are four special properties of water that are significantly altered or modified when solutes are added to and dissolve in water. The alterations or modifications of a colligative property (regarded as a binding property) may be predictable in dilute solutions when the number of solute particles is known. It is the number of solute particles, not their chemical nature, that determines the extent to which a property is modified.

The four colligative properties of water are *vapor pressure* (when water is in equilibrium with its own vapor), *osmotic pressure* (the pressure controlling the diffusion of a solvent across a semipermeable membrane), *boiling point* (the temperature at which water undergoes a phase shift to a gas), and *freezing point* (the temperature at which water undergoes a phase shift to a solid). Even at standardized pressures and temperatures, the extent to which a property is modified depends on the number of solute particles added. Generally, if we add a fixed number of solute particles of a sugar or salt to a liter of pure water, there would be some consequences. The vapor pressure would be lowered but the osmotic pressure would rise. The boiling point would be elevated a bit above the usual boiling point of 100.0 °C (also termed boiling-point elevation). In the latter case, a watery mixture with solutes (e.g., a well-mixed soup being heated for a meal) would have to get hotter than the boiling point of pure water before it would boil. The freezing point would be lower than 0.0 °C. A practical application of this (also termed freezing-point depression) is easily seen in parts of the northerly Temperate Zone in winter, following the application of deicing salts to melt the ice and snow on roads and sidewalks. Although not a colligative property as such, a simple increase in physical pressure also lowers the melting point of ice (~0.007 °C/atm) and helps form snowballs (when the snow is not too cold) and forms a lubricating layer of water under the blade of an ice skate.

Nomenclature

$\vec{a}$	Acceleration
A	Area
f	Coriolis parameter
$\vec{F}$	Force
g	Gravitational acceleration
g'	Reduced gravity (relative buoyancy)
k_a	A constant
p	Pressure
p_d	Dynamic pressure
p_h	Hydrostatic pressure
r	Radial position
u, v, w	Velocity components in x, y, and z directions, respectively
W	Weight
x, y, z	Coordinate directions (z is vertical)
Δx	Length of curved segment projected in z direction, defined in Fig. 7
γ	Specific weight
ν	Kinematic viscosity
$\vec{\Omega}$	Earth's rotation
ω	Angular Velocity
ρ	Density

Introduction

Pressure is an example of a surface stress (defined as force per unit area), and is important in many problems of fluid mechanics, as well as in a variety of chemical and biological responses in natural water bodies. In this article, we deal primarily with the analysis of the physical impacts of pressure, and provide several examples of biological responses to variations in pressure, including algae, fish, and humans.

The study of fluid mechanics is ultimately the study of the response of a fluid to applied forces, subject to certain constraints such as continuity, or mass conservation, momentum and energy conservation, and constitutive functions including the relationship between shear stress and rate of strain. Stress is defined as force per unit area on which the force acts. Fluid forces can generally be divided into body forces and surface forces. Body forces act on all the fluid within a defined control volume, or fluid element, while surface forces act on the surface that encloses that volume. Furthermore, surface forces can be separated into those that act either normal to or in the plane of (called shear forces) the surface of interest (Fig. 1). Problems that are addressed on the basis of force balances include calculation of forces acting on a pipe bend or forces acting on a sluice gate or canal lock. Solutions to these types of problems would be needed in the design of a pipe distribution system or for structures in an open channel flow, respectively.

For differential analysis of fluid flow, such as would be used in describing details of the velocity distribution, stresses are generally of more direct interest than forces. Normal stress is called pressure, and pressure at a point has the same magnitude in all

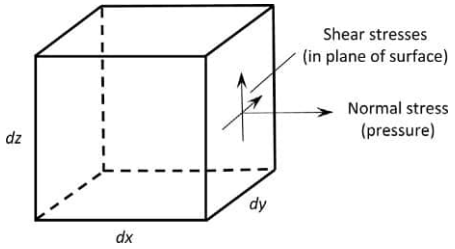

Fig. 1 Stresses acting on one surface of a small fluid element.

directions. Although by mathematical convention, the normal stress in Fig. 1 is considered positive as shown, pointing outwards from the fluid element, pressure is considered positive as a compressive stress (pointing inwards), since fluids cannot withstand tension forces. Thus, pressure acting on a fluid element as a result of the surrounding fluid is the negative of the normal stress and points inward on all faces of the element.

In general, pressure can be divided into two parts, the hydrostatic and dynamic components. Hydrostatic pressure is generated by the force of gravity acting on fluid that lies above a particular point of interest at which the value of pressure is desired, and dynamic pressure is due to the movement of the fluid. As shown below, hydrostatic pressure can be assumed in many analyses of fluid flow, especially in environmental applications where water velocities are low. For so-called Newtonian fluids, which encompass most fluids of practical interest including water, it is assumed that the shear stress is proportional to the rate of strain, which in turn can be approximated by the velocity gradient in the direction normal to the surface on which the shear stress acts. This characteristic is a fundamental difference between the mechanical description of fluids and solids, where for solids the shear stress is often assumed to be directly proportional to strain. Thus, in a static fluid, or in a fluid that is moving but in which there are no velocity gradients, the only forces to consider are the body and normal forces.

In the present article, although many of the concepts apply to fluids in general, it will be assumed that the main fluid of interest is water, either fresh or saline. The main property of interest that pertains to water and is useful for the analysis of pressure distributions is that of incompressibility, meaning that the density of the fluid is not a function of pressure. In addition, a normal right-handed Cartesian coordinate system is assumed.

Hydrostatic pressure

As the name implies, hydrostatic pressure (here denoted by p_h) is the pressure that is exerted under conditions of no or little fluid motion. To understand how p_h varies, first consider a small element of fluid within a larger volume of that same fluid (Fig. 2). The top of this element is at a depth h below the water surface. Similar to Fig. 1, the element has sides dx, dy, and dz, aligned with each of the respective coordinate directions. The forces acting on the element include its own weight and the forces of the surrounding fluid acting on the surface of the element. Since there is no fluid motion, or more precisely, no relative motion of the fluid element with respect to its surroundings, the only surface force to consider is pressure. If the element is to be in equilibrium, and therefore to remain motionless (as a result of Newton's First Law), the forces acting on it in each direction must be in balance.

In Fig. 2, the sides of the fluid element are numbered for convenience, with sides 1 and 2 referring to faces with perpendiculars (to the faces) along the x direction, sides 3 and 4 referring to sides with perpendiculars along the y direction, and sides 5 and 6 with perpendiculars along the z direction. Note that the z direction is oriented parallel to the direction of gravity, but points positive upwards. If p_h is the pressure at the center of the element, then pressures along each of the faces can be expressed in terms of p_h using a truncated Taylor Series expansion, and force (product of stress and area on which it acts) balances in each of the three coordinate directions may be written as

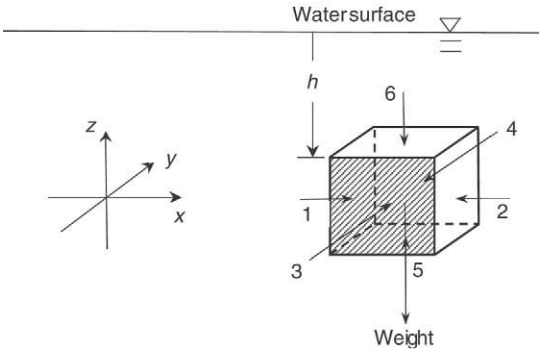

Fig. 2 Forces acting on a small fluid element under static conditions; forces include the weight of the fluid enclosed by the rectangular surface and the pressure acting on each of the faces (six total) of the element. Face 3 is the front (shaded) and face 4 is the back.

$$(x)\ p_{h1}(dydz) = p_{h2}(dydz) \Rightarrow \left(p_h - \frac{\partial p}{\partial x}\frac{dx}{2}\right) = \left(p_h + \frac{\partial p}{\partial x}\frac{dx}{2}\right) \tag{1}$$

$$(y)\ p_{h3}(dxdz) = p_{h4}(dxdz) \Rightarrow \left(p_h - \frac{\partial p}{\partial y}\frac{dy}{2}\right) = \left(p_h + \frac{\partial p}{\partial y}\frac{dy}{2}\right) \tag{2}$$

$$(z)\ p_{h5}(dxdy) - p_{h6}(dxdy) - g(\rho dxdydz) = 0 \Rightarrow \left(p_h - \frac{\partial p}{\partial z}\frac{dz}{2}\right) = \left(p_h + \frac{\partial p}{\partial z}\frac{dz}{2}\right) + \rho g dz \tag{3}$$

where p_{hi} is the hydrostatic pressure acting on face i, g is gravitational acceleration, the products $(dxdy)$, $(dxdz)$, and $(dydz)$ are the areas of each of the faces of the element, and ρ is the fluid density, which is assumed to be constant over the small volume $(dxdydz)$. Note also that dx, dy, and dz are assumed to be small enough that any variations in p_{hi} over the area of the side may be neglected. Eq. (3) differs from Eqs. (1) and (2) only in that the fluid weight is included in the force balance. Eq. (1) and Eq. (2) show

$$\frac{\partial p_h}{\partial x} = \frac{\partial p_h}{\partial y} = 0 \tag{4}$$

In other words, p is constant on a horizontal plane. Eq. (3) can be simplified as

$$-\frac{\partial p_h}{\partial x} = \gamma \tag{5}$$

where $\gamma = \rho g$ is known as the specific weight of the fluid. If density is constant this result can be integrated between two points z and $(z + \Delta z)$ to obtain

$$p_h(z + \triangle \mathbf{z}) = p_h(z) - \gamma \triangle \mathbf{z} \tag{6}$$

This is the basic equation of hydrostatic pressure variation in a constant density fluid, where pressure decreases linearly with increased elevation in a fluid (or, increases linearly with increasing depth). For environmental applications it is more common to express pressure in terms of depth h. If $p_h = p_0$ at the surface (where $h = 0$), then

$$p_h(h) = p_0 + \gamma h \tag{7}$$

(note that $\Delta h = -\Delta z$ since h and z are oriented in opposite directions). This relationship is illustrated in Fig. 3.

If $p_0 = 0$ is assumed, then the pressure acting on the top surface of the fluid element in Fig. 2 is simply the weight of water sitting above the element ($= \gamma\ hdxdy$), divided by the area ($dxdy$). Using similar reasoning, the pressure at the water surface is actually the weight of air above the surface, per unit area (note that pressure can be defined in terms of weight, whether or not the density is constant, but if density is not constant the weight must be determined by integration of the density distribution). In fact, Newton long ago deduced that air has mass by determining that water could be pumped up a tube by extracting air at the top only to a maximum height of about 10 m (33 ft). The reason for this result is because the weight of a column of water 10 m high weighs approximately the same as a similar column of air stretching through the entire atmosphere. Atmospheric pressure changes slightly with weather and with location (elevation), but is usually assumed to be 14.7 psi, 1 atm, or about 101 kPa.

For convenience, the pressure at the water surface is in fact often taken as zero, which facilitates the interpretation of pressure in terms of weight of water above a given point of interest, as shown above. Pressures written with respect to real air pressure as a reference, or boundary condition, are said to be 'absolute' pressures, whereas pressures written in terms of zero pressure at the water surface are said to be 'gauge' pressures. In absolute terms, pressure at a depth of 10 m is approximately double what it is at the water surface, and pressure increases by approximately 1 atm (101 kPa) for every 10 m increase in depth. The lowest possible pressure in absolute terms is zero, which is the pressure in deep space. Gauge pressures, however, may take negative values (indicating a vacuum). In the remainder of this article all pressures are assumed to be in 'gauge' terms.

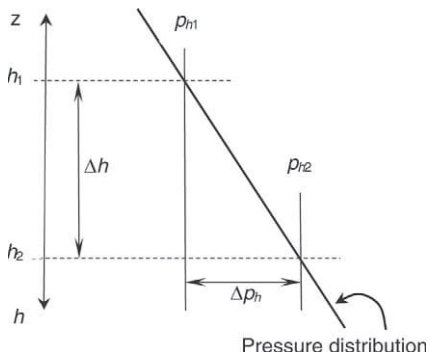

Fig. 3 Pressure variations in a static fluid with constant density.

A further outcome of the constant density assumption is that the pressure difference between two points at different vertical locations in the fluid may be found from Eq. (7) as:

$$p_h(h_2) = p_h(h_1) + \gamma(h_2 - h_1) \tag{8}$$

This relationship holds for either gauge or absolute pressures.

As noted in Eq. (5) and shown in Fig. 3, hydrostatic pressure generally increases with depth, at a rate γ. However, pressure may be forced to increase upwards, if a fluid were to be subjected to a downward acceleration with a magnitude greater than g. For example, consider a fluid in a container (so there is no relative movement of fluid particles with respect to each other) subjected to a downward acceleration of magnitude α, while still assuming gravity is effective, in which case an extra force would have to be included in the above analysis, and Eq. (5) would become:

$$-\frac{\partial p_h}{\partial z} = \rho(g - \alpha) \tag{9}$$

Note that α is negative for downward acceleration. Then if the magnitude of α were greater than g, the pressure would increase upwards in the fluid since the pressure gradient would be positive. Similarly, if the acceleration was upward, (a +g) would be additive, and the magnitude of the pressure gradient would be (a + γ). For a fluid mass in free-fall, $\alpha = -g$ and there is no effective weight, since there is no resistance to gravity, Eq. (9) would result in a zero vertical gradient, and pressure would be constant everywhere within the falling mass (equal to zero, in gauge pressure terms).

For fluids being accelerated in the x or y directions, the appropriate force, or stress would have to be included in either Eq. (1) or (2), depending on the direction of the force, and in general the corresponding pressure gradient would no longer be zero. If a force were applied to accelerate a fluid in a container in a horizontal direction, say in the x direction with magnitude α_x, then Eq. (1) would have to include this force and the resulting gradient would be:

$$-\frac{\partial p_h}{\partial x} = \rho a_x \tag{10}$$

If the container had a surface open to the atmosphere, the gradient in Eq. (10) would be exhibited by a gradient in surface elevation (Fig. 4), where pressure along a horizontal line would be directly proportional to water depth. This result occurs since there is still no relative motion of fluid in any part of the container, relative to fluid in any other part of the container, so hydrostatic pressure would still be seen in the vertical direction. An example of this type of problem would be a tanker truck carrying water with a free surface and accelerating (or decelerating) along a highway. Using the above results, it is possible to calculate the maximum acceleration possible before water would spill over the sides of the tank.

The situation is similar for a fluid in solid-body rotation. Considering a fluid rotating around a vertical axis, applying a similar force balance in the radial direction as was previously done in vertical and horizontal directions (Eq. (1) or (2)) results in:

$$\frac{\partial p_h}{\partial r} = \rho\omega^2 r \tag{11}$$

where r is the radial coordinate and ω is the angular velocity. Note that centrifugal acceleration is equal to $\omega^2 r$. Upon integrating Eq. (11), assuming constant density, pressure is found to vary parabolically with radial distance, and then considering a surface open to the atmosphere, the fluid surface will take a parabolic shape as well, since in this case rotation (about a vertical axis) does not affect forces or pressure distribution in the vertical direction. Although of interest in many applications of fluid mechanics, situations in which a fluid is artificially accelerated, either linearly or in rotation, are rare for environmental applications, except for large systems in which the rotation of the earth must be taken into consideration. This case is addressed below, but otherwise, situations with rotation are not considered further here.

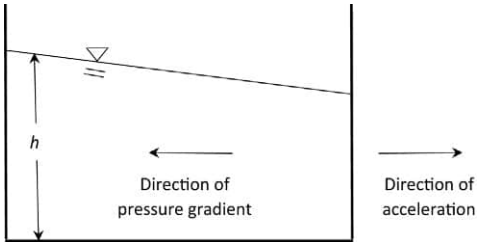

Fig. 4 Response of water surface in a container of fluid of constant density and with a surface open to the atmosphere being accelerated to the right; along the bottom, $Ph = \gamma h$, where h is the depth at any location.

Density variations

When density is not constant, its variation with depth must be known in order to integrate Eq. (5) to obtain the pressure distribution. For example, if density increases linearly with depth, $d\rho/dz = -k$, where k is a positive constant, then the pressure variation would vary with z^2. As previously noted, when working with water, the incompressibility assumption may be applied, so the density is not affected by pressure (density of water becomes a function of pressure only in the deepest parts of oceans), and for inland waters it may be assumed that density depends on temperature and salinity only. This relationship is expressed through an equation of state,

$$\rho = \rho(T, S) \tag{12}$$

where T is temperature and S is salinity. For most inland waters, salinity is small enough (or zero) that only temperature variations are important. For fresh water, the temperature of maximum density is 4 °C, and the variation of density with temperature may be approximated by a parabolic function such as:

$$\rho = \rho_0\left[1 - 0.00663(T-4)^2\right] \tag{13}$$

where $\rho_0 = 999.97$ kg m^{-3} is the density at 4 °C and T is temperature in °C.

Independent of any density stratification, Eq. (5) must still hold. For example, it can easily be shown that lines of constant density must be horizontal in a static fluid, since equilibrium would not otherwise be possible. To see this result, consider a force balance applied to the fluid element as shown in Fig. 5. With lines of constant density oriented as shown, ρ increases downward and also while moving along a horizontal line towards the right. According to Eq. (5), the pressure would then also increase while moving along a horizontal line to the right (assuming a horizontal water surface), resulting in a non-zero pressure gradient in the x direction, which violates Eq. (4). This situation is impossible in a static fluid, although it may be possible in a fluid moving in a body of water large enough that the earth's rotation (i.e., Coriolis acceleration) could generate a pressure gradient (tilt in water surface) to counter-balance the pressure gradient associated with the horizontal density gradient. See section below on Equations of Motion.

Hydrostatic forces on submerged surfaces

In addition to development of the fluid equations of motion (see below), understanding of pressure has practical applications in calculating forces acting on submerged objects. In general, both hydrostatic and dynamic pressures must be considered, but initially we look at hydrostatic forces only.

To start, consider a submerged rectangular planar surface oriented at an angle θ with respect to horizontal, in a fluid as shown in Fig. 6 (note that the submerged surface is shown in an oblique view). To simplify the discussion, it is assumed that the fluid has constant density, although the general approach here is easily extended to conditions of varying density. As discussed above, the pressure at any depth h is $p_h = \gamma h$, which acts perpendicularly on the surface, indicated on the projection of the surface to the right in Fig. 6. The differential force acting on a small area element of the surface dA is $dF = p\,dA = \gamma h B\,dh(\sin\theta)^{-1}$, where B is the width of the surface. Note that dh is assumed to be small enough that pressure may be assumed to be approximately constant over the area dA, which is oriented horizontally. The total pressure force is then obtained by integrating dF between the limits h_1 and h_2,

$$F = \gamma B(sin\theta)^{-1}\int_{h_1}^{h_2} h\,dh = \frac{\gamma B}{2sin\theta}\left(h_2^2 - h_1^2\right) \tag{14}$$

This force may be decomposed into horizontal and vertical components,

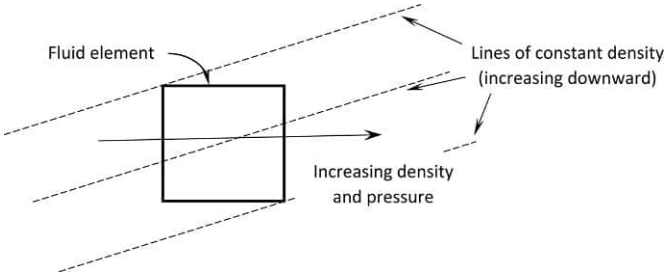

Fig. 5 Fluid element in fluid where lines of constant density are tilted.

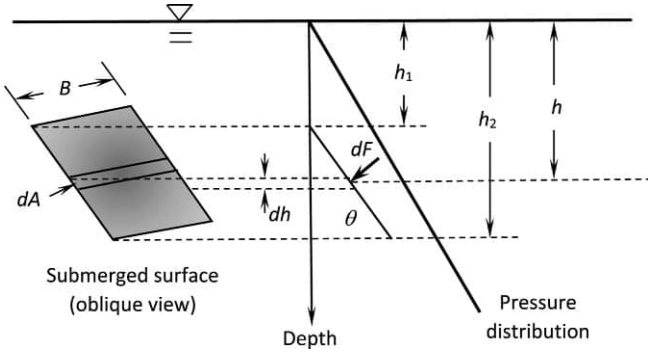

Fig. 6 Hydrostatic forces acting on a submerged planar surface, oriented at angle θ with respect to horizontal.

$$F_{hor} = -\left[\frac{\gamma B}{2sin\theta}\left(h_2^2 - h_1^2\right)\right]sin\theta = \frac{\gamma B}{2}\left(h_2^2 - h_1^2\right); F_{vert} = -\left[\frac{\gamma B}{2}\left(h_2^2 - h_1^2\right)\right]cos\theta \tag{15}$$

where the negative signs indicate forces in the negative coordinate directions. It is useful to note that the pressure at the area centroid of the surface p_{hc} is:

$$p_{hc} = \gamma\frac{(h_1 + h_2)}{2} \tag{16}$$

If this pressure acted on the entire area of the surface, given by $B(h_2 - h_1)(\sin\theta)^{-1}$, the result is identical to Eq. (14). In fact, it can be shown that this is a general result, i.e., that the total pressure force on a submerged planar surface may be calculated as the product of the surface area and the pressure evaluated at the area centroid. It also can be shown (see 'Further Reading') that the location of the resultant pressure force acts through the centroid of the pressure prism defined by the pressure distribution. Similarly, using moment balances it can be shown that the resultant vertical force acting on a horizontal surface passes through the centroid of that area.

For submerged curved surfaces, consider forces acting on the control volume designated by the cross-hatched area shown in Fig. 7. Applying a force balance in the horizontal direction gives:

$$F_{sx} = \frac{\gamma B}{2}\left(h_2^2 - h_1^2\right) \tag{17}$$

where F_{sx} is the force of the curved surface acting on the control volume in the x direction (pointing to the right), B is the width of the surface into the page, and the right-hand-side of Eq. (17) is pressure force acting on the right side of the control volume, given by Eq. (14). In the vertical direction, the force balance gives:

$$F_{sz} = (\gamma h_1)B\Delta x + \gamma V_f \tag{18}$$

where F_{sz} is the force of the curved surface acting on the control volume in the z direction (assumed to point upwards), Δx is the length of the curved segment projected in the vertical direction, and Vf is the cross-hatched volume. The first term on the right-hand-side of Eq. (18) is the pressure force acting on the top surface of the control volume, and the second term is the weight of fluid in the control volume. Eqs. (17) and (18) show that the forces acting on a curved surface may be calculated by considering the projected areas of the surface in the horizontal and vertical directions. In other words, the shape of the surface does not matter, except in so far as it determines the control volume (cross-hatched area in Fig. 7).

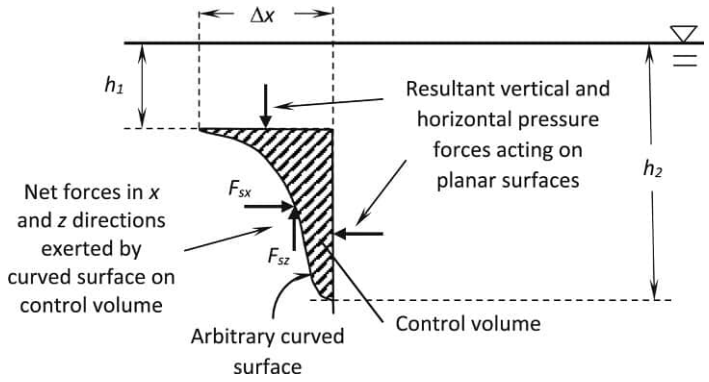

Fig. 7 Pressure forces acting on a curved surface.

Buoyancy

Buoyancy is directly related to hydrostatic pressure, and may be considered as the net upward vertical force due to pressure acting on the surface of a submerged object. This result can be seen by considering an arbitrarily shaped object of weight W and volume V submerged in a fluid of constant density ρ (Fig. 8). A surface is drawn below the object to illustrate a space defined by vertical sides drawn everywhere tangential to the object, intersecting a horizontal plane (this surface is the area of the object projected vertically). A volume of fluid V_f is contained above the object and bounded horizontally by the vertical tangents. The forces acting on the object are the forces of fluid acting on its upper and lower surfaces, F_1 and F_2, respectively, and the object's weight W. There are no net forces in the horizontal direction because there are no horizontal variations in pressure. The force F_1 is simply the weight of fluid sitting above the object, occupying volume V_f. The force F_2 acting on the lower surface is the same as the weight of fluid that would have occupied the volume $(V + V_f)$—this can be seen by thinking of a column of fluid with a surface drawn around the lower half of the object and applying the same sort of force balance as above and noting that pressure is the same upwards as downwards. The force balance for the object in the vertical direction is then:

$$\rho V_f + W = \rho\left(V + V_f\right) \text{ or } F_1 + W = F_2 \tag{19}$$

This result shows that the weight of the object is balanced by the weight of fluid that has been displaced by the object. The displaced weight of fluid is called the buoyancy force, i.e.:

$$F_B = \gamma V \tag{20}$$

where F_B is the buoyancy force. It should be emphasized that the depth at which the object rests is arbitrary, unless the density of the ambient fluid varies, as is its shape. The most important consideration is the displaced volume. If the average density of the object (total mass divided by V) is equal to the density of the fluid, the object will be in equilibrium at any location in the water column. If the density of the object is greater than that of the fluid, it will sink until it hits the bottom. If the density is less than that of the fluid, the object will be partially submerged, with the degree of submersion depending on the relative difference in densities and the displaced volume. Sometimes reference is made to the 'submerged weight' of an object, which is simply the actual weight minus the weight of displaced fluid in which the object is placed. Buoyancy is what allows ships, which are typically made of materials much denser than water, to float. The ship simply has to be designed so that the weight of displaced water is greater than the weight of the ship and all its contents.

Applying a force balance to fluid elements in a fluid with density stratification gives rise to the concept of 'relative buoyancy,' where the density of the fluid element is not the same as the density of its surroundings. There is a net reduced effect of gravity since the weight of the fluid element is partially offset by buoyancy. For analysis of these situations, the net effective gravity is referred to as reduced gravity, or relative buoyancy, defined by:

$$g' = g\frac{\rho_r - \rho}{\rho_r} \tag{21}$$

where ρ_r is a reference density value, usually taken as that of the surrounding fluid. Reduced gravity appears in problems associated with density-stratified flows, and may take positive or negative values, depending on the relative values of ρ and ρ_r.

Dynamic pressure

As previously noted, dynamic pressure is associated with fluid motion. The simplest illustration of dynamic pressure is obtained by considering the Bernoulli equation, which for cases of steady flow, constant density, and negligible friction (or viscosity) may be written as:

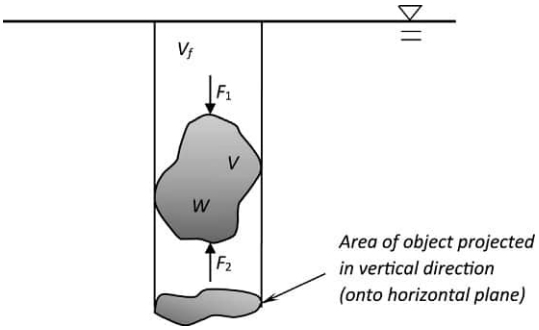

Fig. 8 Object submerged in a fluid of constant density.

$$\frac{v^2}{2g} + \frac{p}{\gamma} + z = H \tag{22}$$

where v is the fluid velocity and H is a constant known as the Bernoulli constant, or total head, and is given by conditions of the problem. This equation is usually applied to compare conditions at two locations along a streamline in the flow, but such application must be done with care to be sure all the conditions mentioned above are satisfied, particularly the negligible head loss assumption (i.e., no frictional losses). Each of the four terms in Eq. (22) has units of length. The first term is known as the velocity head, the second is the pressure head, and the third is the elevation head, or simply elevation. Definitions of these terms, as well as concepts of hydraulic grade line (HGL) and energy line (EL) for open channel flow applications are shown in Fig. 9. The Bernoulli equation represents a statement of conservation of energy, where H represents the total energy of the flow, expressed in units of (vertical) length, or head. To consider this equation in terms of real energy units, Eq. (22) would be multiplied by mass and by g.

The EL is a graphical representation of the magnitude of H. The HGL is a graphical representation of the sum of the pressure head and elevation. This sum is known as the piezometric head. In a system where energy is conserved, the EL, or magnitude of H, is at a constant level when moving from one location to another in the flow. In other words, considering two sections in the flow as in Fig. 9, the total head should be the same at both sections, $H_1 = H_2$ (note that velocity is assumed to be uniform at each cross section in this example—more detailed discussion is needed when velocity gradients are considered). The Bernoulli equation is developed for comparison of conditions at different points along a common streamline, or in the case of irrotational flow as is usually assumed for open channel flow, for any two points in the flow field. By considering a case where velocities are zero everywhere, Eq. (22) reduces to a statement of hydrostatic pressure, where $(p\gamma^{-1} + z)$ is a constant. This result is consistent with the earlier result Eq. (7).

In a moving fluid there is a sort of inverse relationship between velocity and pressure, as indicated in Eq. (22). That is, regions of higher velocity generally have lower pressures, and vice-versa. This is the main effect, for example, that produces lift in airfoils and allows aircraft to fly. Airfoils are designed so that there is a faster flow of air over the top of the airfoil than over the bottom, resulting in lower pressure on the top than on the bottom, and a net upward force. For applications in water flow, a typical problem might involve calculating the pressure force acting on an object submerged in a flow. A simple situation of this type is illustrated in Fig. 10, where a flat plate is placed perpendicular to a moving stream of water. At point 1 the velocity is v_1, the pressure is p_1, and the elevation is z_1. At point 2, which is at the surface of the plate, the velocity is (ideally) zero, while the elevation $z_2 = z_1$. Applying the Bernoulli equation then gives:

$$\frac{v_1^2}{2g} + \frac{p_1}{\gamma} + z_1 = 0 + \frac{p_2}{\gamma} + z_2 \Rightarrow p_2 = p_1 + \rho\frac{v_1^2}{2} \tag{23}$$

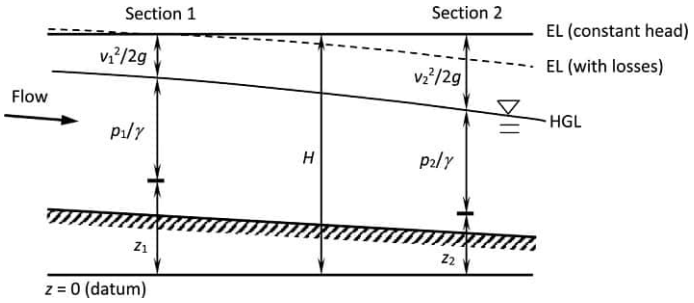

Fig. 9 Definition of head terms for Bernoulli equation Eq. (22). For hydrostatic pressure variations the sum of the elevation and pressure heads is equal to the elevation at the water surface, the position of which is also known as the hydraulic grade line (HGL). The energy line (EL) represents the elevation of total head; in an energy-conserving system the EL is horizontal, but in cases where there is energy loss, as may be induced by friction, the EL slopes downward in the direction of flow (shown as a dashed line).

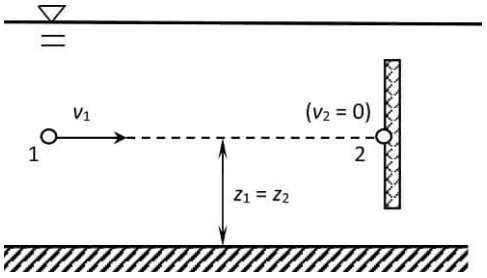

Fig. 10 Dynamic pressure force acting on planar surface in moving stream of water; point 2 is a stagnation point.

Point 2 is known as a stagnation point, which is defined anywhere the velocity is zero, and the second term on the right-hand-side of Eq. (23) is the dynamic pressure component. In this case, in which v_2 is zero, the dynamic pressure acting at point 2 attains the highest value possible, and it is known as the stagnation pressure. When comparing pressures at two points in a fluid, any difference due to different velocities comes from a dynamic pressure effect, which depends on the difference in velocity heads.

In general, to calculate the total pressure force acting on a submerged object with flow around it would require an integration of the pressure distribution on the surface of the object, which as described previously would require detailed knowledge of the velocity distribution. Fortunately, in many cases a simpler approach may be applied, based on general force balance and continuity considerations.

For example, consider calculations of force acting on a sluice gate as shown in Fig. 11. Again assuming constant velocities at each cross section (see "Introduction" and "Hydrostatic pressure"), an integral momentum equation may be applied, along with the continuity and Bernoulli equations, to solve for the net hydraulic (pressure) force acting on the gate. For simplicity it is assumed that the flow section pictured here has a width of one unit of length into the page. This allows the problem to be viewed as two-dimensional flow, since the one unit of width will appear in all force and flow expressions and will thus cancel. Considering a control volume consisting of the water between sections, and assuming steady flow, continuity states that the flow rate of water entering the control section must be the same as the flow leaving, so:

$$v_1 h_1 = v_2 h_2 \tag{24}$$

With the channel bed as datum and neglecting friction head loss, the Bernoulli equation gives:

$$\frac{v_1^2}{2g} + h_1 = \frac{v_2^2}{2g} + h_2 \tag{25}$$

where h is the piezometric head defined above, which in open channel flow is essentially the same as the water depth. If h_1 and h_2 are known, Eqs. (24) and (25) can be used to find the velocities at each section, and therefore the flow in the channel.

One further equation needed here is the integral momentum equation, which allows an interpretation of forces acting on a control volume in terms of momentum flux passing across the surfaces bounding that volume. Applied to the conditions shown in Fig. 11, the result is:

$$-(\rho q_1)v_1 + (\rho q_2)v_2 = p_{c1}h_1 - p_{c2}h_2 - F_g - F_f \tag{26}$$

where $q = vh$ is the two-dimensional flow rate, or flow per unit width, p_c is the (hydrostatic) pressure evaluated at the centroid of each cross section (recall previous discussion of forces on submerged surfaces), F_g is the total force exerted by the gate on the fluid in the control volume, assumed to act in the negative x direction, and F_f is the total friction forces acting on the fluid in the control volume. Note that it is not important which direction is assumed for F_g; if the result of the calculations is negative, it means the wrong direction had been assumed, but the numerical result is correct.

Eq. (26) is a statement of force balance that also accounts for the apparent forces exerted by momentum transport as fluid enters and leaves the control volume. The force imparted by momentum transfer is what must be balanced to prevent a garden hose from flying around when water is flowing out of the nozzle, for example. The force F_g is the net integrated effect of the pressure distribution on the gate, resulting from both hydrostatic and dynamic components, and is found using Eq. (26) without needing to actually calculate the pressures directly. Thus, with a simple measurement of depths upstream and downstream of the gate, the net force on the gate is found, where the force on the gate is in the opposite direction as the force found from Eq. (26).

Pressure in the equations of motion

In several of the above examples it has been implicitly assumed that the pressure variation was approximately hydrostatic, even in the case where velocity was not zero. This assumption is evaluated in this section, which explores the impact of pressure differences on the equations of motion, as would be used in developing mathematical models of flows and circulation for environmental analyses in lakes and streams. The primary equations governing fluid flow consist of statements of conservation of mass

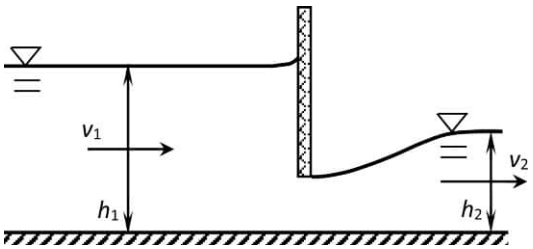

Fig. 11 Forces acting on a sluice gate in (two-dimensional) open channel flow.

(continuity), momentum, and energy. Of particular interest here are the momentum equations, or Navier–Stokes equations, which in component form are written as:

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + w\frac{\partial u}{\partial z} - fv = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \upsilon\nabla^2 u \tag{27}$$

$$\frac{\partial v}{\partial t} + u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} + w\frac{\partial v}{\partial z} + fu = -\frac{1}{\rho}\frac{\partial p}{\partial y} + \upsilon\nabla^2 v \tag{28}$$

$$\frac{\partial w}{\partial t} + u\frac{\partial w}{\partial x} + v\frac{\partial w}{\partial y} + w\frac{\partial w}{\partial z} = -\frac{1}{\rho}\frac{\partial p}{\partial z} - g + \upsilon\nabla^2 w \tag{29}$$

where u, v, and w are the velocity components in the x, y, and z directions, respectively, f is the Coriolis parameter, defined as twice the daily rotation rate of the earth times the sine of the latitude, $\vec{\nabla}$ is the gradient vector ($\nabla^2 = \vec{\nabla} \cdot \vec{\nabla}$), and υ is kinematic viscosity. For inland waters, except for very large lakes such as the Laurentian Great Lakes of North America, the Coriolis terms may be neglected. Also, it is easily seen that in the case of no motion, $u = v = w = 0$, Eqs. (27)–(29) reduce to Eqs. (4) and (5). In most cases of natural flows, the motions are predominantly horizontal, so w is small, as are vertical accelerations, so that all terms in Eq. (29) are negligible except for the first two terms on the right-hand-side, consistent with hydrostatic pressure variation in the vertical direction. There are certain situations where this is not the case, such as during fall or spring overturns in lakes, or when looking at wave motions, but these situations are generally of limited temporal duration. It should be noted that assuming a hydrostatic pressure variation in the vertical direction does not necessarily imply any assumption for horizontal pressure gradients.

For applications in model development for inland waters, it is useful to explore the impact of the pressure term in the Navier-Stokes equations. Here, consider the vector form of Eqs. (27)–(29):

$$\frac{\partial \vec{v}}{\partial t} + \vec{v} \cdot \vec{\nabla}\vec{v} + 2\vec{\Omega} \times \vec{v} = \vec{g} - \frac{1}{\rho}\vec{\nabla} p + \upsilon\nabla^2 \vec{v} \tag{30}$$

where $\vec{\Omega}$ is the earth's rotation vector. The pressure term, as discussed previously, may be considered as the sum of hydrostatic and dynamic components, where the hydrostatic part may be written as:

$$\rho_h = \rho_r - \int_{z_r}^{z} \rho g dz \tag{31}$$

where p_r is a reference value at $z = z_r$. Note that Eq. (31) is simply the integrated form of Eq. (5). Letting $p = p_h + p_d$, where p_d is the dynamic pressure, and substituting Eq. (31), the pressure gradient term in Eq. (30) may be written as:

$$\frac{1}{\rho}\vec{\nabla} p = \frac{1}{\rho}\vec{\nabla} p_r - \frac{g}{\rho}\vec{\nabla}\int_{z_r}^{z} \rho dz + \frac{1}{\rho}\vec{\nabla} p_d$$

$$= \frac{1}{\rho}\vec{\nabla} p_r - \frac{g}{\rho}\int_{z_r}^{z} \vec{\nabla}\rho dz - g\vec{\nabla} z + g\frac{\rho_r}{\rho}\vec{\nabla} z_r + \frac{1}{\rho}\vec{\nabla} p_d \tag{32}$$

Then, substituting Eq. (32) into Eq. (30) and applying the Boussinesq approximation (neglect density variations except in the buoyancy term), the result is:

$$\frac{\partial \vec{v}}{\partial t} + \vec{v} \cdot \vec{\nabla}\vec{v} + 2\vec{\Omega} \times \vec{v}$$

$$= -\frac{1}{\rho_0}\vec{\nabla}(p_r + p_d) + \frac{g}{\rho_0}\int_{z_r}^{z} \vec{\nabla}\rho dz - g\vec{\nabla} z_r + \upsilon\nabla^2 \vec{v} \tag{33}$$

where ρ_0 is a (constant) reference density value, usually taken as the density at 4C in freshwater systems (i.e., maximum density). On the right-hand-side of Eq. (33), the gradient of reference pressure, $\vec{\nabla} p_r$, may usually be neglected. The second term is the effect of density variations, which are important for stratified fluids, and the third term is the effect of reference surface gradients (such as waves). Also, as previously mentioned, the Coriolis term on the left-hand-side will often be negligible. Along with continuity and energy equations, Eq. (33) or a simplified version may serve as a general starting point for developing models of fluid motion in natural waters.

Biological responses

The above discussion focuses on the physical description of pressure, how it varies in a fluid, and how forces are manifested on submerged objects. Other considerations apply to various species that live or at least spend some of their time in water, and examples of issues related to algae, fish, and humans are presented briefly here.

For submerged objects buoyancy is the primary force of interest. As shown previously, buoyancy is the net result of pressure forces in the vertical direction. Pressures in horizontal directions, or at least in the direction of movement, are of interest in determining drag that must be overcome to maintain such movement. (Actually, the resistance to movement, in general, is called drag, which is a combination of both pressure and friction forces. For larger bodies, however, pressure is the more significant contribution to drag.) The simplest biological response and movement in the water column is achieved through the process of buoyancy regulation, which is used by certain species of algae to position themselves optimally in regions of preferable temperature, light, and nutrient availability. These algae are mostly of the blue-green type (or cyanobacteria), which also can cause nuisance and even harmful (toxic) blooms. Buoyancy regulation is achieved by increasing or decreasing gas volume in vesicles in the cells. By increasing or decreasing volume, the displaced water and hence the buoyancy force acting on the cell is altered. Increasing volume increases the buoyancy force and causes the cell to rise, and up to fivefold variations in rising or falling rates have been observed. The actual rate of rise depends on the density structure of the water column in which the organism floats, since buoyancy is the weight of the displaced water, which changes as a function of density.

For fish the physical interactions with the water environment are more complicated, due to locomotion. Some fish make use of a gas-filled cavity, called a swim bladder, or gas bladder, to maintain buoyancy and stability. Additional uplift forces can be obtained by swimming, using the same Bernoulli effect noted above that allows airplanes to fly. However, this dynamic lift is achieved only when there is forward motion. With respect to the swim bladder, in order to maintain a constant buoyancy, the volume of the bladder must remain approximately constant as the fish swims in different depths where pressure changes, and this requires some interesting physiological responses. Near the surface, the pressure in the water is close to atmospheric pressure, but as previously described, pressure increases by about 1 atm for every 10 m of depth. Unlike water, air is compressible and volume decreases as pressure increases, so there is a tendency for reduced buoyancy at greater depths. In order to maintain neutral buoyancy within a water column, an effort must be made by the fish with swim bladders to keep the volume of their swim bladder constant. Methods of maintaining some 'hydrostatic equilibrium' varies among different groups and species of fish. This maintenance is usually done by slight secretions or resorptions of gas within the swim bladder itself, or by release of gas through a duct. 'Physoclists' are fish (e.g., the perch, *Perca fluviatilis*) that have special gas secreting and resorbing sites on the swim bladder wall that let the fish descend or ascend, respectively. 'Physostomes' are fish (e.g., the eel, *Anguilla anguilla*) that have a pneumatic duct that extends from the swim bladder to the esophagus. Such a duct allows these fish to release, or 'burp' some expanding gas as the fish ascends. Still other fish (e.g., castor oil fish, *Ruvettus pretiosus*) are able to maintain neutral buoyancy through alterations in their quantities of lipid storage. Interestingly, fish like tuna (e.g., the little Pacific mackerel tuna, *Euthynnus affinis*) and sharks have no swim bladders. This latter group, as well as species like dolphins, gain hydrodynamic lift by their shape, but they must swim continuously to keep from sinking.

Perhaps of more direct interest for humans is the attention one must pay to pressure when diving. As a diver moves into deeper or shallower water, the pressure changes and affects the balance between concentrations of gases in the dissolved (liquid) and gaseous phases, following Henry's Law. This law expresses the equilibrium between the dissolved phase concentration of a gas and its pressure in the surroundings. In essence, as outside pressure increases, gases are 'pushed' into the dissolved phase. The problem for divers occurs when they ascend too quickly following a deep dive. As pressure is reduced, gases move into the gaseous phase, and if pressure is reduced too rapidly, the gas cannot leave the blood stream quickly enough and gas bubbles, mostly nitrogen, form in the blood. In other words, the re-dissolution process does not have enough time to accommodate the gasses moving out of solution due to the pressure change. This situation leads to 'the bends,' also known as decompression or caisson sickness. This latter name comes from the situation where workers would work in pressurized caissons, or boxes lowered in streams for construction of structures such as bridge towers—the interior of the caisson was pressurized to equal that of the surrounding water to prevent water from entering the work area, and workers leaving the pressurized area too quickly would suffer the same symptoms as divers who ascended too quickly from a dive. This was a significant problem in the building of the Brooklyn Bridge, for example. Symptoms of 'the bends' include pain in the joints, muscle cramps, sensory system failure, and, in extreme cases, even death.

It is important to recognize that different species have different responses to pressure variations. The above examples represent only a small sampling of these reactions, and how pressure and its net vertical force, buoyancy, is important in regulating our physical environment.

Glossary

Boundary layer The layer of fluid within a solid surface such as a riverbed.
Flowing water A general term for brooks, creeks, and rivers.
Laminar flow A flow in which fluid particles move on smooth paths in layers moving smoothly past the other layers in the fluid.
Mixing layer Turbulent flow evolving between parallel flows of different velocity.
Shallow flow The flow which horizontal scales are much larger than its vertical scales.
Shear stress The tangential component of internal force applied to a unit area within fluid.
Turbulence model A relation between shear stress and velocity gradients in the fluid.
Turbulent flow A flow in which fluid particles move on chaotic paths in small unit volumes of fluid which also move chaotically around each other.
Turbulent jet Turbulent flow evolving around fluid moving with higher speed inside the ambient fluid with low velocity.
Turbulent wake Turbulent flow developing around and past an obstruction in the flow.

Introduction

Flowing inland water is an umbrella term for brooks, creeks, and rivers whose waters are moved by the action of gravity and friction forces. Their motion takes place within irregular boundaries imposed by alluvial or bedrock channels. Both these channel types are subject to the intermittent and inhomogeneous processes of erosion, transport, and deposition that result in irregular shapes of the channel surface (Leopold, 2006; Rhoads, 2020). These irregularities force waters to move in the directions orthogonal to the main flow thereby distorting patterns of streamlines from regular and parallel (laminar flow) to irregular and chaotic (turbulent flow). Turbulent flows are the most common and thereby most important kind of flowing waters (Yalin, 1992; Rhoads, 2020). For instance, turbulent instabilities in the flow structure may locally enhance erosion and deposition processes at the opposing banks which eventually increase the local curvature of the channel (Sukhodolov et al., 2017). The curvature of flow streamlines induces centrifugal forces which are counter-balanced by pressure-gradients and generate a secondary flow that further enhances channel alterations. Thereby feedbacks among turbulent flows and sediment transport processes result in the self-regulating adjustments that sustain the form of natural fluvial systems (Grinvald and Nikora, 1988; Yalin, 1992).

Besides their significance for geomorphological processes, flowing waters represent a valuable abiotic component of fluvial ecosystems. Flow rates and patterns of turbulent flows determine transport and mixing of oxygen, nutrients, and pollutants. Distinctive flow patterns form specific habitats for many species of aquatic life. Aquatic biota may also impose strong feedback to the flow by shaping the structure of their habitat. A good example is the interaction between aquatic and riparian vegetation and the river flow.

Although understanding of flowing waters has been attracting the attention of scientists for centuries, their accurate quantitative prediction has been proven elusive due in part to the lack of a general theory of turbulent flows. Therefore, available quantitative

methods describing turbulent flows are based either on semi-empirical techniques or case-specific computational models (Pope, 2000). This article provides an abbreviated overview of the essential physical processes associated with flowing waters and turbulent flows. The simple case of turbulent open-channel flow in wide and straight riverbed is considered first as it introduces the boundary layer theoretical framework. Then spatial non-uniformities of the flow fields that result in the development of horizontal shear layers are considered along with the effects of the riverbed friction on the dynamics of these layers. Further complications in the pattern of turbulent flows are considered using the example of a turbulent jet moving through a discordant river confluence. An illustration of a wake flow past an exposed gravel-bed bar concludes this overview of the basic types of turbulent flows in flowing waters. Conceptual and theoretical approaches are illustrated with the examples of the original field studies completed by the authors.

Turbulent and laminar flows

In contrast to solids, water flows under the action of external forces because its ability to resist a deformation is quite modest. A quantity, which shows how much the water resists the rate of deformation, is the dynamic viscosity μ (8.9×10^{-4} Pa s at 25 °C). The ratio of inertial forces to viscous forces $Re = \rho\, U\, L/\mu$ is the Reynolds number, where L is the characteristic linear scale, U is the flow speed and ρ is water density. The Reynolds number allows distinguishing between *laminar* and *turbulent* flow regimes. Laminar flow is smooth and it occurs at low Re values ($Re < 2300$ in water pipes), while turbulent flow exhibits irregular patterns of motion (Fig. 1) and occurs at high Re values ($Re > 2900$ in water pipes). Historically mathematical theories focused on the laminar flows first, but turbulent flows represent a general case and particular solutions of quantitative theories of turbulent flow can readily provide analytical treatment of laminar flows. Therefore, the rest of the article is focusing on the turbulent regime of flowing water.

Flow classifications

River flows originate at defined sources like channel head or the junction of two streams, and evolve under continued action of gravitational (G) and frictional (F) forces (Leopold, 2006). At the most basic level, flow in rivers can be classified according to whether or not the rate of flow remains constant over time (*steady flow*) or changes (*unsteady flow*), and whether or not the rate of flow remains constant over space (*uniform flow*) or changes over space (*varied flow*). In the case of steady, uniform flow gravity and friction forces are equal ($G = F$). However, in unsteady flow the forces are unbalanced ($G \neq F$) over time, whereas in varied flow they are unbalanced over space. When $G > F$ the flow accelerates, whereas if $G < F$ the flow decelerates.

Motion of water in fluvial systems is a continuous process of energy transformation. Potential energy of water $\rho\, g\, H$ transforms into kinetic energy $\rho\, U^2$, where g is the gravity acceleration, and H is the flow depth. A ratio between those two forces $\mathrm{Fr} = U/\sqrt{gH}$, the Froude number, allows distinguishing between *subcritical* ($Fr < 1$), *critical* ($Fr = 1$), or *supercritical* ($Fr > 1$) flow states. Subcritical flows are typical for lowland rivers and are characterized by smooth, undisturbed water surfaces (Fig. 2). When flow is in the critical

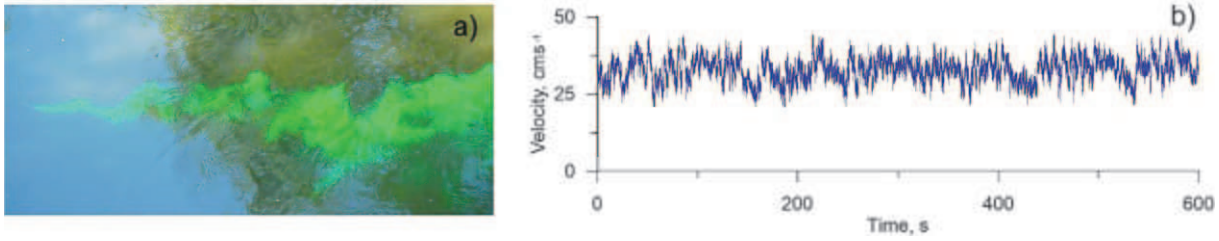

Fig. 1 Patterns of turbulent flow measured in the lowland river Spree: (A) visualization of flow by continuous point-source injection, and (B) a pattern of flow velocity at a point.

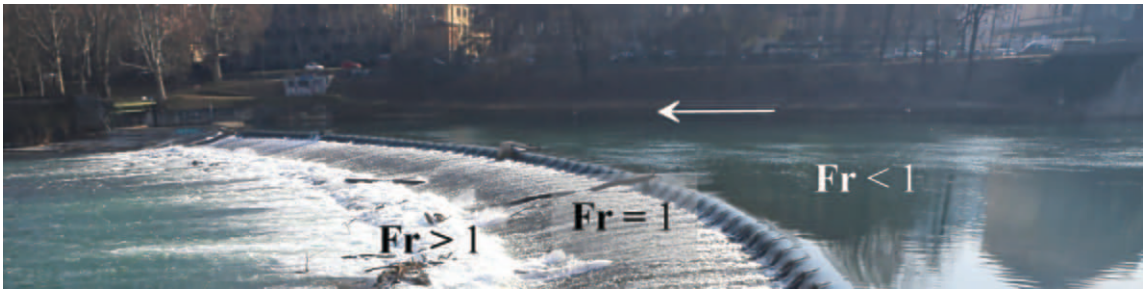

Fig. 2 Patterns of subcritical, critical and supercritical flow at the weir on the Po River, near Turin, Italy.

regime standing waves develops on its surface, which becomes distorted into breaking waves in the supercritical flow (Fig. 2). Both critical and supercritical regimes are the local features in mountain torrents, though they may also be observed in lowland rivers during floods. Transitions between subcritical and supercritical regimes may produce hydraulic drops, or abrupt decreases in flow depth, whereas transitions between supercritical and subcritical regimes result in hydraulic jumps, or abrupt increases in flow depth.

Hydraulic resistance

Flowing waters originate in uplands and flow downhill into larger rivers, lakes, seas, or oceans. They flow within channels with a certain longitudinal gradient $S = \Delta z/\Delta x$, where Δz is the difference in elevation occurring along a streamwise distance Δx. The shear stress associated with the gravitational force per unit area oriented along the inclined plane of the channel bed is ρgHS. Assuming that the gravitational force is balanced by friction force over the streambed, one readily obtains a coefficient of hydraulic resistance $c_f = 2gHS/U^2$. This equation can be rewritten as the Chezy formula $U = C\sqrt{HS}$, where C is the Chezy coefficient. Another common equation is the Manning-Strickler formula $U = H^{2/3}S^{1/2}/n$, where n is the Manning coefficient. Historically both Chezy Manning-Strickler formulae were developed on a purely empirical basis that postulated a certain relationship between depth and velocity. Thereby most empirical hydraulic resistance coefficients are related to c_f and their values have been empirically quantified. Standard manuals report for rivers that the values of the Chezy coefficient vary from 30 to 70, and the Manning coefficient ranges from 0.020 (lowland rivers) to 0.2 (flow over floodplains with terrestrial vegetation).

Although the theory of uniform open-channel flow is capable of describing bulk characteristics of turbulent flows in rivers, the spatial variability of flowing waters always limits the accuracy of this theory. The spatial variability is a distinctive feature which provides diversity of habitat for aquatic life and is therefore a key factor determining patchiness in the community structure of aquatic organisms. This is why it is important to understand and predict complex patterns of turbulent flows correctly. The following sections illustrate spatial patterns of turbulent flows in rivers and illustrate the approaches that quantify the processes producing those patterns.

Fundamentals of turbulent flow theory

The theory of turbulent flows is based on the fundamental physical laws of mass and momentum conservations - incompressible Navier-Stokes equations, which relate instantaneous velocities to the external and internal forces acting on the fluid (Pope, 2000). A fundamental technique allowing analytical and statistical treatments in practical applications of the Navier-Stokes equations is the Reynolds decomposition. With this technique the flow velocity at a point u_i at a time moment t can be represented as $u_i(t) = \overline{u}_i + u'_i(t)$, where overbar indicates time averaging, and subscript refer to a velocity component in the 3-D space. Applying the Reynolds time-averaging operator to the Navier-Stokes equations, the latter translates to a set of the Reynolds-averaged Navier-Stokes (RANS) equations, which relate $\overline{u}_i$ to external and internal forces but contain additional terms $-\rho\overline{u'_i u'_j}$ called Reynolds stresses. Modeling of turbulent flows for practical applications is based on solving RANS together with certain relations between mean velocities and the Reynolds stresses (Pope, 2000; Nezu and Nakagawa, 1993). Turbulence models are usually developed by carrying out experiments in hydraulic labs and verified with the data measured in natural flowing waters. The principles of modeling and the use of the theoretical framework are illustrated on the practical examples in the following sections.

Models of turbulent flows

Turbulence models which are used in RANS relay on a Boussinesq hypothesis according to which the Reynolds stresses is related to the gradients of mean velocity as $-\rho\overline{u'_i u'_j} = \nu_T d\overline{u}_i/dx_j$, where ν_T is turbulent viscosity. The necessity to quantify turbulent viscosity involves schematizations of turbulent flows and provision of typical values or functions for this quantity. On the very basic level turbulent flows are classified as *confined* or *free* turbulent flows (Fig. 3A). Flow confinement may be imposed by a solid boundary such as riverbed, or by the boundary at the interface with a gas or fluid in a solid state (ice). Free turbulent flows are formed when velocity gradients are imposed by an intrusion of flow with flow velocity exceeding that of the ambient flow (jet), by a presence of an obstruction which creates a local velocity deficit (wake), or because of junction of flows differing in their velocities (mixing layer). Because the width of alluvial channels W is usually many times larger than flow depth $W/H > 20$, the jets, wakes and mixing layers, whose lateral scales are not confined sideward by solid boundaries, becomes confined between the river bed and free surface. Such turbulent flows are classified as *shallow* mixing layers, jets and wakes (Jirka and Uijttewaal, 2004).

Turbulent boundary layer

Rivers flow within their alluvial or bedrock channels, whose permeability is generally weak. Therefore velocities in a river cross-section reduce to zero at the bottom and bank and they are maximal at the surface in the center of the channel. In a steady uniform flow not close to the river banks, the gravitational shear-stress component ρgHS is balanced by friction over the boundary that produces a shear stress within the water column $\tau(z) = -\rho\overline{u'w'}$, where τ is Reynolds shear stress, and u', w' are turbulent fluctuations (standard deviations) of velocity in the streamwise and vertical directions, h is the local flow depth, and z is distance

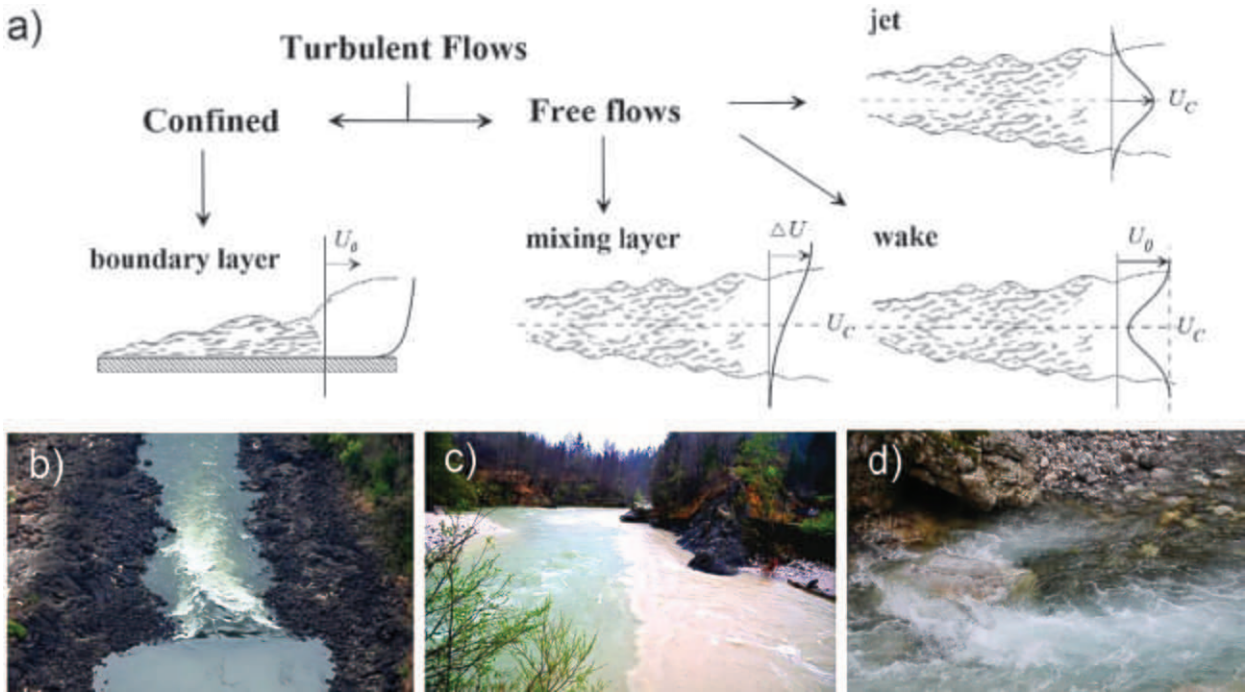

Fig. 3 (A) Classification scheme of turbulent flows, (B) and example of a jet structure at the rapid N17 of the Zambezi River, (C) a mixing layer at the confluence of the Soča and Koritnica Rivers, and (D) a wake downstream of a boulder in the Tolminka River.

from the riverbed. Analytical solution of simplified RANS for this case of quasi-two dimensional uniform open-channel flow predicts that shear stress is linearly distributed over the flow depth

$$\tau = \tau_0(1 - z/H) \tag{1}$$

with a maximum, bed shear stress $\tau_0 = \rho gHS$, at the riverbed. Then an important velocity scale - the *shear velocity* is defined as $u_* = \sqrt{\tau_0}/\rho = \sqrt{gHS}$. Prandtl's mixing length theory for boundary layers suggests that the velocity gradient near the boundary is $d\bar{u}/dz = \kappa u_*/z$, where $\kappa = 0.4$ is the von Karman constant. Eq. (1) together with the mixing length theory and Boussinesq hypothesis yields the parabolic profile for the turbulent viscosity over the flow depth $\nu_T = \kappa u_* z(1 - z/h)$. Integration of $\tau = \nu_T d\bar{u}/dz$ with (1) and assuming a parabolic profile of turbulent viscosity, yields a logarithmic profile for mean streamwise velocity

$$\frac{\bar{u}}{u_*} = \frac{1}{\kappa} \ln \frac{z}{k_s} + B \tag{2}$$

where k_s is a characteristic height of roughness elements, and $B = 8.5$ is a constant of integration. Integrating (2) over river depth provides a logarithmic law of resistance illustrating the effect of riverbed friction on the depth-averaged mean velocity

$$\frac{C}{\sqrt{g}} = \frac{1}{\kappa}\left(\ln \frac{z}{z_0} - 1\right), z_0 = exp\ (\ln k_s + \kappa B) \tag{3}$$

Experimental and field studies provide evidence that boundary layer theory predicts the behavior of flow in natural rivers quite well. Fig. 4 illustrates the performance of the theory by comparing Eqs. (1)–(3) with the data collected in Germany and Italy (Sukhodolov et al., 1998; Sukhodolov and Sukhodolova, 2019). Mean velocities are normalized as $\zeta = exp\,[\bar{u}\kappa/u_* - ln\,(H/z_0)]$. Measured vertical profiles of Reynolds shear stress show the effect of riverbed roughness (Fig. 4A). With an increase of mean diameter of riverbed material, the distance from the riverbed at which measured values separate from the linear profile (1) is increasing. This layer from the riverbed up to the point of separation (indicated by arrows at Fig. 4A) is called the roughness sublayer. Recent extensions of the boundary layer theory based on double averaging methodology provide also a quantitative assessment of the flow turbulence in the roughness sublayer.

The boundary layer theory is intensively used in hydraulic, geomorphologic and ecological studies in flowing waters. It guides the surveys of the velocities by suggesting that depth averaged velocity is measured at $z/H = 0.4$ and Eq. (2) is used to evaluate the shear velocity u_* from the measured velocity profiles.

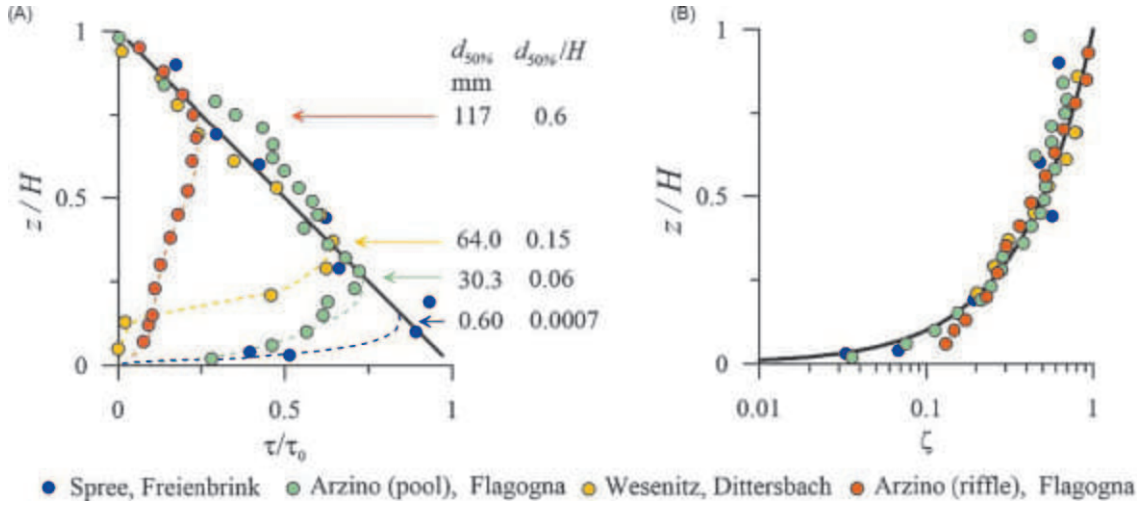

Fig. 4 Boundary layer theory of the turbulent open-channel flow and its comparison with the measurements in natural rivers: (A) the vertical profile of normalized Reynolds shear stresses (solid line is Eq. (1), arrows indicate the height of roughness sublayer, and $d_{50\%}$ is mean diameter of riverbed material), and (B) the vertical profile of normalized streamwise velocities (solid line is Eq. (2)).

Mixing layer

Brooks, creeks and rivers comprise fluvial networks of streams whose channels are interconnected to each other through the nodal locations called confluences (Rhoads, 2020). Because of differences in geology, hydrological regime, and land use on the watersheds of joining streams their waters often differ in volume, sediment content and temperature (Fig. 3C). Lateral velocity gradients occurring at a confluence between merging flows produce flow patterns similar to those of turbulent mixing layers (Fig. 3A). Velocity difference ΔU within confluences generates turbulent structures which exchange momentum between merging flows by which they reduce ΔU in the downstream of the confluence. Because of shallowness of fluvial systems ($H << W$), the larger-scale lateral turbulent structures become affected by the smaller-scale turbulence generated in the boundary layer over the riverbed. This smaller-scale turbulence enhances dissipation of larger-scale turbulence and affects its generation thereby reducing the streamwise growth of the mixing layer width δ as (Sukhodolov et al., 2010)

$$\delta(\mathrm{x}) = \alpha\frac{\Delta \mathrm{U}_0}{\mathrm{U}_0}\mathrm{x}\left(1 - \frac{\beta}{2\Delta \mathrm{U}_0}\mathrm{x}\right), \beta = \frac{\mathrm{g}}{\mathrm{U}_0}\left(\Delta \mathrm{S_f} + \Delta \mathrm{S_{xy}} - \Delta \mathrm{S_x}\right), \tag{4}$$

where $\alpha = 0.11$ is a spreading rate, ΔS_f, ΔS_{xy}, ΔS_x are the differences in friction slopes, lateral and streamwise energy gradients, respectively, the subscript 0 is referring to the origin of mixing layer ($x = 0$). The lateral profile of depth-averaged velocities $\tilde{u}$ in the mixing layer is described as

$$\tilde{\mathrm{u}}(\mathrm{y})/\Delta \mathrm{U} = 0.5\tanh\ (2\mathrm{y}/\delta), \tag{5}$$

where y is the lateral distance with the origin in the middle of the mixing layer y_c. Differentiating Eq. (5) and assuming constant turbulent viscosity, the Boussinesq hypothesis yields the reciprocal hyperbolic cosine profile for the lateral Reynolds stress

$$-\frac{\overline{\mathrm{u'v'}}}{\Delta \mathrm{U}^2} = \frac{\nu_\mathrm{T}}{\delta \Delta \mathrm{U}}\cosh^2(2\mathrm{y}/\delta), \nu_\mathrm{T}/\delta\Delta \mathrm{U} = 0.01. \tag{6}$$

Eqs. (1)–(6) provide the theoretical framework for predicting turbulent flow in shallow mixing layers. Fig. 5 illustrates the performance of the theory by comparing Eqs. (1)–(6) with the results of field-based experiments completed in Italy and Germany (Sukhodolov and Sukhodolova, 2019). In these experiments the width of the mixing layer at short distance from the origin ($x/H < 20$) growths similar to a free mixing layer (Fig. 5A). As the distance increases the lateral larger-scale turbulence becomes strongly affected by the bed friction and further downstream the dynamics of the mixing layer width is accurately predicted by shallow mixing layer theory (Fig. 5A). The depth-averaged profiles of streamwise velocity inside the shallow mixing layer agree with the predictions of Eq. (5) (Fig. 5B). Measured lateral profiles of lateral Reynolds shear stress also confirm that assuming the constant turbulent viscosity provides a reasonably accurate model for the shallow mixing layers (Fig. 5C).

The theory of mixing layers has valuable implications for studies of pollutant spread in fluvial networks, transport of suspended sediments and effects of aquatic and riparian vegetation on flow dynamics (Jirka and Uijttewaal, 2004; Rhoads, 2020).

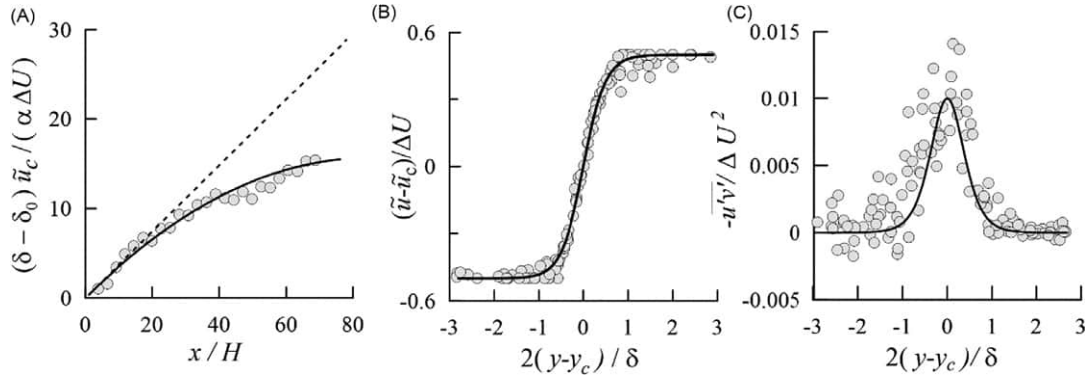

Fig. 5 Shallow mixing layer theory of the turbulent flow and its comparison with the field-based experiments in rivers: (A) dynamics of a shallow mixing layer width (solid line is Eq. (4), dashed line is dynamics of a free mixing layer), (B) normalized depth-averaged velocity across the mixing layer (solid line is Eq. (5)), and (C) lateral profile of normalized Reynolds shear stress measured in the mid-depth (solid line is Eq. (6)).

Turbulent jets

In the upper parts of fluvial networks, the tributaries may have substantially larger gradients of riverbeds and even overhanging channels in the bed rocks. Such tributary streams will also have velocities faster than those in the main rivers. By entering the waters of the main river, the flow from the tributary keeps moving for some distance with gradual loss of momentum, which drives the flow through the ambient water (Fig. 6A). At the interface with the ambient waters evolve two turbulent mixing layers, one on each side of the potential core of a jet. Theoretical and experimental research shows that velocity excess in a free plane jet is decaying with the distance from the origin (x) as $\overline{u}_{max}(x) = 1/\sqrt{x}$. A lateral profile of mean streamwise velocity in the jet is represented by an exponential function

$$\overline{u}/\overline{u}_{max} = \exp\left(-A\eta^2\right), \eta = 2y/b, \tag{7}$$

$$-\frac{\overline{u'v'}}{\overline{u}^2_{max}} = \gamma \frac{\exp\left(-A\eta^2\right)}{\sqrt{A}\eta}\left[1 - \exp\left(-A\eta^2\right)\right], \tag{8}$$

where $\gamma = 0.066$ is the spreading rate for plane jets, $A = 0.693$ is a constant, and b is the width of a jet. Following the method of turbulence modeling based on the Boussinesq hypothesis, one obtains a lateral profile of the Reynolds shear stress. Although results

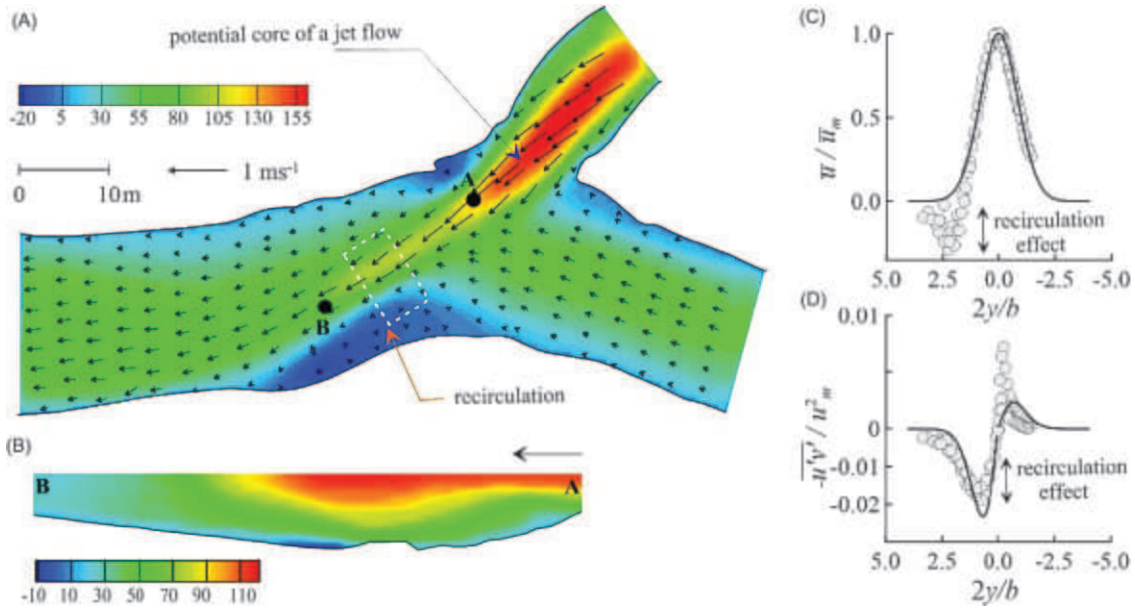

Fig. 6 Turbulent jet at a discordant river confluence of the Ledra with the Torrente Sorgive die Bars, Italy: (A) velocity vectors near the free surface of the flow (color scale shows velocity magnitude in cms^{-1}), (B) longitudinal section of streamwise velocity field (points A-B indicate beginning and end of the section), (C) lateral profile of normalized streamwise velocity near the free surface (location of profiles is shown by the dashed rectangle, solid line is Eq. (7)), and (D) lateral profile of normalized Reynold shear stress near the free surface (solid line is Eq. (8)).

of field studies show that in natural rivers the simple turbulence theories agree with measurements in the central part the jet, complex flow structure of the ambient stream may produce significant deviations from the theory (Fig. 6) (Sukhodolov et al., 2017). The effects of flow recirculation can be especially strong, which enhance lateral gradients and increase turbulence structures both in size and magnitude (Fig. 6C and D).

Besides the importance of jet models for confluences, these turbulent flows are also of a fundamental importance for understanding flow structures in the riffle-pool and step-pool sequences, and within engineering structures (e.g., dams, fish passages, and groyne fields).

Turbulent wakes

Diversity in fluvial ecosystems is perceived in a context of a tight link between spatial heterogeneity in environmental factors and biota. Central to this topic is the flow heterogeneity produced by natural in-stream obstructions such as boulder clusters, log jams, and patches of riparian and aquatic vegetation. Turbulent flows evolving around these obstructions are referred to as turbulent wakes. Downstream these obstructions the width of a free wake δ_w increases as a root square of distance $\delta_w = \sqrt{x/D}$, where D is the diameter of an obstruction. However, in shallow fluvial environments the shallowness may restrict the growth of the wake. This effect is quantified by the stability parameter $S_w = c_f D/H$. For $S_w \leq 0.2$ the wake's dynamics is similar to a free wake and at $S_w > 0.5$ the wake width is not laterally expanding. Lateral velocity profiles in a turbulent wake can be scaled with a velocity differential as characteristic velocity scale as

$$\frac{|\tilde{u}_c - \tilde{u}|}{\Delta U} = \exp\left[-A\left(\frac{2y}{\delta_w}\right)^2\right]. \tag{9}$$

Differentiating Eq. (9) with a constant turbulent viscosity, the Boussinesq hypothesis yields the lateral profile for the Reynolds stress

$$-\frac{\overline{u'v'}}{\Delta U^2} = -4A\varepsilon\frac{2y}{\delta_w}\left[-A\left(\frac{2y}{\delta_w}\right)^2\right], \varepsilon = \nu_T/\Delta U\delta_w, \tag{10}$$

where $\varepsilon = 0.01$is a constant. Performance of wake theory is illustrated by comparing Eqs. (9)–(10) to the results of field-based experiments in a gravel bed river (Fig. 7) (Sukhodolov and Sukhodolova, 2014; Shumilova et al., 2021). In turbulent flows past solid objects a recirculation zone forms immediately downstream of the obstruction (Fig. 7A). The width of the wake assumes the dynamics of a free wake for some distance that is then stabilized by bed friction further downstream (Fig. 7A). The lateral profile of depth-averaged streamwise velocity across the shallow wake agrees with the predictions of Eq. (9) (Fig. 7B). A good agreement can be also concluded for the lateral profiles of lateral Reynolds shear stress predicted with Eq. (10) (Fig. 7C).

Conclusions and knowledge gaps

This chapter briefly reviews the main features distinguishing laminar and turbulent flows in flowing waters and it focuses on the turbulent flows and on the concepts of their modeling. These are illustrated with four basic types of turbulent concepts: boundary layer, mixing layer, jet and wake. For each of these flows turbulence modeling is illustrated by applying the Boussinesq hypothesis with appropriate assumptions on the turbulent viscosity. Predictions of turbulence modeling are compared to the results of field-based experiments completed on rivers in Germany and Italy.

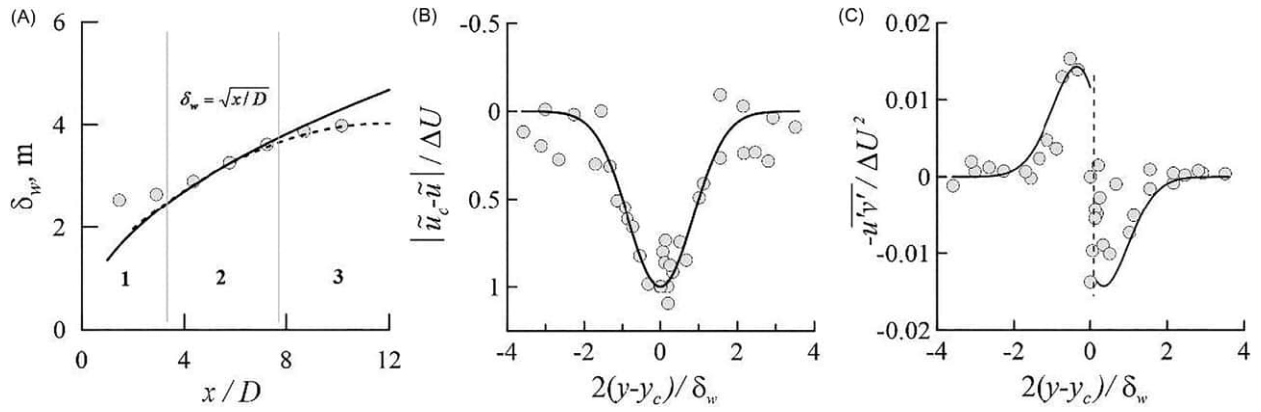

Fig. 7 Turbulent wake past a deposition bar in a gravel bed river: (A) dynamics of the wake width in the downstream (solid line corresponds to a free wake and dashed line is shallow wake), (B) normalized mean streamwise velocity profile in the wake (solid line is Eq. (9)), and (C) the lateral profile of normalized lateral Reynolds stress (solid line is Eq. (10), the dashed line shows the centerline).

Although turbulent flows and their modeling are considered complex and difficult to predict, advances in the past decades have led to substantial progress in our understanding of these flows. Especially important is the development of theoretical, field, experimental and numerical studies of shallow turbulent flows, which allows separation of different sources and the contributions of physical forces. Because of their mathematical simplicity and clearly defined parameters, analytical models of turbulent shallow flows are easy to incorporate into complex mechanistic models of river ecosystem such as individual-based models of aquatic organisms.

Mutual interaction between flow, channel, and biota at different spatial and temporal scales ranging from a sediment grain to the scale of a river reach, and from milliseconds to hundreds of years complicate unambiguous studies of turbulent flows in natural environments. Therefore, available data on model parameters of river flows include significant scatter that leads to uncertainties in prediction of magnitudes and patterns of flows. Some of this uncertainty reflects the fact that most theoretical, laboratory, and field studies investigate or assume uniform steady flow, while in nature these flows are always an idealization. To overcome these limitations, further research needs to address the following knowledge gaps:

- effects and feedbacks of free surface dynamics;
- hydrodynamics and turbulent flow structure in large rivers;
- details of turbulent flow structure in riffle-pool sequences;
- hydrodynamics of river flows during floods.

Glossary

1% Attenuation depth, $z_{1\%}$ (m) The depth to which 1% of subsurface irradiance of a given wavelength penetrates in the water column. Using subsurface measurements gives a surface reference that excludes albedo and thus more accurately reflects water transparency.
Absorptance (A, unitless) Fraction of flux that is absorbed across the medium relative to the incident flux.
Absorption coefficient (a, m^{-1}) Rate of flux decrease due to absorption with thickness of the medium.
Beam attenuation coefficient (c, m^{-1}) Flux lost from a beam of light as a result of both absorption and scattering, per unit thickness of the medium.
Diffuse attenuation coefficient (K_d, m^{-1}) Rate of decrease of subsurface irradiance with depth.
Irradiance (E, W m^{-2} or Q, μmole quanta m^{-2} s^{-1}) Measure of the radiant power (E) or quantum flux (Q) within a wavelength range, incident per unit area on a surface.
Photosynthetically active radiation (PAR) Irradiance in the 400–700 nm wavelength range, as either radiant power (W m^{-2}) or quantum flux (μmole quanta m^{-2} s^{-1}).
Scatterance (B, unitless) Fraction of flux that diverges from the parallel beam as it passes through a medium relative to the incident flux.
Scattering coefficient (b, m^{-1}) Rate of flux decrease due to scattering with thickness of the medium.
Spectral slope (S, nm^{-1}) The slope of the plot of the natural log of the absorbance versus wavelength for a specified wavelength range such as all UV (280–400 nm).
Volume scattering function (β, steradian^{-1}) Angular distribution of scattered flux.
Zenith The point in the sky directly overhead from the location of interest.

The nature of light

Sunlight is essential for photosynthesis which provides the energy essential to all but a few of the simplest microbial communities in aquatic ecosystems. Sunlight is also critical in structuring aquatic ecosystems. Seasonal variations in the heat energy provided by sunlight are responsible for thermal stratification and mixing regimes in aquatic systems.

The term "light" is commonly referred to as that portion of the electromagnetic spectrum that is visible to the human eye. This visible light accounts for a very narrow portion of the electromagnetic spectrum that ranges from cosmic rays to radio waves. Although some electromagnetic radiation originates from outside our solar system (indeed some as remnants of the "Big Bang"), an overwhelming majority of the electromagnetic radiation reaching the Earth originates from the Sun.

☆*Change History*: January 2021. PJ Neale and CE Williamson updated abstract, text and further readings. Figs. 4, 5 and 7 were revised with updated information. One annotation in Fig. 8 was corrected.

All electromagnetic radiation should be viewed as having two fundamental properties, which include both a physical entity (photons/quanta) and wave properties. Thus, electromagnetic radiation is a transverse wave of energy that behaves as a particle with a defined momentum. The photon carries energy in the form of a wave; each discrete photon has a distinct wavelength and frequency associated with it. The wavelength (λ, m) and frequency (ν, Hz) of electromagnetic radiation are inversely related by

$$\lambda = c/\nu \tag{1}$$

where c is the speed of light (3.0×10^8 m s^{-1} in a vacuum). When dealing with light, it is more typical (and convenient) to express wavelength in units of nanometers (10^{-9} m).

The energy content of discrete photons (in Joules) of electromagnetic radiation is inversely related to wavelength via the Planck equation

$$\varepsilon = h\nu = hc/\lambda \tag{2}$$

where h is Planck's constant (6.63×10^{-34} J s).

The bulk of solar radiation spans wavelengths from approximately 100–3000 nm (Fig. 1). A relatively small proportion of this spectrum corresponds to 'visible' light (400–700 nm). Wavelength bands within the visible spectrum are perceived as colors by the human eye. The perceived colors of blue (450–500 nm), green (500–550 nm), yellow (550–600 nm), orange (600–650 nm) and red (650–700 nm) are all associated with distinct wavelength bands within the visible spectrum. Wavelengths of ultraviolet radiation are shorter than the visible spectrum (200–400 nm) while those of infrared radiation are longer (700–3000 nm).

Planck's Eq. (2) can be used to calculate the energy content of photons associated with any of these wavelengths. Relative to photons with a wavelength of 665 nm (a major absorption peak for chlorophyll *a*), infrared photons at 1000 nm contain only 66% of the energy. In contrast, photons associated with UV-B radiation at 300 nm contain 221% of the energy compared to those at 665 nm. This explains why UV-B radiation can cause erythema (sunburn) while infrared radiation produces only a gentle warming sensation.

Even more ecologically significant than the phenomenon of vision, light provides the energy necessary for photosynthesis. The energy utilized in photosynthesis is restricted to a relatively narrow spectrum referred to as "photosynthetically active radiation" (PAR). Interestingly, and probably not coincidentally from an evolutionary perspective, PAR and visible light are essentially identical (400–700 nm). The long wavelength limit of PAR is defined because photons at a wavelength greater than 700 nm have too little energy to overcome the biochemical threshold for production of electrons by photosystems I and II used in photosynthesis. In contrast, the intensity of the solar spectrum drops off sharply below 400 nm (Fig. 1) so there is little energetic benefit to be derived from harvesting the shorter (UV) wavelengths. Although vision and photosynthesis utilize only a narrow band of the solar spectrum, the region from 400 to 700 nm contains almost 45% of the energy output of the sun (at Earth's surface). Evolution of vision and photosynthesis to use this narrow band resulted from a balance between available solar radiation and the optimum energy content per photon for biological systems.

As a result of the nature of electromagnetic radiation, the radiant flux density, or irradiance, of light may be quantified in one of two ways: by counting quanta or measuring energy. Each method has utility with respect to the study of aquatic systems.

Full summer sunlight at the surface of the Earth delivers a quantum flux density (Q) of approximately 1.2×10^{21} quanta m^{-2} s^{-1} of visible light. Frequently, Q is expressed in terms of moles of photons (1 mol of photons = 6.02×10^{23} photons, also known as 1 Einstein). Thus, a "full sun" value of Q for a typical summer day at noon is approximately 2000 μmole of visible (or PAR) quanta per square meter per second. Alternatively, PAR may also be measured as radiant power, the flux of energy (joules) per square meter per

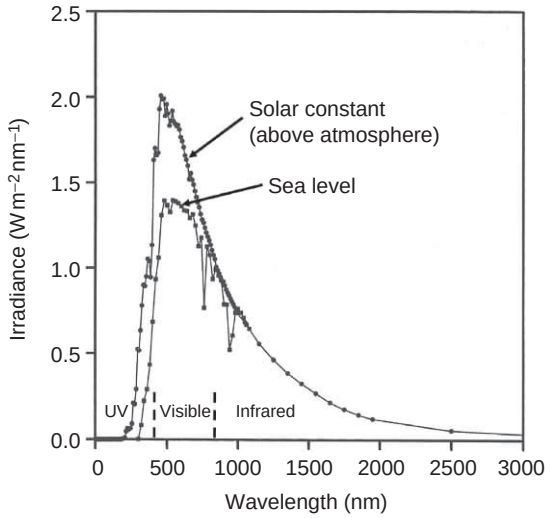

Fig. 1 Spectral distribution of sunlight above the atmosphere and at sea level.

second (E). A "full sun" value for PAR irradiance reported in energy units is approximately 430 J m^{-2} s^{-1} or 430 W m^{-2} (1 J s^{-1} = 1 W).

If the distribution of quanta or energy is known across the solar spectrum, it is possible to convert between the two sets of units using Planck's Eq. (2). Often instrumentation to precisely measure the spectral distribution of quanta or energy in sunlight is not available. In these cases, a conversion factor may be applied based on a typical spectral distribution of sunlight at the Earth's surface. Morel and Smith (1974) found that for solar radiation in the visible (and PAR) spectral range, a conversion factor of 2.77×10^{18} quanta J^{-1} was accurate to a within few percent over a variety of sky conditions for measurements made in the air. This factor (Q/E) is equivalent to 4.6 μmole quanta J^{-1}.

Role of the atmosphere

Solar flux just outside Earth's atmosphere is referred to as the "solar constant" and has a value of approximately 1373 W m^{-2}. Reflectance, scattering, and absorption of light in the atmosphere can reduce this amount by 15–80% before reaching Earth's surface. Scattering and absorption do not influence all wavelengths equally, thus significant changes in the spectral distribution of sunlight will occur as light penetrates the atmosphere.

Scattering of light by gas molecules in the atmosphere is proportional to $1/\lambda^4$ (as described by Rayleigh's law). Some of this light is back scattered into space while some is scattered forward and reaches the Earth's surface as skylight. Since scattering is inversely related to λ^4, the shortest wavelengths are preferentially scattered in the atmosphere, causing a cloudless sky to appear blue. Although not visible, large fluxes of short wavelength UV radiation can reach the surface of the Earth as scattered skylight (in contrast to direct sunlight). In addition to gas molecules, aerosols and water vapor (as clouds) in the atmosphere can also contribute to light scattering.

The absorption of light by the atmosphere is largely a result of naturally occurring oxygen, ozone, carbon dioxide, and water vapor. Anthropogenic air pollution may also have significant effects in some regions.

Ozone strongly absorbs high-energy UV-B radiation and essentially prevents light of wavelengths shorter than 290 nm from reaching the surface of the Earth. Water vapor and carbon dioxide strongly absorb some specific bands of infrared radiation and are significant as 'greenhouse' gases. Fig. 1 compares the spectral distribution of light above the atmosphere and at sea level.

Cloud cover can be effective in both reflecting and absorbing light in the atmosphere. The transmissivity of thick cumulus clouds may be as little as 10% while that of high stratus clouds may be as high as 70%. The transmissivity of total solar radiation can be as high as 86% under dry, cloudless, and "clean" atmospheric conditions. According to Gates (1962), the average annual transmissivity of the atmosphere over a region in the Northern Hemisphere was 47%. Reflectance and back scattering of light into space accounted for a loss of 34% while 19% was lost via atmospheric absorption.

The role of latitude

Latitude plays a critical role in determining solar flux at Earth's surface (E_0), by its influence on sun angle and day length (Fig. 2). Insolation generally declines with increasing latitude through its influence on sun angle. The flux density (irradiance) on a flat surface declines in proportion to the cosine of the incident angle of the sun (angle from the vertical, often referred to as the zenith angle). For example, just considering the effect of sun angle, direct solar irradiance at a zenith angle of 60 degrees (sun 30 degrees above the horizon) is half of what it is when the sun is directly overhead (zenith angle 0 degrees). However, during summer, this phenomenon is countered by increasing day length. The net result is that during mid-summer, high latitude regions may actually receive greater daily insolation than the equatorial regions. Thus, the maximum daily insolation received at the surface of Earth does not vary significantly with latitude (disregarding any variations in atmospheric conditions). The most profound influence of

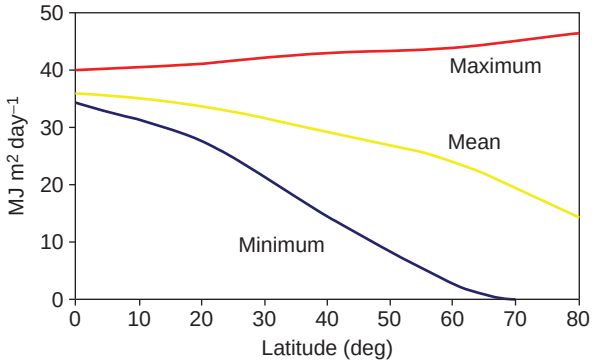

Fig. 2 Maximum, minimum, and mean daily irradiance at different latitudes at the surface of the Earth. Data do not account for regional differences in cloud cover.

latitude on insolation is in determining the minimum daily insolation. During winter, increasing sun angle is accompanied by decreasing day length at high latitudes. In fact, daily insolation falls to zero in polar regions during the winter.

Reflectance, scattering, and absorption of light by the atmosphere also increase with sun angle. Loss of light by scattering and absorption are both a function of the amount of atmosphere traversed. The atmospheric path length is inversely proportional to the cosine of the solar zenith angle. Thus, the atmospheric path length is roughly doubled when the sun is 30 degrees above the horizon than when being directly overhead. For this reason, the transmissivity of the atmosphere will vary greatly according to both latitude and time of day.

Reflectance at the air-water interface

Light at the surface of a water body may be reflected. Unless rereflected or scattered back to the aquatic system from the atmosphere or the surrounding landscape, this light is lost from the system. The amount of light reflected from the water's surface is related to the incident angle of the sun (zenith angle), as described in the Fresnel equation

$$r = \frac{1}{2}\left\{\left[\frac{\sin(\theta_a - \theta_w)}{\sin(\theta_a + \theta_w)}\right]^2 + \left[\frac{\tan(\theta_a - \theta_w)}{\tan(\theta_a + \theta_w)}\right]^2\right\} \tag{3}$$

where r is the reflection of unpolarized light as a fraction of the incident light, Θ_a is the zenith angle of the sun, and Θ_w is the angle of the light transmitted into the water (i.e., the angle of the incident light beam refracted by the air-water interface). The angle of transmitted light is related to the angle of incident light by Snell's law, $n_a \sin\theta_a = n_w \sin\theta_w$ where $n_a = 1$ and $n_w = 1.33$ are the indices of refraction of air and water, respectively. Reflectance for a flat body of water with the sun directly overhead (i.e., $\Theta_a = 0$ degrees) is approximately 2% and remains relatively low for zenith angles of up to about 60 degrees ($r < 6\%$). As the zenith angle approaches 90 degrees, reflectance increases rapidly (e.g., r is approximately 60% at 80 degrees). At small zenith angles, surface disturbances (i.e., small waves) have very little influence on reflectance but at more extreme zenith angles (>60 degrees) reflectance can be increased by as much as 20%. Large waves in combination with high zenith angles may reduce reflectance by decreasing the effective zenith angle between the water's surface and the sun. Reflectance of light from frozen water bodies has been estimated to be as much as 75–95%; however, this value depends on the quality of the ice and particularly the amount of snow.

This discussion of reflectance deals solely with direct solar radiation. Reflection of diffuse solar radiation striking the surface of the water as a result of scattered skylight is difficult to determine precisely because the angular distribution of light is unknown.

Inherent optical properties

Once photons penetrate the air–water interface of aquatic systems they may only be scattered or absorbed. The extent to which either of these phenomena may occur is governed by three parameters: absorption coefficient, scattering coefficient, and the volume scattering function. These three parameters are often referred to as "inherent optical properties" because they only depend on the constituents of the aquatic medium and not on the geometry of the light field.

To define these parameters, it is necessary to consider an infinitesimally thin layer of medium being illuminated at right angles by a parallel beam of light (Fig. 3). The fraction of flux that is absorbed across the medium relative to the incident flux is defined as the absorptance (A) and the fraction of flux that diverges from the parallel beam of incident flux is referred to as the scatterance (B)

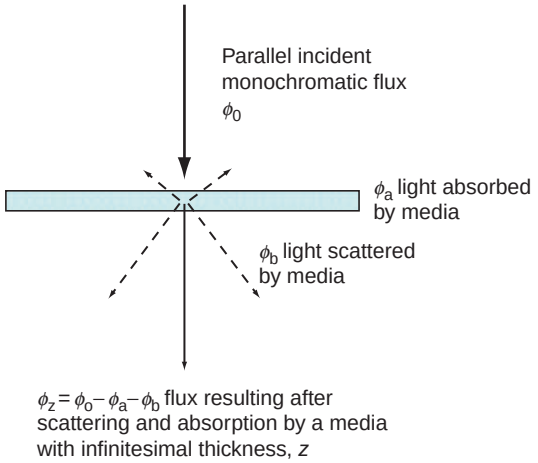

Fig. 3 Schematic diagram illustrating absorption and scattering of light by an infinitesimally thin layer of water.

$$A = \Phi_a/\Phi_0 \tag{4}$$

$$B = \Phi_b/\Phi_0 \tag{5}$$

where Φ_0 is the incident flux of the parallel beam of light, Φ_a is the flux absorbed and Φ_b is the flux scattered by the thin medium. If we represent the change in absorptance (ΔA) and scatterance (ΔB) with infinitesimal changes in the thickness of the medium (Δz), we can estimate the absorption coefficient (a) and the scattering coefficient (b)

$$a = \Delta A/\Delta z \tag{6}$$

$$b = \Delta B/\Delta z \tag{7}$$

The beam attenuation coefficient (c), an additional inherent optical property, is simply an expression of the amount of flux lost from the beam of light as a result of both absorption and scattering, per unit thickness of the medium

$$c = a + b \tag{8}$$

The absorption coefficient, scattering coefficient, and beam attenuation coefficient each have units of 1/length and are typically expressed as per meter.

Another inherent optical property of the aquatic medium is the volume scattering function (β). As light is scattered within a medium, the photons may be dispersed in a variety of different directions. The volume scattering function defines the angular distribution of the resulting scattered flux. This function differs according to the medium but generally describes a radially symmetrical cone of distribution around the direction of the incident beam.

Scattering

Scattering of light in aquatic ecosystems can be thought of as the deflection (reflection) of photons at a large number of angles due to water and its dissolved and particulate constituents. Although scattered photons are largely distributed in a radially symmetrical cone around the direction of the incident beam, there is a finite statistical probability that photons may be deflected in any direction. Scattered photons that are deflected back may leave the aquatic ecosystem along with their energy content. Scattering varies with wavelength according to the differential absorption and scattering characteristics of the aqueous medium. In very clear aquatic ecosystems, the greatest amount of scattering occurs in UV wavelengths. These systems appear blue because blue is the shortest visible wavelength backscattered that is detected by the eye. Systems with large concentrations of dissolved organic carbon appear yellow/brown because blue photons are strongly absorbed and thus not available to be backscattered to the eye of the observer.

Scattering may be greatly influenced by the nature of particulate material in an aquatic ecosystem. For instance, fine glacial "flour" may be highly reflective and can enhance scattering at the mouth of rivers draining glaciers and lakes receiving glacial meltwater. White calcium carbonate (marl) at the bottom of lakes may also enhance scattering (reflectance) in shallow systems or in the water column of deeper systems if sediments are resuspended by wind driven mixing. In contrast, organic particulate material (colloids of humic substances, detritus, etc.) may strongly absorb rather than scatter photons. The net result of scattering is that it can greatly increase the path length (Δz) taken by a photon as it passes through an aqueous medium. For instance, it is not uncommon for the "average" photon to travel a path of 1.2 m (as a result of multiple scattering events) before reaching a depth of 1 m in an aquatic ecosystem. Scattering also has important implications for aquatic photosynthetic organisms because scattered photons are available from all directions (including the bottom) and not just that oriented toward the downward welling light.

Absorption

Photons of light may interact with the electron shell of molecules and be absorbed. During this process, the photon is destroyed but its energy is transferred to the molecule that absorbed it. This energy is used to transition electrons from the ground state to higher energy levels. Molecules can have very distinct absorption spectra because the energy content of some photons (Eq. (2)) match exactly the energy required for the electron transition. The energy of absorbed photons may be used to break chemical bonds or generate electrons (in the case of photosynthesis). However, because energy has to be conserved, the energy of all absorbed photons is eventually released in aquatic ecosystems as heat.

Light absorption can be measured with a spectrophotometer, which is an instrument specifically designed to measure the absorbance of light by a medium of known thickness. Values obtained by spectrophotometers are known equivalently as absorbance (A) or optical density (OD). Here, we use the latter term (OD) to avoid confusion with the related but different property of absorptance (Eq. (4)). Using a spectrophotometer, optical density (OD) can be calculated as

$$OD = \log_{10} \frac{I_0}{I_z} \tag{9}$$

where I_0 is the intensity of incident light and I_Z is the intensity of light transmitted through the medium. If we arrange the system so that any light scattered in the medium is also included in our measurement of I, we can use Eq. (9) to determine the absorption coefficient (a) of the medium

$$a = \frac{2.303\ OD}{Z} \tag{10}$$

where 2.303 is the constant to convert base 10 to natural logarithms and Z is the path length of the medium. The absorption coefficient is given in units of 1/path length (typically m^{-1}). Under ideal measurement conditions, the result of Eq. (10) is identical to the theoretical absorption coefficient as defined in Eq. (6).

In aquatic ecosystems, photons may be absorbed by the water itself, dissolved substances, and particulate material. Pure water is not a colorless liquid. As is obvious by observing very deep, clear systems, water is a blue liquid. This color implies that there is significant spectral variation in absorption over the visible region. As seen in Fig. 4, the absorption of light by pure water decreases from the UV to a minimum in the blue range of the visible spectrum then increases substantially from 430 to 760 nm. Following a small decline centered around 810 nm, absorption increases markedly through the infrared region, peaking at about 975 nm. In the infrared, the absorption coefficient is more than 100 times greater than in the UV and visible region (compare left- and right-hand axes in Fig. 4). The strong absorbance peak in the IR region highlights the great importance of infrared radiation in influencing the heat budgets of aquatic ecosystems.

Dissolved organic matter (DOM) plays the most critical role in influencing the absorption spectrum of natural waters in the visible and UV wavelengths. The colored fraction (typically yellow/brown) of DOM is referred to as chromophoric dissolved organic matter (CDOM). This material consists mainly of humic and fulvic compounds originating from the decomposition of terrestrial plant material under anaerobic conditions. DOM released from microalgae and other aquatic plants is another source. DOM is typically characterized by its carbon content, dissolved organic carbon (DOC). The global mean concentration for DOC in freshwater systems is approximately 5 mg C L^{-1} but can vary widely ($\ll$1 mg C L^{-1} in very clear systems to >100 mg C L^{-1} in bogs). CDOM is generally an important component of DOM in high DOC lakes. As seen in Fig. 5, the presence of CDOM causes an exponential increase in absorption from the short visible wavelengths through the UV-B region of the spectrum. The slope of this exponential curve (S, $\ln(a)$ vs. $\lambda_{280-400nm}$) has been measured for a variety of freshwater systems and averages –0.0181 nm^{-1}. S typically ranges between –0.020 and –0.010 nm^{-1} and seems to be related to qualitative differences in CDOM (likely due to CDOM source or photobleaching). CDOM has the greatest influence on short wavelength UV radiation but also strongly affects the absorption of visible light (especially blue). The optical property often referred to as "color" is typically measured as the absorption coefficient at 440 nm and is a reflection of CDOM concentration for a particular aquatic ecosystem. In systems with high CDOM concentrations, absorption of PAR can significantly reduce light available for photosynthesis. Because of the shape of the absorption spectrum, much smaller concentrations of CDOM can effectively absorb damaging solar UV-B radiation, producing refugia from damaging UV at depth in aquatic systems. Above approximately 600 nm, CDOM has little influence on the absorption spectrum. Other dissolved constituents of aquatic systems (e.g., nitrate) may also absorb light but their specific absorption coefficients are very low compared to that of CDOM. Thus, these compounds will only be optically significant in systems with very low concentrations of CDOM.

Suspended particulate matter may also absorb light in aquatic systems (Fig. 6). Phytoplankton evolution has produced photosynthetic pigments that are highly efficient at absorbing light in the PAR and UV spectrum. These cells often contain a variety

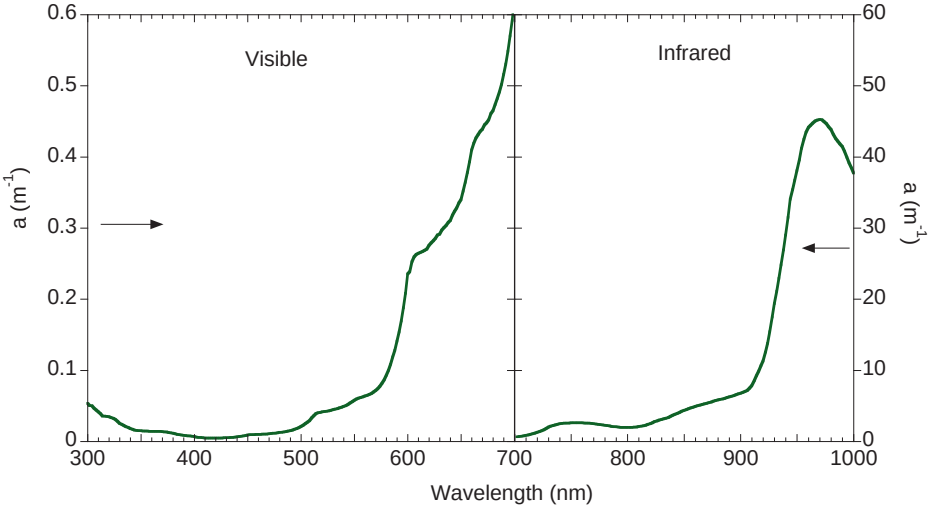

Fig. 4 Spectral distribution of the absorption coefficient for pure water. Measurements were made with a spectrophotometer, with air as reference. Note that the absorption coefficient in infrared is plotted using the right hand y-axis, which has a 100 times larger scale than the left hand y-axis for the UV and visible.

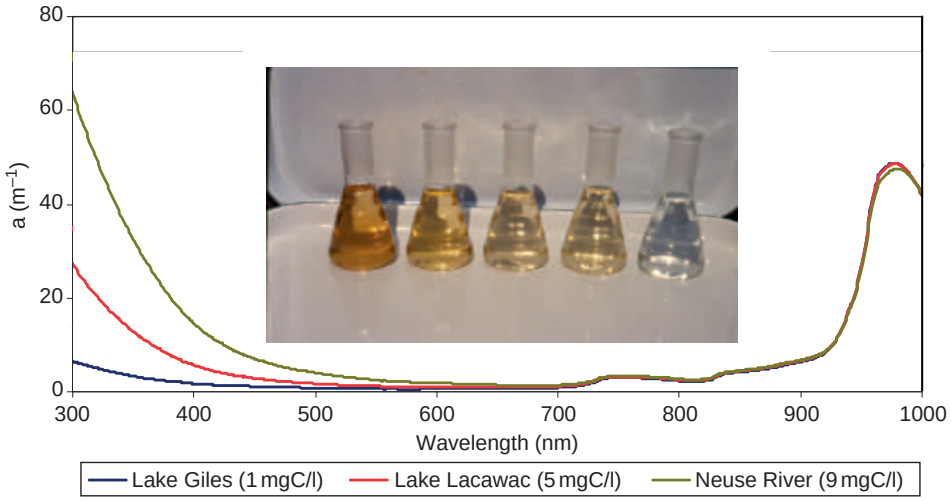

Fig. 5 Spectral distribution of absorption for filtered water from lakes with different concentrations of CDOM. The inset shows the visual color of four lake water samples ranging from approximately 1 to 15 mg C L^{-1} of dissolved organic carbon. Measurements were made with a spectrophotometer referenced to air.

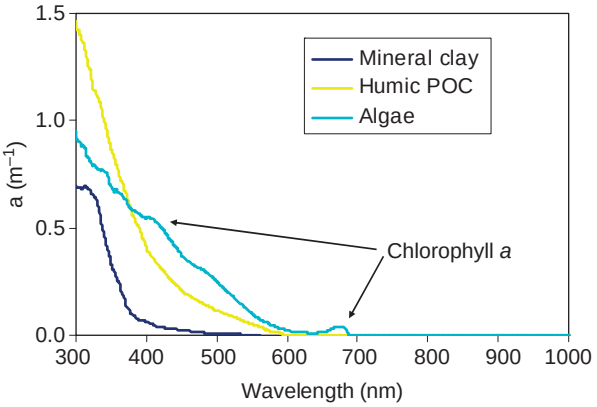

Fig. 6 Spectral distribution of absorption for three categories of particulate material commonly found in aquatic ecosystems. These are only examples, the shape and absolute size of the peaks will depend upon the composition and concentration of these materials in the water column. The "fingerprint" of the chlorophyll *a* absorption peaks (665 and 425 nm) can be seen in the sample of algae. Data were obtained using spectrophotometry and the quantitative filter pad technique.

of accessory pigments (e.g., carotenoids, chlorophyll *b*, and chlorophyll *c*, etc.) as well as chlorophyll *a*. As seen in Fig. 6, the absorbance peaks of chlorophyll *a* (425 and 665 nm) are often apparent in the spectral analysis of suspended particulate matter over and above that of accessory pigments. Systems with high concentrations of CDOM may also have significant amounts of suspended organic colloids composed of humic matter. The chemical composition and absorption spectrum of this particulate matter is often similar to that of CDOM (compare Figs. 5 and 6). Fig. 6 also shows an absorption scan for mineral clay particles. In contrast to either phytoplankton or colloidal CDOM, kaolin (a type of clay) exhibits very little absorption above 400 nm. However, mineral particles make an important contribution to scattering that extends across the spectrum (see "Scattering" section).

Optical properties of aquatic ecosystems

The transparency of aquatic systems is represented by a value referred to as the extinction coefficient or diffuse attenuation coefficient (K_d). This value may be determined empirically for an aquatic system using the following equation:

$$E_{dz} = E_{d0}\, e^{-K_d z} \tag{11}$$

where E_{dz} is the downward welling irradiance at depth z, E_{d0} is the downward welling irradiance just below the water's surface, and K_d is the diffuse attenuation coefficient. K_d has units of reciprocal depth (typically m^{-1}). As demonstrated in the previous section, the attenuation coefficient in aquatic systems will be influenced by absorption and scattering by pure water (K_{water}), by materials dissolved in the water ($K_{dissolved}$), and by particulate material ($K_{particulate}$). Thus, the total measured diffuse attenuation coefficient for a given system will be the sum of each of the partial diffuse attenuation coefficients.

As illustrated by data presented in Figs. 4–6, each of these partial diffuse attenuation coefficients have a strong spectral component. Thus, the relative contribution of each of these partial diffuse attenuation coefficients to the total diffuse attenuation coefficient will vary substantially across the solar spectrum and between systems. For instance, due to the spectral distribution of CDOM absorption, $K_{dissolved}$ in lakes comprised an average 68% of K_{total} at 305 nm compared to only 33% for PAR. In contrast, K_{water} contributes a much larger fraction (>95%) of K_{total} in the infrared portion of the spectrum than do the other partial diffuse attenuation coefficients. For lakes in general, the concentration of CDOM is the single most important determinant of K_d in the UV region of the spectrum while a combination of both CDOM concentration and phytoplankton biomass are significant determinants of K_d for PAR.

Plots showing examples of the extinction of light in an aquatic ecosystem are shown for Lake Superior, MI (Fig. 7). The top panel shows the comparative depth penetration of different wavelengths of solar irradiance, with lighter gray tones indicating higher

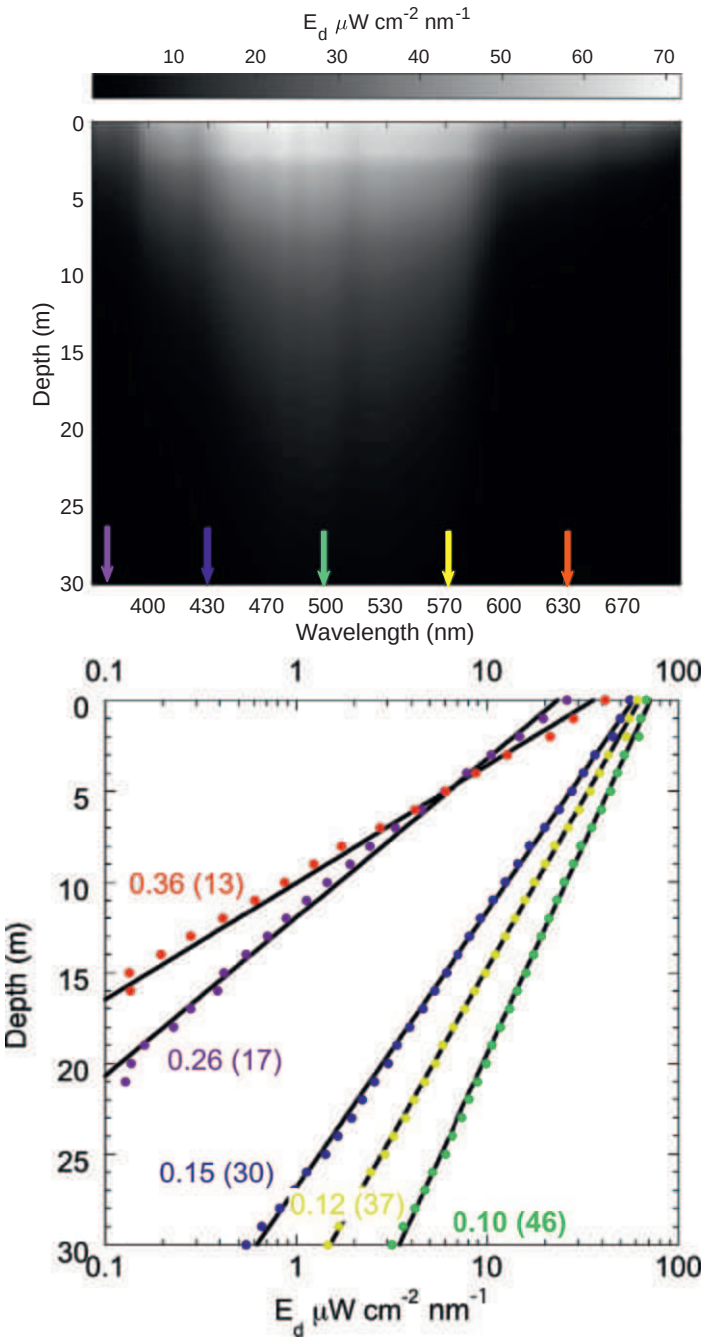

Fig. 7 Attenuation of downward welling irradiance (E_d) in Lake Superior. In the top panel, the extent of vertical penetration of irradiance from 370 to 700 nm (horizontal axis) with depth (vertical axis) is shown. Flux intensity is scaled by gray scale at top. In the bottom panel the line of best fit is plotted through the data points of ln(E_d) vs. depth for selected wavelengths indicated by arrows in upper panel. The negative slope of this line is the value of K_d for each wavelength. The values of K_d ($z_{1\%}$) are provided. Data from Mouw CB, Ciochetto AB, Grunert B and Yu A (2017) Expanding understanding of optical variability in Lake Superior with a 4-year dataset. *Earth System Science Data* 9: 497–509.

irradiance. The intensity of incident irradiance (i.e., at a depth of 0 m) follows from the data presented in Fig. 1, where the highest value of radiant flux (E_d in this case) is in the wavelength range of 470–530 nm (blue to green) with a progressive decrease in surface flux toward both the shorter (UV) and longer (red) wavelengths. As would be expected from the exponential form of Eq. (11), irradiance decreases quickly with depth such that 90% of PAR irradiance is attenuated in the first 18 m. Blue and green wavelengths, in addition to having the highest flux, also penetrate the deepest. Below 18 m in this near-shore area of Lake Superior, a diver in the water would see almost monochromatic bluegreen light as little remains of the rest of the spectrum. The color (wavelength) of this deepest penetrating light varies between lakes depending primarily on the absorption spectrum (Figs. 5 and 6), varying from a deep blue in lakes with low CDOM and particulates to yellow in lakes with a high concentration of these constituents.

Light of each of the wavelengths diminishes through the water column with a characteristic slope. Using Eq. (11), the value of K_d for each wavelength can be derived from the negative slope of the plot of $\ln(E_{dz})$ vs. depth. To illustrate, irradiance on a log scale is plotted (Fig. 7, bottom panel) for five selected wavelengths shown by the color-coded arrows along the lower axis of the upper panel. For near-shore Lake Superior, the highest K_d is in the red and the lowest K_d is in the green.

Since K_d is an exponential rate constant, it is often difficult for the general public to embrace it as an estimate of water column transparency. A more generally understandable parameter is the 1% attenuation depth for light. This parameter is the depth in the water column at which 99% of the surface irradiance has been attenuated. This parameter is useful in that for PAR it approximates the compensation depth, a depth at which daily photosynthesis = respiration, above which there is net oxygen production, and below which there is net oxygen consumption. The 1% attenuation depth for any given wavelength or wavelength range can be calculated as

$$z_{1\%} = \frac{4.61}{K_d} \tag{12}$$

where $z_{1\%}$ is the 1% attenuation depth (m) and K_d is the diffuse attenuation coefficient (m^{-1}). The value 4.61 is the $-\ln(1\%)$. Lower values of K_d correspond to higher water column transparency. In Lake Superior (as well as many other aquatic systems) the low transparency in the UV is due to the presence of CDOM which in this case accounts for more than 70% of the lake water absorbance at 370 nm (Mouw et al., 2017). The relationship between K_d and λ generally follows the relationship between the absorption coefficient (a) and λ observed in different concentrations of CDOM (Fig. 5).

The transparency of PAR in aquatic ecosystems can vary tremendously. Fig. 8 shows the vertical penetration of PAR in five lakes that span a range of transparency typically found in aquatic systems. In extremely clear Lake Correntoso, $z_{1\%}$ is in excess of 45 m while 99% of PAR is attenuated in the first meter of Little Echo Lake, which has moderate concentrations of chlorophyll a (~6 mg L^{-1}) and a high concentration of CDOM (~23 mg C L^{-1}).

One method of estimating the transparency of visible light (PAR) in aquatic systems is the Secchi disk. First used in the 1860s, the black and white Secchi disk (20 cm diameter) is lowered through the water column on a calibrated line. The depth at which the disk disappears is termed the Secchi depth (z_{sd}).

Although the Secchi depth can vary between users, light conditions, and surface conditions, generally the $z_{1\%}$ for PAR corresponds to approximately 2–3 times z_{sd}. The value of Secchi measurements lies not in its accuracy, but in its ease of use and the extremely long records of transparency based on this simple and inexpensive device.

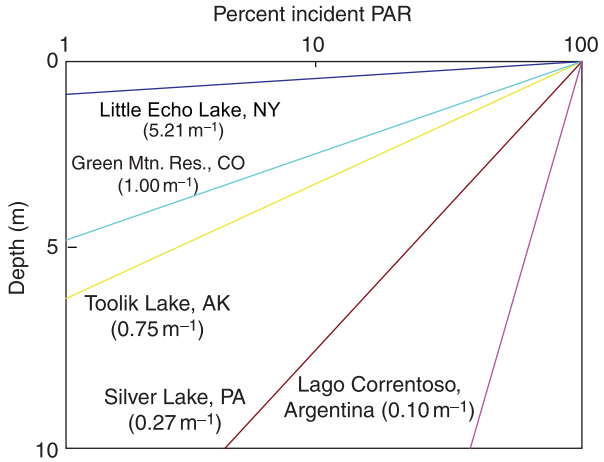

Fig. 8 Penetration of PAR for lakes with widely differing transparency. Diffuse attenuation coefficients are provided for each lake (K_d).

Conclusion

In conclusion, light is critical in structuring aquatic ecosystems. Seasonal variations in the heat energy provided by sunlight are responsible for thermal stratification and mixing regimes so fundamental to aquatic systems. The energy of sunlight used in photosynthesis forms the foundation of all but the simplest microbial communities on Earth. Thus, an understanding of the nature of light, and how it interacts with the atmosphere and the water column, is fundamental to our understanding of how aquatic ecosystems function.

Glossary

1% Attenuation Depth (m) The depth to which 1% of subsurface irradiance of a given wavelength penetrates in the water column. Using subsurface measurements gives a surface reference that excludes albedo and thus more accurately reflects water transparency. When estimated from epilimnetic diffuse attenuation coefficients the attenuation depths may be somewhat greater than the actual attenuation depths due to higher absorptivity of the deeper hypolimnetic waters.

Biolabile The degree to which a compound such as dissolved organic matter is available for biological uptake, usually by microbes.

Chromophore A molecular structure that absorbs photons, usually in a wavelength selective fashion.

Diffuse attenuation coefficient ($K_{\lambda d}$, m^{-1}) Exponential rate of decrease of subsurface irradiance with depth which varies by wavelength.

Dobson Unit (DU) A measure of total column content of a gas, frequently used for ozone. The thickness of the layer (in 10's of μm's) of the total mass of the gas in the column at standard temperature and pressure (STP, 0 °C, 1 atm). For example, 300 DU = 3 mm of ozone at STP.

Dose ($J\ m^{-3}$ or $J\ g^{-1}$) Total radiant energy in a given wavelength range absorbed by a specific chromophore (per volume or per mass). Compare exposure.

Dose Rate ($W\ m^{-3}$ or $W\ g^{-1}$) Measure of the radiant energy absorbed per unit time ($J\ s^{-1}$) by a specific chromophore (per volume or per mass). Compare irradiance.

Erythemal UV index (UVI) A derived unit that expresses the potential for sunburn in Caucasian humans estimated by multiplying the solar irradiance spectrum by the CIE action spectrum for sunburn (McKinlay and Diffey, 1987) and multiplying by 40 (for irradiance in $W\ m^{-2}\ nm^{-1}$).

Irradiance (E or E_λ, $W\ m^{-2}$, or $W\ m^{-2}\ nm^{-1}$) Measure of the radiant power within a wavelength range or at a given wavelength, λ, incident per unit area on a surface; exposure rate. Compare dose rate. Fluence rate is the analogous term for radiant power (energy received per unit time, $J\ s^{-1}$) from all directions to a point.

Photobleaching The removal of a chromophore in a chemical compound induced by the absorption of photons.

Photodegradation Photochemical transformation of a molecule into lower molecular weight fragments, usually by oxidation (photooxidation).

☆*Change History*: March 2021. CE Williamson and PJ Neale updated the abstract, text and further readings. Figure 4 was revised with updated information.

Photolabile The degree to which a chemical compound is susceptible to being broken down by photolysis.
Photolysis The cleavage of chemical bond induced by the absorption of photons.
Photooxidation Oxidation reactions induced by absorption of photons.
Radiant Exposure (H or H_λ, J m^{-2}, or J m^{-2} nm^{-1}) The total amount of radiant energy within a wavelength range or at a given wavelength, λ, incident on a surface. Compare dose. Fluence is the analogous term for radiant energy received from all directions to a point.
Reactive oxygen species (ROS) Potentially damaging highly reactive forms of oxygen such as hydrogen peroxide, superoxide or hydroxyl radicals, or singlet oxygen.
Spectral slope (S, nm^{-1}) The slope of the plot of the natural log of the absorbance versus wavelength for a specified wavelength range such as all UV (280–400 nm), UV-A (320–400 nm), or UV-B (280–320 nm).
Total column ozone The amount of ozone in the entire atmospheric column over a given area, expressed in Dobson Units.
Zenith The point in the sky directly overhead from the location of interest.

Introduction

The important role of UV in inland aquatic ecosystems went largely unrecognized for many years because it was believed that incident solar UV was rapidly absorbed within the surface waters. Although a few early studies demonstrated that UV penetrated many meters into the water column of highly transparent lakes, these studies were unappreciated. Instrumentation for measuring underwater UV was not widely available for many years and few measurements were made of UV attenuation in inland waters. This all changed following the discovery of severe ozone depletion in Antarctica (the "ozone hole") in the mid-1980s and subsequent evidence for ozone depletion and elevated UV exposure in the Arctic and even temperate latitudes. Submersible UV radiometers became more widely available to study this disturbing global UV trend and recognition of the importance of UV in inland waters has increased in recent decades.

While ozone is the major UV-absorbing substance in the atmosphere, colored, or chromophoric dissolved organic matter (CDOM) is the primary UV-absorbing substance in most inland waters. Variations in CDOM concentrations in inland waters contribute far more to the regulation of underwater UVR than variations in atmospheric ozone. The strong CDOM-driven gradients in UV transparency in inland waters lead underwater UV exposure to vary by orders of magnitude across water bodies. High elevation alpine waters often exhibit the highest levels of underwater UV exposure due largely to low CDOM concentrations, while lowland waters with extensive wetlands in their watersheds that contribute to high CDOM production have lower UV transparency. The sensitivity of UV transparency of inland waters to CDOM changes related to natural and anthropogenic disturbances makes UV transparency a good sentinel of environmental change. Climate warming and other disturbances including UV can in turn alter concentrations and quality of CDOM in inland waters and contribute to strong temporal and spatial gradients in underwater UV exposure. It is these strong and dynamic gradients in underwater UV exposure and the sensitivity of UV transparency to environmental change that drive the need to understand the causes and consequences of UV exposure in inland waters.

Main topics/concepts

Wavelengths and units of measurement

Ultraviolet radiation can be separated according to wavelengths into UV-C (200–280 nm), UV-B (280–320 nm) and UV-A (320–400 nm). The Commission Internationale de l'Eclairage, CIE (International Commission on Illumination) uses 280 nm to separate UV-C and UV-B, 315 nm to separate UV-B and UV-A, and 400 nm to separate UV-A and photosynthetically active radiation (PAR). Some investigators use 290 nm and 320 nm as breakpoints. Here we adopt the 280 and 320 nm wavelengths to separate out the types of UV as these are most commonly used in aquatic studies (Hargreaves, 2003; Hargreaves et al., 2007; Kirk, 2011). While PAR is most commonly measured in quantum units (moles of photons), UV is more commonly measured in energetic units. Radiant flux of UV is measured in Watts (J s^{-1}), radiant exposure (dose or fluence) in J m^{-2}, and irradiance (dose rate, fluence rate, or radiant flux density) in W m^{-2}.

Atmospheric controls on incident UV in inland waters

The amount of solar UV radiation incident on inland waters is influenced by sun angle, elevation, cloud cover, and atmospheric aerosol and ozone concentrations. Sun angle (usually measured from the zenith, directly overhead), is the most important determinant of UV exposure due to two primary mechanisms. The length of the slant path through the atmosphere is a function of zenith angle. Longer paths through the atmospheric increase absorption and scattering. In addition, at higher angles the incident beam is projected over a larger area. Changes in sun angle drive the diurnal and seasonal variation in UV (Fig. 1), and most of the UV variation with latitude. Aerosols and clouds are the most important factors affecting the day-to-day variation in incident UV (Fig. 1), primarily by scattering radiation back to space. Aerosols scatter the shorter UV wavelengths more efficiently than visible light, so UV can be substantially lowered by "hazy" conditions even under apparently "sunny" conditions. Under most conditions, aerosol and

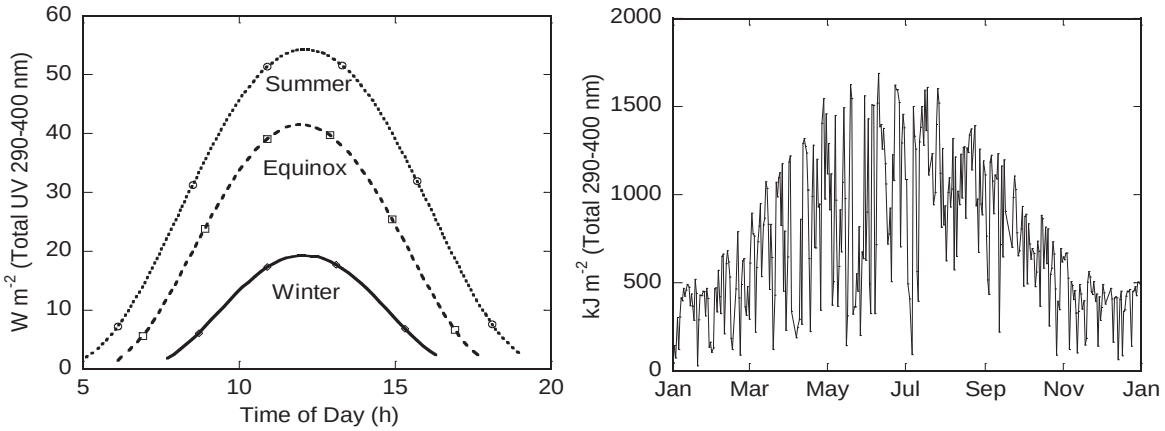

Fig. 1 Example plots for diurnal and annual variation in total UV radiation (290–400 nm) for summer and winter solstices and equinoxes (left panel, fall shown, spring is similar) at a temperate location (Edgewater, MD, United States, ~39°N latitude). The diurnal curves show maximum (clear sky) irradiance (W m^{-2}) calculated using a radiative transfer model. The annual curve is for total daily UV (J m^{-2}) as measured at the Smithsonian Environmental Research Center (Edgewater, MD, United States) for 2003 (right panel). The annual range for total daily UV at this latitude is a factor of three, a similar range of variation occurs day-to-day due to variations in cloud cover, aerosols and ozone.

molecular (Rayleigh) scattering divert so many UV photons from a straight path (direct beam) that UV exposure is primarily from sky (diffuse) light. The ratio of diffuse to direct light increases with shorter wavelengths. This phenomenon leads to much more variability ("noise") in underwater vertical profiles of visible and long-wavelength UV than shorter-wavelength UV during wavy rather than calm conditions.

Clouds are less wavelength-selective than are aerosols, but can still have different effects on UV than visible light. This is another consequence of the higher diffuse/direct ratio in UV: clouds blocking the solar disc, but not the sky, have only a small effect on UV. Incident irradiance can actually exceed "clear sky" levels when high clouds not actually covering the sun act as reflectors. Uniform cloudiness, on the other hand, has about the same effect on UV as visible light, usually >50% overall reduction.

Ozone absorbance is the most wavelength selective of all atmospheric controls on UV, absorbing essentially all UV shorter than about 290 nm and having little effect for wavelengths longer than 330 nm. Because of existing concentrations of atmospheric ozone, only UV-A and UV-B components impinge on inland waters. Total column ozone in the atmosphere varies across Earth's surface and with season independent of any of the ozone depletion events reported in recent decades. Column ozone generally varies from about 240 Dobson units (DU) at the equator to over 440 DU near the North Pole. The seasonal variation in ozone is minimal at the equator with a range between 240 DU and 260 DU. At the North Pole ozone ranges more widely from 280 DU in September to over 440 DU in March. At the South Pole the seasonal variation in the absence of the ozone hole ranges from less than 300 DU in the austral fall to over 340 DU in the austral spring.

The combination of a sun angle closer to the zenith and the reduced ozone at the equator leads inland waters in tropical regions to be exposed to much higher UV levels than temperate, boreal, or polar systems. A major exception to this is in regions with severe ozone depletion. For example, the World Health Organization uses an erythemal UV index that ranges from 1 to 18 to reflect potential biological damage (sun burn in this case). This UV index generally ranges from 4 to 10 in temperate zones and from 10 to 16 in the tropics. During ozone hole events total column ozone in Antarctica can be depleted to levels less than 100 DU. Although UV indices around Antarctica are typically low at all times due to the southerly location, it increases from 1–3 to 4–6 in coastal locations under ozone-depleted air masses and values as high as 12 have been observed.

The potential for increased exposure to damaging UV as a consequence of ozone depletion inspired the Vienna Convention for the Protection of the Ozone Layer in 1985 and the Montreal Protocol on Substances that Deplete the Ozone Layer in 1987. These international agreements were successful in reducing the levels of anthropogenic ozone-depleting substances in the atmosphere and subsequently the rate of stratospheric ozone depletion. The beginning of a significant long-term trend of recovery of ozone over Antarctica has now been documented. However, current concentrations of chlorine and bromine in the stratosphere are still adequate to catalyze depletion of nearly all of the ozone in the critical 14–21 km altitude layer of the polar vortex. Ozone depletion now varies greatly from year to year depending on the temperature of the stratosphere (which is being affected by climate change). The 2019 "ozone hole" was one of the smallest on record while 2020 had the 12th largest ozone hole observed over the past 40 years. Full recovery to the levels observed in the 1970s is not expected until the middle of the 21st century.

Environmental regulation of underwater UV exposure and impacts

Measuring UV transparency

Submersible radiometers are used to measure depth profiles of UV at various wavelengths. These profiles follow an exponential trend and thus appear as straight lines when plotted on a logarithmic scale in a semi-log plot (Fig. 2). The slope of this line, the rate of exponential decrease, is the diffuse attenuation coefficient ($k_{\lambda d}$, m^{-1}) which is specific to a given wavelength λ. Derived from the

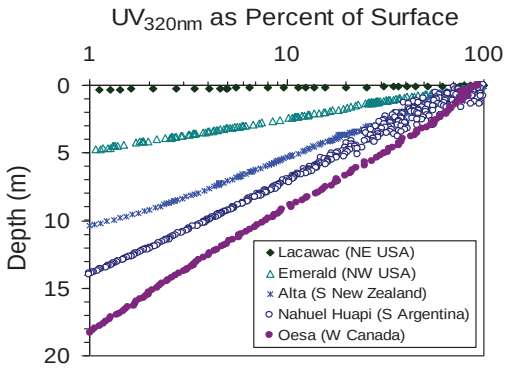

Fig. 2 Depth profiles for five selected lakes showing the wide variation in UV attenuation in inland waters. The intersection with the vertical axis shows the depth to which 1% of the subsurface 320 nm UV penetrates, referred to as the 1% attenuation depth ($Z_{320nm1\%}$). Wavelengths in the 320 nm range are among the most highly damaging solar radiation when you combine the solar spectrum with a biological weighting function to get the biologically effective exposure (see Fig. 9).

$k_{\lambda d}$ (often just k_d is used, but attenuation is strongly wavelength dependent) is the depth at which UV declines to 1% of the surface value, the 1% attenuation depth ($z_{\lambda 1\%}$, m), which is an overall measure of UV transparency for a given wavelength. For more general information about the derivations of $k_{\lambda d}$ and $z_{\lambda 1\%}$ see Kirk (2011).

Effects of CDOM on UV transparency

UV transparency can vary greatly among inland water bodies with the 320 nm 1% attenuation depths ranging from a few centimeters to well over 10 m (Fig. 2). This variation is largely a function of dissolved organic carbon (DOC), the optically active component of which is colored dissolved organic matter (CDOM) (Fig. 3). Environmental change, and "browning" of water due to observed increases in CDOM can similarly reduce UV transparency within a single water body leading to strong long-term changes in UV transparency (Fig. 4).

A wide variety of dissolved and particulate compounds contribute to the UV transparency and hence underwater UV exposure levels in inland waters. The most important of these is CDOM. Similar to ozone, CDOM selectively absorbs shorter wavelengths of solar radiation, leading to more rapid attenuation of shorter wavelengths in the water column (Fig. 5). CDOM also plays a major role in determining the depth of the surface mixed layer in small lakes and ponds which will in turn influence UV exposure of non-motile planktonic organisms in this stratum. During winter ice formation CDOM is excluded such that clear ice with few air bubbles is more UV transparent than unfrozen water. Air bubbles and snow cover dramatically decrease transmission of UV by ice. In lakes with anoxic hypolimnia the oxidation of ferrous iron to ferric iron may cause substantial increases in UV absorbance. DOM can complex with the iron and increase its retention in the surface waters, thus decreasing UV transparency.

CDOM in inland waters may come from autochthonous sources such as algae or macrophytes, but the primary source is generally allochthonous sources derived from the leaching and decomposition of terrestrial vegetation within the surrounding watershed. Peat-based wetlands can be particularly strong sources of allochthonous CDOM to associated water bodies. Allochthonous CDOM is generally composed of more refractory, higher molecular weight compounds that are more highly UV-absorbing and

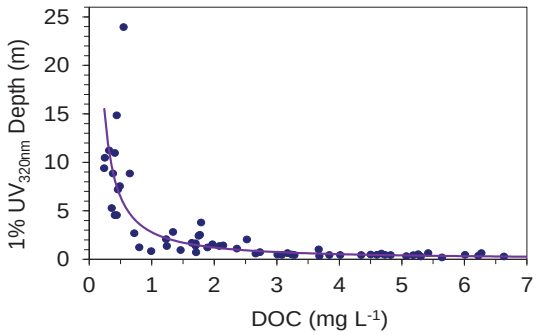

Fig. 3 Variation in UV attenuation among lakes as a function of DOC concentration. The depth to which 1% of 320 nm UV penetrates as estimated from diffuse attenuation coefficients is shown for a series of glacial lakes from the northern and southern hemisphere. Each data point represents one lake. Note the strong inflection point below about 1–2 mg L^{-1} DOC, indicating the high sensitivity of these low DOC lakes to small changes in DOC inputs. Modified from Fig. 1, page 1026 in Williamson CE, Stemberger RS, Morris DP, Frost TM and Paulsen SG (1996) Ultraviolet radiation in North American Lakes: Attenuation estimates from DOC measurements and implications for plankton communities. *Limnology and Oceanography* **41**: 1024–1034, Copyright (1996) by the American Society of Limnology and Oceanography.

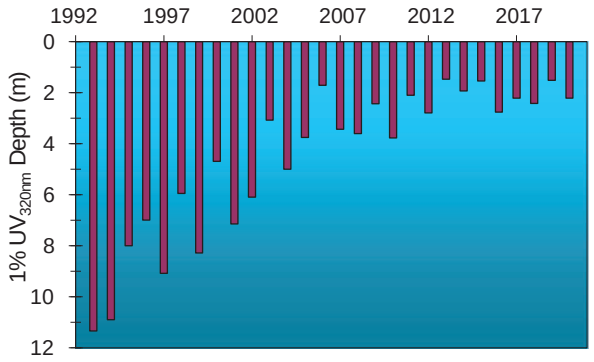

Fig. 4 Trends of changing UV transparency in an eastern Pennsylvania, United States lake in recent decades. The changes in the actual measured 1% 320 nm UV attenuation depth in Lake Giles are plotted for the past 27 years. These decreases in UV transparency over time are due largely to "browning," a phenomenon documented in lakes across large regions of northern Europe and northeastern North America where both the concentration and color of CDOM have been increasing over time.

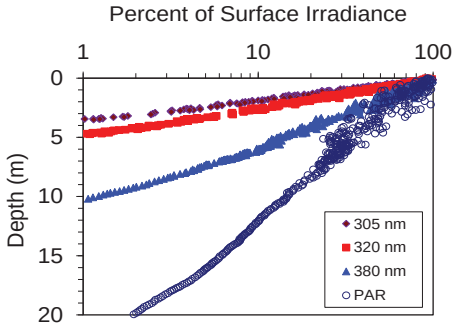

Fig. 5 Attenuation of 305, 320, and 380 nm UV and PAR in Lake Giles, NE Pennsylvania, United States showing the wavelength-dependent attenuation with depth in the water column that is characteristic of most lakes. In lakes with extremely low concentrations of CDOM such as Lake Tahoe, the 380 nm UV may actually attenuate less rapidly than longer wavelength PAR due to the peak transparency of pure water in the short wavelength blue which is close in wavelength to UV-A.

thus more photolabile. Autochthonous CDOM on the other hand is composed of smaller molecular weight compounds that are less UV-absorbing and correspondingly less photolabile but more biolabile. When exposed to solar UV radiation CDOM undergoes important photochemical changes that involve photolysis and photobleaching, rendering it less UV-absorbing and more aliphatic. Photobleaching of CDOM in combination with other seasonal changes in hydrologic inputs and biota can substantially increase the UV transparency of inland waters during the summer months (Fig. 6). In endorheic hypersaline lakes the long residence time of CDOM leads it to be strongly photobleached and much less UV absorbing.

Effects of elevation, plankton, and particulates on UV transparency

Living organisms in alpine waters are exposed to particularly high levels of UV radiation. Shorter wavelength UV-B (300 nm) may increase by as much as 24% per 1000 m in elevation due to the shorter pathlength through the atmosphere. The low densities of terrestrial vegetation in alpine ecosystems also reduce the inputs of UV-absorbing CDOM into alpine waters (Fig. 7). The timing of ice-out in alpine environments is often close to summer solstice, thus exposing aquatic organisms to maximum UV levels at very low temperatures that slow down DNA repair enzymes.

In extremely low DOC alpine systems and in higher DOC hypereutrophic, algal-rich systems phytoplankton may play an important role in regulating UV transparency. While zooplankton are known to increase visible transparency in lakes during seasonal "clear-water phases" through their grazing on phytoplankton, the contribution of zooplankton to seasonal increases in UV transparency is small relative to photobleaching of CDOM. In highly turbid systems like glacial lakes and shallow, wind-mixed reservoirs, suspended particulates may play a primary role in reducing UV transparency (Rose et al., 2014; Olson et al., 2018).

Mechanisms of UV damage in aquatic organisms

UV can cause substantial damage to a wide variety of aquatic organisms ranging from viruses, bacteria, and phytoplankton to zooplankton, fish, and amphibians (Peng et al., 2016; Alves and Agusti, 2020). Direct and indirect mechanisms of UV damage influence critical cellular processes in aquatic organisms ranging from DNA replication and transcription to cell survival, growth, motility, photosynthesis, orientation, and nutrient uptake. The relative importance of overall exposure versus irradiance (often

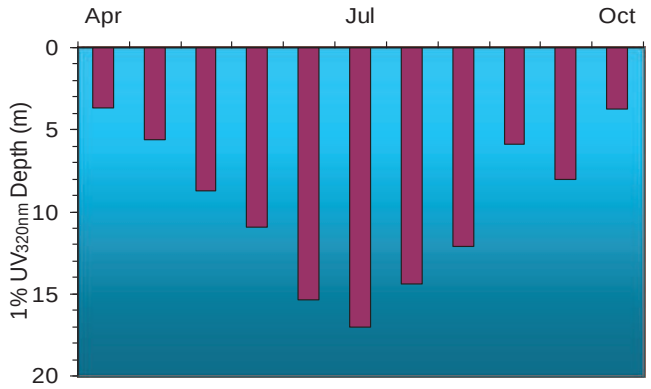

Fig. 6 Seasonal variation in UV transparency in Lake Giles, a low DOC lake in northeastern Pennsylvania, United States. These seasonal changes are largely driven by photobleaching, with minimal change in DOC concentrations. Values are expressed as the 1% attenuation depth for 320 nm UV from epilimnetic diffuse attenuation coefficients. Note the change in the 1% attenuation depth from 3 m in April to over 15 m in mid-July. This is an extreme example of the more subtle seasonal changes that are observed in most lakes. Actual depths to which UV penetrates may be somewhat less when UV penetrates into the hypolimnion where UV transparency may be lower. Modified with permission from Fig. 4 in Williamson CE, Hargreaves BR, Orr PS and Lovera PA (1999) Does UV play a role in changes in predation and zooplankton community structure in acidified lakes? *Limnology and Oceanography* **44**: 774–783. Copyright (1999) by the American Society of Limnology and Oceanography.

Fig. 7 Watersheds of alpine Lake Alta in New Zealand with very little vegetation (left) and temperate lowland Lake Lacawac in the northeastern United States with abundant vegetation (right). The amount of vegetation in the surrounding watershed is a key source of CDOM inputs and thus variations in UV transparency among inland waters.

referred to imprecisely as "dose" and "dose rate" respectively, see glossary) in causing UV damage is a major concern. The reciprocity principal argues that damage is a function of total dose and independent of dose rate. However, the presence of active repair processes generally invalidates the reciprocity principle because repair of UV damage permits high survival rates over long periods of low exposure. Short-term periods of exposure to high dose rates of UV often have a much more severe effect on organism survival ("one bad day" hypothesis).

Primary mechanisms and targets of UV damage

There are two primary mechanisms of UV damage to living organisms at the subcellular level: damage by direct absorption of UV by a molecule or complex, and damage through the production of reactive oxygen species (ROS). Biomolecules that absorb the shorter wavelength, higher energy UV are most susceptible to direct damage. DNA and RNA are the two most highly UV-absorbing biomolecules, and due to its lower turnover rate in the cell, DNA is considered the primary target of UV damage. The primacy of DNA damage has given rise to the use of DNA dosimeters to assess DNA damage in the environment. These are small quartz tubes with DNA solutions that provide an assessment of potential DNA damage to aquatic organisms by examining the UV-induced photoproducts in the absence of repair processes that do occur in living cells. The primary photoproduct in UV-irradiated DNA is the cyclobutane pyrimidine dimer (CPD), followed by the pyrimidine (6–4)pyrimidone dimer [(6–4)PD]. While CPDs are the most abundant photoproduct (up to 80–90% of total photoproducts), the (6–4)PD photoproducts may be as much as 300 times more cytotoxic than the CPDs due to their effectiveness at blocking DNA polymerase.

The second major type of UV damage results from the production of ROS that cause cell damage, like hydrogen peroxide, singlet oxygen, and hydroxyl and superoxide radicals. The lower energy, longer wavelengths of UV are largely responsible for ROS production both in organisms and the surrounding water. Damage from ROS may be at sites within the organism that are remote from the site of UV exposure. The short half-life of most UV-induced ROS prevents them from accumulating in inland waters. The exception is hydrogen peroxide with a half-life on the order of a few hours to a day.

UV damage to proteins and lipids

UV can influence protein metabolism through inhibition of nitrogen uptake and thus the rate of protein synthesis. The absorption of UV by aromatic amino acids makes many proteins susceptible to UV damage including nitrogenase, the enzyme responsible for nitrogen fixation. Structural proteins can be damaged by UV due to the disruption of covalent sulfur bonds that are important in tertiary protein structure. UV damage of proteins in the lens of the eye can lead to cataracts in aquatic organisms as in humans. Damage to proteins is also thought to be the major reason for inhibition of photosynthesis by UV through largely UV-A damage to photosystem II and the RUBISCO pathway. The double bonds in many lipids also absorb UV and combined with lipid peroxidation can damage lipid-rich membranes.

Importance of spectral composition

The division of UV into the three bands gives a rough indication of biological threat—increasing from A to C. The biological effect varies almost continuously with wavelength for several reasons. The energy of a photon is inversely proportional to its wavelength (Planck's Law). Thus UV-C is the highest energy and has the greatest effect per photon while UV-A has the least. The effectiveness of short wavelength UV, however, increases more rapidly with decreasing wavelength than the increase in photon energy because biomolecules have higher absorbance at shorter wavelengths. Thus effectiveness typically rises exponentially with decreasing wavelength, with the slope and shape varying for different effects (Fig. 8). Processes driven by DNA damage have a characteristically different shape than when damage is also induced by production of ROS. Effectiveness curves are termed biological weighting functions (BWFs), and must be considered when comparing responses to exposures that differ in spectral composition such as experiments with artificial lamps versus natural solar exposures (Fig. 9).

Mechanisms to reduce UV damage

There are three possible levels of response of aquatic organisms to reduce UV damage in nature: behavioral avoidance, photoprotection by sunscreens or antioxidants, and molecular repair following the damage.

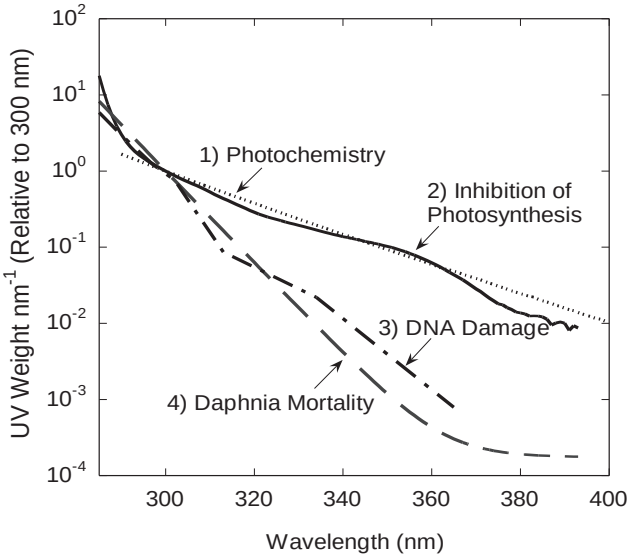

Fig. 8 Photochemical weighting function for production of hydrogen peroxide (ROS that contribute to CDOM photobleaching) (1), and biological weighting functions (BWFs) for the effect of UV on inhibition of photosynthesis, average for natural populations of phytoplankton (2), DNA damage in alfalfa seedlings (3), and mortality of *Daphnia* (4). Note the shape is different when ROS are important (1 and 2) versus when DNA damage is important (3 and 4). The weights have been normalized to 1 at 300 nm. Data sources are (1) and (2) Neale PJ and Kieber PJ (2000) Assessing biological and chemical effects of UV in the marine environment: Spectral weighting functions, In RE Hester and RM Harrison [eds.], *Causes and Environmental Implications of Increased UV-B. Radiation. Issues in Environmental Science and Technology*. pp. 61–83, Royal Society of Chemistry. Fig. 9 Spectral distribution of UV (280–400 nm) in a UV incubator (Phototron) using fluorescent lamps (combination of Spectronics XX15-B and UVA-340, Q-Panel) and the average spectral irradiance in a shallow water column (1.5 m deep) (Rhode River, MD, United States, near summer solstice, noon, 40°N latitude). (A) unweighted radiation; (B) radiation weighted by the BWF for inhibition of photosynthesis in natural phytoplankton populations; (C) radiation weighted by the BWF for DNA damage in alfalfa. The BWFs are shown in Fig. 8. Total (280–400 nm) UV is the same for the unweighted spectra, but the lamps emit a greater proportion of more damaging UV-B, so that the weighted irradiance in the incubator is >3 times higher for inhibition of photosynthesis and >11 times higher for DNA damage compared to water column irradiance. Source for spectra: Rhode River—Litchman E and Neale PJ (2005) UV Effects on photosynthesis, growth and acclimation of an estuarine diatom and cryptomonad. *Marine Ecology Progress Series* **300**: 53–62.; Williamson CE, Neale PJ, Grad G, De Lange HJ and Hargreaves BR (2001) Beneficial and detrimental effects of UV radiation on aquatic organisms: Implications of variation in spectral composition. *Ecological Applications* **11**: 1843–1857.

Behavioral avoidance of UV damage

Behavioral avoidance of UV requires the ability to detect UV (photoreceptors sensitive to UV) as well as the ability to avoid UV (motility). A wide range of aquatic organisms do have UV photoreceptors including some bacteria, phytoplankton, protozoa, annelids, mollusks, crustaceans, and fish. Negative phototaxis to longer wavelength PAR may also be effective in UV avoidance. However, the selective absorption of the short-wavelength damaging UV-B irradiation by ozone and DOM create wide variations in UV:PAR ratios. The disproportionate increase in damaging UV-B with decreasing wavelength may lead to UV damage under scenarios of ozone depletion or reduced DOM if organisms cannot detect and avoid UV ("solar ambush" hypothesis). Exposure to UV-B can also damage both motility and orientation behavior, rendering any potential phototactic avoidance less effective.

Several species of zooplankton and fish can detect and avoid UV. *Daphnia* have UV photoreceptors with peak absorption at 348 nm and can avoid damaging UV in situ by downward migration. The larval and juvenile stages of some species of fish have photoreceptors with absorption peaks in the UV-A range. Laboratory studies have demonstrated that these UV-A photoreceptors

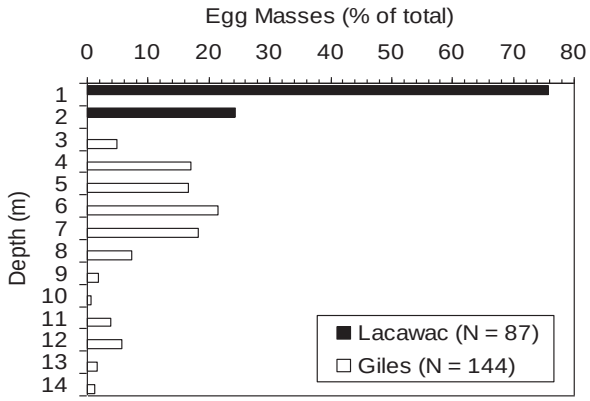

Fig. 10 Spawning depth of yellow perch (*Perca flavescens*) in two lakes in the same geographic area, one of high (Giles) and one of low (Lacawac) UV transparency. Note that all eggs in Lake Giles were spawned deeper than 2 m, while in Lake Lacawac all eggs were spawned at depths shallower than 2 m. It is not known whether the deeper spawning in the high UV lake is a result of UV avoidance behavior or differential survival coupled with strong fidelity to spawn at natal sites. Deposition of eggs in the deeper, colder waters may slow development and hatching and consequently reduce the time available for perch to reach the critical size needed to survive the following winter. Modified with permission from Fig. 3 in Huff DD, Grad GG and Williamson CE (2004) Environmental constraints on spawning depth of yellow perch: The roles of low temperature and high solar ultraviolet radiation. *Transactions of the American Fisheries Society* **133**: 718–726.

may enhance feeding in larval fish, and field experiments have demonstrated the ability of juvenile Coho salmon (*Oncorhynchus kisutch*) to avoid solar UV in shallow streams. Yellow perch (*Perca flavescens*) spawn deeper in more UV transparent lakes, but it is not clear that this is a behavioral response (Fig. 10).

Protection against UV damage: Sunscreens and defense compounds

There are two major types of UV photoprotective compounds: sunscreens that absorb UV radiation directly and antioxidants that reduce damage from ROS. Some compounds serve both functions. Sunscreens are less effective in very small organisms such as bacteria where the pathlength of a UV photon is too short to be effectively absorbed before causing damage. Photoprotective compounds present in aquatic organisms include carotenoids, mycosporine-like amino acids (MAAs), and melanin. Carotenoids have absorption peaks in the short-wavelength blue range but this absorption extends into the UV, thus allowing absorption and dissipation of UV energy as heat. Carotenoids are also important quenching agents that react with ROS to reduce levels of cellular damage. Environmental concentrations of carotenoids are not consistently correlated with UV exposure, and plant-derived carotenoids in zooplankton may actually reach their highest concentrations in colder waters under non-peak UV conditions, suggesting that their function is not only one of photoprotection.

Mycosporine-like amino acids (MAAs) are photoprotective compounds with absorption peaks generally in the 310–360 nm range; with some functioning also as antioxidants. The MAAs derive their name from fungi where they were initially discovered to be abundant during sporulation. Fungi, bacteria, and algae are the only groups that can synthesize MAAs because they have the shikimate pathway, a biochemical pathway related to the pathway used to produce photoprotective flavonoid compounds in higher plants. Animals must acquire MAAs through their diet. The production of MAAs is photoinducible and MAA concentrations in both phytoplankton and zooplankton are known to be correlated with environmental UV exposure.

Among the crustacean zooplankton, cladocerans generally have low concentrations of carotenoids and MAAs but a few species do utilize melanin. Copepods have little melanin but depend heavily on carotenoids and MAAs. In marine copepods, and thus by inference in freshwater copepods, ingestion of MAAs may increase fitness. Though some fish use melanin for photoprotection, especially in juvenile stages, it is often lacking in their epidermal layers. Melanin is common in the epidermis of many amphibians, particularly in early developmental stages such as eggs and larvae. Some fish secrete UV-absorbing compounds in their mucus while others have UV-reflective guanine-based compounds in their scales.

Several common antioxidant enzymes and vitamins in algae are capable of reducing oxidative damage from ROS produced during UV exposure, but little is known about how widespread this process is in other aquatic organisms. These compounds include superoxide dismutase (SOD), glutathione peroxidase, ascorbate peroxidase, catalase, vitamin E (α-tocopherol) and vitamin C (ascorbic acid).

Molecular repair of UV damage

UV-induced DNA lesions can be repaired by a variety of molecular processes including photoenzymatic repair (PER, also referred to as photorepair or photoreactivation), nucleotide excision repair (NER), and base excision repair (BER). PER is mediated by a single enzyme, photolyase, which requires UV-A or visible light for activation. Thus, PER is often referred to as "light repair". PER is specific to damage induced by UV and is present in a wide range of organisms but not all species. NER and BER on the other hand are not

specific to UV damage and are universal among all organisms. NER is often referred to as "dark repair" because it does not require UV-A or visible light but rather depends on the metabolic energy of ATP. In bacteria the recA gene codes for a protein that promotes DNA recombinational repair. Exposure to UV transforms the recA derived protein into a proteinase that destroys a repressor and subsequently enables the expression of a suite of DNA repair genes. Because these DNA repair processes are enzyme-dependent, they are often less effective at lower environmental temperatures.

Interactive and indirect effects of UV in aquatic ecosystems

Perhaps the most compelling role of UV in inland waters is not the potential for direct damage, but how it interacts with other important limnological and ecological stressors across gradients of UV transparency. Organisms that respond to UV by behavioral avoidance may be forced into habitats where temperature, food, or potential predators are suboptimal. For example, migration by zooplankton or egg deposition by amphibians and fish into deeper, cooler waters may reduce rates of growth and reproduction, or expose them to higher levels of tactile invertebrate predators.

Aquatic organisms ranging from bacteria and phytoplankton to zooplankton and fish have UV photoreceptors and can use UV as an environmental cue. Coral reef fish use UV in mate selection, but this has yet to be investigated in freshwater fish. Similarly, in the African Rift lakes there is evidence that a narrowing of the spectral transmission of water due to pollution has influenced mate selection and contributed to the decline of the species richness of African Cichlids. The transparency loss is primarily in the UV range but its importance has not been investigated.

Variation in UV tolerance among organisms at different trophic levels may alter aquatic food webs. For example, UV exposure can inhibit uptake of critical nutrients such as N and P as well as alter the concentrations and quality of pigments, proteins, lipids, and fatty acids in phytoplankton with important consequences for their productivity and nutritional quality to zooplankton grazers. Zooplankton that respond to UV by increasing their concentrations of dietary photoprotective compounds may increase their susceptibility to visual predators. In shallow lakes and ponds UV-sensitive tactile predators such as *Chaoborus* may benefit from the refuge from underwater exposure to UV caused by increases in CDOM, thus permitting them to decimate certain of their prey species. While bacteria in surface waters can suffer direct damage from UV, the generation of biolabile DOM by UV photolysis may enhance bacterial productivity, which can also be enhanced by increased release of DOM by phytoplankton subjected to UV stress.

UV exposure of a variety of anthropogenic pollutants such as polycyclic aromatic hydrocarbons (PAH) can enhance their toxicity. The primary mechanism of this phototoxicity is the production of ROS by the photosensitizer (PAH or other), with subsequent biological damage such as lipid peroxidation by the ROS. The phototoxicity of PAHs such as pyrene, fluoranthene, and anthracene is driven much more by UV-A, even though some absorb both UV-B and UV-A, due to the greater number of UV-A versus UV-B photons present in incident solar radiation, and the more rapid attenuation of UV-B versus UV-A in the water column. Due to the role of ROS, oxygen concentrations may alter phototoxicity. Diel variation in metal speciation and photodegradation of compounds such as methyl mercury suggest that UV may also play a role in the phototoxicity of heavy metals. Phototoxicity may also be ameliorated by complexation of contaminants with DOM, or enhanced by UV photolysis of CDOM and subsequent release of toxic compounds.

Climate change can alter the importance of UV in inland waters by modifying cloud cover, aerosols, stratospheric ozone, and CDOM inputs from the surrounding watershed (Williamson et al., 2019). Increases in dissolved CO_2 can also alter the sensitivity of algal photosynthesis to UV inhibition. Decreases in precipitation combined with increased temperatures reduce the saturation and inundation of soils with water, resulting in better oxygenation of soils and more complete decomposition of dead organic matter to inorganic C rather than CDOM. Consequent reductions in CDOM can dramatically increase the UV transparency of lakes (Williamson et al., 2016). UV spectral composition can be used as an assay to sort out whether these responses to climate change are due to alteration of autochthonous or allochthonous processes. The spectral slope (280–400 nm) is generally steeper for CDOM from autochthonous sources than for CDOM from allochthonous sources. Photobleaching of allochthonous CDOM produces a characteristic bending of the absorbance spectrum with a steeper slope at short wavelengths and shallower slope at longer wavelengths.

Conclusion/synthesis

Ultraviolet (UV) is short wavelength, high energy solar radiation that plays multiple different roles in inland waters. At high exposure levels, UV has sublethal and lethal effects on organisms ranging from bacteria, phytoplankton, and protozoa to zooplankton, benthic invertebrates, fish, and amphibians. While UV is mutagenic, carcinogenic, and can cause a variety of other damage in living organisms, small amounts of UV may actually be quite beneficial (Williamson et al., 2001). For example, a small amount of UV at potentially damaging wavelengths less than 315 nm is necessary for the synthesis of vitamin D, while longer wavelength UV activates DNA repair enzymes and serves as an environmental cue in mate selection and foraging behavior in fish as well as in the vertical migration of zooplankton. Solar UV exposure can kill parasites, pathogens, and vectors of disease such as mosquito larvae in surface waters, thus aiding in the disinfection of water supplies. UV also plays important roles in biogeochemical processes including carbon cycling and the ecotoxicology of heavy metals and pesticides. UV stimulates photodegradation as well as photobleaching of CDOM, contributing to seasonal variations in water transparency. While ozone is the primary regulator of UV in the atmosphere, variations in the quantity and quality of CDOM in inland waters are much more important regulators of

underwater UV exposure than atmospheric ozone. The strong CDOM-driven gradients in UV transparency in inland waters lead underwater UV exposure to vary by orders of magnitude across inland waters. High elevation alpine waters often exhibit the highest levels of underwater UV exposure, while lowland waters with inundated watersheds with high CDOM production have low UV transparency. The sensitivity of UV transparency of inland waters to CDOM changes related to natural and anthropogenic disturbances makes UV transparency a good sentinel of environmental change.

Knowledge gaps

- Data on the UV transparency of inland waters remain sparse, but are essential to elucidate the role of this high energy radiation in aquatic ecosystems.
- While we know a great deal about the negative effects of UV on aquatic organisms, most studies of UV effects on aquatic organisms have been in the laboratory. More field data under natural solar UV radiation are needed due to the critical importance of differences in the spectral composition of UV from artificial versus solar sources. Biological weighting functions are needed for more organisms as well due to the fact that wavelength matters to the biological response.
- While we know that UV can alter the balance of trophic interactions due to the differential effects of UV on different trophic levels, we still have only very limited appreciation for the net effects of UV at the community and ecosystem levels.
- The balance of the beneficial *vs.* detrimental effects of UV, and whether or not this balance varies across trophic levels is necessary to understand community and ecosystem level effects.
- The interactive effects of UV and other environmental factors such as temperature and pH have been demonstrated in many cases, but their net effects remain poorly understood.
- While UV has in several cases been demonstrated to have positive effects on certain zooplankton and other aquatic species, we still do not understand the underlying mechanisms of these positive effects. Do they relate to resolving vitamin D deficiencies, reducing parasites, pathogens, competitors or predators, or other mechanisms?
- While solar UV radiation has been repeatedly demonstrated to have the ability to kill parasites and pathogens, the relative sensitivity of hosts versus pathogens still needs to be elucidated in order to understand the net effects of UV exposure on host-parasite interactions and infectious diseases.

Glossary

Dipole moment A measure of the polarity of a chemical bond between two atoms in a molecule, due to separation of positive and negative charges in a molecule. The dipole moment of water is 1.85 D (debye), or 6.17×10^{-30} C · m (coulomb-meter).
Heat of fusion The amount of energy required to transform a quantity of a substance from a solid state to a liquid state at a constant pressure.
Heat of vaporization The amount of energy required to transform a quantity of a substance from a liquid state to a gaseous state. It is a function of pressure and, to a smaller degree, temperature.
Hydrogen bond Non-covalent bond between water molecules, due to the electrostatic attraction between a hydrogen proton in one molecule and the electronegative oxygen in another molecule.
Major ion Cations (positively charged) and anions (negatively charged) that contribute the majority of salinity in water. In most aquatic systems, major ions are conservative, meaning their concentration is minimally affected by biological processes.
Nutrient From a limnological perspective, nutrients are elements such as nitrogen, phosphorus and iron required for the growth of algae and photosynthetic cyanobacteria. Note that this differs somewhat from the description of the term when applied to animal nutrition, in which case it can include organic compounds that serve as an energy source.
Solvation The process by which solvent molecules (such as water) surround and interact with solute ions or molecules. Solvation of a solute by water is referred to as hydration.
Surface tension Attractive force exerted on the surface molecules of a liquid by underlying molecules, making the liquid assume a shape that results in minimal surface area. Measured as the energy required to increase the surface area of a liquid by a unit of area.

> Water is H_2O, hydrogen two parts, oxygen one, but there is also a third thing, that makes it water and nobody knows what that is. D.H. Lawrence (1929).

Introduction

Water is the most abundant molecule on Earth. In spite of being so common, water is quite unusual—from its high melting and boiling points to its tremendous solvating power, high surface tension, and the largest dielectric constant of any liquid. In this chapter, we present an overview of the chemical properties of water and their implications for aquatic ecosystems. The phrase "chemical property" is context-dependent, which we define in general as a description of the way that a substance changes its

☆*Change History:* November 2020. H. Bootsma updated and revised the text in the "Dissolved Gases", "Major Ions", and 'Nutrients" sections. Minor edits made in the "Structure of Water" section for clarification. Revised and updated Figs. 8 and 9. Updated the "Further Reading" section with two references: Nilsson and Pettersson (2015), and Tainter et al. (2011). Added a glossary.

identity in the formation of other substances. A universally accepted set of chemical properties does not exist in the same way that there is, more or less, a standard set of physical properties for a given substance. Whereas a given substance has intrinsic physical properties (such as melting point), by our definition chemical properties are clearly tied to change. In addition to reactivity, a substance's "chemical properties" also typically include its electronegativity, ionization potential, preferred oxidation state(s), coordination behavior, and the types of bonding (e.g., ionic, covalent) in which it participates. Because these properties are extensively studied in general chemistry courses, we will not further discuss them here. Rather we move beyond the basic general chemistry concepts and focus upon water in a limnologic context—particularly, its bulk fluid structure and aspects of its chemical reactivity in the hydrosphere.

In the following pages, we begin by briefly reviewing the molecular structure of water, and then discuss models for its structure in "bulk" solution. We then turn our attention to the hydration of ions and an overview of important reactions that involve water, including acid-base, complexation, precipitation, and electron transfer. We conclude with a discussion of trends and patterns in the chemical composition of freshwater that are fundamental to the field of limnology.

The structure of water

Knowledge of the structure of water is the basis for understanding its unique chemical and physical properties. Like the other non-metallic hydrides of the elements of Group 16 in the periodic table, water is a triatomic molecule that forms a non-linear structure. In terms of group theory (which is used to explain the physical properties of a molecule based on its properties of symmetry), water has two planes of symmetry and a twofold rotation axis, and is therefore assigned point-group C_{2v}. The H—O—H angle is 104.5 degrees, formed as a result of the distortion of the O—H bond axes by the two pairs of non-bonding electrons on the oxygen atom. Although water is often described as having four sp^3-hybridized molecular orbitals in a slightly distorted tetrahedral geometry, models based solely upon that configuration fail to accurately predict the properties of liquid water, particularly the extent and influence of hydrogen bonding on the structure of the bulk fluid state. However, a tetrahedral geometry is in fact present in the solid state, giving rise to the sixfold axis of symmetry that is characteristic of ice, and in large part is the basis of the networks that form in the bulk liquid, though in a rapidly fluctuating dynamic state.

Models for the bulk fluid structure of water are a function of the non-covalent van der Waal's forces that exist between water molecules. There are five major types of van der Waal's forces that occur between neutral molecules and ions in solution: (a) London (or dispersion) forces, in which transient dipoles form by variations in electron density between neutral molecules; (b) Debye forces, in which the dipole of a molecule induces the formation of a dipole in an adjacent neutral molecule; (c) Keesom forces, which form between neighboring dipoles; (d) Coulombic forces, the electrostatic attraction (and repulsion) of ions; and (e) hydrogen bonds, which involve the electrophilic attraction of a proton to electronegative atoms such as oxygen and nitrogen. All of these forces are present in aqueous solution to varying degrees—hydrogen bonding being the most dominant. The high negative charge density of the oxygen atom relative to the high positive charge density of the hydrogen atom creates a large (1.84 D) electric dipole moment for the water molecule (Fig. 1). Because of the large dipole moment, the partial positive charge on the H atom is attracted to electron density, while the partial negative charge on the O atom causes the attraction of electrophilic H atoms. In this way, hydrogen bonds are formed, representing the strongest of the van der Waal's forces that exist between neutral molecules. While each hydrogen bond is approximately 20 times weaker than a typical covalent bond, each water molecule can participate in multiple hydrogen bonds—one to each H atom and one (or more) to each non-bonded pair of electrons on the O atom.

The key to understanding the structure of bulk water—and its abnormal properties—is understanding the way that non-covalent hydrogen bonds affect its intermolecular interactions. Although one might expect that the random translational motion of molecules in a liquid results in an amorphous structure, the extensive network of hydrogen-bonded molecules in the liquid state

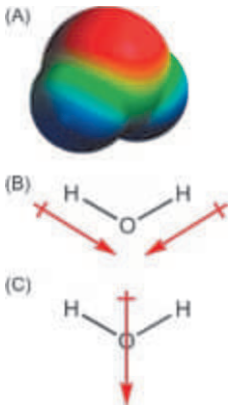

Fig. 1 (A) The distribution of electron density in molecular water (red = high, blue = low). Representation of the electric dipolar nature of molecular water, as contributing dipoles along each O—H axis (B) and as a net dipole (C).

of water gives rise to a surprisingly high degree of order. Water has considerable short range order out to at least ~10–15 Å from the 2.75 Å diameter water molecule (1 Å is 10^{-10} m). Hydrogen bonds are certainly not peculiar to water, but in water they form such elaborate, extensive, and strong networks that they create a "bulk" structure with significant order, order that is in fact maintained up to its boiling point.

A great deal of research has been devoted to improving our understanding of water's structure in condensed phases (ice and liquid)—broadly divided into studies of short-range and long-range order, the latter defined as beyond approximately 15 Å. These research endeavors have been both theoretical and empirical, with theoreticians employing advanced computational tools for molecular modeling, and experimentalists armed with a wide variety of spectroscopic techniques. Models for the structure of water in the solid-phase (various forms of ice) generate little controversy because theoretical models can be directly verified by crystallographic and neutron-scattering techniques. Because of the much more limited atomic motion in the solid state, crystallographic methods have provided an accurate picture of the various ices that form as a function of temperature and pressure. The most common type of ice under ambient conditions is hexameric ice, in which six water molecules are hydrogen-bonded to form a hexagonal ring, as shown in Fig. 2. The most stable state for this structure is a so-called "chair" conformation (analogous to cyclohexane), in which H—O · · · · · H bonds alternate around the ring (where — is a covalent and · · · · · is a hydrogen bond). Also shown in Fig. 2 is the "boat" conformation, an energetically less stable conformation than the "chair" structure. Each O atom has a nearly tetrahedral arrangement of H atoms surrounding it, in which two H atoms are covalently bonded and two non-covalently as hydrogen bonds. The sixfold axis of symmetry found in ice (Fig. 3) is the result of the building blocks of cyclic hexamers.

Unlike models for ice, much controversy continues to surround models for the structure of liquid water. This may be somewhat surprising given that water is a simple molecule, yet general agreement on a realistic model remains elusive despite the application of powerful computational and experimental approaches. Predicting the precise arrangements of hydrogen-bonded neighboring water molecules is challenging because the structures are in a state of rapid flux (at sub-picosecond timescales). Some insight into the structure of bulk water can be gleaned by examining the structural changes that occur upon the melting of ice. When ice melts, the increase in temperature causes a slight disruption of the hydrogen-bonded network, thereby initially causing the ice crystalline lattice to collapse. Whereas the structure of ice is >80% ordered, only an approximately 10% decrease in order occurs upon transition to the liquid phase, resulting in a heat of fusion (334 joules per gram) that is small relative to the heat of vaporization (see below). In this way, much if not most of the short-range order is maintained, and this short-range order persists to the boiling point at 100 °C, where the order is essentially lost completely. The partial collapse of the ordered environment during melting results in slightly more compact hexameric chairs. Consequently, water has the very unusual property of maximal density at a temperature that is higher than its melting point. Above 4 °C, further disruption of the intricate networks of cyclic hexamers by more intensive thermal agitation causes the structures to become more open with a consequent decrease in water's density.

Water forms clusters in the liquid state. The presence of "ice-like" structures in water, based on not only hexameric but also pentameric and octameric building blocks, along with "free" swimming water molecules in more amorphous regions, is the generally accepted model (Fig. 4). However, there have been intriguing studies that suggest that there are regions that are far more complex than the structures analogous to ice. Curiously, one of the earliest is found in Plato's dialogue *Timaeus*, where the ancient Greek's classification of matter—Earth, fire, air, and water—is described in mathematical (geometric) terms. In Plato's view, water is the most complex structure, taking the form of an icosahedron. A regular icosahedron has 20 faces, with five equilateral triangles meeting at each of the 12 vertices. Thus, along with the dodecahedron, these regular convex polyhedral comprise the famous "Platonic Solids." This ancient conception of water may seem quaint, yet it is strikingly similar in concept to several recent

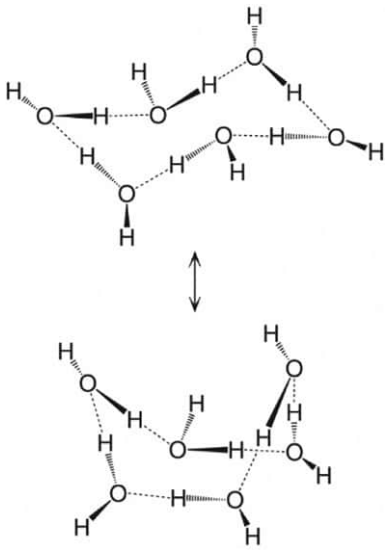

Fig. 2 The arrangement of hexagonal water into a "chair" conformation (top) and less stable 'boat' conformation (bottom).

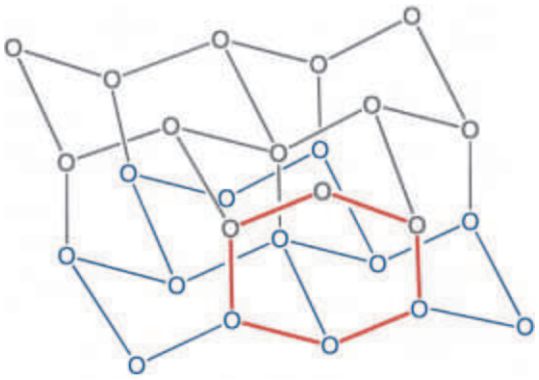

Fig. 3 The structure of the most common form of ice (hexagonal ice), an arrangement based upon the HOH "chair" hexamer. Each oxygen atom is at the approximate center of a tetrahedron formed by four other oxygen atoms. The sixfold axis of symmetry is shown in red for a layer of water "chairs" (black) overlaying another layer (blue). (Hydrogen atoms are not shown for clarity.)

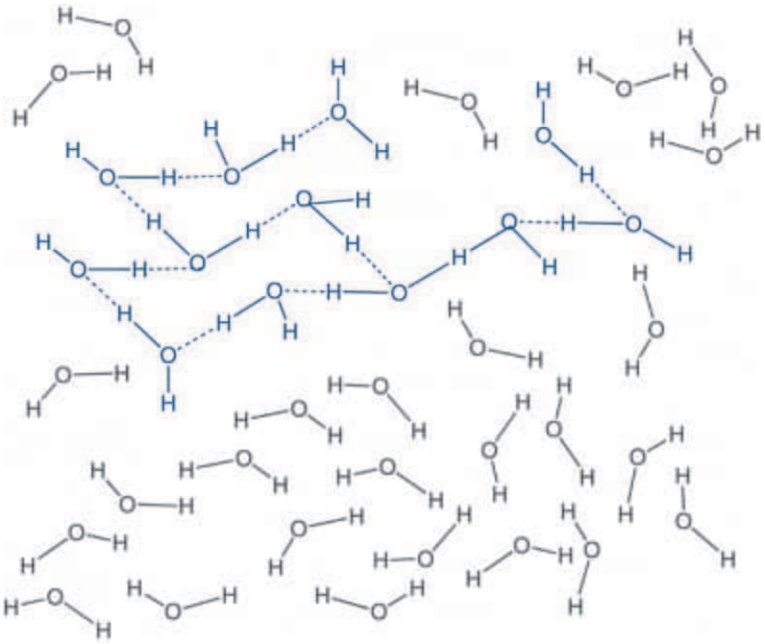

Fig. 4 Proposed models for the structure of bulk water. (Top) The "flickering cluster" model, with ice-like ordered regions highlighted in blue surrounded by amorphous regions where little short-range order is present. (Bottom) Molecular modeling and some experimental evidence suggests that quite complex structures, such as dodecahedra (left) and icosahedra (right), may also exist.

theoretical models of the structure of water in the bulk liquid phase. Clusters based on dodecahedra and icosahedra have been proposed by molecular modeling and supported by experiment to exist in water—though the evidence remains somewhat controversial. Early work by Searcy and Fenn on protonated water clusters by molecular beam mass spectrometry found that a large peak in the spectrum was present, i.e., for a cluster of unusual stability, that corresponded to 21 water molecules—a so-called "magic number." Speculation arose that the structure of this "magic" cluster was a dodecahedral complex of 20 water molecules, each vertex occupied by an oxygen atom and a hydronium ion trapped within (e.g., as in clathrates). Recent work by Dougherty and Howard has indeed found evidence for dodecahedral clusters, and Chaplin has proposed a theoretical model for the formation of icosahedral clusters, a model that has been supported by recent neutron scattering experiments.

The polarity of the water molecule and the hydrogen bonding that results from this polarity have important biological implications. Molecular cohesion produces surface tension that is strong enough to support small animals like water striders and the basilisk lizard, allows for the formation of drops and bubbles, and along with adhesion (attraction to charged surfaces) allows for the transport of water through plants by capillary action. The hydrogen bond also results in a high heat of vaporization (2444 joules per gram at 25 °C and 1 atm), so that evaporation is an important temperature regulation mechanism for both lakes and endothermic animals.

Solvation by water

Ions in aqueous solution interact with one another and with other non-electrolytes, and their presence in water's dipolar electronic field creates relatively strong non-covalent bonds such that the hydrated ion is the form that undergoes further interactions and chemical reactions, with consequent implications for the rates of these processes. Only in the gas phase do "bare" (unsolvated) ions exist; in the liquid phase, all ions are hydrated to some degree.

To appreciate the solvating power of water, the solubility parameter (δ) provides a useful measure, defined as the ratio of the energy required to completely break all intermolecular forces that maintain the liquid state to the molar volume. We represent δ quantitatively as:

$$\delta = \sqrt{\left(\frac{\Delta E_v}{V}\right)}$$

where ΔE is the total energy required to vaporize a solute and V is molar volume. One can think of δ as the "cohesive energy density" of a substance. Of course, δ correlates strongly with polarity, with water not surprisingly having the highest value of δ when compared to other common solvents (Fig. 5).

Before studying an example of the structure of a hydrated metal ion, we recognize that each water molecule is already "solvated" to a very high degree of structural complexity. And because of the auto-ionization reaction of water, which can be represented as a net reaction:

$$H_2O \rightleftharpoons H^+ + OH^- \quad (1)$$

Protons and hydroxide ions are formed that also become hydrated. Realistic structures of the reaction (1) products continue to be the subject of debate, but much evidence suggests that a more realistic way to describe the auto-ionization of water is:

$$6H_2O \rightleftharpoons (H_2O)_2H^+ + (H_2O)_3OH^- \quad (2)$$

Proposed structures for these ions are shown in Fig. 6. For convenience, the simplistic products of reaction (1) are commonly used in the literature. However, more complex structures, such as those depicted in Fig. 6, are themselves not yet fully accepted as realistic.

For ions in aqueous solution, the structures formed by hydration reactions are driven by geometric and electronic factors. The number of water molecules that coordinate as ligands to an ion typically varies from four to nine, and is a function of factors that include ion size, the number of vacant orbitals present, and the degree of ligand-ligand repulsion. Given the great interest in pollution by toxic metals, our understanding of cation hydration is more extensive than for anions, yet hydration of the latter should not be surprising given the dipolar nature of water as a ligand.

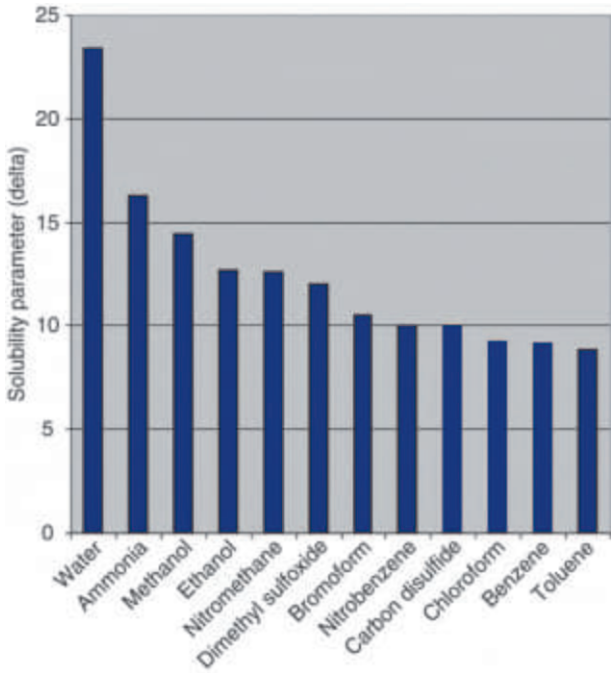

Fig. 5 A comparison of Hildebrand's solubility parameter (δ) for various liquids (25 °C).

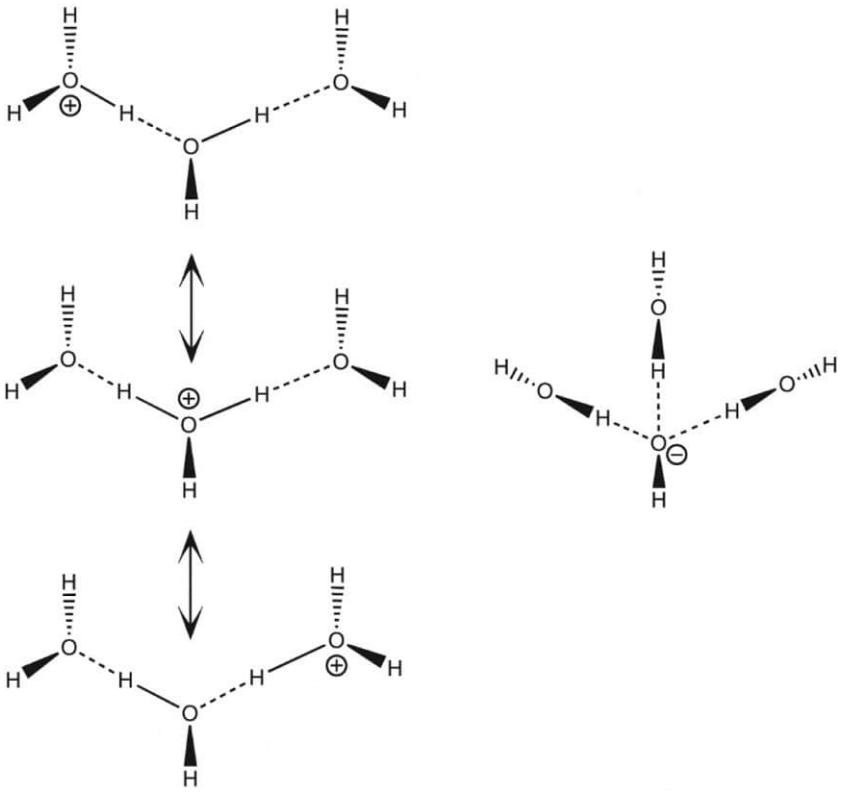

Fig. 6 'Proton hopping' among three water molecules which together constitute a more accurate representation of a hydrated proton ($H_5O_2^+$). The center structure is the most energetically stable of the three shown. A more realistic structure for solvated hydroxide ion ($H_7O_4^-$) is also shown (right). Hydrogen bonds are denoted by dashes (–).

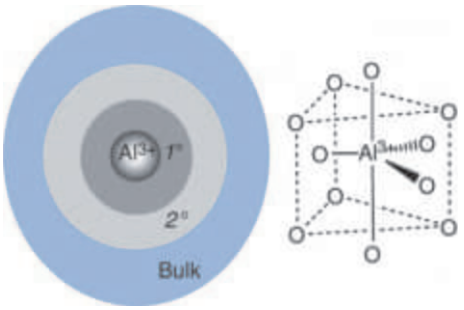

Fig. 7 The "concentric shell" model (left) for the hydration spheres surrounding a cation, showing the primary, secondary, and bulk solution shells. The primary hydration shell of aluminum ion (right), a tricapped trigonal prismatic geometry in which only the O atom positions for the 11 coordinating water molecules are shown.

In Fig. 7, the "concentric shell" model for the hydration of an ion is illustrated for aluminum ion, which exists under ambient conditions in the +3 oxidation state. Three regions form the shells – an inner layer, known as the primary (1°) shell, an intermediate layer known as the secondary (2°) shell, and a third region comprised of the bulk fluid. The structure of the 1° shell is highly ordered, as shown in Fig. 7 for the tri-capped trigonal prismatic arrangement of 11 water molecules closely surrounding the trivalent cation. In the 2° shell, the influence of the Al(III) ion's high charge density would create a more loosely held though structurally defined layer. The bulk fluid extends beyond the 2° shell where the range of the ion's force field has no apparent effect on the fluid structure. It is important to note that the concentric shell model is simplistic, focusing on the strongest inner layers that are present. That is, the model ignores long-range ordering effects, which because of their weakness are inherently difficult to study. For example, studies have shown that for Pb(II) in aqueous solution, the surrounding water is affected by the electronic field of the heavy metal ion to a distance corresponding to ~90 layers of intervening water molecules. Only beyond ~90 layers does the bulk water reflect the "undisrupted" structural state of a pure solution of water.

The reactivity of water

While we may tend to think of water as relatively inert, it is actually a very reactive molecule, with the oxygen atom behaving as a strong electrophile and the protons involved in auto-ionization reactions. However, water's reactivity is attenuated by its extensive hydrogen-bonding. The eightfold mass ratio between water's single relatively heavy (O) atom and two light (H) atoms, and the charge inequity that exists between them, gives rise to a rapid exchange of protons between adjacent water molecules ("proton hopping"). In a pure solution of water, proton hopping among water molecules is constantly occurring at a high rate (Fig. 5). Even at pH 7 where it is slowest, it occurs on the order of 1000 times per second. In studies of hydrogen-bonding and the solvation of ions by water, the exchange of protons is even faster than the millisecond time scale observed for a bulk solution of pure water. Nevertheless, water is treated as a stable molecule because the net structure (H—O—H) is maintained despite its intrinsic dynamic state.

Fundamentally, chemical reactions occur as means for a species (atom, molecule, or ion) to increase its thermodynamic stability. We can generally classify chemical reactions into two broad categories: (i) those that involve changes in oxidation state, and (ii) those that involve changes in coordination environment. While the former redox processes stand alone, the latter type of reaction can be divided into acid-base, complexation, and precipitation reactions. We can illustrate these three sub-categories of coordination reactions by the example of a series of hydrolytic reactions involving the Al(III) ion:

$$\begin{aligned}
&Al^{3+}_{(aq)} + H_2O \rightleftharpoons Al(OH)^{2+}_{(aq)} + H^+_{(aq)} && pK_1 = 8.2\\
&Al(OH)^{2+}_{(aq)} + H_2O \rightleftharpoons Al(OH)_2{}^{+}_{(aq)} + H^+_{(aq)} && pK_2 = 19.0\\
&Al(OH)_2{}^{+}_{(aq)} + H_2O \rightleftharpoons Al(OH)_{3\,(s)} + H^+_{(aq)} && pK_3 = 27.0\\
&Al(OH)_{3\,(s)} + H_2O \rightleftharpoons Al(OH)_4{}^{-}_{(aq)} + H^+_{(aq)} && pK_4 = 31.4
\end{aligned} \qquad (3)$$

The subscript "aq" denotes "in aqueous solution," a reminder that all of these species are hydrated, the structures of which are not shown. While none of the reactions above cause changes in oxidation states, all are acid-base reactions because of the generation of a (hydrated) proton. All can be classified as complexation reactions as well because of hydroxide ion acting as a ligand in its coordination to the metal cation, with the formation of complex cations and anions (with the exception of the third reaction). For the third reaction, because of the formation of a solid product, we classify it as a precipitation reaction. Chemical reactions in the environment that involve water as a reactant or product—that is, each type of reaction illustrated above as well as redox reactions—represent an enormous volume of scholarly work; the interested reader is therefore referred to the "Further Reading" listed at the end of this chapter and elsewhere in this *Encyclopedia*.

Aquatic biogeochemistry

The chemistry that is mediated by water in natural aquatic systems varies in space and time. Often this variability is expressed in the form of trends and patterns, and by understanding their causes it is possible to gain insight into the mechanisms that control water chemistry. Ultimately, variation in the chemistry of lakes and rivers can be attributed to three controlling factors: (1) physical processes and properties, including lake morphometry, weather, and climate; (2) geologic setting; and (3) biological factors, including the abundance and composition of biota within the water body and its watershed. Each of these factors may in turn be influenced by human activities. A discussion of how these factors influence water chemistry is best facilitated by examining some observed patterns for three important classes: dissolved gases, major ions, and nutrients.

Dissolved gases

The dissolved gases of primary interest in most aquatic ecosystems are oxygen and carbon dioxide. Both of these molecules are non-polar, so as they partition at the air-water interface their hydration by water is minimal and consequently their solubility is very low. The only van der Waal's forces that act upon them are very weak Debye forces, in which water's strong dipolar field induces a transient dipole in the non-polar molecule's electronic field. These gases are of primary importance because they both influence and reflect biological processes. Because they are regulated primarily by photosynthesis and respiration, they serve as tracers of electron flow (i.e., energy flow) in an ecosystem. Reactions that convert energy into an organic form will reduce CO_2. In the case of photosynthesis, energy is derived from light and water is the electron donor, with the resultant production of O_2. CO_2 can also be reduced by chemoautotrophic bacteria using other alternate electron donors such as ammonium (NH_4^+), methane (CH_4), and hydrogen sulfide (H_2S). In each case, anabolic processes result in the reduction of CO_2 to form organic compounds. Conversely, the microbial decomposition of organic material results in the production of CO_2, which is accompanied by the reduction of electron acceptors that are used by various microbial taxonomic groups in an order that corresponds to the free energy yield: $O_2 > Mn^{3+/4+} > Fe^{3+} > NO_3^- > SO_4^{2-}$. Following depletion of all these electron acceptors, CO_2 itself can serve as an electron acceptor during

microbial methanogenesis. As a result of decomposition, a vertical redox gradient is created in the water column and/or the underlying sediment, in which the concentrations of the various electron acceptors vary with depth.

The effect of photosynthesis and decomposition on concentrations of dissolved O_2 and CO_2 is modulated by hydrodynamics and lake-atmosphere gas exchange. In systems that are vertically stratified due to a chemically- or thermally-driven density gradient, prolonged separation of deep water from the atmosphere results in deep waters being CO_2 supersaturated and hypoxic or anoxic. In lakes that are well mixed, anoxia may occur in the underlying sediment.

For lakes of a given size and within a geographic/climatic region, dissolved gas concentrations can vary according to the loading of nutrients and organic carbon. Lakes with high nutrient loads will exhibit large diurnal fluctuations in surface dissolved O_2 and CO_2 concentrations, because of high photosynthetic rates during the day and high respiration rates at night. Lakes with high organic carbon loads may be persistently supersaturated with CO_2 and undersaturated with O_2.

Temperature is a key property that determines the solubility of gases in water (Fig. 8). This has ramifications both for the distribution of dissolved gases within lakes, and for the relationship between climate and dissolved gases, especially O_2. Within large, deep temperate lakes in which plankton metabolism is generally slow, there is usually sufficient dissolved O_2 at all depths to support aerobic organisms. Smaller lakes that stratify may develop an anoxic hypolimnion, with the probability of anoxia increasing with the duration of stratification and lake productivity. In tropical lakes and rivers, warm temperatures result in lower O_2 solubility and higher decomposition rates, making these systems more prone to anoxia than their temperate counterparts.

While oxygen retains its molecular structure when dissolved in water, carbon dioxide reacts with water to form carbonic acid, which dissociates to form bicarbonate and carbonate ions, as well as H^+:

$$H_2O + CO_2 \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \rightleftharpoons 2H^+ + CO_3^{2-} \quad (4)$$

Therefore, processes that influence the concentration of dissolved CO_2 in water also affect pH. At pH > 6.5 the formation of bicarbonate and carbonate ions results in a concentration of total dissolved inorganic carbon ($CO_2 + HCO_3^- + CO_3^{2-}$) that is much greater than that of CO_2 alone. As a result, oceans and lakes have absorbed much more of the anthropogenically CO_2 produced since the industrial revolution than they would have if CO_2 did not react with water.

Major ions

Major ions are those that contribute significantly to the salinity of water. Major cations generally include Ca^{2+}, Mg^{2+}, Na^+, and K^+, while major anions include HCO_3^-, CO_3^{2-}, Cl^-, SO_4^{2-}, and sometimes NO_3^-. All these species are of course solvated by water, and the concentric shells that are formed may extend relatively far into the "bulk" water. The absolute and relative abundance of the hydrated major ions in rivers and lakes are controlled by three factors: basin geology, rainfall, and evaporation—crystallization processes. Hence geographic variations in major ion composition can be related to one or more of these factors. For example, the relatively low Ca^{2+} concentrations in lakes and rivers of Precambrian Shield regions of North America and northern Europe reflect the dominance of igneous granite in their watersheds, while the high sodium and chloride concentrations of lakes in many dry regions are due to evaporative concentration of these salts. Because the above three factors differentially influence various major ions, the salinity and relative abundance and distribution of ions can be used to infer which of these processes is most significant for a given water body (Fig. 9).

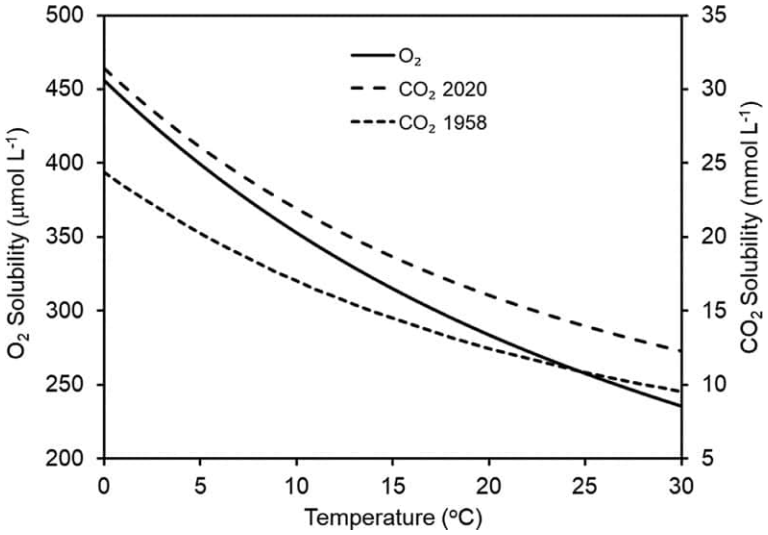

Fig. 8 The solubility of oxygen and carbon dioxide in freshwater at a pressure of 1 atm. CO_2 solubility is shown for both 1958 (when the global average atmospheric CO_2 concentrations was 316 ppm) and 2020 (when the global average was 407 ppm).

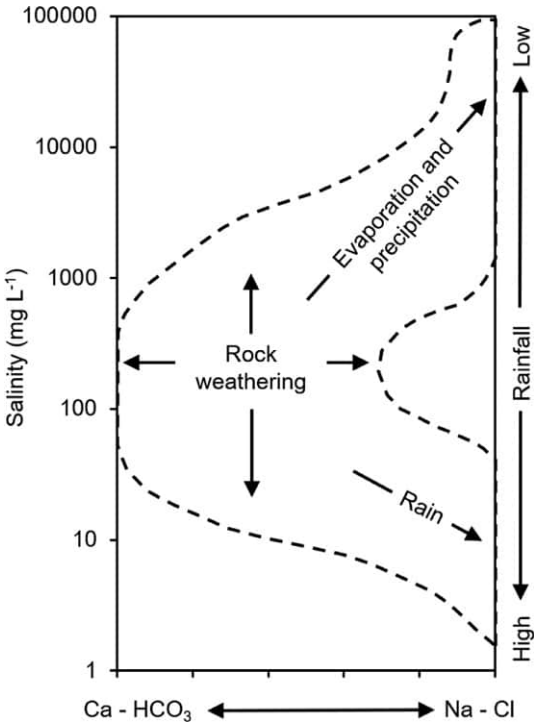

Fig. 9 Influence of geology and climate on salinity and major ion composition of inland waters. Some exceptions to this pattern occur, especially in Africa, where a combination of intense weathering, low Ca^{2+} concentrations in rock, and evaporative concentration can result in moderately high salinities that are dominated by Na^{+} and HCO_3^{-}.

Nutrients

Most algae require a minimum of 17 essential nutrients to grow. The nutrient that limits algal growth in a water body depends on the availability of these nutrients relative to algal demand. In most water bodies, phosphorus or nitrogen is the limiting nutrient, but trace elements such as iron and molybdenum may also be limiting in some systems.

The effects of accelerated nutrient loading to lakes and rivers resulting from human activities, referred to as eutrophication, are well documented in the scientific literature, and are not addressed here. Phosphorus input to lakes and rivers is controlled primarily by rock composition and weathering intensity, but its availability to algae is influenced by the availability of other elements, and by biologically mediated processes. In iron-rich waters, inorganic phosphorus is bound as insoluble ferric phosphate or adsorbed onto ferric oxides and oxyhydroxides, and such systems tend to be unproductive and phosphorus-limited. In calcareous regions, including the Laurentian Great Lakes, calcium minerals may serve as a source of phosphorus through weathering, but this phosphorus is often biologically unavailable because of adsorption to minerals such as calcium carbonate and precipitation with calcium to form apatite. The equilibrium between dissolved and particulate phosphorus is influenced by redox potential, with phosphorus dissolution often being accelerated under anoxic conditions. Such conditions also promote denitrification, through which biologically available nitrate is ultimately reduced to nitrogen gas, which cannot be assimilated by most algae. Over an annual cycle, water column anoxia is more prevalent in tropical lakes than in temperate lakes, which may increase the recycling of phosphorus while enhancing denitrification. As a result, nitrogen limitation of algal growth tends to be more common in the tropics. These patterns can be modified by lake depth. In deep lakes, phosphorus may be sequestered more efficiently into sediment. Consequently, such lakes tend to have lower concentrations of phosphorus in the water column relative to shallow lakes with similar external phosphorus loads.

Conclusion

Primarily because of an extensive network of hydrogen bonding, water is structurally complex and has very unusual properties, with important consequences for biological and biogeochemical processes. Ions and molecules are solvated by water, and the resulting structures affect their reactivity and hence their toxicity, transport, and fate. To understand how nutrients and pollutants are transformed by their interaction with water is essential to understanding the dynamics of the Earth's hydrosphere. Furthermore, these chemical transformations affect how these compounds are transported to other environmental compartments (e.g., the lithosphere and biosphere).

Water is said to be the most studied molecule. Yet while theory and experiment have greatly improved our knowledge of water's structure, important questions remain only partially answered. In particular, questions concerning the structure of water in the liquid state, specifically how hydrogen bonding determines long-range ordering effects, continue to intrigue researchers. Given the astonishing properties of such a simple molecule, one might conclude that hydrogen bonding is indeed that "third thing" to which D.H. Lawrence was alluding to in the 1929 quote at the beginning of this article.

Glossary

Apparent quantum yield Efficiency of photochemical reaction, expressed per mol of photons absorbed by an unknown mixture of compounds such as CDOM.
BAPs Biologically available photoproducts, which are generated when biologically non-labile dissolved organic matter is photochemically transformed into biologically labile forms.
CDOM Chromophoric dissolved organic matter, the major absorber of solar radiation in surface waters. Defined as an absorption coefficient "m^{-1}" in sensu stricto, but also as a mixture of dissolved organic compounds able to absorb solar radiation in sensu lato used in this article.
CDOM(S_1) The first short-living (<1 μs) excited singlet state of a CDOM-molecule after the absorption of a photon.
CDOM(T_1) or ^{3}CDOM* The short-living (>1 μs) excited triplet state of a CDOM-molecule formed from CDOM(S_1) and capable of mediating indirect photochemical reactions.
Direct photochemical reactions Reactions where the primary absorber will be transformed.
Indirect photochemical reactions Reactions mediated by sensitizers and PPRIs.
Photobleaching Photochemical transformation, which decreases absorbing or fluorescing properties of dissolved organic matter.
PPRIs Photochemically produced reactive intermediates such as $^1O_2$, CDOM(T_1) and reactive oxygen species (e.g., $^{\bullet}OH$).
Quantum yield Efficiency of a photochemical reaction expressed in unit such as mol of photochemical product per mol of photons absorbed by a known compound.
Scavenger A compound which reacts with PPRIs.

☆*Change History*: July 2021. Anssi V. Vähätalo, Luca Carena, and Davide Vione updated the title of article as "Photochemical reactions in inland waters." Two authors, Luca Carena and Davide Vione, have been added. The text in the entire article has been edited for clarity. Earlier section "Contribution of Photochemistry to the Biogeochemistry of Organic Matter" has been removed. Two new sections "Photodegradation of pollutants" and "Photochemical reactions and climate change" have been added.

Sensitizer The primary absorber of sunlight for indirect photochemical reactions.
Singlet oxygen, $^1O_2$ The first activated form of molecular oxygen produced in the reaction between CDOM(T_1) and O_2.

Introduction

Photochemical reactions take place in surface waters and on irradiated surfaces of organic or inorganic substrates. The prerequisite for photochemical reactions is the absorption of radiation. Section "Mechanisms of photochemical reactions" explains the mechanistic principles of photochemical reactions. They start from the primary photophysical events, but the following thermal secondary reactions are responsible for chemical transformations.

Photochemical transformations modify the molecular composition of dissolved organic matter. Section "Photochemical transformations" illustrates how photochemistry changes the composition of the natural and xenobiotic organic matter as well as metals associated to them. The transformation of nitrogen-, phosphorus- and iron-containing compounds are treated separately as they produce nutrients, which contribute to the productivity of aquatic ecosystems. Although most photochemical transformations are mediated by chromophoric dissolved organic matter, CDOM, and concern dissolved compounds, this section introduces also heterogeneous photochemical transformations on solid surfaces and material adsorbed on them.

The importance of photochemical transformations depends on their rates. Section "Photochemical reaction rates" examines the rates of photochemical transformations in surface waters. Often it is easiest to estimate the photochemical rates in the environment based on (apparent) quantum yields measured in the laboratory. Section "Photochemical reaction rates" introduces models, which use spectral (apparent) quantum yields for the estimation of rates in surface waters. These models also reveal the spectral solar radiation responsible for the photochemical reactions and can describe the attenuation of photochemical reaction rates with depth into a water column.

Finally, Section "Photochemistry, food webs and climate change" points out that photochemical transformations are coupled to the biological communities and their metabolism. This section also outlines likely changes in the photochemistry of inland water under predicted scenarios of climate change.

Mechanisms of photochemical reactions

Primary photophysics and subsequent secondary chemical reactions

During the absorption of radiation, a photon ($h\nu$) delivers its energy (250–400 kJ mol^{-1} at the wavelengths 280–500 nm) to the absorber molecule and excites the molecule from its ground state (S_0) to the first excited electronic singlet state (S_1; Vione et al., 2014). In surface waters, chromophoric dissolved organic matter (CDOM) dominates the absorption of photolytic solar radiation. In a strict sense, CDOM is an optical property of water bodies, an absorption coefficient with a unit of m^{-1}. This article takes a broader definition, where CDOM refers also to dissolved organic compounds, which can absorb solar radiation. The absorption event can be described as: CDOM(S_0) + $h\nu$ → CDOM(S_1). Excited CDOM releases its excitation energy mostly as heat (with 0.95–0.98 probability) but also as fluorescence (probability of ~0.01; CDOM(S_1) → CDOM(S_0) + $h\nu$) at the nanosecond time scale. The excited singlet state of CDOM may be converted into an excited triplet state (T_1, probability of 0.001–0.04; CDOM(S_1) → CDOM(T_1)). The excited triplet state of CDOM has > microsecond-lifetime and may undergo secondary (thermal) chemical reactions, but it can also transfer its excitation energy to another compound or release it as heat or a photon (phosphorescence).

Numerous reaction pathways are available for excited states e.g., homolysis or heterolysis of bonds, ionization, intermolecular oligomerization, intramolecular rearrangements, and photoisomerization. Because the energy of a photon can be larger than the dissociation energy of a chemical bond, the excited molecules may dissociate (probability of $\leq 10^{-5}$) or ionize (e.g., CDOM + $h\nu$ → CDOM$^+$ + $e^-_{(aq)}$; probability of 10^{-3}–10^{-4}). The fragmentation may take place via homo- or heterolysis of σ- and π-bonds e.g., next to the carbonyl functional groups of CDOM (e.g., type I and II Norrish reactions). The fragmentation of excited molecules results in radical species (such as organoperoxy radicals), which can further lead to the expulsion of carbon monoxide, carbon dioxide, or other small molecules.

The excited CDOM (triplet states in particular) can transfer their excitation energy to other molecules (McNeill and Canonica, 2016). Dissolved dioxygen is a common acceptor of this energy. Transfer of energy or an electron to O_2 generates singlet oxygen, $^1O_2$, or superoxide, $O_2^{\bullet -}$, respectively. The latter can be further reduced to hydrogen peroxide, H_2O_2, and hydroxyl radicals, $^\bullet$OH. The generation of these reactive oxygen species causes photochemical consumption of O_2. The hydroxyl radical is the most reactive oxygen species and can react effectively with organic and inorganic matter as well as cause oxidative damage to organisms. In surface waters, the lifetime of H_2O_2 can be longer than several hours, while those of $^1O_2$, $O_2^{\bullet -}$, and $^\bullet$OH are often much lower than a second. The photochemical formation of reactive oxygen species can proceed also via photolysis of nitrate and nitrite as well as via photo-Fenton reactions involving iron. The reactive oxygen species along with excited CDOM-molecules are examples of photochemically produced reactive intermediates (PPRIs).

The photochemical reactions concerning the primary absorber are called direct photochemical reactions. A direct photoreaction takes place, e.g., when a CDOM-molecule absorbs solar radiation and becomes photochemically transformed. An example is the photobleaching of CDOM, where the light absorbed by CDOM decreases the absorption coefficient of CDOM itself. If photochemical reactions concern molecules other than the primary absorber, they are called indirect photochemical reactions and the primary absorber is called a sensitizer. In these cases, photochemically produced reactive intermediates mediate chemical reactions and may even target molecules, which cannot absorb solar radiation themselves.

Photochemical transformations

Photochemistry of organic carbon

In many fresh waters, the major part of organic carbon (50–90%) consists of a diverse group of dissolved compounds, which can form high molecular weight (>1000 g mol^{-1}) colored aggregates (CDOM), traditionally called humic substances (Nebbioso and Piccolo, 2013). These aggregates are too large for a direct microbial uptake and are rich in chromophoric non-hydrolyzable aromatic moieties, which make them biologically non-labile but sensitive to photochemical degradation.

The most abundant single photochemical product of CDOM is carbon dioxide (CO_2). It typically originates as a scission of carboxylic groups, which are abundant functional groups in (C)DOM (Fig. 1, Doane, 2017). Photochemical reactions produce low

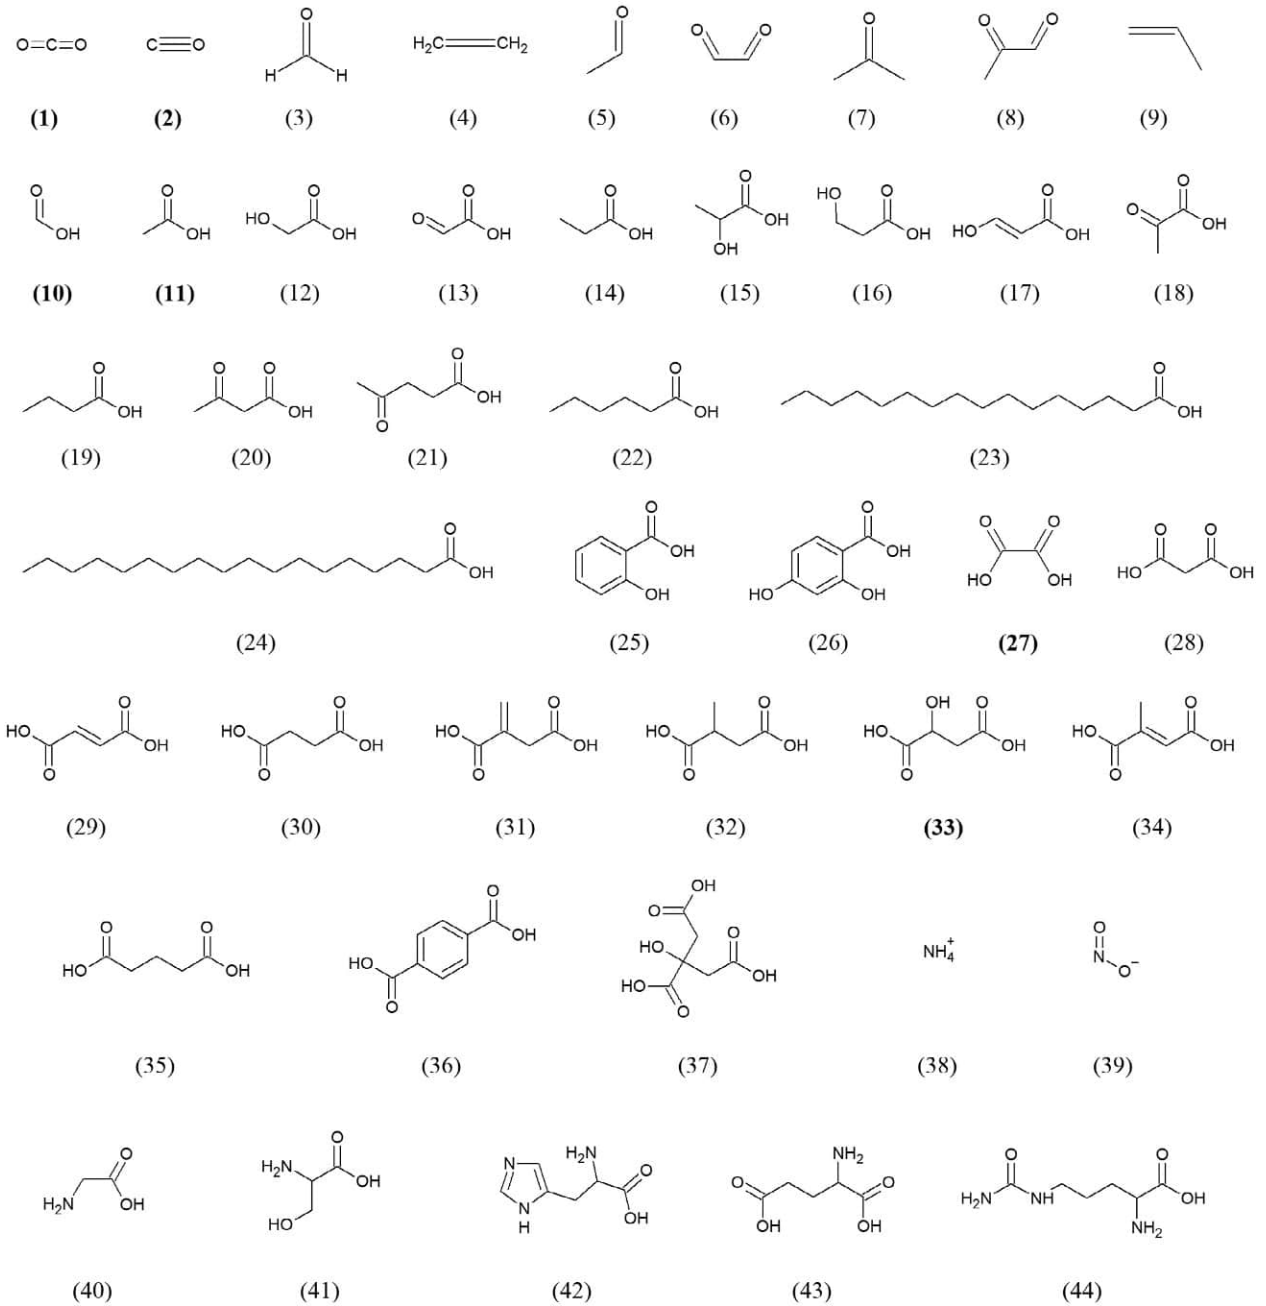

Fig. 1 Identified photoproducts of natural dissolved organic matter. The most abundant products are marked with bold. **(1)** carbon dioxide; **(2)** carbon monoxide; (3) formaldehyde; (4) ethene; (5) acetaldehyde; (6) glyoxal; (7) acetone; (8) methylglyoxal; (9) propene. *Monocarboxylic acids*: **(10)** formic acid; **(11)** acetic acid; (12) glycolic acid; (13) glyoxylic acid; (14) propionic acid; (15) lactic acid; (16) 3-hydroxypropanoic acid; (17) 3-hydroxy-2-propenoic acid; (18) pyruvic acid; (19) butanoic acid; (20) 3-oxobutanoic acid; (21) levulinic acid; (22) hexanoic acid; (23) hexadecanoic acid; (24) octadecanoic acid; (25) salicylic acid; (26) 2,4-dihydroxybenzoic acid. *Di-tricarboxylic acids*: **(27)** oxalic acid; (28) malonic acid; (29) fumaric acid; (30) succinic acid; (31) methylene succinic acid; (32) 2-methylsuccinic acid; **(33)** malic acid; (34) 2-methylfumaric acid; (35) pentanedioic acid; (36) terephthalic acid; (37) citric acid. *N containing products*: (38) ammonium; (39) nitrite; (40) glycine; (41) serine; (42) histidine; (43) glutamic acid; (44) citrulline. Sources: (Kieber, Zhou and Mopper, 1990; Mopper et al., 1991; Backlund, 1992; Allard et al., 1994; Wetzel, Hatcher and Bianchi, 1995; Corin, Backlund and Kulovaara, 1996; Kulovaara et al., 1996; Bertilsson and Tranvik, 1998; Kieber, Li and Seaton, 1999; Riemer et al., 2000; Tarr et al., 2001; Shiller et al., 2006).

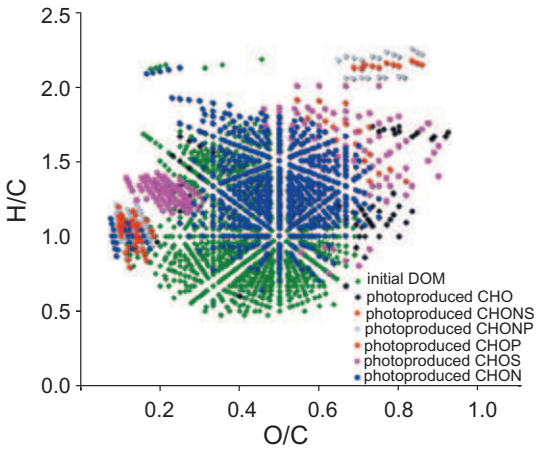

Fig. 2 Van Krevelen diagram for the photochemical transformation of DOM. Each dot refers to an assigned molecular formula containing carbon (C), hydrogen (H), oxygen (O), nitrogen (N), sulfur (S) and phosphorus (P) atoms arranged according to H/C and O/C-ratios in the formulas. Initial DOM refers to the composition of DOM prior to an exposure to solar radiation. Photoproduced CHO, CHONS, CHONP, CHOP, CHOS and CHON refer to the photochemically produced new formulas containing C, H, O, N, S and P atoms (Rossel et al., 2013).

molecular mass organic compounds from CDOM (Fig. 1). Identified abundant products include carboxylic acids, few carbonyl compounds, volatile alkenes and carbon monoxide (Fig. 1). Fourier-transform ion cyclotron resonance mass spectrometry has shown that photochemistry transforms a major portion of compounds, which collectively make up DOM (Fig. 2). A large portion of DOM-molecules and their photochemical transformation products consists of carbon, hydrogen and oxygen atoms (Figs. 1 and 2). Photochemical reactions lead to disappearance of some compounds, create new compounds, but decrease eventually the molecular diversity upon prolonged irradiation (Fig. 2). Photochemically produced compounds can also contain nitrogen, phosphorus and sulfur atoms (Fig. 2).

Photochemical reactions typically decompose aromatic moieties, decrease the molecular mass of CDOM and increase the oxidation number of compounds e.g., through an introduction of functional groups containing oxygen (Riedel et al., 2016). These photochemical transformations increase the water solubility of humic acids, decrease the light absorption of CDOM, decrease the adsorption of CDOM on surfaces as well as the sorption of hydrophobic organic chemicals on CDOM, and change the composition of functional groups (ligands) responsible for the chelation of metals. In some instances, photochemical reactions can cross-link molecules into di- or oligomers and cause the precipitation of CDOM.

As CDOM typically consists of biologically non-labile organic matter, its photochemical transformation into small molecular mass organic photoproducts generates biologically labile substrates for bacterioplankton (Fig. 1). These biologically available photoproducts (BAPs) are quickly consumed by bacterioplankton. Thus, in addition to the direct photochemical mineralization of CDOM to CO_2, a combined action of photochemistry and microbial respiration based on BAPs facilitates the mineralization of organic carbon. When photochemical reactions cross-link biologically labile compounds together into less labile forms, they slow down biological consumption of labile compounds.

Solar radiation decomposes the fluorophores and the light absorbing moieties of CDOM in a process called photobleaching. An extensive photobleaching requires the presence of O_2. The photochemical loss of carbonyl chromophores, their transformation into low molecular weight organic compounds, and the destruction of aromatic and quinone-structures of CDOM are likely responsible for photobleaching. Under extensive exposure to solar radiation, photochemical reactions can destroy the chromo- and fluorophores of organic matter completely. The photobleaching of CDOM takes place faster than the mineralization of DOC. After complete photochemical loss of chromophores, DOM consists of non-chromophoric compounds that cannot be transformed by direct photolysis. Because CDOM is largely responsible for the absorption of UV- and short wavelength visible radiation, photobleaching increases the penetration of solar radiation into the water column, and thus interferes with the exposure of organisms to UV radiation, the light availability of photosynthetic organisms, and the thermal stratification of the water column.

Photochemistry of nitrogen

Photochemical reactions can release ammonium (NH_4^+) from dissolved organic nitrogen when the concentration of dissolved organic nitrogen (DON) is high and that of NH_4^+ is low (<6 μM, Tarr et al., 2001). The proposed mechanism for the photochemical release of NH_4^+ includes a photoreaction of organic amines with ketones and aldehydes to produce imines, which hydrolyze to NH_4^+. The photoproduction of nitrite (NO_2^-), primary amines, and amino acids along with NH_4^+ provides a source of biologically labile nitrogen (Fig. 1). The photochemical reactions mineralize more carbon than nitrogen, and therefore decrease the C/N-ratio of DOM.

In the presence of high concentration of NH_4^+ (>8 μM) or NH_3, photochemical reactions can also incorporate these inorganic N-species into DON. In addition, photochemical reactions can convert aromatic amino acid (tryptophan) and protein (in the presence of CDOM) into less bioavailable forms.

Photochemistry of phosphorus

Ferric iron, Fe(III), binds phosphate ion (PO_4^{3-}, hereinafter P_i) tightly and can associate with organic matter, CDOM, to form Fe(III)-P_i-CDOM (Gerke, 2010). The phosphorus of these associations is not readily available for organisms. Photochemical reactions can release phosphate from Fe(III)-P_i-CDOM. When these associations absorb solar radiation, ferric iron, Fe(III), can be photoreduced into ferrous iron, Fe(II), and the phosphate ion is released. Unlike many photochemical reactions of CDOM, the photoreduction of ferric iron and subsequent release of phosphate can proceed with high quantum yields. The photochemical release of P_i from Fe(III)-P_i-CDOM may be an important pathway in some environments for converting non-bioavailable P into bioavailable form.

The coupling of photo-oxidation of organic matter to the photoreduction of metals

Metals can associate with organic matter and can become photochemically reduced via a ligand-to-metal charge-transfer pathway when exposed to natural solar radiation (Fig. 3). For example, when organic matter is associated with ferric iron, its light absorption and the probability for photochemical transformation increases. Photochemical reactions can reduce ferric iron to more soluble ferrous iron and at the same time oxidize organic matter e.g., via decarboxylation-reaction, which can lead to production of CO_2 and hydrogen peroxide (H_2O_2). Ferrous iron, Fe(II), is often quickly oxidized to ferric iron, Fe(III), in a dark process, which consumes dissolved oxygen or reactive oxygen species. If H_2O_2 is the oxidizer of Fe(II), the process produces hydroxyl radicals via the Fenton reaction: Fe(II) + H_2O_2 → $^{\bullet}$OH + Fe(III). When solar radiation produces both Fe(II) and H_2O_2, this reaction is known as photo-Fenton reaction (Vione et al., 2014).

Photodegradation of pollutants

Photochemical reactions transform contaminants and contribute to the self-purification of water bodies. Many pollutants absorb sunlight, and absorption triggers their direct photochemical transformation. The direct photolysis of contaminants is most efficient in waters with low CDOM-content, because CDOM decreases the availability of light to contaminants and, therefore, their rates of direct photolysis.

Indirect photochemical reactions can also transform pollutants, which cannot absorb solar radiation themselves (Remucal, 2014). The major sensitizers for the indirect photochemical transformation of contaminants are CDOM, nitrate and nitrite (Fig. 4). Indirect photochemical transformations involve the PPRIs, of which the main ones are $^{\bullet}$OH, $^1O_2$, CDOM(T_1) and the carbonate radical, $CO_3^{\bullet-}$ (Fig. 4). The PPRIs are photochemically generated by the sensitizers and quickly consumed by scavengers or otherwise quenched (Fig. 4). For example, DOM is a major scavenger of $^{\bullet}$OH and $CO_3^{\bullet-}$ (Fig. 4). Effective scavenging keeps the steady-state concentrations of PPRIs at low level, such as 10^{-15}–10^{-18} mol L^{-1} for $^{\bullet}$OH.

Although scavenging and quenching consume PPRIs effectively, the comparatively minor reactions of PPRIs with contaminants are of prime importance in the ecology of rivers and lakes (Remucal, 2014; Vione et al., 2014). PPRIs react with man-made pollutants (e.g., pesticides, pharmaceuticals and personal care products, industrial chemicals) to induce their transformation, which often leads to partial or even complete detoxification. Unfortunately, in some cases the transformation intermediates can be more toxic/harmful/mutagenic than their parent compound. This means that the actual impact of photochemical processes on the environmental status of water bodies has to be assessed on a case-by-case basis: (i) in the same water body, some pollutants may

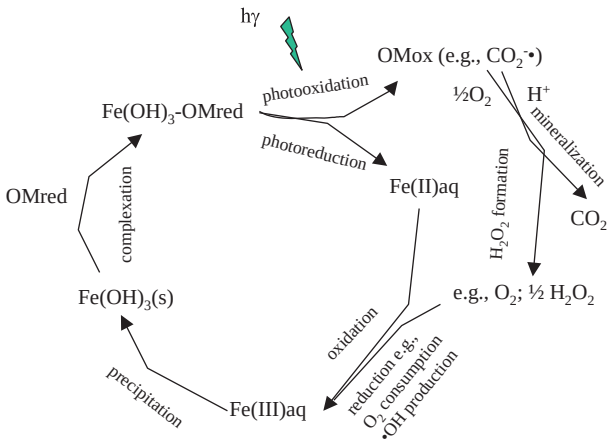

Fig. 3 Schematic representation of the aquatic photo-redox cycling of iron and its coupling to the oxidation of organic matter (OM) in illuminated surface waters. Fe(II)aq = dissolved ferrous iron; Fe(III)aq = dissolved ferric iron; Fe(OH)$_3$(s) = ferric hydroxide; OMred = reduced organic matter, which is a ligand for Fe(III); Fe(OH)$_3$-OMred = a complex between reduced OM and Fe(III); OMox = oxidized organic matter; $CO_2^{\bullet-}$ = carboxylic radical. The oxidation of Fe(II) with hydrogen peroxide is called the Fenton reaction (H_2O_2 + Fe(II) → Fe(III) + $^{\bullet}$OH + OH^-) and generates hydroxyl radicals (Sulzberger, 1992).

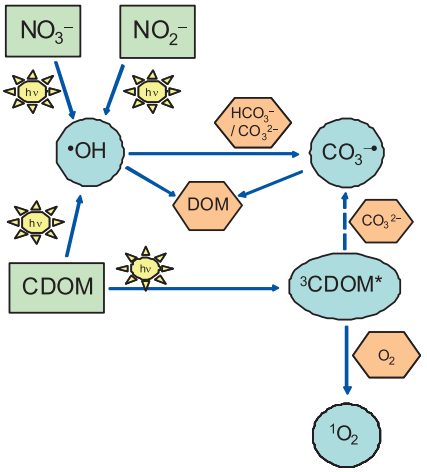

Fig. 4 Schematic of the main processes leading to the generation of photochemically produced reactive intermediates, PPRIs, in surface fresh waters. These PPRIs play a major role in pollutant attenuation. The rectangles represent the photosensitizers, ellipses the PPRIs, and hexagones the main scavengers. Note that $^3CDOM^* = CDOM(T_1)$ (Vione et al., 2014).

undergo detoxification but others may produce hazardous intermediates; (ii) the same pollutant may be detoxified in some water bodies but be transformed into harmful compounds in others, depending on different environmental conditions.

The occurrence of PPRIs depends on water quality. In particular, the concentration of DOC regulates the pathways of photoreactions (Fig. 5). Low-DOC waters favor the reactions involving $CO_3^{\bullet -}$, especially if pH and alkalinity are also high, because HCO_3^- and (predominantly, at pH > 8) CO_3^{2-} are the sources of $CO_3^{\bullet -}$. Intermediate-DOC waters are favorable environments for $^\bullet OH$ and for the direct photolysis (see below), while high-DOC waters favor the reactions induced by $CDOM(T_1)$ and $^1O_2$ (Fig. 5).

Heterogeneous photochemistry

Photochemistry can modify particulate organic matter or organic matter adsorbed on the surfaces. The photochemical reactions associated with surfaces are called heterogeneous in contrast to the homogenous photochemistry of dissolved molecules.

Heterogeneous photochemical reactions take place on any surfaces exposed to photolytic solar radiation, e.g., on the surfaces of sediment or particles in suspension. For example, irradiation can reduce ferric iron of particulate iron oxides and release it into solution as ferrous iron (Doane, 2017). Concomitantly with the photoreduction of iron(III), organic carbon adsorbed on particles is oxidized and O_2 consumed. Solar radiation can mineralize, and decrease the molecular mass of, organic matter adsorbed on the

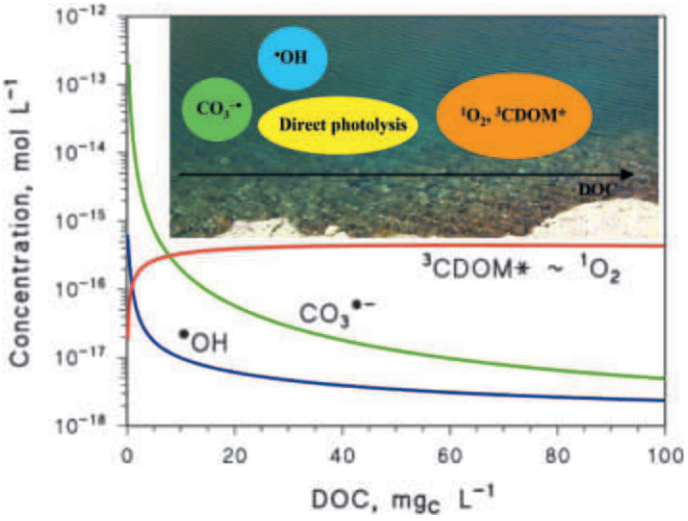

Fig. 5 DOC trend of the steady-state concentrations of the main PPRIs occurring in surface waters, under fair-weather summer sunlight at mid-latitude, for a water column depth of 3 m. Note the logarithmic scale on the Y-axis, which was needed to accommodate the very different concentration values. The insert provides qualitative insight into the relative role played by direct photolysis and indirect photochemistry in different environmental (DOC) conditions. Note that $^3CDOM^* = CDOM(T_1)$.

surfaces of mineral (e.g., clay) particles. This process decreases the adsorption of CDOM on surfaces and leads into the dissolution of DOC. Such DOC is biologically labile compared to organic matter adsorbed on the surfaces of mineral particles.

Photochemical reactions also interfere with the decomposition of particulate dead organic matter (detritus) such as senescent phytoplankton or macrophytes (King et al., 2012). The (photosynthetic) pigments are primary absorbers of solar radiation, and they are susceptible for photolysis in detrital plants with non-functional photoprotective apparatus. The photolysis of pigments in surface waters is an important pathway for their decomposition, because pigments decompose ineffectively in dark anaerobic sediments.

The lignin of vascular plant detritus is highly susceptible for photolysis (King et al., 2012). The photochemical decomposition of lignin can break down the structural integrity of detrital plant material, enhance the leaching of particulate organic matter into DOM, and induce the loss of particulate organic matter. Photochemical reactions can also directly mineralize detrital plant material into CO_2. The exposure of detrital leaves to solar radiation can increase or decrease microbial activity on leaves, possibly depending on the diagenetic state and the bioavailability of detrital leaves.

Photochemistry can transform organic matter differently in frozen (ice/snow surfaces on glaciers and lakes) than in liquid water. Freezing can create highly concentrated microenvironments on the surface of snow/ice and in channels between ice crystals. Photochemical condensation is more common in highly concentrated solutions associated with snow/ice than in dilute solutions e.g., in lake water.

Photochemical reaction rates

Photochemical reactivity of organic matter

Photochemical reactivity of organic matter describes the susceptibility of organic matter to photochemical transformation and is quantitatively described by a quantum yield (often abbreviated by ϕ). The ϕ for a photochemical reaction describes the magnitude of a certain reaction (for example with a unit "mol of photochemical product") in relation to the number of photons absorbed (mol of absorbed photons).

The variability of ϕ-values is large among different photochemical reactions (Fig. 6). An example of high reactivity is the ϕ-value around one for the photochemical transformation of ferrioxalate (Fig. 6). In this case, every photon absorbed by ferrioxalate reduces Fe(III) to Fe(II). An example of a lower quantum yield is the photochemical production of hydroxyl radicals from nitrate: $NO_3^- + h\nu (+H^+) \rightarrow NO_2 + {}^{\bullet}OH$. The quantum yield for this reaction is ~0.01 (Vaughan and Blough, 1998; Fig. 6). The quantum yield is

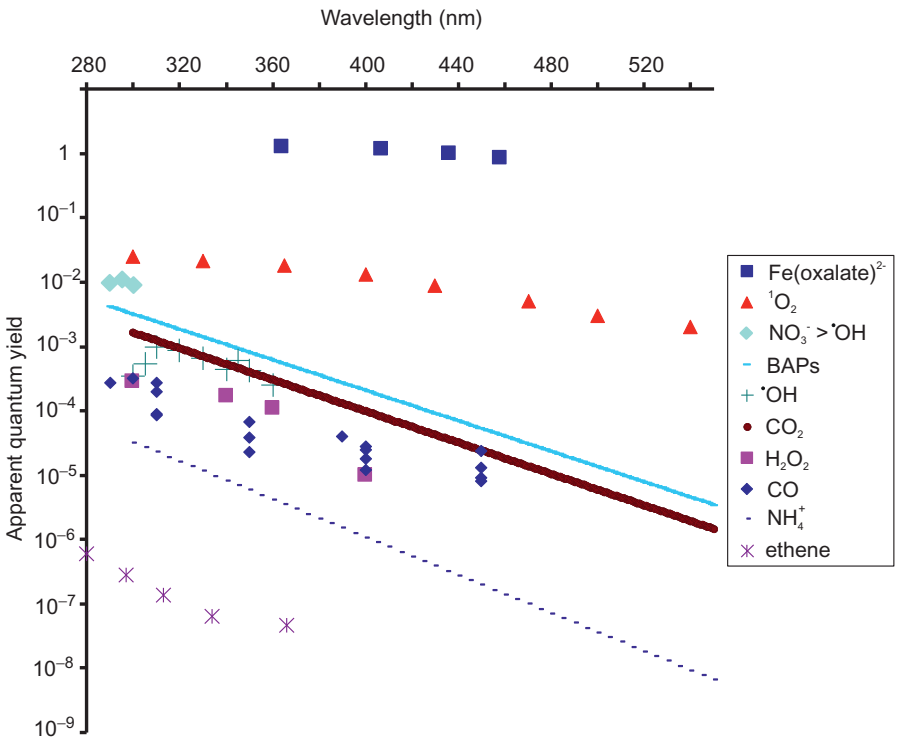

Fig. 6 Apparent quantum yield for the photochemical reactions of CDOM and those of nitrate and ferrioxalate. Photoreduction of ferrioxalate ($Fe(oxalate)^{2-}$) (Demas et al., 1981; Faust and Zepp, 1993). $^{\bullet}OH$ production from photolysis of nitrate (Vaughan and Blough, 1998). Photoproduction of singlet oxygen ($^1O_2$) from Suwannee River natural organic matter (Partanen et al., 2020). Biologically available photoproducts (BAPs) in Altamaha River, United States (Miller et al., 2002). CO_2 photoproduction in L. Valkea-Kotinen (Vähätalo et al., 2000). $^{\bullet}OH$ photoproduction from Suwannee River fulvic acid (Vaughan and Blough, 1998). H_2O_2 photoproduction in Sharpes Bay (Scully et al., 1996). Photoproduction of carbon monoxide (CO) in Satilla and Suwannee River, L. Kinoshe, Houghton wetland and Okefenokee Swamp (Valentine and Zepp, 1993; Gao and Zepp, 1998). NH_4^+ photoproduction in the Baltic Sea (Vähätalo and Zepp, 2005). Ethene photoproduction in Shark River (Riemer et al., 2000).

typically assumed to be spectrally independent for a defined photochemical reaction, when initiated by light absorption by a known compound (Kasha's rule, which is usually valid with a few exceptions). Examples that follow Kasha's rule are the photoproduction of $^{\bullet}OH$ from nitrate in the environmentally significant UV-B and UV-A wavelength ranges, and the direct photolysis of most organic contaminants.

For the photochemical reactions associated with CDOM, the light absorption cannot be assigned to any specific compound, because the chromophores of CDOM contribute to light absorption collectively. In these cases, the quantum yields receive a prefix "apparent," the ϕ-values are low (typically <0.02) and have a strong spectral dependence (Fig. 6). The apparent ϕ-values often decrease exponentially with increasing wavelength, likely reflecting the heterogeneity of chromophores and the photochemical reactivity of thousands of compounds in CDOM. Examples of these types of reactions are the photoproduction of $^1O_2$, BAPs, CO_2, $^{\bullet}OH$, H_2O_2, CO and ethene by irradiated CDOM (Fig. 6). The exponential spectral dependence of ϕ-values can be approximated as (Vähätalo et al., 2000): $\phi_\lambda = c \exp(-d\,\lambda)$, where ϕ_λ is the apparent quantum yield at the wavelength λ, c is an apparent quantum yield at a reference wavelength λ (e.g., mol product mol photons^{-1}), and d is a spectral slope coefficient for ϕ_λ (nm^{-1}). This approximation is shown as lines in Fig. 6, where the ϕ-values for the photoproduction of BAPs, CO_2 and NH_4^+ are reported in the logarithmic scale.

Regulators of the photochemical reactivity of organic matter

The characteristics of DOM and environmental conditions affect the photochemical reactivity of DOM. For example, the ϕ-values for the mineralization of DOC can vary 10-fold in different water bodies depending on pH, the concentration of iron and O_2, as well as the quality of CDOM. CDOM exported from organic soils without previous exposure to solar radiation is most sensitive for the photochemical transformations (Cory et al., 2018). The first exposure to solar radiation decomposes the most photoreactive parts of DOM (e.g., the aromatic structures) and can decrease the photoreactivity of DOM quickly. Later the decrease in ϕ-values is more gradual when DOM has been already exposed to solar radiation e.g., in large lakes with long water retention times.

The rates of photochemical reactions depend on temperature but to a lesser degree than typical chemical reactions. Typical activation energies for photochemical reactions are 10–30 kJ mol^{-1}. The activation energies 10 and 30 kJ mol^{-1} correspond to 1.5- and 3-times faster rates at 25 °C than at 0 °C, respectively. By comparison, the rates of chemical reactions can be 4–5 times faster at 25 °C than at 0 °C.

Estimating the rates of photoreactions in the environment

The rates of photochemical reactions related to CDOM depend on (i) the amount of spectral solar irradiance, (ii) its absorption by CDOM and (iii) the spectral apparent quantum yield for the reaction (Cory et al., 2018). The volumetric photochemical transformation rate of DOM at the depth z (pr_z, e.g., mol m^{-3} day^{-1}) can be expressed as:

$$pr_z = \int_{\lambda\ \min}^{\lambda\ \max} Q_{s,z,\lambda}\, a_{CDOM,\lambda}\, \phi_\lambda\, d\lambda \tag{1}$$

where $Q_{s,z,\lambda}$ is the scalar photon flux density at λ and depth z (e.g., mol photons m^{-2} d^{-1} nm^{-1}; Fig. 7A), $a_{CDOM,\lambda}$ is the absorption coefficient of CDOM at λ (m^{-1}; Fig. 7B), and ϕ_λ is the apparent quantum yield for the photochemical reaction at the wavelength λ (mol product mol absorbed photons^{-1}; Fig. 7C). The integration range refers to the solar radiation contributing to the photochemical reaction from the shortest λ_{min} to the longest λ_{max} wavelengths (nm). The term $Q_{s,z,\lambda}$ describes photon flux density to a point from all directions. Fig. 7A–D illustrate the use of Eq. 1 for the estimation of the volumetric photochemical mineralization rate of DOC at three depths in a humic lake.

The areal rate for photochemical transformation of CDOM over the entire water column (pr, e.g., mol m^{-2} day^{-1}) can be expressed as:

$$pr = \int_{\lambda\ \min}^{\lambda\ \max} Q_{a,\lambda}\, a_{CDOM,\lambda}/a_{tot,\lambda}\, \phi_\lambda\, d\lambda \tag{2}$$

where $Q_{a,\lambda}$ represents mol of photons absorbed by the water column (mol photons m^{-2} day^{-1} nm^{-1}; Fig. 7E), and the ratio $a_{CDOM,\lambda}/a_{tot,\lambda}$ describes the contribution of CDOM to the total absorption coefficient, $a_{tot,\lambda}$ (Fig. 7F). Fig. 7E–H illustrate the use of Eq. (2) for the estimation of the areal photochemical mineralization rate of DOC.

Similar equations as Eqs. (1) and (2) hold for the photochemical generation of PPRIs by irradiation of CDOM, NO_3^- and NO_2^-, and for the direct photolysis of pollutants (Vione, 2020). The relevant set of equations can be included into software that predict the direct and indirect phototransformation kinetics of contaminants, due to the action of sunlight. One such examples is APEX (Aqueous Photochemistry of Environmentally-occurring Xenobiotics), a software that predicts the photochemical lifetime of contaminants based on (i) pollutant properties: absorption spectrum, direct photolysis quantum yield and second-order reaction rate constants with PPRIs, and (ii) environmental features: sunlight spectrum and irradiance, depth and chemical composition of natural water (Vione, 2020).

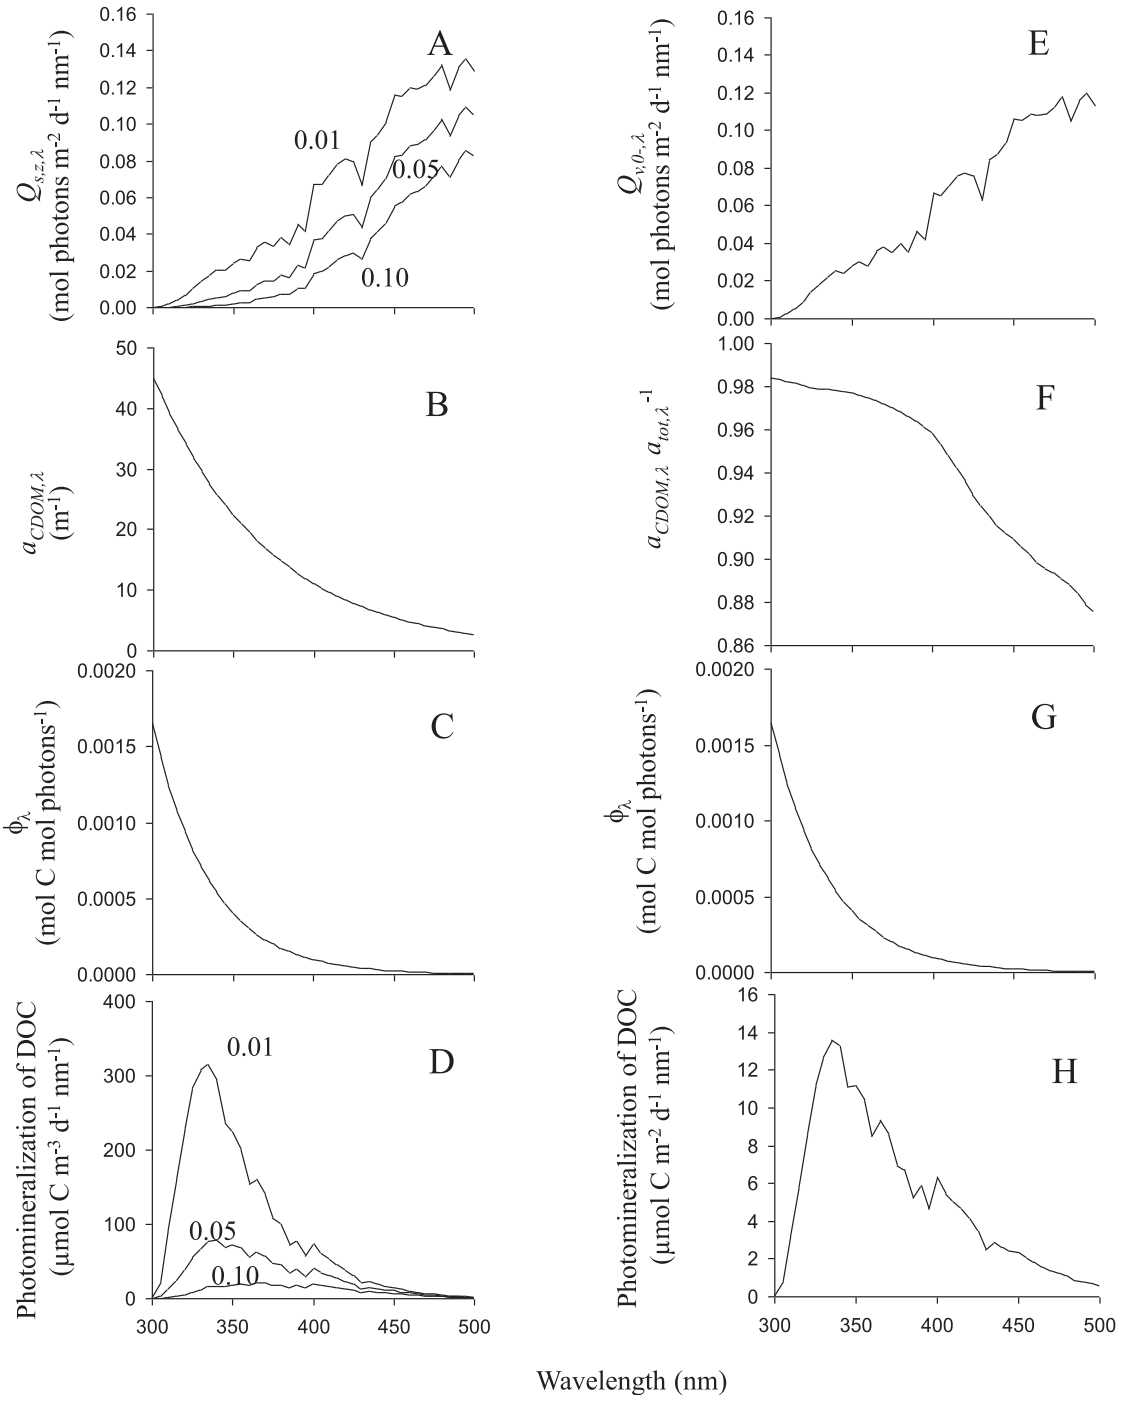

Fig. 7 Modeling the photochemical production of CO_2 from DOC in Lake Valkea-Kotinen at three depths (panels A–D, Eq. 1) and over the entire water column (panels E–H, Eq. 2). Volumetric CO_2 photoproduction rates at three depths: (A) Solar scalar photon flux density at the depths of 0.01, 0.05 and 0.10 m, (B) the absorption coefficient of CDOM, (C) the apparent quantum yield spectrum for CO_2 photoproduction, and (D) the action spectra for CO_2 photoproduction rates at the depths of 0.01, 0.05 and 0.10 m. Areal CO_2 photoproduction rate over the entire water column. (E) Vector photon flux density just below the surface, (F) the proportion of radiation absorbed by CDOM, (G) the apparent quantum yield spectrum for CO_2 photoproduction, and (H) the action spectrum for CO_2 photoproduction over the entire water column (Vähätalo et al., 2000).

Solar radiation spectrum responsible for photochemical reactions and the attenuation of photochemical rates with depth

The UV- and short wavelength visible part of solar radiation are mostly responsible for photochemical reactions in surface waters, as illustrated by the action spectra for CO_2 photoproduction in Fig. 7D and H. Although the UV-B radiation (290–315 nm) has high energy per photon, it contributes only 0.1% to the global radiation (290–3000 nm). Therefore, the less energetic but more abundant UV-A (315–400 nm, ca. 6% of global radiation) is often mostly responsible for photochemical reactions. The solar radiation peaks at the visible range of spectrum (400–700 nm, ca. 50% of global radiation), but at that range of spectrum the energy of photons is lower and much of the radiation is absorbed by suspended particles and by H_2O.

The short wavelength solar UV radiation contributes a lot to photoreactions in a narrow stratum close to surface (Fig. 7D). Such UV-radiation attenuates quickly in the water column and, therefore, radiation at longer wavelengths (UV-A and visible radiation) becomes more important for photochemical reactions at deeper depths (Fig. 7A and D).

The optical characteristics of water bodies regulate the attenuation of both the solar UV radiation into water columns and the photochemical reaction rates. Because solar UV-A radiation is often mostly responsible for the photochemical transformation of DOM, the attenuation of solar UV-A radiation into the water column approximates the attenuation of many photochemical reactions. Photochemical reactions can reach a depth of ~30 m in the most transparent water bodies, but they are limited into depths of less than 0.1–0.2 m in waters rich in suspended particles or CDOM as exemplified by Lake Valkea-Kotinen in Fig. 7. On solid surfaces, such as plant detritus or sediments, the solar UV radiation and photochemical transformations are limited to a very narrow (<1 mm) surface stratum.

The rates of photochemical reactions in the environment

In water bodies with high light extinction coefficients, CDOM absorbs solar UV radiation effectively and the rates of resulting photochemical reactions (such as photochemical production of CO_2) can exceed the corresponding rates of biological processes (such as respiration) in a narrow surface stratum (Cory et al., 2014). In these cases, photochemical rates also attenuate steeply with depth and their overall importance depends on the depth of the water column.

It is often more informative to examine the rates per area, as those rates give more information about the role of photoreactions on the biogeochemistry of whole ecosystems. Table 1 presents examples of areal rates of photochemical reactions measured directly, calculated according to Eq. (2) or from mass balances. The summertime rates for the photochemical mineralization of DOC range from 1000 to 24,700 μmol C m^{-2} day^{-1} in the 20 freshwaters exemplified in Table 1. In the perspective of the epilimnion or the

Table 1 Areal summertime rates for the photochemical production of CO_2, biologically available photoproducts (BAPs) and NH_4^+ over the entire water column.

Rate μmol m^{-2} day^{-1} (% of BR or BCD)	*Site (depth of integration)*	*References*
DOC → CO_2		
3700–4800[a] (>7–11% of BR)	Four lakes, Sweden (1.5–7.5 m epilimnia)	Granéli et al. (1996)

23–26[c]	Coastal Baltic Sea	Vähätalo and Järvinen (2007)

The rate of photochemical CO_2 production is given as a percentage of bacterial respiration (BR). The contribution of BAPs is given in percentages of bacterial carbon demand (BCD).

* = measured, [c] = calculated, [a] = mean annual rate.

BR = bacterial respiration = biological mineralization of DOC; BCD = bacterial carbon demand in the epilimnion.

entire water column, the photochemical mineralization of DOC typically corresponds to 3–31% of the biological mineralization of DOC, but in some cases exceeds bacterial respiration (Table 1).

Altogether, solar radiation mineralizes 13–35 Tg C $year^{-1}$ DOC directly to CO_2 in freshwaters and contributes 10% to the CO_2 evasion from inland waters (Koehler et al., 2014). Rivers transport photoreactive CDOM from the inland waters to the coastal waters. In the coastal waters, solar radiation mineralizes 31–58 Tg C $year^{-1}$ of the DOC transported by rivers (Aarnos et al., 2018). The mineralization of freshwater DOC is larger in the coastal than in the inland waters, because the mixing of CDOM from river water to low-CDOM seawater and the advection of river plumes over extensive areas facilitate the photochemical transformation of CDOM.

The photochemical production rate of BAPs ranges from 570 to 3800 μmol C m^{-2} day^{-1} and has often similar magnitude as direct photochemical mineralization to CO_2 in the examples reported in Table 1. The total impact of solar radiation on the mineralization of DOC consists of direct photochemical mineralization (DOC → CO_2) and microbial mineralization of BAPs (BAPs → CO_2). BAPs can satisfy 10–20% of bacterial carbon demand in the epilimnion or the mixed layer of coastal ocean (Table 1). The rates of photochemical production of ammonium from dissolved organic nitrogen are one to two orders of magnitude lower that the rates concerning DOC (Table 1).

Photochemistry, food webs and climate change

Responses of food webs to the photochemical transformation of organic matter

Bacteria are the primary consumers of dissolved organic matter and the first component of the food web to respond to the photochemical transformation of DOM (Cory et al., 2018). When photochemical reactions break down aromatic compounds into bioavailable substrates, bacterial communities may suppress the gene expression of enzymes for degradation of aromatic compounds (Nalven et al., 2020). Photochemically produced low molecular mass compounds are typically enriched in carbon relative to the essential N- or P-nutrients, and more oxidized than is CDOM before exposure to solar radiation (Fig. 1). Therefore, BAPs often support more respiration than the production of new bacterial biomass and result in a reduced bacterial growth efficiency. The BAPs favor bacterial strains, such as *Polynucleobacter necessarius* subspecies *asymbioticus*, which can efficiently consume them (Hahn et al., 2012). Bacterioplankton species consuming BAPs are most abundant during summertime when the concentration of BAPs is highest. When BAPs increase bacterial production, the increased production transfers first to the grazers of bacterioplankton (e.g., flagellates and ciliates) but can extend up to metazooplankton (*Daphnia*). The nutrients released from CDOM through photochemical reactions, such as nitrogen, phosphorus and iron, also support phytoplankton (Vähätalo et al., 2011).

Photochemical reactions can also decrease the bioavailability of organic matter, when they act on biologically labile organic matter such as proteins or other fresh organic matter produced by phytoplankton or macrophytes. For example, solar radiation can cross-link simple unsaturated fatty acids and NH_3 and consequently decrease the bioavailability of both carbon (fatty acids) and nitrogen (NH_3) substrates.

The same solar UV-radiation that transforms CDOM into biologically labile forms also causes harmful effects on organisms, for example via formation of thymidine dimers in DNA (pairing of two consecutive bases on one single strand), which can cause misreading during transcription or replication and even the stop of the replication. The sensitivity of organisms to UV-radiation varies and the net impact of UV-radiation on food webs depends on the balance between the beneficial and harmful effects.

Photochemical reactions and climate change

By deeply affecting the chemistry and hydrology of surface waters, climate change may modify the photochemical processes in aquatic environments (Vione and Scozzaro, 2019). For example, increased runoff exports CDOM from soils to the water bodies and causes browning of inland waters in the Boreal region. An increase in the DOC concentration usually slows down the phototransformation of pollutants. As suggested by Fig. 5, an enrichment in CDOM favors the CDOM(T_1)/$^1O_2$-induced processes at the expense of the $^{\bullet}OH/CO_3^{\bullet-}$ reactions and direct photolysis. For example, browning inhibits the $^{\bullet}OH$-induced transformation of phenylurea herbicides into toxic N-formyl compounds. In contrast, browning is expected to enhance the CDOM(T_1)-induced transformation of the drug (lipid regulator) metabolite clofibric acid into toxic 4-chlorophenol.

Additional predicted impacts of climate change are (i) increased summer stratification period in lakes; (ii) longer ice-free period, and (iii) alternation of water scarcity with flood events, because a similar amount of average precipitation will be distributed over fewer rainy days. (i) Water stratification enhances the photobleaching of CDOM, the penetration of sunlight, and the direct photochemical transformations in the epilimnion. At the same time, a larger amount of matter may be protected from photochemical transformation in the dark hypolimnion, and the photochemical turnover time in the perspective of the entire lake may increase. (ii) Compared to the albedo of water, the albedo of ice and snow is high and limits the sunlight available to photochemical reactions in aquatic systems. Therefore, a longer ice-free period will increase photochemical processes in the water column of lakes. This increase is highest during earlier melting of ice in spring, because sunlight is more intense than with delayed freezing in early winter. (iii) Water scarcity usually increases the importance of photochemical reactions. Decreasing water levels enhance photochemistry because sunlight reaches a higher fraction of the water column. In the case of rivers there would be the additional effect of a decreased water flow velocity during drought events. Therefore, the same river stretch could accommodate water for longer in water-scarcity conditions, which provides a longer time scale for photoreactions to operate. In some cases, enhanced photochemistry in rivers during droughts might offset the higher levels of contaminants that would result from lesser dilution of the wastewater inputs.

Conclusion

Photochemical reactions in sunlit surface waters modify the chemical properties of natural and anthropogenic organic matter and shift the speciation of metals. The rates of photochemical reactions can exceed those of other transformations carried out by biological or thermal abiotic processes in a narrow surface stratum or shallow waters. Photochemical transformations provide an ecosystem service by re-mineralizing organic matter and self-depolluting surface waters. Photochemical processes couple to biological processes and this interplay speeds up remineralization of organic matter. Photochemical transformations of organic matter partially support the aquatic food webs and modify their composition.

Knowledge gaps

Although many works have been published about photochemical reactions taking place in inland waters, several aspects of these processes still have to be completely understood. For instance, there is still debate about the chromophores and pathways that account for light absorption by CDOM, which is the main source of photochemical processes in surface waters. Moreover, the photoproduction mechanisms of some PPRIs by irradiated CDOM are still unclear, such as $^{\bullet}OH$ radicals. As far as the photodegradation of pollutants is concerned, there is need of additional data about phototransformation products and about their toxicity towards aquatic organisms. This kind of information would be helpful to assess the ecological impacts of photochemical reactions in inland waters. Finally, the evaluation of several real-case studies such as drought events, e.g., by means of modeling tools will allow for a better understanding of the effects of climate change on the photochemistry of surface waters.

Glossary

Acetogenesis Synthesis of acetate as cell carbon from CO_2 via the acetyl-CoA pathway.
Anabolism Anabolic metabolism can be understood as a coordinated metabolic activity for construction processes in which macromolecules are synthesized, which results in the formation of more complex molecules from simpler ones, both for cell growth and for its maintenance.
Anaplerotic metabolism Inorganic carbon assimilation in central physiological pathways of cell metabolism. These include the presence of carboxylases, e.g., pyruvate carboxylase and phosphoenolpyruvate carboxylase which recycle and incorporate inorganic carbon into TCA cycle intermediates.
Anoxic Denotes the absence of molecular oxygen (O_2).
Autotroph Organism that derives the carbon needed for biosynthesis from inorganic molecules (carbon dioxide) independent of their energy source. *Photoautotrophs* and *chemoautotrophs* obtain their energy from sunlight and the oxidation of inorganic molecules respectively.
Bacterial growth efficiency The fraction of the total carbon in the metabolized substrates that is used for biomass production (the remainder is used for energy generation). Bacterial growth efficiency is usually calculated as the bacterial production divided by the sum of bacterial production and bacterial respiration.
Bacterial production Production of bacterial biomass C per time unit.
Carbon fixation The formation of organic biomolecules from inorganic carbon (e.g., CO_2).

☆*Change History*: November 2021. F Machado-Silva and C Signori were invited to new contributions. A Enrich-Prast, F Machado-Silva, D Bastviken, P Crill, and C Signori worked on the whole text. All sections have been updated, Table 3 has been updated, and Figure 6 has been included.

Catabolism Catabolic or oxidative metabolism is the metabolic activity used to degrade molecules to produce simpler constituents and energy. All biochemical reactions that aim to break down or unfold molecules to release of energy necessary to carry out various metabolic activities. It is in catabolism that carbohydrates, lipids and proteins, for example, are broken down into smaller, simpler products.
Chemolithotrophic heterotrophs Organisms that use energy from the oxidation of reduced inorganic compounds to support growth on organic substrates as carbon source.
Chemosynthesis Can be defined as the biological production of organic compounds from inorganic C-1 molecules (e.g., carbon dioxide and methane) and nutrients using the energy generated by the oxidation of inorganic (e.g., hydrogen gas, hydrogen sulfide, ammonium) or organic C-1 (e.g., methane, methanol).
Chemosynthetic mixotrophs Organisms that utilize at the same time CO_2 and organic carbon compounds as carbon source and/or organic and inorganic substrates as energy source.
Chemotrophs Organisms that use chemical reactions as energy source. *Chemoorganotrophs* or *chemolithotrophs* obtain their energy for biosynthesis or energy conservation via aerobic or anaerobic respiration from the oxidation for organic or inorganic molecules respectively.
Chironomids A family of non-biting midges. Larval stages can be found in surface sediments in most freshwater habitats. The larvae of some species are tolerant to low O_2 conditions.
Dark carbon fixation Term widely used in aquatic sciences and applies primarily to chemosynthetic reactions where organic matter production occurs without sunlight.
Electron acceptor A chemical entity that accepts electrons transferred to it from another compound. It is an oxidizing agent that, by accepting electrons, is itself reduced in the process.
Electron donor A chemical entity that donates electrons to another compound. It is a reducing agent that, by donating electrons, is itself oxidized in the process.
Endosymbiosis Term for a symbiotic relationship when one organisms live inside another organism and when both organisms benefit from this relationship.
Epilimnion The uppermost surface wind mixed water layer of a thermally stratified lake.
Fermentation The incomplete anoxic degradation of organic matter resulting in e.g., small organic acids, alcohols, H_2 or CO_2.
Heterotrophs Organisms relying on organic matter as their source of carbon.
Hypolimnion The bottom water layer in thermally stratified lakes positioned below the strong temperature gradient.
Metabolism Metabolism describe the various chemical reactions existing in organisms that ensure structural and energy needs, such as the synthesis and breakdown of biomolecules. The biochemical reactions can be classified into two major metabolic processes: anabolism and catabolism.
Mineralization The complete degradation of organic matter to CO_2 under oxic conditions, or CO_2 and CH_4 under anoxic conditions.
One-carbon (C-1) compounds Carbon dioxide (CO_2) and carbon monoxide (CO) are examples of inorganic molecules and methane (CH_4), methanol (CH_3OH), methylamine (CH_3NH_2) and methane thiol (CH_3SH) are examples or organic molecules.
Oxidation Describes the loss of electrons by a molecule, atom or ion.
Oxycline The steep O_2 concentration gradient that represent the border between oxic and anoxic environments.
Phototrophs Organisms that use sunlight as energy source.
Phylogeny The study of evolutionary relatedness among various groups of organisms.
Primary production The production of organic matter from carbon dioxide (CO_2).
Redox (Shorthand for reduction/oxidation reaction) describes all chemical reactions in which atoms have their oxidation number (oxidation state) changed.
Reduction Describes the gain of electrons by a molecule, atom or ion.
Syntrophic consortia Term for the aggregates of different microbial groups depending on each other for optimizing their metabolic energy yield. En example is H_2 producing fermenting bacteria living together with H_2 utilizing methanogenic or sulfate reducing bacteria. The organization into a consortium result in an efficient and rapid H_2 transfer to the H_2 utilizing bacteria and the rapid removal of H_2 increase the thermodynamic energy yield of the fermentation process.
Thermodynamic energy yield ($\Delta G_0'$) The amount of Gibbs free energy yielded in a chemical reaction.

Introduction

All known life forms depend on the biosynthesis of complex organic compounds. Hence, the capability to produce such biomolecules from abiotic carbon sources, e.g., one-carbon (C-1) compounds such as carbon dioxide (CO_2) and methane (CH_4) was, and still is crucial for the development of life. The formation of biomolecules from C-1 compounds, often referred to as carbon fixation or autotrophy, requires energy. *Chemosynthesis* can be defined as the biological production of organic compounds from C-1 compounds and nutrients using the energy generated by the oxidation of inorganic molecules, e.g., hydrogen gas, hydrogen sulfide, ammonium, or C-1 organic molecules, e.g., methane, methanol. This process contrasts with *photosynthesis*, a process in which organic compounds are synthesized from CO_2 using energy generated from sunlight radiation.

Table 1 Classification of microbial metabolism on the basis of energy source, the type of electron donor and the type of carbon source.

Energy source				
Chemical	*Chemo-*			
Light	*Photo-*			
Electron donor				
Inorganic		*-litho-*		
Organic		*-organo-*		
Carbon source				
CO_2			*-auto-*	
Organic			*-hetero-*

				-troph

Reproduced from Overman J (2006) Principles of enrichment, isolation, cultivation and preservation of prokaryotes. In: Dworkin M, Falkow S, Rosenberg E, Schleifer K-H and Stackebrandt E (eds.) *The Prokaryotes*. (3rd edn.), vol. 1, pp. 80–136. New York: Springer.

Organisms that use sunlight as energy sources are called *phototrophs* and those that use chemicals are called *chemotrophs* (Table 1). Chemotrophs can be classified as *chemoorganotrophs* or *chemolithotrophs* depending on their use of organic or inorganic energy sources, respectively (Table 1). The term chemolithotroph literally means "chemical rock eaters" and is used to designate organisms that derive energy by the oxidation of inorganic molecules and the transfer of electrons either aerobically or anaerobically to other chemical acceptors for biosynthesis or energy conservation (Overman, 2006).

Many chemosynthetic organisms are usually referred to as *chemoautotrophs*. The term *autotroph* (self-feeding) denotes organisms that derive their metabolic carbon from CO_2 independent of their energy source. *Photoautotrophs* and *chemoautotrophs* obtain their energy from sunlight and the oxidation of inorganic molecules, respectively (Table 1). All chemoautotrophs are chemosynthetic organisms, but not all autotrophs are chemosynthetic.

Some chemosynthetic organisms can assimilate organic molecules, i.e., they are anabolically heterotrophic. There are also facultative chemolithoautotrophs that can grow autotrophically or heterotrophically depending on conditions such as substrate availability. Chemolithotrophic heterotrophs use energy from the oxidation of reduced inorganic compounds to support growth on organic substrates as carbon sources. Chemosynthetic mixotrophs are organisms that at the same time utilize CO_2 and organic carbon compounds as carbon sources and/or organic and inorganic substrates as energy sources. These classifications based on the energy and carbon sources and on electron acceptor utilization are reviewed in Table 1.

Redox processes associated with chemosynthesis are important drivers of many biogeochemical cycles and have profound roles in the production and cycling of climate forcing trace gasses such as CH_4 and N_2O. In addition, chemosynthetic processes have to be considered in studies regarding biochemical or microbial diversity, ecosystems and the origin of life on Earth. It is likely that the earliest self-sustaining metabolism was based on chemosynthesis. This hypothesis is supported by the fact that many of the deepest branching lineages of the phylogenetic tree contain chemoautotrophic organisms.

This chapter primarily focuses on autotrophic chemosynthesis, i.e., inorganic carbon fixation, and aims to present chemosynthesis from an inland water perspective. In aquatic sciences, the term "dark carbon fixation" is widely used and applies primarily to chemosynthetic reactions where organic matter production occurs without sunlight. Considerations of all existing processes associated with chemosynthesis, their biochemistry and the organisms involved is outside the scope of this chapter and can be found in the more specialized literature listed in Further Readings.

Carbon fixation pathways

The most studied CO_2 fixation pathways for chemosynthesis are the Calvin-Benson-Bassham cycle and the reductive acetyl-CoA pathway (also known as Wood-Ljungdahl pathway), of a total of six CO_2 fixation pathways. The other four pathways are the reductive tricarboxylic acid (rTCA) cycle, the 3-hydroxypropionate (3-HP) bicycle, the 3-hydroxypropionate/4-hydroxybutyrate (3-HP/4-HB) cycle and the dicarboxylate/4-hydroxybutyrate (DC/4-HB) cycle. The Calvin cycle is the only one observed in eukaryotes. Here the first step of CO_2 fixation is the Rubisco reaction combining CO_2 with the 5 carbon compound Ribulose-1,5-bisphosphate and forming a 6 carbon compound that is later cleaved into two molecules of glycerate 3-phosphate that are used in cellular anabolism. The reductive acetyl-CoA pathway leads to the fixation of CO_2 into acetate. This is the main pathway of acetogenic microorganisms. Methylotrophs can metabolize C-1 compounds as energy and carbon sources by three major assimilation pathways: (1) the Calvin cycle, (2) the Ribulose monophosphate (RuMB) pathway, and (3) the serine pathway (Fig. 1). For all aerobic methylotrophs, formaldehyde is a central intermediate, which is partly oxidized to CO_2 and is partly assimilated into cell carbon via the serine or RuMB pathways (Lindstrom, 2006). Other methylotrophs are able to oxidize C-1 compounds to CO_2 with subsequent assimilation via the Calvin cycle. For chemosynthetic sulfate-reducers the synthesis of acetyl-CoA from CO_2 has been demonstrated to occur via the citric-acid cycle or the CO-dehydrogenase pathway.

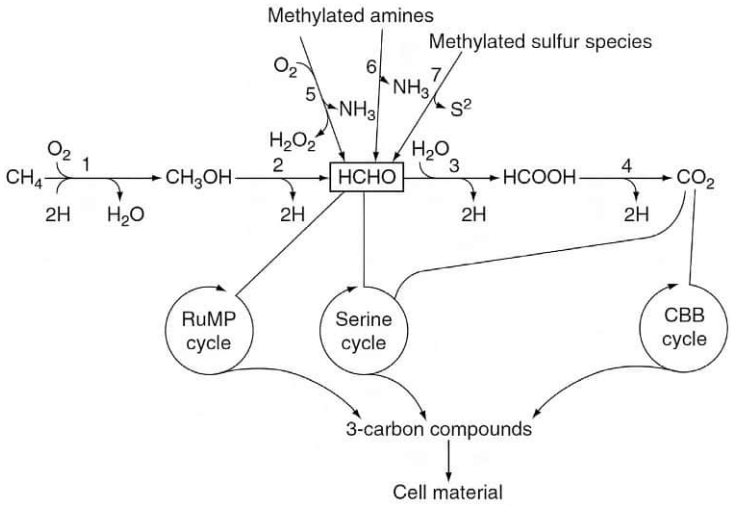

Fig. 1 Metabolism of one-carbon compounds in aerobic methylotrophic microorganisms. (1) Methane monooxygenase; (2) methanol dehydrogenase; (3) formaldehyde oxidation system; (4) formate dehydrogenase; (5) halomethane oxidation system; (6) methylated amine oxidases; (7) methylated amine dehydrogenase and (8) methylated sulfur dehydrogenase or oxidase. RuMB is ribulose monophosphate, CBB is the Calvin-Benson-Bassham cycle. For more information about RuMP, Serine, CBB and other carbon fixation pathways we refer to Dworkin et al. (2006). Some of the cycles such as CBB are also described in most general microbiology textbooks. Reproduced from Lindstrom ME (2006) Aerobic methylotrophic prokaryotes. In: Dworkin M, Falkow S, Rosenberg E, Schleifer K-H and Stackebrandt E (eds.) *The Prokaryotes* (3rd edn.) vol. 2, pp. 618–634. New York: Springer.

Energetics of chemosynthesis

Redox reactions involving the transfer of electrons from reduced compounds (*electron donors*) to more oxidized molecules (*electron acceptors*) are important in the energy metabolism of all organisms. Electron transfer in redox reactions is used both for ATP production and for acquiring reducing power for biosynthesis, e.g., production of NADPH. In this text, both mechanisms are included when considering the energy yield of the reaction. A limited number of inorganic redox reactions are used for chemosynthesis. Examples of such reactions, along with their thermodynamic energy yield ($\Delta G^{\circ\prime}$), are presented in Table 2. In general, chemosynthetic microorganisms grow very slowly, and growth rates may be limited by the energy yield of the associated redox reactions. However, energy limitation is not always the case. For example, the doubling time of anaerobic ammonium oxidizers (ANAMMOX) in the laboratory varies from 11 days to 3 weeks, a much higher value than for aerobic ammonium oxidizers, although the biomass yield and Gibbs free-energy change of both anaerobic and aerobic groups is approximately the same. This means that the low growth rate of ANAMMOX bacteria is not caused by inefficient energy conservation but by other constraints such as a low substrate conversion rate (Thauer et al., 1977).

Chemosynthetic organisms and associated redox processes

Chemosynthetic organisms are highly diverse in terms of phylogeny, substrate requirements, morphology, habitats, and metabolism. They can be strictly aerobic, strictly anaerobic, or facultative anaerobes. Similarly, some are strictly autotrophic, while others can metabolize either heterotrophically or mixotrophically depending on the environmental conditions and substrate availability. Major identified groups of chemoautotrophs and associated key processes are presented briefly below. It should be remembered that much of our information is based on studies of specific strains grown in the laboratory and many aspects of the organisms and their metabolism in situ are still unknown.

Ammonium and nitrite oxidizers

Since the first discovery of nitrification, this process has always been attributed to the action of a two-step aerobic chemosynthetic process in which ammonium is oxidized to nitrite, and nitrite is then oxidized to nitrate by ammonia oxidizers and nitrite oxidizers (Table 2). However, single nitrifiers that can oxidize ammonia to nitrate, complete ammonia oxidizers (COMAMMOX), have been identified and isolated (van Kessel et al., 2015). These microorganisms are members of the genus *Nitrospira* and have a higher affinity for ammonia than all studied ammonia-oxidizing bacteria and archaea but a low affinity for nitrite. The COMAMMOX metabolism is highly efficient, producing a high biomass yield per mol of ammonia oxidized. These microorganisms are widespread in terrestrial and freshwater habitats, but their relative activity in inland waters in relation to other groups of nitrifiers is still unknown.

Table 2 Examples of the principal redox reactions associated with chemosynthesis and their Gibbs free energy yields ($\Delta G_0'$).

Processes	*Substrates*[a]		*Products*	*$\Delta G_0'$ (kJ mol substrate^{-1})*[b]
Aerobic				
Methane oxidation[c]	$CH_4 + 2O_2$	→	$CO_2 + 2H_2O$	−818
Hydrogen oxidation	$2H_2 + O_2$	→	$2H_2O$	−237
Ammonium oxidation	$2NH_4^+ + 3O_2$	→	$2NO_2^- + 4H^+ + 2H_2O$	−275
Nitrite oxidation	$2NO_2^- + O_2$	→	$2NO_3^-$	−76
Sulfur oxidation	$H_2S + 2O_2$	→	$SO_4^{2-} + 2H^+$	−796
Sulfur oxidation	$2HS^- + 2H^+ + O_2$	→	$2S^0 + 2H_2O$	−209
Sulfur oxidation	$S^0 + 2H_2O + O_2$	→	$SO_4^{2-} + 4H^+$	−587
Thiosulfate oxidation	$S_2O_3^{2-} + H_2O + 2O_2$	→	$2SO_4^{2-} + 2H^+$	−823
Iron oxidation[d]	$4Fe^{2+} + 4H^+ + O_2$	→	$4Fe^{3+} + 2H_2O$	−31
Iron oxidation[d]	$4FeS_2 + 14H_2O + 15O_2$	→	$4Fe(OH)_3 + 16H^+ + 8SO_4^{2-}$	−164
Anaerobic				
Sulfate reduction	$4H_2 + SO_4^{2-} + H^+$	→	$HS^- + 4H_2O$	−152
Sulfite reduction	$3H_2 + SO_3^{2-} + 2H^+$	→	$H_2S + 3H_2O$	−173
Sulfite reduction	$H_2 + S^0$	→	H_2S	−34
Thiosulfate reduction	$2H^+ + S_2O_3^-$	→	$SO_3^{2-} + HS^- + H^+$	−22
Hydrogenotrophic methanogenesis	$4H_2 + CO_2$	→	$CH_4 + 2H_2O$	−131
Methanogenesis	$H_2 + CH_3OH$	→	$CH_4 + H_2O$	−113
Methanogenesis	$4CO + 2H_2O$	→	$CH_4 + 3CO_2$	−210
Methane oxidation[c]	$CH_4 + SO_4^{2-} + H^-$	→	$CO_2 + HS^- + 2H_2O$	−21
Methane oxidation[c]	$CH_4 + 2NO_3^- + 4H^+$	→	$CO_2 + N_2 + 4H_2O$	−766
Methane oxidation[c]	$CH_4 + 4NO_2^- + 8H^+$	→	$CO_2 + 2N_2 + 6H_2O$	−928
Acetogenesis	$4H_2 + 2CO_2$	→	$CH_3COOH + 2H_2O$	−95
Acetogenesis	$4CH_3OH + 2CO_2$	→	$3CH_3COOH + 2H_2O$	−93
Acetogenesis	$4H_2 + 2HCO_3^- + H^+$	→	$CH_3COO^- + 4H_2O$	−105
Ammonium oxidation (ANAMMOX)	$NH_4^+ + NO_2^-$	→	$N_2 + 2H_2O$	−238
Iron reduction	$H_2 + FeOOH + H^+$	→	$Fe^{2+} + 2H_2O$	−110
Manganese reduction	$2S^0 + 2H_2O + MnO_2$	→	$H_2S + SO_4^{2-} + 2H^+ + Mn^{2+}$	−297

The more negative $\Delta G_0'$, the greater the energy yield.

[a]The first substance is the electron donor and the last the electron acceptor.

[b]Standard Gibbs free energy ($\Delta G_0'$) in kJ mol substrate^{-1}, at pH 7 and 25 °C.

[c]The main carbon sources for all processes is CO_2. The main carbon sources for methane oxidizers are CH_4 or C-1 compounds.

[d]Calculations for Fe^{2+} at pH 2.

Modified from Thauer RK, Jungermann J, and Decker H (1977) Energy conservation in anaerobic chemotrophic bacteria. *Bacteriological Reviews* 41:100–180.

Nitrifiers fix CO_2 via the Calvin cycle but, to a minor extent, also via the phosphoenolpyruvate carboxylase pathway. Some nitrifiers use the reverse tricarboxylic acid cycle (TCA cycle), where CO_2 is eventually fixed into acetyl-CoA and pyruvate. By convention, the ammonium oxidizers are characterized by the prefix Nitroso- and the nitrite oxidizers by the prefix Nitro-, i.e., yielding strain names like *Nitrosomonas* and *Nitrobacter*, respectively. The two groups of gram-negative bacteria are not phylogenetically related. Some heterotrophic bacteria, fungi, and algae can also oxidize ammonium to nitrate in a process known as heterotrophic nitrification. This process depends on the oxidation of organic compounds and, distinct from chemosynthetic nitrification, is not related to energy generation. The relative importance of heterotrophic nitrification in inland waters has not yet been clarified (Ward, 2011).

Ammonium and nitrite oxidizers are slow-growing bacteria with doubling times that can vary from 7 to 10 h in the laboratory and up to weeks in natural environments depending on conditions (Andersson et al., 2006). Aerobic ammonium oxidation is regulated by oxygen and substrate availability, temperature, and pH. Under low oxygen tension, aerobic ammonium oxidizing bacteria can act mixotrophically using CO_2 and organic compounds as carbon sources and can also reduce nitrite (NO_2^-) to nitric oxide (NO) and nitrous oxide (N_2O). Ammonium oxidizers grow very well at low ammonium concentrations, and can survive ammonium starvation for up to a year. Under anoxic conditions, some ammonium and nitrite oxidizers can also denitrify.

Anaerobic ammonium oxidation (ANAMMOX) is utilized by members of the order Planctomycetales to oxidize ammonium using nitrite as the electron acceptor (Table 2). The bacteria that perform this process are very slow-growing organisms using different metabolic pathways compared to aerobic ammonium oxidizers, such as the use of nitrite as an electron acceptor for ammonium oxidation and as an electron donor for the reduction of carbon dioxide (Kuenen, 2008).

Sulfur reducers

Chemosynthetic sulfur-reducers transfer electrons to oxidized sulfur compounds, e.g., sulfate, in association with a respiratory type of energy conservation (Table 2). Sulfate reduction usually occurs via heterotrophic anaerobic respiration, i.e., oxidation of organic matter. However, sulfate-reducing bacteria are metabolically very versatile, and many can utilize H_2 as an electron donor to synthesize cell material from both acetate and CO_2 (mixotrophs) or only from CO_2 (chemolithoautotrophs). Some sulfate-reducing bacteria can use nitrate and nitrite as electron acceptors, even in the presence of sulfate. The end product of this reaction is ammonium and not N_2 as it is for denitrifiers. In the absence of sulfate or other inorganic electron acceptors, some sulfate reducers can grow by fermentation of several organic substrates (Li et al., 2018).

Sulfur oxidizers

Reduced sulfur compounds such as sulfide (H_2S), thiosulfate ($S_2O_3^{-2}$), tetrathionate ($S_4O_6^{-2}$), and elemental sulfur (S^0) are used as the electron donors by sulfur oxidizers (Table 2). Such organisms are capable of performing extensive chemosynthesis in inland waters having high concentrations of e.g., hydrogen sulfide, sulfide, and sulfur (Table 3). Reduced sulfur compounds are usually formed as a product of anaerobic heterotrophic respiration with sulfate, but some waters receive large inputs of sulfide via groundwater. Oxygen is the most common electron acceptor, but other potential electron acceptors such as nitrate have been proposed. Sulfur reducers and oxidizers can be active under extreme pH, temperature, and saline conditions. Phototrophic H_2S oxidizers use carbon dioxide as the electron acceptor, and evidence of light-dependent sulfide consumption across stratified environments suggests that this process should be pervasive rather than relying on the presence of other chemical oxidants (Hanson et al., 2013).

Iron and manganese oxidizers

In aquatic environments, iron and manganese are found both in oxidized (Fe^{3+} and Mn^{4+}) and reduced (Fe^{2+} and Mn^{2+}) forms depending on pH and O_2 concentrations (Table 2). Dissimilatory Fe^{3+} and Mn^{4+} reduction are processes by which microorganisms transfer electrons from the oxidized to the reduced form of the metal. Most Fe^{3+} reducers seem able to reduce Mn^{4+} as well. Fe^{2+} and Mn^{2+} are more soluble than Fe^{3+}. The oxidized forms (Mn^{4+} and Fe^{3+}) are highly insoluble at neutral pH but highly soluble at low pH. Recent studies indicate that sediment microorganisms may be able to access particle-associated Fe^{3+} in spite of its low solubility and that some freshwater environments have the potential for anaerobic oxidation of methane coupled to the reduction of iron and manganese mediated by particular groups of archaea and bacteria that play an important role in the regulation of methane fluxes (Bar-Or et al., 2017).

Methanogens

Methane-producing microorganisms belong to the Archaea domain and are called methanogens. Methanogens are strict anaerobes that can be found in a variety of environments across extreme pH, temperature, and salinity conditions. Methanogens are limited in their capacity to use different substrates, with acetate and CO_2/H_2 being the most common. The use of acetate is a heterotrophic process whereas hydrogenotrophic methanogens rely on H_2 as the electron donor and CO_2 as the carbon source and hence carry out a chemosynthetic process (Table 2). About half of the described species of methanogens are hydrogenotrophic. Methanogens are abundant in habitats with very low availability of oxygen, sulfate, nitrate, Fe^{3+}, and Mn^{4+}, i.e., competitive substrates. In the presence of these electron acceptors, methanogens are thermodynamically out-competed (Table 2) for reduced substrates, e.g., H_2 and acetate. Hydrogenotrophic methanogenesis contribution to total methane production varies from 0% to 100% in lake sediments, and temperature is one of its main regulating factors, as higher temperatures usually favor hydrogenotrophic methanogenesis (Conrad et al., 2007).

Methylotrophs

Methylotrophs are chemosynthetic microorganisms that can utilize C-1 organic molecules as their sole source of carbon and energy (Anthony, 1978). Methylotrophs are phylogenetically diverse, and they obligately require an available methylated compound (methylated amines, halogenated methanes, and methylated sulfur species). Many methylotrophs are capable of N_2 fixation and can use N_2 as a nitrogen source. Those methylotrophs capable of growth on methane are distinguished as methanotrophs. Methane is the main electron donor for methanotrophs, but other C-1 compounds like methanol, methylamine, or carbon monoxide, and formate can also be used. Limited amounts of CH_4 have been shown to be produced by bacteria by methylphosphonate degradation and demethylation of osmotica such as dimethylsulfoxide, methylamines, and methanol.

Methanotrophs

Methane oxidizers have been divided into two groups (Type I, II), depending on their internal cell structure and carbon assimilation pathway (Murrell, 2010). Type I assimilate C-1 carbon via the ribulose monophosphate cycle and are α-Proteobacteria, while Type II

Table 3 Examples of in situ chemosynthesis rates in various aquatic systems.

System	Primary Electron Donor[a]	Habitat[b]	Max S_2^-/NH_4^+/CH_4 (μM)[c]	Volumetric rate (mmol $m^{-3}day^{-1}$)	Areal rate (mmol m^{-2} day^{-1})	% of total C fixation	Area integration[a,d]	Notes[e]	Source

[a]ns denote not specified.

[b]w indicates water column and sed denotes sediment.

[c]nd denote no data.

[d]WL denotes that area integration was made on a whole lake basis taking the volumes of different water layer into account. 1 m^2 denotes that a 1 m^2 water column was used, and ox/an indicates that depth integration was made over the oxic/anoxic interface only.

[e]Chemos, MBP, HBP, SOC denote chemosynthesis, methanotrophic bacterial production, heterotrophic bacterial production, and sediment oxygen consumption, respectively.

Modified from Enrich-Prast A, Bastviken D and Crill PM (2009) Chemosynthesis. *Encyclopedia of Inland Waters*, pp. 211–225. Oxford Elsevier.

assimilate C-1 compounds via the serine pathway and are γ-Proteobacteria. Both types utilize the enzyme methane-monooxygenase (MMO) to oxidize methane to methanol. Methanotrophs are found in most environments with both methane and O_2. Methanotrophs generally are able to oxidize ammonium to nitrite, while some ammonium oxidizers can oxidize methane and incorporate some methane as cell material, but methanotrophs and ammonium oxidizers are taxonomically different (Strous and Jetten, 2004).

Anaerobic methane oxidation has been reported in sediments and the water column in inland waters (Deutzmann et al., 2014). This process appears to be mediated by microbial consortia as some isotopic studies suggested that methane is not directly utilized by sulfate- or nitrate-reducing bacteria. Methanogens may incorporate light CO_2 from methane oxidation into their cell material or may use some of the light CO_2 produced by the anaerobic oxidation to make the very highly depleted CH_4 (>−100‰) (Bastviken et al., 2003; Sanseverino et al., 2012), which is seen in some marine and freshwater sediments. The presence of multiple active pathways of anaerobic methane oxidizers is associated with the availability of different electron acceptors in reduced river beds, including nitrite, nitrate, sulfate, and ferric iron (Table 2). Nitrite and nitrate-dependent anaerobic oxidation of methane could be the most important in regulating methane emissions from sandy riverbeds (Shen et al., 2019). The diversity of pathways is greatest where methane concentration is highest, suggesting a link between the diversity of anaerobic methane oxidation pathways and methane availability.

Hydrogen oxidizers

Molecular hydrogen (H_2) is a powerful electron donor in cellular metabolism in both prokaryotes and eukaryotes. The capability of using H_2 is spread across many taxonomic groups of different and independent phylogenetic origins. Hydrogen oxidation occurs in restricted habitats and is catalyzed by hydrogenase enzymes. Aerobic hydrogen oxidizers, sulfate reducers, methanogens, acetogens, and cyanobacteria are some groups that metabolize H_2. The main biogenic source of H_2 is anaerobic metabolism and the fermentation of organic matter in sediments. However, the H_2 turnover time in sediments is estimated to be on the order of 2 min, and therefore, almost all H_2 that is produced in the sediment is rapidly consumed. H_2 concentrations in lake sediments vary from 1 to 150 nM. The main sedimentary H_2 consumers that have been studied are methanogens and sulfate-reducing bacteria, and both groups compete for H_2. Sulfate reducers out-compete the methanogens in the presence of sulfate because they have a higher affinity for H_2 and there is a higher thermodynamic yield for the reaction and thus a higher growth yield (Table 2). The occurrence of one or the other process seemingly depends on sulfate availability which is often low in most inland waters but not in coastal environments. The importance of and competition for H_2 in anoxic microbial metabolism is illustrated by the development of consortia of fermenters and H_2 oxidizers. Such consortia facilitate "interspecies hydrogen transfer," a process whereby H_2 that is produced by the fermenter is rapidly transported to the H_2 consumer. This favors the H_2 consumer and keeps H_2 concentrations low, which increases the energy yield of the fermentation.

As demonstrated in the field and laboratory-based investigations, soil bacteria consume molecular hydrogen (H_2) from the Earth's atmosphere and serve as the main sink in the global biogeochemical H_2 cycle. Hydrogenases catalyze the conversion of H_2 to protons and electrons. Recent genomic and metagenomic studies have identified other bacteria within the phyla Acidobacteria, Proteobacteria, Planctomycetes, Chloroflexi, and Verrucomicrobia. Recent evidence shows acidobacteria are active and abundant members of diverse atmospheric H_2-oxidizing communities detected in temperate soils (Giguere et al., 2021).

Acetogens

Acetogens are organisms that utilize the acetyl-CoA pathway for the synthesis of acetate as cell carbon from CO_2. Homoacetogen is a more specific term and is often used to describe organisms that only produce acetate. However, most acetogens that use the acetyl-CoA pathway often form products other than acetate, such as butyrate, succinate and ethanol. Acetogens are anaerobes, but they can tolerate small amounts of O_2. Acetogens can grow chemoautotrophically on H_2, but also heterotrophically depending on environmental conditions (Table 2). Because CO_2 is the most common terminal electron acceptor for acetogens, CO_2 availability may regulate their growth and determine what substrate will be metabolized. However, other electron acceptors can also be used, allowing these microbes to adapt to a wide range of redox conditions and optimize their growth efficiency. Their competitive ability for H_2 increases when alternate electron acceptors, e.g., nitrate, are used.

Spatial and temporal distribution of chemosynthesis in aquatic environments

Chemosynthesis depends on the presence of both reduced and oxidized compounds to be used as electron donors and acceptors, respectively. At oxic-anoxic interfaces, the simultaneous access to reduced and oxidized substrates, e.g., S^{2-}, NH_4^+, or CH_4, and O_2, creates thermodynamic gradients that can support chemosynthesis (Schlegel and Jannasch, 2006; Stahl et al., 2006). However, electron acceptors other than O_2, such as NO_3^-, SO_4^{2-}, Fe^{3+}, can also be used, and thereby, other interfaces, e.g., the sulfide-nitrate interface, may also be important (Figs. 2 and 3). In general terms, chemosynthesis is expected to be most extensive at sites with steep redox gradients like sediments (Stahl et al., 2006; Santoro et al., 2021) and stratified water columns (Schlegel and Jannasch, 2006; Stahl et al., 2006; Casamayor et al., 2008) and can also exist over small scales within microbial mats, biofilms, and crumbs of organic matter in more oxic environments (Fig. 2). In stratified lakes, a more significant contribution of carbon production through chemosynthesis would come from chemoclines. They have steep redox gradients where the energy yield of redox reactions must

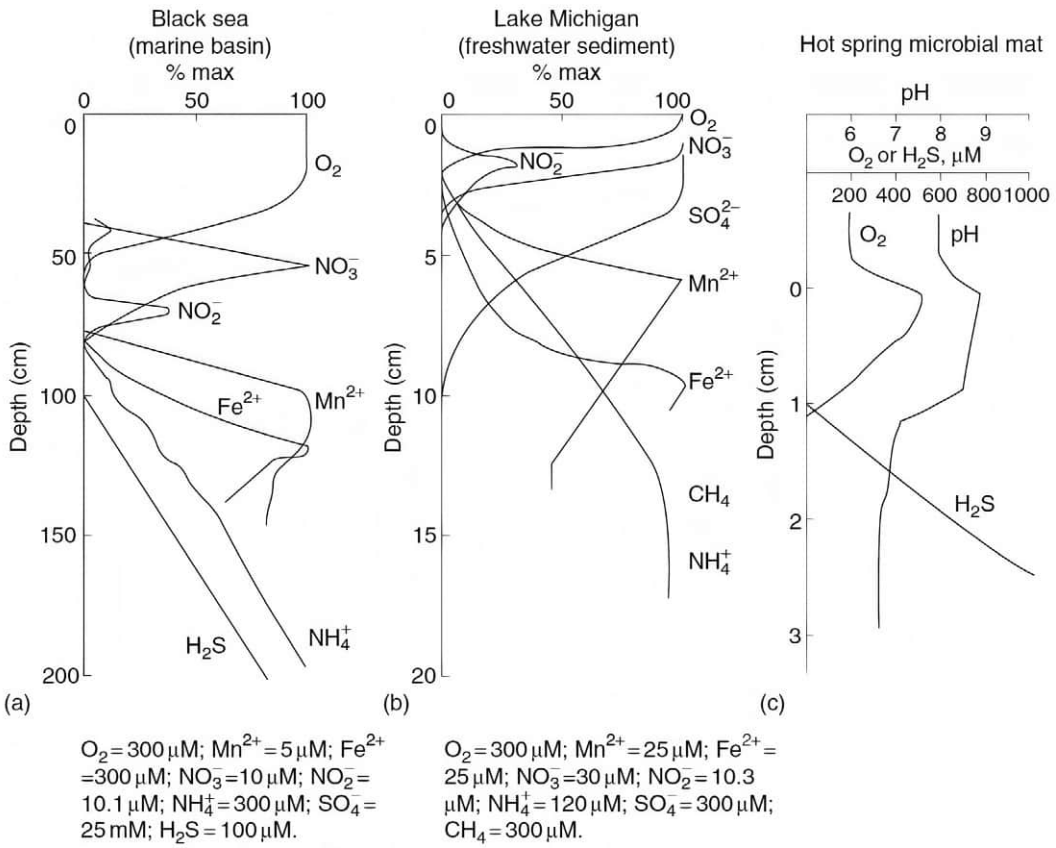

Fig. 2 Distribution of oxidized and reduced compounds related with chemosynthesis at: (A) the water column from the Black Sea; (B) the sediment from Lake Michigan and (C) a hot spring microbial mat. The scales vary from hundreds of meters in the water column, to centimeters and millimeters at the sediment and microbial mat respectively. Note the different scales at the y-axis. Reproduced from Stahl DA, Hullar M and Davidson S (2006) Prokaryotes and their habitats. In: Dworkin M, Falkow S, Rosenberg E, Schleifer K-H and Stackebrandt E (eds.) *The Prokaryotes*. Fig. 3 Idealized vertical profiles in a temperate lake during summer stratification according. Note that this illustration is conceptual only and that absolute concentrations, rates, or biomasses are not given. Profiles: (1) CO_2 fixation in the light (oxygenic photosynthesis); (2) dark CO_2 fixation; (3) CO_2 fixation in the light (anoxygenic photosynthesis); (4 and 5) sulfate reduction; (6) biomass of algae and cyanobacteria; (7) total bacterial biomass; (8) biomass of phototrophic bacteria; (9) biomass of protozoa and (10) biomass of Copepoda and Cladocera. Chemosynthesis is directly related with profiles 2, 4, 5, 6 and 7 and indirectly with profiles 9 and 10 as microbial biomass formed via chemosynthesis is consumed by predators. From Schlegel HG and Jannasch HW (2006) Prokaryotes and their habitats. In: Dworkin M, Falkow S, Rosenberg E, Schleifer K-H and Stackebrandt E (eds.) *The Prokaryotes*. (3rd edn.), vol. 1, pp. 137–184. New York: Springer.

support effective CO_2 uptake rates. Inland waters with seepage of reduced compounds of geochemical origin can also be important for chemosynthesis. Examples include hot springs and lakes fed by sulfide-rich groundwater (Yang et al., 2011).

Chemosynthesis seems to be a quantitatively important carbon fixation pathway in shaded ecosystems. Caves are a very appropriate environment for chemosynthesis. For instance, the Movile Cave in Romania is flooded by thermomineral groundwater that is completely anoxic with high amounts of CH_4 and H_2S. Microbial mats can be seen on the water surface, and the cave ecosystem is supported exclusively by chemoautotrophic production of methane- and sulfur-oxidizing bacteria. Some studies reported that the Frasassi caves in Italy and both the Lower Kane Cave and Cesspool Cave in the USA are also important sulfidic ecosystems sustained via chemosynthesis (Kumaresan et al., 2014).

Direct studies of in situ chemosynthesis in inland waters (usually measured as dark fixation of $H^{14}CO_3$) have mostly addressed oxic-anoxic interfaces in sulfide-rich water columns (Table 3). These studies confirm a highly stratified distribution of the chemosynthesis with the highest rates of radiocarbon incorporation at the oxic-anoxic interface. Some cases also suggest considerable chemosynthetic activity in the anoxic water below the interface (Figs. 3 and 4). The most likely explanation for anoxic chemosynthesis is that electron acceptors other than O_2 are being used deeper in the anaerobic water column or are being supplied by high temperature water-rock interactions. The stratified location of the associated redox processes implies that chemosynthesis is generally most extensive in narrow zones at redox interfaces under field conditions (Fig. 4).

Due to the limited number of systems in which chemosynthetic carbon fixation has been measured, the spatial distribution of chemosynthesis among different types of inland waters is poorly known at present. Very high rates of chemosynthesis have been measured in saline sulfide-rich water columns (Table 3), but comparable methods to estimate chemosynthesis have so far rarely been reported from sulfide-poor water columns, where chemosynthesis associated with other redox reactions could dominate. Increasing ammonium oxidation associated chemosynthesis with decreasing salinity along the Scheldt estuary (see Table 3) indicates that sulfide and ammonium may be important electron donors for chemosynthesis in different environments. It has also been proposed that sulfide oxidizers could thermodynamically out-compete ammonium oxidizers in sulfide-rich environments. Substantial chemosynthesis associated with electron donors other than sulfide is possible.

In some aquatic systems, chemosynthetic processes appear to account for a major share of the total carbon fixation and may exceed 90% of the total carbon fixation under certain conditions (Table 3), contributing significantly to primary productivity and as a relevant energy source for aquatic food webs. The highest rates have been reported for saline sulfide-rich environments, such as mono- or meromictic lakes with haloclines from temperate and boreal regions. Lakes fed by sulfide-rich groundwater also have high rates of chemosynthesis. In contrast, other aquatic ecosystems such as estuaries, lagoons and rivers that often lack chemoclines usually have relatively lower rates of chemosynthesis, although the relative contribution of chemosynthesis in these systems may

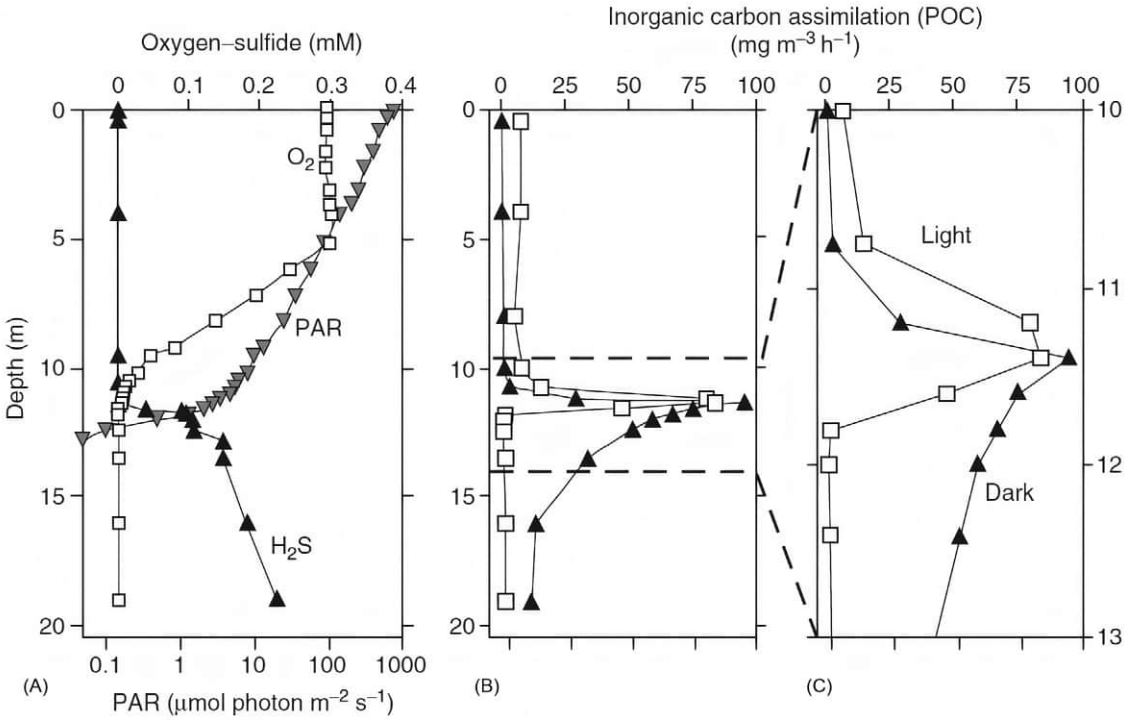

Fig. 4 Concentrations of H_2S and O_2, and PAR (A), and light versus dark CO_2 fixation (B) in Lake Cadagno, Switzerland, September 13, 1999, at noon. (B_1) represent detailed rates from B between 10 and 13 m. Reproduced from Camacho A, Erez J, Chicote A, Florín M, Squires MM, Lehmann C and Backofen R (2001) Microbial microstratification, inorganic carbon photoassimilation and dark carbon fixation at the chemocline of the meromictic Lake Cadagno (Switzerland) and its relevance to the food web. *Aquatic Sciences* 63: 91–106.

vary spatially and can be important when compared to other microbial processes like heterotrophic bacterial production and oxygen consumption (Table 3). However, the identification of carbon fixation in the dark in extremely heterogeneous environments and in close relation to the hydrological cycle remains a challenge due to the small spatial and time scale intensification of biogeochemical processes, also referred to as hotspots and hot moments. More efforts are needed to improve our understanding of the extent to which chemosynthesis contributes to total CO_2 fixation in inland waters and sediments.

Sediment-water interfaces of aquatic environments offer sites of rapid organic matter deposition and degradation. In many cases, organic matter inputs are faster than the oxygen diffusion into the sediment, and microbial activity may deplete oxygen in the superior millimeters, creating a steep thermodynamic chemical gradient with high chemoautotrophic potential. In Subglacial Lake Whillans in Antarctica, dark carbon fixation is at least three times higher in the sediment than in the water column due to a diverse microbial community consisting of bacteria and archaea that are close relatives of species known to use reduced compounds of N, S, or Fe, and CH_4 as energy sources (Mikucki et al., 2016). Some chemosynthetic processes can reach rates up to three orders of magnitude higher in the sediment (dominated by diffusional processes) than in the water column (dominated by advective processes), favored by a combination of different factors that influence the formation of microhabitats and consequently the reduction or oxidation of chemical elements. An extensive microbial metabolism in the anaerobic sediment below the top centimeter indicate that the anaerobic chemoautotrophic processes below the oxic surface layer may be relevant for the overall sediment processes of tropical lacustrine systems (Santoro et al., 2021). Dark carbon fixation may be greater in the sediment than in the water column at volumetric rates; however, rates per area should be used for standardized comparison between habitats.

Although symbiosis is well known and much more investigated in marine ecosystems, chemosynthesis can occur inside macrofauna in inland waters. Peat mosses (*Sphagnum* sp.) can have methane oxidizers in their tissue which seems to be associated to water table level (Putkinen et al., 2012). Mussels of the genus *Congeria* from Late Miocene of Lake Pannon, an ancient lake in eastern and central Europe had large, heavy shells that likely formed with chemosymbiosis and suggest a long-life span that contrasts with the extant genus *Mytilopsis*, which tends to form temporary boom-and-bust populations during cyclic shifts in the epilimnion/hypolimnion when carbon uptake is favored by chemosynthesis production (Harzhauser and Mandic, 2004). Anchialine caves in the Yucatan peninsula characterized by steep chemocline showed evidence of *Typhlatya* shrimp harboring endosymbiotic mutualistic bacteria and taking advantage of chemosynthesis to survive under extreme conditions (Pakes et al., 2014).

The temporal distribution of chemosynthesis is related to the development of redox gradients. Water column studies indicate chemosynthesis is most extensive during stratification, which usually depends on seasonality. The turbulence of advective processes is reduced, and slower diffusional processes allow the development of the necessary thermodynamic/redox gradients. In sediments overlain with oxic water, redox gradients are likely to be permanently present, although the oxygen penetration and consequently the depth of the redox interfaces may vary over time due to hydrodynamics combined with other environmental conditions, e.g., turbulent mixing, insolation, and wind. Dark carbon fixation may be greater during winter stratification than in summer, when ice cover promotes more stable conditions that favor steeper redox gradients and low light decrease competition with photosynthetic microorganisms for dissolved components (Table 3).

Implications of chemosynthesis in aquatic ecosystems

Chemosynthesis and carbon cycling

The highly stratified distribution of free-living chemosynthetic microorganisms implies that intensive rates of chemosynthesis can be spatially restricted. In some systems, chemosynthetic processes appear to account for a major share of the total carbon fixation and may exceed 90% of the total carbon fixation under certain conditions (Table 3). The highest rates have been reported for saline, sulfide-rich environments, such as mono- or meromictic lakes with haloclines. Lakes fed by sulfide-rich groundwater also have high rates of chemosynthesis. Saline inland waters with haloclines may dominate globally in terms of water volume, especially if the Caspian Sea, Lake Baikal, the African rift lakes, and large estuaries such as the Baltic Sea are included in the accounting. However, inland waters without haloclines and with moderate to low concentrations of sulfide are more abundant by numbers. The limited data from such non-saline inland waters makes it unclear to what extent chemosynthesis contributes to the total CO_2 fixation.

The contribution of chemosynthesis to overall carbon fixation in aquatic ecosystems is limited by the availability of electron donor substrates, e.g., sulfide, ammonium, etc. In most inland waters, the electron donors that are the energy source for chemosynthesis typically originate from the degradation of organic matter. Organic matter is typically produced by photosynthesis, either in the aquatic system itself or in the terrestrial surroundings transported to the aquatic environment. Hence, from an energetic point of view, most chemosynthesis in inland waters is indirectly driven by sunlight energy, given the dependence of chemosynthesis on photosynthesis supplying organic material (Fig. 5). An exception would be systems with an extensive supply of electron donors from hydrothermal or geochemical external sources (Yang et al., 2011). Therefore, chemosynthesis should only be able to dominate carbon fixation relative to aquatic photosynthesis in (1) systems receiving substantial input of organic matter from the surroundings, or (2) systems with large inputs of reduced substrate compounds directly suitable as electron donors, e.g., waters receiving reduced compounds of geochemical origin such as hot springs or some saline sulfide-rich lakes.

In addition to chemosynthesis, heterotrophic inorganic carbon uptake has been reported for a wide range of organisms from prokaryotes and fungi to vertebrates, compensating for dependence on organic matter (Braun et al., 2021). More than 20 carboxylases are known to form an integral part of the central and peripheral metabolic pathways of heterotrophic metabolism, e.g., in gluconeogenesis, the synthesis of fatty acids, amino acids, vitamins, nucleotides, the assimilation of leucine, and anaplerosis.

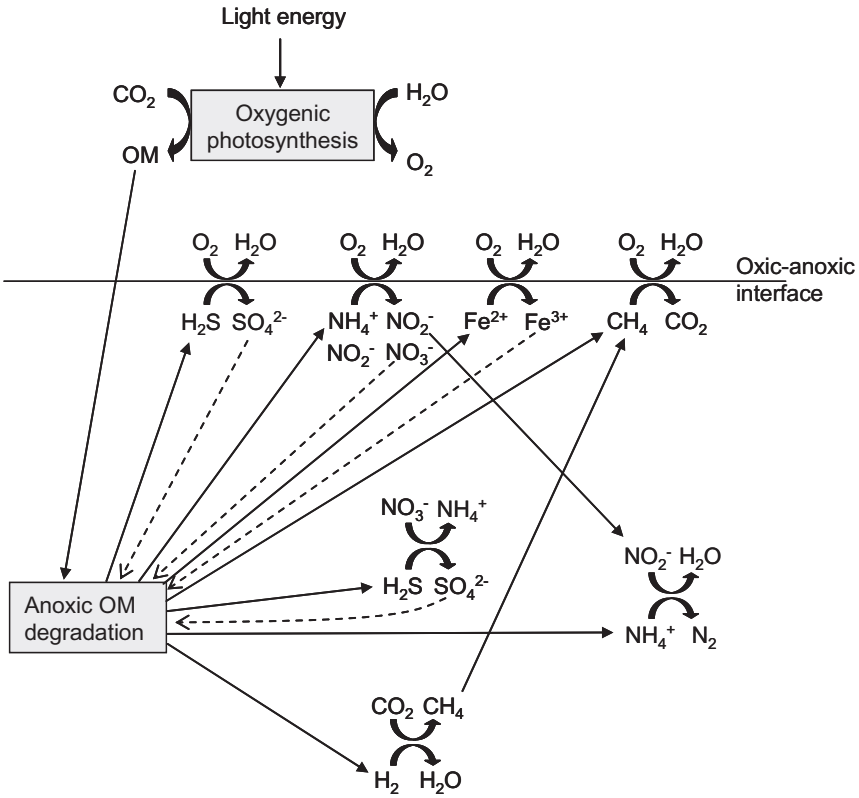

Fig. 5 Illustration of the connections between some redox processes associated with chemosynthesis and anoxic organic matter (OM) degradation. Solid arrows indicate contribution of reduced compounds produced by anoxic OM degradation processes. These reduced compounds function as electron donors in the redox processes associated with chemosynthesis. The contribution of OM (functioning as electron donor in anoxic OM degradation) from oxygenic photosynthesis is also indicated. Note that OM can be both produced in the aquatic system (aquatic photosynthesis) and transported from the terrestrial surroundings (i.e., depend on terrestrial photosynthesis). Dashed arrows indicate re-supply of oxidized compounds that can function as electron acceptors in anoxic OM degradation. From Enrich-Prast A, Bastviken D and Crill PM (2009) Chemosynthesis. *Encyclopedia of Inland Waters*, pp. 211–225. Oxford Elsevier.

The most important CO_2 fixation pathway in all organisms is anaplerosis, which replaces endogenous components of the tricarboxylic acid (TCA) cycle with either inter- or extra-cellular exogenous products. Although dark carbon incorporation appears to function at low levels in heterotrophic bacteria, it has been suggested that the carboxylase activity increases in situations of organic matter deficiency and slow growth (Moran and Miller, 2007). Then, these processes may significantly contribute to the total dark carbon fixation.

Chemosynthesis and climate

Globally, it is now clear that climate changes can be caused by changes in atmospheric content of radiatively important gasses including CO_2, CH_4, and N_2O in the atmosphere. Chemosynthetic processes are directly related to the natural production and consumption of these gasses. Inland waters can be simultaneously both carbon sinks for organic matter accumulating in sediments and major sources of climate forcing gasses such as CO_2 and CH_4. Chemosynthetic processes are involved in both production and consumption of CH_4 and nitrous oxide. Wetlands and lakes together contribute more than 75% of the natural CH_4 emissions to the atmosphere (Tranvik et al., 2009; Saunois et al., 2020). However, these CH_4 emissions would be much higher without CH_4 oxidation since freshwater aquatic CH_4 oxidation may consume >50% of the produced CH_4 (probably much higher in marine systems) and thereby substantially limit emissions (Sawakuchi et al., 2021). While the N_2O emission from inland waters to the atmosphere is relatively low, N_2O emission rates per surface area are substantially higher in reservoirs than in rivers. Short events of massive N_2O emissions have been reported in tropical floodplains suggesting that N_2O emissions from inland waters may be spatially and temporally localized and could be overlooked.

Chemosynthesis and food webs

Chemosynthesis can contribute carbon to food webs both through endosymbiosis (see above) and by direct or indirect predation on chemosynthetic microorganisms. Stable isotope studies confirm that carbon fixed by chemosynthesis enters food webs, although the magnitude and importance of this contribution are still unknown (Fig. 6). Chemosynthetic biomass is generally depleted in ^{13}C

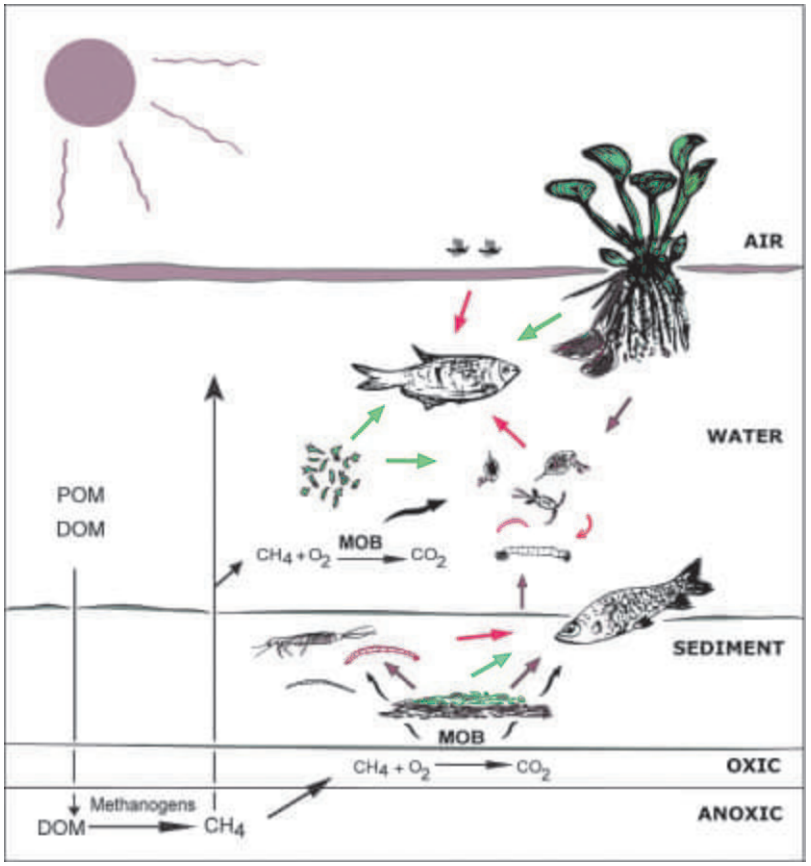

Fig. 6 Schematic illustration of the incorporation of carbon of aerobic methane oxidizing bacteria (MOB) into the food web of a tropical shallow lake. Particulate and dissolved organic matter (POM and DOM, respectively) of autochthonous and allochthonous origin support anaerobic methane (CH4) formation. CH_4 is oxidized by MOB and CH_4-derived carbon is transferred to higher trophic levels subsidizing pelagic and benthic organisms, reaching the fish level. Arrows with different colors indicate potential food sources: black- MOB; green-herbivory on phytoplankton and/or plant material; blue- herbivory on bottom filamentous algae; red-carnivory on aquatic and/or terrestrial organisms; brown detritivory. Reproduced from Sanseverino AM, Bastviken D, Sundh I, Pickova J and Enrich-Prast A (2012) Methane carbon supports aquatic food webs to the fish level. *PLoS One* e42723. doi: 10.1371/journal.pone.0042723.

relative to terrestrial organic carbon in inland waters, while ^{34}S signatures can be used to trace the contribution of sulfide-dependent chemosynthesis. Several studies in freshwater ecosystems have reported ^{13}C depleted values from tissues of organisms and have also suggested that oxidizing bacteria would be an important food source for different trophic levels.

The use of carbon isotopes to identify different organic matter sources and to elucidate carbon flow in food webs has shown that non-symbiotic metazoans also assimilate CH_4 carbon. The transfer of carbon and energy from CH_4 to higher food web levels was confirmed by the presence of fatty acids diagnostic for methane-oxidizing bacteria (MOB) in animal tissues. The first evidence came from ^{13}C content of zooplankton that is frequently found to be ^{13}C-depleted compared to seston particles in size range of their prey (Bastviken et al., 2003). In general, $\delta^{13}C$ signatures in methane in surface and bottom water of lakes are relatively ^{13}C-depleted compared to organic matter sources indicating a significant contribution of methanogens to the flow of energy and carbon to zooplankton, insects, and fish. In addition, the presence of MOB-fatty acids was first detected in tissues of larval chironomids, aquatic insects abundant in many freshwater environments, and then found in fish tissues (Sanseverino et al., 2012). These findings demonstrated that CH_4 could be a significant carbon source not only for the microbial food web and primary consumers but also for higher trophic levels (Fig. 6). Another example of the importance of chemoautotrophic production is associated with sulfidic waters in caves and karst aquifers. Examples included the Lower Kane Cave and Cesspool Cave (United States), Movile Cave (Romania) and Frasassi cave system (Italy) which all supports diverse terrestrial and aquatic invertebrate communities and can be considered subterranean biodiversity hotspots (Kumaresan et al., 2014).

Chemosynthesis and element cycling

Redox-driven biogeochemical element cycling plays a key role in organic matter cycling in aquatic ecosystems. As already mentioned in this chapter, redox processes associated with chemosynthesis are crucial for the biogeochemical cycling of many

common elements. For example, nitrogen cycling depends upon nitrification (ammonium oxidation to nitrite, primarily a chemoautotrophic process) and chemosynthesis is therefore vital for remineralization of nitrogen, and indirectly for denitrification. Another example is anaerobic CH_4 and ammonium oxidation which have been estimated to account for more than 75% and 30–50% of all marine CH_4 oxidation and ammonium oxidation (Strous and Jetten, 2004). The overall importance of these processes in inland water ecosystems is still unknown, but the number of lakes and rivers where these processes have been measured is increasing. There are many other examples where chemosynthetic processes are critical in biogeochemistry, including the cycling of sulfur, iron, and manganese (Table 2). From a general element cycling point of view, chemoautotrophic microorganisms function as catalysts for a large number of redox reactions, greatly increasing reaction rates.

Knowledge needs

Even after more than a decade from the publication of the first version of this chapter, it is remarkable how few new studies related to chemosynthesis in inland waters have been published. New methodologies in Molecular Biology have emerged that have been revelatory of the detail and metabolic complexity of the microbial communities that fix and cycle the biological processes important to planetary climate processes. It is exciting that more holistic studies combining microbial community structure with in situ-simulated rates obtained from the traditional dark ^{14}C fixation and other isotopic and biogeochemical methods are beginning to appear. The determination of specific chemosynthetic pathways through genetics, genomics, and multiple isotopic observations and experiments will enhance our knowledge of biogeochemical processes related to chemosynthesis in aquatic ecosystems. Scientists need to combine all information related to in situ rates of the chemosynthetic process(es) involved and the main actors in chemosynthetic primary production to have a complete understanding of ecosystems.

From the ecological perspective, more studies on chemosynthesis in inland waters are still needed, both in the water column and in sediments comprising spatial (geographically and vertically) and temporal dynamics. More detailed measurements with new technologies in non-saline waters, in sediments, and in common microenvironments such as biofilms will be very valuable. A focus on non-sulfide-dependent chemosynthesis would also supplement current data greatly, e.g., redox processes associated with iron or manganese could potentially be important in many soft water ecosystems and even for the management of water quality. It would also be interesting to further investigate the anaerobic (non-O_2 dependent) chemosynthesis shown to be extensive in some anoxic hypolimnia where it is unclear which electron acceptors are used (Fig. 3). Important processes are likely ignored because of the limited number of systematic studies in many common types of inland waters. The importance of chemosynthesis as a source of organic matter to macrofauna, with or without endosymbiosis, is another important area of study to understand food webs. Chemical redox interfaces induce high microbial activity, and high biomass, representing hot spots of microbial food web interactions. In addition, chemosynthesis could be very important for specific species having certain feeding strategies or depending on endosymbiotic microorganisms. An apparent extension of the studies examining the carbon transfer from chemosynthetic organisms to higher trophic levels would help to quantify the magnitude of this contribution.

Finally, it should be noted that chemosynthetic microorganisms provide important ecosystem services, such as providing and cycling carbon to shaded systems, mitigating climate forcing trace gas emissions to the atmosphere, and removing environmental pollutants. The fact that their function is ultimately linked to biogeochemical elemental cycles suggests that they can influence, and be strongly influenced by, climate and land-use changes. Floods and droughts exacerbate hydrological fluctuations in water balance and alter the linkages between surface and groundwater. Intensification of the hydrological cycle is likely to alter redox gradients in space and time. We also need to understand the importance of dark carbon fixation in the hydrological cycle and pursue new links between microscale processes to more fully understand the large-scale cycling of biogeochemical elements in aquatic systems.

Methane[☆]

David Bastviken, Department of Thematic Studies—Environmental Change, Linköping University, Linköping, Sweden

This is an update of D. Bastviken, Methane, in Encyclopedia of Inland Waters, edited by Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00117-4.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Lars Rudstam.

Glossary

Emission Flux in a specified direction given by the context—often from an environment or source to the atmosphere.
Flux Transport of a compound without specification of the transport direction.
Greenhouse gas Gasses that absorb infrared light in the atmosphere, thereby delaying the heat transport through the atmosphere towards space, resulting in warming of the atmosphere.
Methane (CH_4) The most reduced organic compound. Formed in e.g., anaerobic microbial metabolism upon degradation of organic matter. An effective energy carrier for food webs and society and represents a powerful greenhouse gas.
Methane oxidation Processes resulting in transformation of methane into carbon dioxide and water.
Methanogenesis The microbial processes resulting in methane formation.

Introduction

Methane (CH_4) is a major product of organic matter decomposition in freshwater environments. CH_4 is both produced and consumed in aquatic environments. This results in local within-system carbon cycling providing a link between anoxic and oxic processes or habitats. CH_4 produced in anoxic sediments can represent an overlooked carbon source for aquatic food webs in oxic habitats. Recently, it has been shown that oxic methane production in surface waters can occur with amounts and implications being discussed. The local consumption of CH_4 is not complete and CH_4 emissions from inland waters represent a substantial greenhouse gas contribution to the atmosphere. The aim of this chapter is to review various aspects of CH_4 cycling in inland waters, including:

1. the fundamentals of CH_4 formation and oxidation in aquatic environments,
2. the contribution of CH_4 dynamics to overall carbon cycling in aquatic systems,
3. the potential contribution of CH_4 carbon to aquatic food webs,
4. the role of CH_4 emissions in linking aquatic carbon cycling and global atmospheric chemistry and climate regulation.

[☆]*Change History*: November 2021. D Bastviken updated all sections.

CH_4 is an odorless organic trace gas melting at −182.5 °C and boiling at −161.5 °C (Haynes, 2016). It is combustible at concentrations of 5–15% in air and it represents the major component of natural gas, biogas and marsh gas (Liao et al., 2005). CH_4 has a Henry's law constant of 1.29×10^{-3} M atm^{-1} (1.27×10^{-5} mol m^{-3} Pa^{-1}) at 25 °C, expressing a low water solubility (Wiesenburg and Guinasso, 1979). CH_4 absorbs infrared radiation with strong adsorption bands between 1 and 13 μm. The greenhouse warming potential, a function of atmospheric residence time and radiative properties, is approximately 28–32 times greater than for carbon dioxide (CO_2) on a molecular basis over a 100 year timescale (Myhre et al., 2013). The atmospheric mixing ratio of methane has more than doubled over the past 250 years and has increased from 1.5 to near 1.9 ppmv between 1977 and 2018 (Saunois et al., 2020). It has been estimated that CH_4 accounts for approximately 20% of the increase in the greenhouse gas effect observed since the mid-1700s.

CH_4 is constantly being degraded in the atmosphere by photo-oxidative and hydroxyl radical associated processes (Saunois et al., 2020). The estimated lifetime of CH_4 in the atmosphere is 8–12 years. Hence, steady-state or increasing atmospheric concentrations require large continuous emissions from various sources.

CH_4 formation

Biochemical and microbiological aspects of methanogenesis

The CH_4 in the atmosphere is primarily of biogenic origin as determined by its ^{14}C age (Saunois et al., 2020). Most biological production of CH_4, methanogenesis, is anaerobic and performed by methanogenic archaea. They share some characteristics including high intracellular concentrations of co-enzyme F_{420} (resulting in autofluorescence after stimulation under a fluorescence microscope), the presence of the enzyme methyl co-enzyme M methylreductase and the presence of unique phospholipid membrane components (Garcia et al., 2000).

The anaerobic methanogenesis (AMG) relies on a limited number of low molecular weight substrates (Garcia et al., 2000; Segers, 1998). The two principal pathways are acetotrophic (acetate dependent) and hydrogenotrophic (H_2 dependent) methanogenesis, respectively. In the former case, acetate (CH_3CO_2H), is cleaved into CH_4 and carbon dioxide (CO_2). During hydrogenotrophic methanogenesis, H_2 reacts with CO_2 forming CH_4 and H_2O. Other low molecular weight organic molecules, such as formate, methanol, dimethyl sulfide (DMS), tri-, di- and monomethylamines and ethylamine can also be used for methanogenesis, but acetate or H_2 and CO_2 are believed to be the quantitatively most important substrates. Thereby AMG represents a terminal step of anoxic organic matter degradation (Table 1). Before the terminal anoxic degradation can occur, complex organic substrates have to undergo several degradation steps (Fig. 1). Complex organic matter is fermented to intermediate fermentation products including acetate, H_2 and CO_2, which can then be utilized in methanogenesis. Typically this requires the activity of several different bacterial groups, which organize in syntrophic consortia facilitating the transfer of the reaction products between cells. In the presence of oxidized compounds that can function as electron acceptors, e.g., nitrate (NO_3^-), manganese (IV) (Mn^{4+}), iron (III) (Fe^{3+}) and sulfate (SO_4^{2-}), terminal degradation steps like denitrification, iron reduction, manganese reduction and sulfate reduction may yield more energy than methanogenesis (Table 1). Hence, because microorganisms capable of utilizing alternative terminal electron acceptors often have a superior energy gain, and sometimes also more efficient substrate uptake systems (greater substrate affinity), they are likely to outcompete methanogenic archaea. Thereby, the presence of alternate electron acceptors inhibits AMG (Table 2).

Recently, oxic methane production (OMP) in lake water has been highlighted (e.g., Hartmann et al., 2020). Mechanisms are not yet clear but OMP have been associated with cyanobacteria and photosynthesis and methylphosphonates and trimethylamine have been discussed as precursors. AMG in anaerobic micro-niches in oxic waters have also been suggested. There is an ongoing discussion on the extent, regulation, and implications of OMP in various inland waters (e.g., DelSontro et al., 2018; Günthel et al., 2019; Peeters et al., 2019).

Table 1 Examples of redox reactions used in the microbial degradation of organic matter.[a]

Process	*Substrates*		*Final products*		$-\Delta G^\circ$ *kJ/mol* e^- *(pH = 7)*
	e^- *donor*	e^- *acceptor*			
Aerobic respiration	OM	O_2	CO_2	H_2O	125
Denitrification	OM	NO_3^-	CO_2	N_2	112
Manganese reduction	OM	Mn(IV)	CO_2	Mn(III), Mn(II)	95
Iron reduction	OM	Fe(III)	CO_2	Fe(II)	24
Fermentation	OM	OM	CO_2	LMWOM, H_2	5–60
Sulfate reduction	LMWOM	SO_4^{2-}	CO_2	S^{2-}	18
Methanogenesis	LMWOM, H_2	LMWOM, CO_2	CO_2	CH_4	14–28

[a]The general principle of these metabolic processes is that organisms gain energy by transferring electrons from an electron (e^-) donor to an e^- acceptor. The e^- donor has to be more reduced than the e^- acceptor to allow energy gain. The difference in degree of reduction or oxidation between the e^- donor and acceptor is roughly proportional to the energy gain. $-\Delta G^\circ$ indicates the energy yielded from the listed processes. Values of $-\Delta G^\circ$ are related to specific reactions in Zehnder and Stumm (1988) and should only be used for comparison between the different processes in the table. OM and LMWOM denote organic matter and low molecular weight organic matter (i.e., fermentation products), respectively.

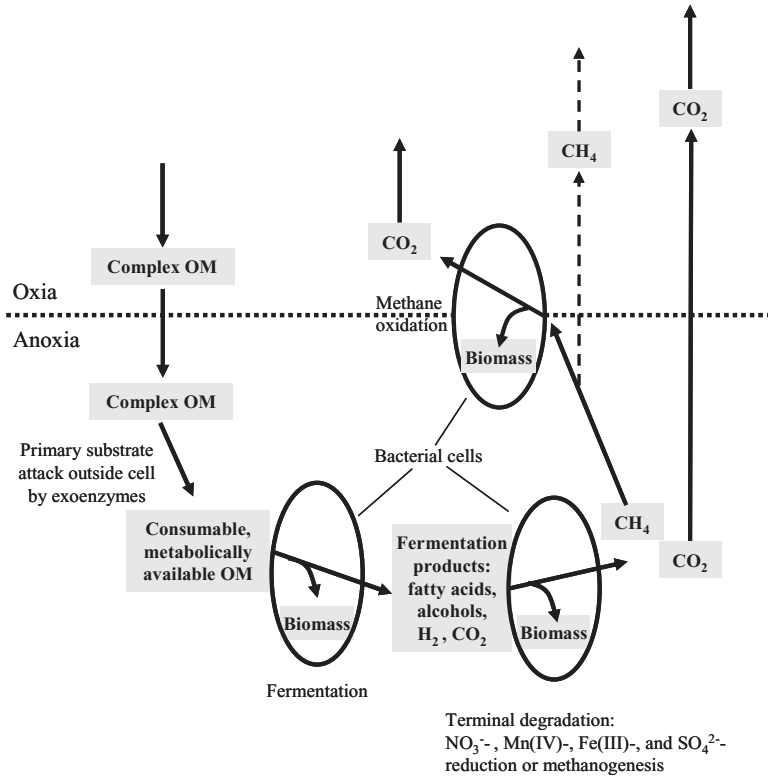

Fig. 1 Simplified illustration of anoxic degradation of organic matter and of CH_4 oxidation in an aquatic sediment. Complex polymeric organic matter (OM) reaching the sediment is subjected to hydrolysis and fermentation to low molecular weight intermediary products. Production of CH_4 is one of several alternative terminal anoxic degradation processes. CH_4 oxidation, primarily occurring at the oxic-anoxic interface, results in the formation of CO_2 and biomass from CH_4. Some CH_4 may escape oxidation and leave the system leading to emissions. See text for details.

Table 2 Effects of some environmental factors on CH_4 production rates in aquatic systems.[a]

Environmental factor	*Effect on CH_4 production (±)*	*Notes*	*Sources*[b]
O_2	–		1, 6
Alternative electron acceptors (NO_3^-, Fe^{3+}, Mn^{4+}, SO_4^{2-})	–		2, 6, 7

Environmental factors affecting anaerobic methanogenesis

The effects of various environmental factors on AMG are summarized in Table 2 (factors affecting OMP remain to be established). It is now established that many methanogenic archaea can tolerate substantial O_2 exposure even though O_2 inhibits AMG. Likewise, the inhibition by sulfate is not strict, but primarily results from substrate competition. The temperature optimum of AMG is usually well above in situ temperatures, and the potential CH_4 production rates increase about fourfold if the temperature increases by 10 °C (Table 2). Therefore, AMG has a substantially higher temperature sensitivity than photosynthesis or overall organic matter respiration. pH within the natural variation found in aquatic habitats does not seem to limit methanogenesis directly but can affect what substrates are available and used. Under low pH, acetotrophic methanogenesis seems to be favored, while higher pH favors H_2 dependent methanogenesis. Often both acetotrophic and hydrogenotrophic methanogenesis occur simultaneously in sediments with either process contributing between 20% and 80% of the overall AMG.

Spatial distribution of methanogenesis in freshwater environments

AMG is restricted to environments with low concentrations of alternate electron acceptors (e.g., O_2, NO_3^-, Mn^{4+}, Fe^{3+}, and SO_4^{2-}), at the same time having a high enough concentration of the AMG substrates needed. Such conditions are common in freshwater sediments. If the sediments are overlain with oxic water, or in the proximity of roots of aquatic plants from which O_2 diffuses into the sediment, there is often a redox gradient over a few mm to cm's in the sediment. In this gradient, the organic remineralization processes using alternate electron acceptors often occur in the energy yield sequence according to the order in Table 1. In these cases AMG dominates terminal organic matter degradation in subsurface sediments or at longer distance from the roots, where the other electron acceptors are depleted. If the sediment is overlain with anoxic water and lacks roots contributing O_2, AMG may dominate terminal organic matter degradation in the whole sediment column. In wetlands, the depth distribution of AMG often depends on the position of the ground water table which regulates the availability of O_2 and other electron acceptors.

So far there is little evidence of significant rates of AMG in anoxic water columns, possibly due to low concentration of substrates relative to that found in the sediment. It is also possible that the establishment of stable syntrophic microbial consortia is more difficult in the water column due to higher turbulence than in the sediments, and this may also restrict methanogenesis. Anoxic microenvironments such as digestive tracts of animals or the interior of suspended detrital particles are sites of AMG that may be of importance for the depth distribution of CH_4 in the oceans, but in freshwaters the sediments appear to be the dominant source. The recent discussion about OMP has highlighted the potential for CH_4 production also in surface oxic lake water (e.g., Hartmann et al., 2020).

CH_4 oxidation

Aerobic methane oxidation

The fact that CH_4 is the most highly reduced organic compound means that energy can be gained by the oxidation of CH_4 in the presence of O_2 or other potent oxidants. Aerobic methane oxidizing bacteria (MOB) take advantage of this by using CH_4 as energy and carbon source and O_2 as electron acceptor. MOB oxidize CH_4 sequentially to methanol, formaldehyde, formate, and finally to CO_2. The intermediate product, formaldehyde (CHO) is a primary carbon source for growth.

MOB have been identified in several phyla including Proteobacteria (Gammaproteobacteria and Alphaproteobacteria classes), Verrumicrobia, and Methylomirabilota (Smith and Wrighton, 2019). Studies of isolated strains from these groups have revealed differences in morphology, membrane structures, resting stages and metabolic pathways. Some phospholipid fatty acids represent biomarkers unique for MOB and can be used for identification and biomass estimation. The key enzymes responsible for the CH_4 oxidation are the methane monooxygenases (MMOs). There are both particulate and soluble types of MMOs. Particulate MMO appears to be common to most MOB while soluble MMO is not. Some MOB are obligately methanotrophic, while other are methylotrophic and can use methyl groups on various small organic molecules. A chemically diverse catalytic capacity has been found for soluble MMO, including the oxidation of many aromatic and alicyclic organic compounds, and oxidative dehalogenation of halomethanes, haloalkanes and haloalkenes. Ammonia monooxygenase, used by ammonia oxidizing bacteria is similar to MMO and many MOB may be able to perform ammonia oxidation. Another link to nitrogen cycling, although not specifically associated with MMO, is that many MOB can fix molecular nitrogen (N_2) at low O_2 concentrations (Kallistova et al., 2017; Smith and Wrighton, 2019).

Environmental factors affecting CH_4 oxidation

Aerobic CH_4 oxidation depends on the presence of both CH_4 and O_2 (Table 3). CH_4 oxidation rates appear less sensitive to temperature than methanogenesis (Tables 2 and 3). There is no clear pattern regarding how pH affects CH_4 oxidation rates, possibly due to local adaptations to various pH ranges by the microbial communities. Likewise, the effects of ammonium and nitrate are contradictory and seem to differ between environments (Table 3). High salinity inhibits CH_4 oxidation as does high light intensity. Light can also indirectly favor CH_4 oxidation by enhancing photosynthesis and thereby oxygenation of sediments or water columns.

Table 3 Effects of some environmental factors on aerobic CH_4 oxidation rates (MOX) in aquatic systems (anaerobic oxidation of methane. AOM, is discussed separately in the text).[a]

Environmental factor	*Effect on CH_4 oxidation (±)*	*Notes*	*Sources*[b]
CH_4	+	Given that O_2 is available	9, 10, 11
O_2	+	Given enough CH_4 present; + or – at high O_2 levels debated	4, 5, 9, 10, 11, 12
Temperature	+	Q_{10} 1.4–2.4 (data from wetland and lake systems)	8, 11, 13

[b]Only examples of sources are given. Source 4, 8, and 13 are review papers representing many studies.

Anaerobic oxidation of CH_4

It can be thermodynamically favorable to oxidize CH_4 using any electron acceptor that gives a higher energy yield than methanogenesis (see Table 1). The anaerobic oxidation of CH_4 (AOM) by syntrophic interactions between bacteria performing sulfate reduction and reverse methanogenesis, respectively, was first discovered in marine environments. In inland waters, AOM coupled to reduction of sulfate, nitrate, (denitrification), iron or manganese have been shown (Kallistova et al., 2017). Anaerobic CH_4 oxidation can be considerable, particularly in saline environments, but in freshwaters anaerobic CH_4 oxidation often appears to be of less importance compared to aerobic CH_4 oxidation.

Spatial distribution of aquatic CH_4 oxidation

Aerobic CH_4 oxidation is most extensive at the oxic-anoxic interface where both O_2 and CH_4 are available. The oxic-anoxic interface can be situated in the surface sediment, in deeper sediments close to roots releasing O_2, or in the water column (Fig. 2). The zone with extensive CH_4 oxidation is usually confined to a layer only a few millimeters thick in the sediment, but can be extended over decimeter or meter scales in the water column. The location of this zone varies with time depending on how the oxygenation of the water varies temporally. For example, in a lake which develops an anoxic hypolimnion during summer stratification, the most extensive CH_4 oxidation is expected at the oxic-anoxic interfaces in the water column and in the shallow sediment at depths above the oxycline. During the rest of the year most of the CH_4 oxidation would be expected to occur in the sediment surface if the water column is oxygenated. In wetlands, the oxic-anoxic interface, and thereby the zone of CH_4 oxidation follows the movements of the ground water table (Le Mer and Roger, 2001).

Similarly, anaerobic CH_4 oxidation is favored where both the substrate (CH_4) and a suitable electron acceptor are present at adequate levels. If anaerobic CH_4 oxidation depends on syntrophic relationships, the process may be sensitive to physical disruption such as turbulence breaking microbial associations, and this may limit the distribution in the water column.

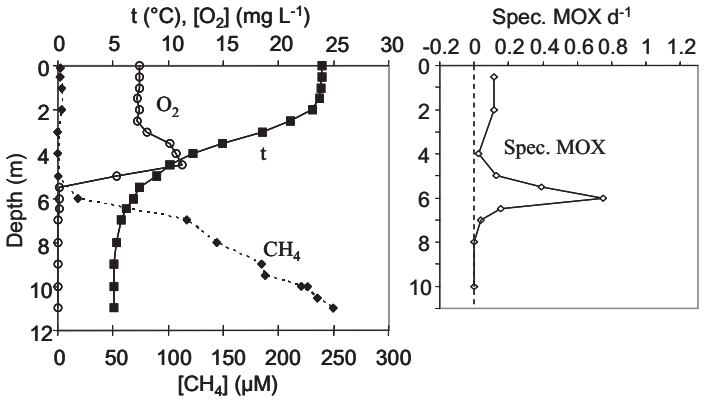

Fig. 2 Example of water column profiles of temperature (t), O_2 concentration ($[O_2]$), CH_4 concentration ($[CH_4]$), and specific CH_4 oxidation rates (Spec. MOX; the fraction of the present CH_4 being oxidized each day), in a temperate lake during summer stratification. Data from Paul Lake, Northern Michigan, USA, July 2001.

At marine hydrocarbon seeps CH_4 oxidation can occur in association with animals (e.g., endosymbiotic MOB in mussels; Nix et al., 1995). In freshwaters, methane oxidation may be enhanced by the extended zones with redox gradients forming in the burrows created by benthic fauna (e.g., chironomids; Kiyashko et al., 2004).

Aquatic CH_4 dynamics

CH_4 concentrations in aquatic environments

The CH_4 concentrations in sediments or water columns are the consequence of formation rates, import rates, CH_4 oxidation rates and rates of export to the water column or the atmosphere. High porewater concentrations, at which CH_4 is saturated at the prevailing pressure, are typical for subsurface sediment layers, and excess CH_4 that is produced will then form bubbles. If surface sediments are oxygenated, CH_4 oxidation can keep CH_4 concentrations low (<10 μM) at the sediment surface. If the sediment is overlain with anoxic water and CH_4 oxidation in the sediment is low, concentrations will be high in the whole sediment resulting in greater export to the water. CH_4 concentrations in anoxic parts of stratified water columns can exceed 1000 μM. Consequently, steep concentration gradients influenced by physical transport patterns and CH_4 oxidation are frequently found in stratified waters (Fig. 2). In strongly stratified systems, lack of advective transport may efficiently trap CH_4 below the thermocline. In such cases most of the surface water CH_4 may be derived from shallow sediments above the thermocline and OMP in surface water (e.g., Bastviken et al., 2008). CH_4 concentrations in well mixed oxygenated parts of water columns are typically ranging from 0.01 to 10 μM. The equilibrium concentrations relative to the atmosphere range from 0.002 to 0.005 μM at an atmospheric CH_4 partial pressure of 2 μatm and temperatures of 0–40 °C, meaning that inland waters are generally supersaturated.

Rates of CH_4 formation and oxidation

Most available assessments of CH_4 production and oxidation rates in sediments are based on incubations of sediment slurries. Slurries are made to ensure well mixed conditions and to avoid the development of gradients that may affect CH_4 production. It is well recognized that such measurements, although providing good potential production rates under experimental conditions, may not reflect actual in situ rates. In situ rates are more difficult to measure and different approaches have been tried including studies of intact sediment cores and whole system CH_4 budgets. Table 4 provides an overview of some CH_4 production, CH_4 oxidation, and CH_4 release rates in lake sediments acquired by different methods. CH_4 production rates range from almost zero to 68 mmol m^{-2} day^{-1}. In oxic surface sediment, 50–95% of the produced CH_4 was oxidized. CH_4 release, representing the net transport of CH_4 to the water, may to a large extent depend on CH_4 oxidation rates and regulation by the O_2 penetration depth has been suggested. The release of CH_4 to the water column in previously studied lakes was 0.04–46 mmol m^{-2} day^{-1} (Table 4). Production or release values greater than 2.9 mmol m^{-2} day^{-1} only occurred in the more nutrient rich systems (mesotrophic or eutrophic), indicating some influence of nutrient levels, probably indirectly by affecting supply rates and quality of the sediment organic matter as well as the frequency of anoxia in bottom waters.

The oxidation of CH_4 in the water column is highly dependent on the mixing regime and the depth of lakes. Hence, reported water column oxidation rates are highly variable ranging from zero in deep anoxic water layers to very high rates in the oxycline where O_2 and CH_4 concentrations gradients meet (Fig. 2) or during lake overturn periods when concentrations of both CH_4 and O_2 are elevated throughout the entire water column. Rates can vary from zero to 27 mmol m^{-3} day^{-1} at individual depths and areal CH_4 oxidation rates, taking the average depth into account, range from 0 to 31 mmol m^{-2} day^{-1} (Table 5). Apparently, a large proportion of the CH_4 entering the water column will get oxidized (45–100%; Table 5). Hence, considering both surface sediments and water columns, CH_4 oxidation substantially reduces the amount of dissolved CH_4 that can be emitted from aquatic environments by diffusion across the water-atmosphere boundary layer.

CH_4 and aquatic food webs

To explain observations that zooplankton and chironomids are frequently depleted in ^{13}C relative to assumed food sources such as algae and bulk particulate organic matter, they have to partly rely on more ^{13}C-depleted carbon sources (Grey, 2016). Biogenic CH_4, and consequently also the biomass of MOB are very depleted in ^{13}C. Accordingly, studies using ^{13}C or MOB phospholipidic fatty acids (PLFA) as tracers of food web connections indicate that CH_4 carbon transformed to MOB biomass can support higher food web levels (Fig. 3); a result that has also been supported by carbon mass balances. CH_4 oxidation in aquatic environments is extensive and the high MOB growth efficiency ranging from 0.15 to 0.8 means that a high proportion of the consumed CH_4 is transferred to biomass. The production of MOB biomass can be of the same order of magnitude as the total heterotrophic bacterial production and even comparable to the primary production in some lakes (Table 6). Therefore, MOB biomass could represent a substantial food resource in many aquatic environments. Until now, there are examples that CH_4 carbon indeed can substantially support zooplankton and chironomid populations, at least in some lakes, during some seasons (e.g., when CH_4 oxidation can be extensive compared to algal production), or for zooplankton or benthic animals preferentially feeding at oxic-anoxic interfaces (Table 7). There is also support that CH_4 carbon can reach fish biomass. However, there are also studies showing negligible food web contributions of CH_4 carbon and the overall extent of a methanotrophic microbial loop is still poorly understood. While it is likely that CH_4 carbon can substantially support aquatic food webs in some cases, future studies are needed on under what conditions this is important.

[a]Lake trophic states based on definition total phosphorous concentrations (TP; $\mu g\ P\ L^{-1}$) denoted are eutrophic (Eu; TP 24–96), mesotrophic (Meso; TP 12–24), oligotrophic (Oligo; TP 0–12). Acidotrophic (Acid) and dystrophic (Dys) denote low pH and high levels of colored organic matter, respectively, as defined by the source. Profundal (Prof) or littoral (Litt) sediment, and in one case sediment in contact with the thermocline water layer (metalimnion) is represented. The studies have been grouped based on the approach (see original source for method details). Mean values or ranges are given. CH_4 leaving the sediment by ebullition is not accounted for by sediment CH_4 production values, meaning that total sediment CH_4 production may be greater.

[a] Various methods were used including monitoring CH_4 concentration decline over time in closed vessels, changes in $\delta^{13}CH_4$ values, or ^{14}C based approaches. Studies attempting to quantify actual in situ rates were selected (i.e., potential rate measurements in incubations with substantial additions of CH_4 were not included). Averages or ranges are reported.

[b] Of the CH_4 reaching the water column.

CH_4 and whole system carbon cycling

Methanogenesis is the dominating terminal organic matter degradation process in anoxic freshwater environment. The significance of CH_4 cycling compared to overall carbon cycling in aquatic environments is large where comparisons have been made. Methanogenesis has been reported to account for 20–56% of the total carbon mineralization in lakes (Table 6). CH_4 oxidation can be comparable to primary production and has the potential to rapidly consume large amounts of O_2. In isolated water bodies, CH_4 oxidation has caused hypoxia or anoxia, resulting in fish kill events. CH_4 emissions may correspond to up to 37% of the primary productivity (Table 6). Altogether, the existing comparisons indicate that CH_4 dynamics can represent a substantial proportion of the total carbon cycling in some aquatic systems. This means that lakes and wetlands represent environments where CO_2, fixed by terrestrial and aquatic primary production, is converted to CH_4 with a relatively high efficiency.

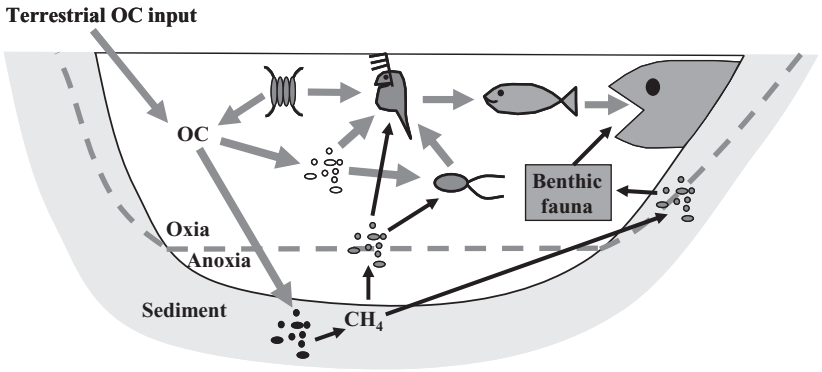

Fig. 3 Schematic illustration of how CH_4 carbon can be incorporated into aquatic food webs. Organic carbon (OC) from terrestrial sources or aquatic primary production (symbolized by Scenedesmus algae) reach anoxic sediment where methanogenic archaea (black dots) produce CH_4. At the oxic-anoxic interface in the water column or in sediment, CH_4 oxidizing bacteria (gray dots) transform CH_4 carbon to bacterial biomass that can be grazed upon by pelagic or benthic bacterivores. Narrow black arrows illustrate the potential routes for CH_4 carbon to various food web levels. The large gray arrows symbolize the classical food web carbon transfer including the microbial loop. (The arrows were made different to make the figure easier to read, and size does not represent quantities or rates).

Table 6 Comparisons between parts of the CH_4 cycling and other parts of the carbon cycling in some freshwater environments.

Lake	*System/Study information*	*Comparison*	*Sources*
Methanogenesis (AMG)			
7 North American lakes		AMG accounted for 19–87% of the anaerobic or 20–25% of the total C mineralization	4, 13, 14
Ryans I Billabong, Australia	Small shallow oxbow lake	AMG accounted for 30–60% of the sediment carbon flux or at least one third of total wetland respiratory carbon losses	3, 7
Pantanal, Brazil	Various waters on floodplain	AMG represented 20% of total heterotrophic metabolism in water and sediment	9
Lake St George, Ontario, Canada	Mesotrophic	AMG accounted for 56% of organic carbon mineralization during lake stratification	2
Lake 227, Canada	Eutrophic, dimictic	AMG equal to 55% of C input from runoff and atmosphere, and 13% of primary production	17
Methane oxidation (MOX)			
Lake Tanganyika, East Africa	Meromictic	MOX $\geq$ primary productivity on annual basis	16
Mekkojärvi, Finland	Dystrophic	Water column MOX rates during fall overturn similar to rates of primary production during July	12
Lake Sebasticook, Maine, United States	Hypereutrophic	MOX accounted for 62–70% of hypolimnetic O_2 demand	15
Lake 227, Canada	Eutrophic, dimictic	MOX consumed all available O_2 under ice during winter resulting in water column anoxia and widespread suffocation of fauna	17
Lake Constance	Mesotrophic	MOX corresponded to 9% of the sediment O_2 demand	8
Methane oxidizing bacteria (MOB)			
Lake Plußsee, Germany	Eutrophic, hypolimnion	MOB biomass 1.4–3% of total bacterial biomass	6
Three Swedish lakes	Two eutrophic lakes and one dystrophic lake	MOB growth rates 0.5–119% of heterotrophic bacterial production, or 0.3–7% of primary production. MOB biomass 5.4–41% of total bacterial biomass at different depths in the water column	1, 19
Lake Nojiri, Japan	Mesotrophic	Production of MOB biomass during fall overturn similar to primary production	20
Lake Kjelåsputten, Norway	Dystrophic	Production of MOB biomass similar to all C fixation by heterotrophic bacteria	10
Valkea-Kotinen, Finland	Dystrophic	Production of MOB biomass equivalent to 23–81% of heterotrophic bacterial production and 5–10% of primary production	11
CH_4 emission			
Wintergreen Lake, Michigan, United States	Small, shallow, hypereutrophic	Summer CH_4 emissions corresponded to 24–37% of summer productivity	18
Everglades, Florida, United States	Plant mediated wetland flux	CH_4 emissions corresponded to 3–14% of net ecosystem production	5

AMG, MOX, and MOB denote anaerobic methanogenesis, oxic methane oxidation, and methane oxidizing bacteria, respectively.

CH_4 emissions from inland waters

Flux pathways

Emission of CH_4 from freshwater ecosystems to the atmosphere can occur in several different ways (Fig. 4):

1. *Ebullition* via bubbles released from the sediment that rapidly pass through the water column. Most of this CH_4 thereby escapes CH_4 oxidation. The ebullition rate is related to CH_4 formation rates in the sediment and also to the hydrostatic pressure and sediment coherence that has to be overcome to allow release of the bubbles. Ebullition is often depth dependent and most extensive from shallow sediments where the hydrostatic pressure is low (Fig. 5), although highest ebullition rates are sometimes found at high depths in steep-sided basins where sediment focusing leads to highest sediment and organic matter accumulation at deeper water. The relation to hydrostatic pressure allows weather to influence the timing of bubble release, and a higher occurrence of ebullition has been observed coincident with drops in the air pressure (Table 8) due to storms or frontal passages. Where ebullition depends on biogenic AMG there can be a bubble recharge-time between ebullition events, while in systems fueled by either geogenic CH_4 or where biogenic CH_4 produced over extensive sediment volumes are channeled to specific spots, more continuous ebullition has been observed (e.g., in some thermokarst systems).
2. *Continuous background flux of dissolved CH_4 from the water surface* (usually called diffusive emission as explained below). The transport of dissolved CH_4 from the sediment through the water column occurs primarily along concentration gradients through advective processes or eddy diffusion (turbulence enhanced diffusion). Very low diffusion rates similar to molecular diffusion may occur across stably stratified water layers at the sediment-water interface, across water column density gradients, or across the diffusive boundary layer at the water-atmosphere interface. As these lower diffusion rates are considered rate limiting (compared to the turbulence enhanced diffusion), this flux is often named "diffusive flux." Because the transport of dissolved CH_4 is much slower than transport by ebullition, a large portion of dissolved CH_4 is oxidized in oxic sediments or water layers (Tables 4 and 5), resulting in low CH_4 concentrations in surface waters. However, due to the poor solubility of CH_4, surface freshwater is still nearly always oversaturated (3–3000 times oversaturation given a concentration interval of 0.01–10 μM) with respect to atmospheric CH_4 (1.8 ppmv). The diffusive flux is regulated by the concentration difference between the water and the air, and by factors affecting the physical transport rate across the water-air interface. Accordingly, the diffusive flux is enhanced by high surface water concentrations or by high turbulence in the surface water making more water coming in contact with, and exchanging gas with the air per time unit (Table 8).
3. *Episodically enhanced flux of dissolved CH_4*. This can occur (a) when deep anoxic and CH_4 rich water in stratified water bodies is mixed up to the surface and comes in contact with the atmosphere during lake circulation (in some papers referred to as "storage flux"). Much of the CH_4 stored in the anoxic water can in this way be vented to the atmosphere over a timescale of days. It is still discussed to what extent enhanced water column CH_4 oxidation during lake overturn can reduce the storage flux, and estimates of how much of the stored CH_4 was oxidized instead of emitted range between >50% and 5%. If substantial parts of this stored

CH_4 are emitted, the storage flux represents a significant flux pathway in many freshwaters (Table 9; Fig. 6). Partial upwelling of CH_4-rich deep water can lead to several such events apart from the full lake circulation events. Episodically enhanced diffusive flux can also occur after (b) ice-out if the surface water suddenly being exposed to the atmosphere after being under the ice is rich in CH_4. Another and more immediate enhanced ice-melt flux occur if (c) there are considerable amounts of CH_4 in bubbles trapped under or in the ice, being released when the ice melts (Denfeld et al., 2018). Overall, more research is needed to constrain all types of episodically enhanced fluxes.

4. *Flux through rooted emergent plants*. Many aquatic plants transport air to the roots to supply them with O_2. Such gas transport systems also transfer gasses such as CH_4 from the roots to the leaves and the atmosphere. These transport systems can be pressurized (e.g., *Typha* spp., *Phragmites* spp., *Nuphar* spp.) or passive (e.g., *Carex* spp., *Peltandra* spp., *Eriophorum* spp.) depending on the plant species. These plants function as conduits for CH_4 that enters the roots allowing rapid transport to the atmosphere bypassing the zones of CH_4 oxidation. At the same time fewer bubbles have been noted where emergent plants are growing. For some species, diel patterns in the transport as an effect of light and solar heating on the plant physiology has been proposed (Table 8).
5. *Transport* via *microbubbles* have been suggested to explain continuous fluxes that were higher than expected from the continuous diffusive flux, in the absence of detectable bubbles as for ebullition (Prairie and del Giorgio, 2013; McGinnis et al., 2015). The formation of pure CH_4 micro bubbles in surface water are typically not physically possible given that the surface inland waters are rarely supersaturated towards 100% CH_4 (although the water is generally supersaturated towards an atmosphere with 2 ppm CH_4). If microbubbles are generated by other processes (e.g., turbulence, or O_2 supersaturation) dissolved CH_4 may however diffuse into such bubbles. Overall, the extent and importance of this microbubble transport pathway is not yet clear.
6. *Specific emission pathways for hydropower reservoirs* include emissions in turbines and in downstream rivers (Johnson et al., 2021; Harrison et al., 2021). Such emissions can be very large if deep anoxic and CH_4-rich water is drawn into the turbine, and therefore hydropower reservoir design is highly important for the associated CH_4 emissions.

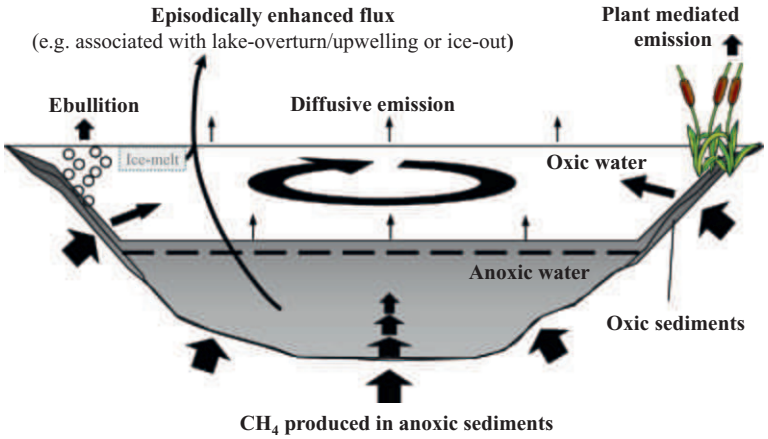

Fig. 4 Illustration of CH_4 emission pathways and transport patterns in a stratified lake with anoxic bottom water. The gray area represents the zone where CH_4 oxidation may be extensive given availability of suitable electron acceptors. When possible anoxic electron acceptors have been depleted CH_4 will start to accumulate in the bottom water, while most of the CH_4 oxidation occur at the oxic-anoxic interface in the water column or in the surface of the shallow sediment. See text for details. Adapted from Bastviken D, Cole J, Pace M and Tranvik L (2004). Methane emissions from lakes: Dependence of lake characteristics, two regional assessments, and a global estimate. *Global Biogeochemical Cycles* 18: GB4009 (12 pages), with permission from American Geophysical Union.

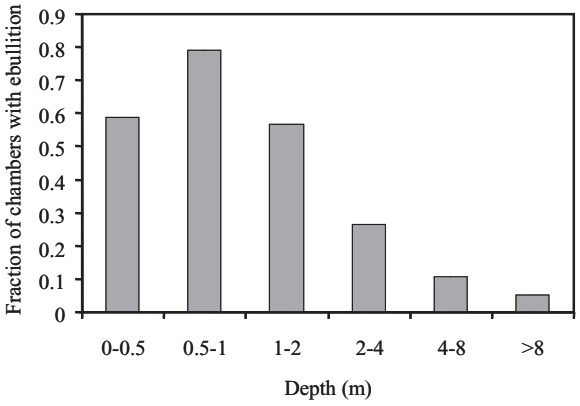

Fig. 5 Fraction of floating chambers receiving ebullition over a 24 h period at different depths. Data are based on 242 measurements in 11 lakes. Fig. 6 Relative contribution of different open water methane flux pathways versus lake area. Based on data from 73 boreal and temperate lakes. Reproduced from Bastviken D, Cole J, Pace M and Tranvik L (2004). Methane emissions from lakes: Dependence of lake characteristics, two regional assessments, and a global estimate. *Global Biogeochemical Cycles* 18: GB4009 (12 pages), with permission from American Geophysical Union.

The contribution of different flux types and their regulation

Plant mediated emission and ebullition dominates CH_4 emissions from most lakes and wetlands. Ebullition often (but not always) accounts for about 50% or more of the open water emission (Fig. 6). However, it should be emphasized that ebullition, being episodic and having a heterogeneous spatial distribution, is challenging to quantify by the temporally and spatially limited measurement efforts typically being feasible, and a general underestimation of ebullition has been hypothesized.

At a small-scale level (<1 m^2), emission rates are regulated by a combination of CH_4 production and oxidation rates, and transport. In turn, this small-scale regulation depends on larger scale environmental factors as summarized in Table 8. In general, open water emissions from lakes seem related to lake area (Fig. 7), lake morphometry, and the amount and degradability of the organic matter reaching the sediments. Wetland emissions, dominated by plant-mediated flux, depend on sediment or peat temperature, the depth of the water table, plant community composition and biomass, and net primary production. In northern areas, alterations in the permafrost distribution are important by affecting the surface hydrology, inundation and plant community structure.

Open water mean emissions from lakes typically range between 0.01 and 20 mmol m^{-2} day^{-1}, while the range for wetland and plant mediated emissions is 0.01–40 mmol m^{-2} day^{-1}, with higher rates under conditions characterized by higher temperature and higher primary productivity. Smaller lakes have higher emissions per m^2 than larger lakes (Holgerson and Raymond, 2016). Rivers also emit CH_4 with total mean rates >8.5 mmol m^{-2} day^{-1} reported (Stanley et al., 2016). Fluxes have been linked to a large number of environmental variables (Table 8). Temperature and primary productivity regulating net supply of organic matter substrates for methanogenesis and microbial metabolic rates, and also being linked with physical forcing in various ways, seems to be key variables. Other variables, linked to transport may determine the residence time of CH_4 in the systems, thereby regulating the time for methane oxidation and the share of the produced CH_4 being emitted. There is growing concern that inland water CH_4 emissions are highly climate sensitive for multiple reasons including the strong direct temperature sensitivity, the enhancement of fluxes in lakes forming in tundra areas with melting permafrost (thermokarst lakes), and the enhancement of primary productivity from the combination of eutrophication and elevated temperature (e.g., Marotta et al., 2014; Wik et al., 2016; Yvon-Durocher et al., 2014).

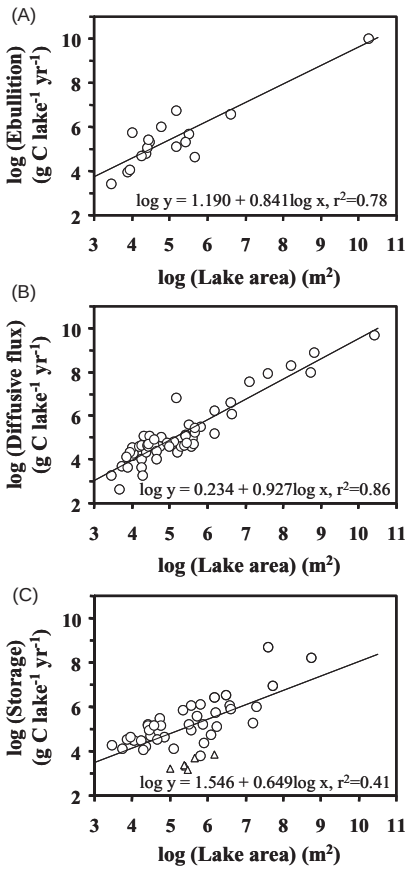

Fig. 7 Ebullition (A), diffusive flux (B), and water column methane storage during stratification periods (C) for lakes of different size. The triangles in panel C represent lakes without anoxic parts of the water column. Linear regression lines are given in the graphs. Adapted from Bastviken D, Cole J, Pace M and Tranvik L (2004). Methane emissions from lakes: Dependence of lake characteristics, two regional assessments, and a global estimate. *Global Biogeochemical Cycles* 18: GB4009 (12 pages), with permission from American Geophysical Union.

Reservoirs also emit CH_4 (Johnson et al., 2021; Harrison et al., 2021; IPCC, 2019). Old reservoirs have been suggested to emit CH_4 at rates similar to or somewhat higher than lakes. However, recently established reservoirs can emit much higher amounts of CH_4 due to the flooding of soils and rapid transformation of soil organic matter to CH_4. Consequently, reservoir fluxes are highly variable, with emissions being very low in some reservoirs, while very high emissions have been observed from shallow reservoirs in warm climate regions. Such emissions may offset the climate benefits with hydropower in some cases, making reservoir CH_4 emissions important to consider when prioritizing between different sustainable energy sources for the future. Recent work provides best estimates of reservoir emissions of 10–22 Tg CH_4 $year^{-1}$ (Johnson et al., 2021; Harrison et al., 2021).

Plant mediated emissions are highly variable based on local conditions (Table 9). Global CH_4 emissions from natural wetlands range between 100 and 222 Tg CH_4 $year^{-1}$ Other inland waters, including lakes, reservoirs, and running water, have been estimated to contribute 48–212 Tg CH_4 $year^{-1}$. Given total natural and anthropogenic global emissions estimates of 524–896 Tg CH_4 $year^{-1}$, natural wetlands and other inland waters account for in the order of 19–25% and 11–24%, respectively (Saunois et al., 2020). It has been estimated that lakes, various types of reservoirs or artificial impoundments, and running water contribute approximately 70%, 13%, and 17% to the global mean inland water fluxes, respectively (Saunois et al., 2020). Notably, inland water emissions is seen the most uncertain part of the global CH_4 budget and numbers provided here are recent estimates awaiting further refinements. Considerable uncertainty can be linked to the uncertainties in total inland water and wetland areas, to the distinction between various types of inland waters and wetlands which strongly impact fluxes and are important for flux modeling, and to spatiotemporal patterns in the various fluxes.

Knowledge needs

The knowledge about CH_4 in inland waters still suffers from scarcity of long-term systematic and coordinated data collection at multiple sites. Such efforts are key to determine e.g., climate impacts on CH_4 dynamics and emissions. Given the increasing evidence of strong temperature sensitivity and seasonality, future data collection face the challenge to cover all seasons adequately in spite of practical and financial constraints. It is also clear that variability at multiple scales e.g., across diel, seasonal and among-year time frames, should be considered. It should be noted that low latitude regions have received much less attention than high latitudes, yet low latitudes may contribute the greatest fluxes and the greatest flux changes in the future (Bastviken et al., 2011; Borges et al., 2015; Marotta et al., 2014). It would be highly beneficial to further constrain process regulation, flux rates, and area distributions in ways that are compatible with large-scale modeling (Matthews et al., 2020). Previously neglected fluxes, such as large emissions via trees in flooded forested wetlands (Pangala et al., 2017), also need attention and will challenge the traditional distinctions between environment types (such as "lakes" versus "wetlands"), as these definitions are not necessarily compatible with the key environmental features regulating CH_4 dynamics and emissions. For example, both lakes and wetlands can include partially open water areas and areas with emergent aquatic plants and the extent and characteristics of theses specific land cover types (open water versus water with emergent plants) are more important for CH_4 dynamics and flux regulation than if we define the environment as a lake or a wetland. In addition, method development towards easier and less expensive CH_4-measurements would be highly beneficial to resolve all types of CH_4-related knowledge gaps more effectively.

An important challenge is to estimate how CH_4 emissions from inland waters will be affected by climate change as emissions are considered highly sensitive to climate and there is a risk of increased CH_4 emissions in a warmer future. At the same time, some studies point towards the potential of MOX to prevent increased emissions (Oh et al., 2020). In any case, such emission feedback responses represent important links between aquatic methane cycling and the future climate.

Acknowledgments

I wish to thank Patrick Crill and Nguyen Than Duc for very valuable comments on the 1st edition manuscript.

Nitrogen☆

Robert W Howarth, Cornell University, Ithaca, NY, United States

This is an update of R. Howarth, Nitrogen, In Encyclopedia of Inland Waters, Edited by Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00098-3.
This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Lars Rudstam.

Glossary

Anoxic Oxygen-free, lacking oxygen.
Denitrification The process of converting nitrate to molecular N_2; also called dissimilatory nitrate reduction.
Eutrophic Characterized by high levels of primary production and high algal biomass.
Hypoxic Having oxygen present at only low concentrations (generally less than 2–3 mg/l).
Nitrification The oxidation of ammonium to nitrite and nitrate by bacteria.
Nitrogen fixation The conversion of molecular N_2 into reactive nitrogen compounds such as ammonium.
Nutrient limitation The condition of rate of growth of production by photo-autotrophs being less than maximum due to a constraint by one or more nutrients, usually phosphorus or nitrogen.
Oligotrophic Characterized by low levels of primary production and low algal biomass.
Oxic Having oxygen present.
Primary production The rate of accumulation of new biomass by plants, algae, and photosynthetic bacteria through photosynthesis.
Rhizosphere The roots, rhizomes, and associated micro-organism of a vascular plant.

Introduction

Nitrogen is an essential element for life and is the fourth most abundant element in the living biomass (by moles) after hydrogen, carbon, and oxygen. Nitrogen is in all amino acids and nucleotides, and therefore in all proteins and nucleic acids. Nitrogen is also a major component of the chitin that makes up the cell walls of fungi and the exoskeletons of aquatic insects and crustaceans. Together with phosphorus, nitrogen limits rates of primary production in most of the ecosystems on Earth, including inland waters. However, unlike phosphorus, nitrogen has a very active oxidation–reduction cycle, and nitrogen in nature exists in valence states from −3 to +5. Curiously, and unlike the biogeochemical cycle of any other major element, most of the nitrogen on Earth is present with an intermediate valence state of 0 (as molecular, gaseous N_2). More than any other major element cycle, human activity has accelerated the nitrogen cycle leading to many critical changes in the aquatic ecosystems.

Forms and transformations of nitrogen

Nitrogen occurs as both organic and inorganic nitrogen in aquatic ecosystems. Frequently, the organic forms dominate, including both particulate organic nitrogen (PON) and dissolved organic nitrogen (DON). The PON not only includes the nitrogen in living organisms, but also large amounts of nitrogen in detritus or dead organic matter. The DON consists of a wide range of organic substances, including simple substances such as free amino acids. Much of the DON, however, consists of higher molecular weight compounds. Most of the DON in natural waters has never been chemically characterized at the level of individual compounds because of the analytical challenge of measuring thousands of unknown substances, each often present at relatively low concentrations.

The inorganic nitrogen in aquatic ecosystems includes dissolved N_2 gas, oxidized ions such as nitrate (NO_3^-) and nitrite (NO_2^-), the reduced ammonium ion (NH_4^+), and the reduced ammonia gas (NH_3). Nitrate is the most oxidized form of nitrogen (valence

☆*Change History*: October 2021. RW Howarth updated all sections. Figs. 1, 3, and 4 are new.

state of +5), while ammonia and ammonium are most reduced (valence state of −3). Ammonium is a weak acid that in solution is in equilibrium with ammonia gas, which is a base. The equilibrium constant for this relationship is $10^{-9.3}$. Thus, ammonium is more dominant whenever the pH is less than 9.3, as is almost always the case in aquatic ecosystems. At pH = 8.3, the ammonium concentration is 10-fold greater than the ammonia concentration. At pH = 7.3, the ammonium concentration is 100-fold greater than the ammonia concentration. Since ammonia is a gas, it can be volatilized to the atmosphere. The rate of loss is a function of the ammonia concentration, and so this process is much greater at higher pHs, where higher concentrations of ammonia are favored.

The vast majority of the nitrogen on the Earth is present as N_2 gas. This becomes biologically available only through bacterial nitrogen fixation, fixation by lightning or volcanic activity, or fixation by human activity. Before the industrial revolution, bacterial nitrogen fixation was by far the major mechanism for the creation of reactive, biologically available forms of nitrogen on the planet. Increasingly, human activity is fixing nitrogen, and this now exceeds the natural biological nitrogen fixation globally and dominates the nitrogen cycle in many regions, as discussed below.

The primary forms of reactive nitrogen assimilated by algae, rooted plants, fungi, and bacteria are nitrate, nitrite, ammonium, and ammonia. Once taken up, nitrate and nitrite are reduced to ammonium in processes called assimilatory nitrate or nitrite reduction. Ammonium – whether taken up directly or formed by assimilatory reduction in the organism – is used by plants, algae, and microorganisms to produce organic nitrogen compounds. The organic nitrogen of plants, algae, and microorganisms can flow through a food web to animals, and detrital PON and DON is decomposed by bacteria and fungi. The organic nitrogen eaten by animals or decomposed by microorganisms is excreted as ammonium or sometimes as urea, a low-molecular weight compound that is quickly hydrolyzed to ammonium in water. These processes of releasing nitrogen back to the environment are called nitrogen mineralization (Fig. 1).

The forms of inorganic, reactive nitrogen are converted from one to another in aquatic ecosystems through a variety of bacterially mediated processes. Ammonium is oxidized to nitrate in a process called nitrification, an energy-yielding process. The nitrifying bacteria that catalyze the reaction gain energy and use this energy to fix carbon dioxide into new bacterial biomass, a process called chemosynthesis. The energy yield of the reaction is low compared with many chemosynthetic processes based on oxidizing sulfur or iron compounds, and so the growth of nitrifying bacteria is slow. Nitrification rates are in part a function of the population size of nitrifying bacteria; where mortality on the bacteria is high due to grazing, the slow growth result keeps population sizes low, and rates of nitrification can be very low, allowing ammonium to accumulate.

Nitrate is reduced to nitrite and nitrite is reduced to N_2 in a process called denitrification, also called dissimilatory nitrate reduction. The bacteria that catalyze these reactions are heterotrophic bacteria that gain their energy from the degradation or organic matter; they use the nitrate or nitrite as an electron acceptor, very much as plants and animals and many other microorganisms use oxygen as an electron acceptor for respiration. Since the energy yield of respiring organic matter using nitrate as the electron acceptor is somewhat less than when using oxygen as the electron acceptor, denitrification tends to occur only when oxygen is absent or present at very low levels. This is frequently the case in aquatic sediments, and often in the bottom waters of stratified lakes and estuaries. Denitrification is the major sink for reactive nitrogen in natural ecosystems. At the global scale, denitrification serves to balance nitrogen fixation and maintains N_2 gas as the major form of nitrogen on the planet.

Many of these nitrogen-cycle processes have been understood in broad brush since the early years of the 20th century, but other nitrogen processes have been discovered only in the past 30–40 years. One of these is denitrification based on chemosynthetic oxidation of sulfide or reduced iron rather than respiration of organic matter. Another is the anaerobic oxidation of ammonium to N_2 (ANAMOX), which is also a chemosynthetic process. And a third is the dissimilatory reduction of nitrate to ammonium (DNRA). The DNRA process is a form of respiration, with organic matter being consumed using nitrate as the electron acceptor; however, the

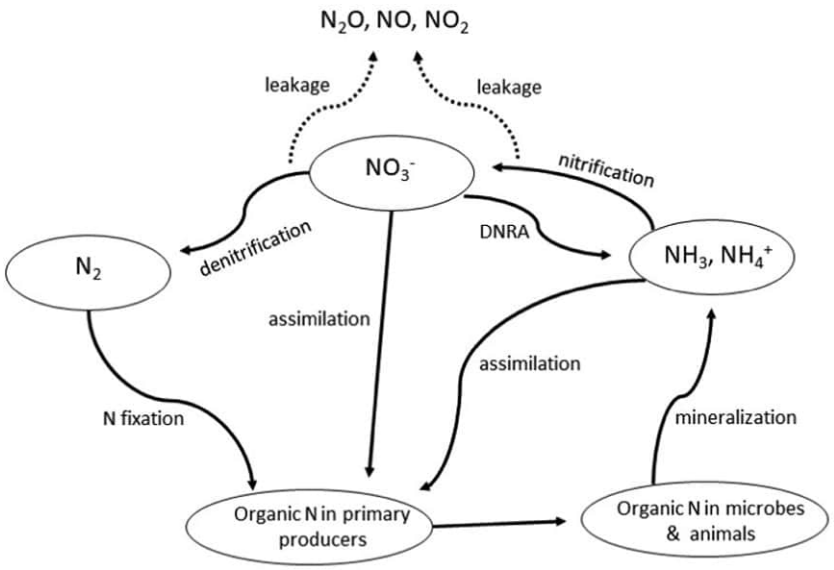

Fig. 1 Simplified diagram of the nitrogen cycle in aquatic ecosystems.

nitrogen is reduced to ammonium rather than to N_2. Unlike denitrification, DNRA conserves the nitrogen in the ecosystem in a reactive, biologically available form. The controls that may make denitrification or DNRA more important in any particular situation remain imperfectly known, but evidence suggests that DNRA may dominate in sediments that are more reducing and have higher concentrations of dissolved sulfides (Burgen and Hamilton, 2007).

Nitrogen cycling at the ecosystem scale

The nitrogen budget of most lakes, streams, and rivers is dominated by nitrogen inputs from their watersheds and often include flows through groundwaters as well as in surface waters. As discussed elsewhere within this encyclopedia, bacterial nitrogen fixation can be an important source, but in most aquatic ecosystems this is far less than the inputs from upstream sources. Direct deposition from the atmosphere can also be an important input of nitrogen, that is nitrogen inputs in rain and snowfall as well as uptake of nitrogen gases by the water body from the atmosphere and deposition of nitrogen particles onto the water surface. However, only in aquatic ecosystems with very small watersheds does the direct deposition of nitrogen from the atmosphere rival the input of nitrogen in stream and river flow and in groundwaters. Estuaries can receive nitrogen inputs from adjacent coastal ocean sources, as well as from their watersheds.

In most aquatic ecosystems, the rate of nitrogen uptake by plants, algae, and microorganisms is far greater than the rate of inputs from external sources, and the nitrogen needs of primary production and uptake by bacteria and fungi is supported by rapid recycling of nitrogen within the ecosystem. In oligotrophic lakes, the rate of uptake of nitrate and ammonium by phytoplankton is generally 50- to 100-fold more than the rate of input of nitrogen from external sources. In highly productive eutrophic lakes, the rate of nitrogen uptake by phytoplankton is often 10- to 30-fold greater than the rate of external inputs. In some very productive coastal salt marshes with huge inputs of nitrogen delivered by twice-daily tides, nitrogen uptake by the primary producing organisms is roughly equal to the external nitrogen inputs, but this is an extreme case of very high inputs.

In streams and rivers, the uptake of nitrogen and other nutrients can be considered in the context of spiraling distances, or the average distance over which an atom flows before being assimilated by plants, algae, bacteria, or fungi. In streams that are not heavily impacted by humans, this distance may be just meters to perhaps a hundred meters. After assimilation, the nitrogen atom is eventually remineralized and moves downstream again; again, on average, it moves the same spiraling distance. In larger rivers, the distances can be much greater, up to tens or hundreds of kilometers or even greater. And in landscapes with heavy human influences, the distances can be much greater; for instance, the spiraling distance for nitrogen in a ditch draining agricultural lands may be kilometers or more.

Denitrification can be a major sink of nitrogen in aquatic ecosystems, including wetlands, lakes, reservoirs, estuaries, streams, and rivers. Denitrification can occur in anoxic waters, such as often occur in stratified lakes and estuaries. However, in these stratified systems, the rate of supply of nitrate into the anoxic waters is often low, keeping rates of denitrification relatively low. Denitrification readily occurs in the sediments of virtually all inland water ecosystems due to low oxygen levels, and rates can be high when nitrate concentrations in the overlying waters are high. Commonly in many sediments and in wetland soils, nitrification and denitrification co-occur in close proximity in microzones where oxygen is present (for nitrification) and absent (for denitrification). This coupled nitrification–denitrification can account for a majority of the denitrification in aquatic ecosystems. The coupling of these processes is favored by the bio-irrigating activities of animals and by the rhizosphere of vascular plants.

In aquatic ecosystems with an oxygenated water column, the percentage of the nitrogen inputs that are denitrified is well predicted as a function of the water residence time and the depth of the water. This reflects the interaction time of the nitrogen with the sediments, the site of denitrification. The percentage loss of nitrogen is greater in ecosystems that are shallower and that have longer water residence times. At the landscape scale, the water residence time is frequently more important. Thus, the loss of nitrogen through denitrification tends to be greater in lakes and reservoirs than in streams and rivers (Howarth et al., 1996, Fig. 2).

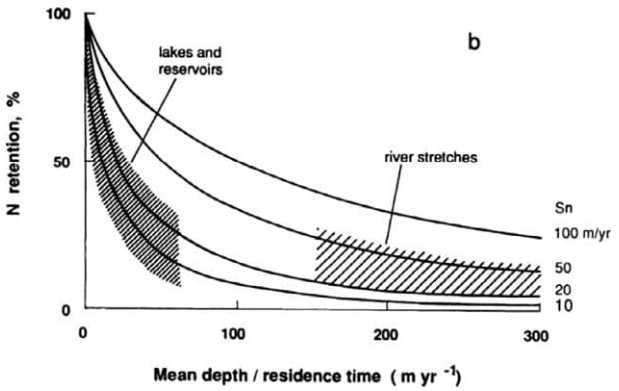

Fig. 2 The percentage of nitrogen inputs to aquatic ecosystems that is lost through denitrification as a function of depth and residence time of the system. Modified from Howarth RW, Billen G, Swaney D, Townsend A, Jarworski A, Lajtha A, Downing J. A., Elmgren R., Caraco N, Jordan T, Berendse F, Freney J, Kueyarov V, Murdoch P, and Zhao-Liang L (1996) Riverine inputs of nitrogen to the North Atlantic Ocean: Fluxes and human influences. *Biogeochemistry* 35: 75–139.

Nutrient limitation of net primary production

In most natural ecosystems, rates of net primary production tend to be limited by the availability of just one or two elements, usually nitrogen, phosphorus, or both. While the primary producers require many other elements, these generally are in abundant supply compared to nitrogen and phosphorus. Despite many decades of research, some disagreement continues to exist regarding nutrient limitation in freshwater lakes. Classic work by David Schindler and his colleagues using whole-lake nutrient additions clearly showed phosphorus to be the limiting nutrient (Schindler et al., 2008; Higgins et al., 2018), as did cross-system studies by Richard Vollenweider and others, showing phosphorus levels to be well correlated with phytoplankton biomass across a wide range of lakes. Phosphorus limitation may well be the norm for mesotrophic to eutrophic lakes, that is lakes of moderate to high productivity, at least in the temperate zone. However, oligotrophic, very low productivity lakes are often limited by nitrogen or co-limited by nitrogen and phosphorus. And some limnologists argue that nitrogen limitation may be more common in mesotrophic and eutrophic lakes than often appreciated, based on the ratio of total nitrogen to total phosphorus in the lakes, as is discussed further below. For temperate-zone estuaries, there is a clear tendency for nitrogen to be the nutrient most limiting net primary productivity. As is discussed in the section below, human activity has greatly accelerated the nitrogen cycle, leading to massive increases in nitrogen inputs to estuaries in many parts of the world. Nitrogen is now the largest source of pollution in estuaries, and in the United States, two-thirds of estuaries are moderately to severely degraded from nitrogen pollution and the eutrophication it causes (Vitousek et al., 1997; Carpenter et al., 1998).

Whether nitrogen or phosphorus is more limiting is a function of the relative availabilities of these two elements in the ecosystem (Howarth and Marino, 2006; Elser et al., 2009). Although there is some plasticity in the elemental composition of phytoplankton, the variation is relatively small and the ratio of nitrogen to phosphorus in phytoplankton biomass is usually in the range of 16:1 by moles (the "Redfield ratio," named after Alfred Redfield who described the relationship between water chemistry and phytoplankton composition in the world's oceans in the 1930s). In ecosystems where the ratio of available nitrogen to phosphorus in the water is well above 16:1, phosphorus is in relatively short supply and will be more limiting to net primary production. In ecosystems where the nitrogen:phosphorus ratio of available nutrients is well below 16:1, nitrogen is in relatively short supply (compared with the needs of the phytoplankton) and will be more limiting. The ratio of dissolved inorganic nitrogen (the sum of nitrate, nitrite, ammonium, and ammonia) to dissolved inorganic phosphorus is a reasonable indicator of the ratio of dissolved nitrogen and phosphorus in many cases and can be used to infer whether nitrogen or phosphorus is more limiting, if the ratio is sufficiently above or below 16:1. However, dissolved inorganic nutrients often recycle quite quickly in the water column of aquatic ecosystems, and so concentrations are not always a reliable indicator of supply. Further, most analytical methods for measuring dissolved inorganic phosphorus overestimate this quantity by some unknown amount due to inclusion of some organic phosphorus and positive interference from arsenic.

The ratio of available nitrogen to phosphorus within an ecosystem is a function of both the ratio in the external inputs of these elements and the processing of nitrogen and phosphorus within the ecosystem. Often, the nitrogen to phosphorus ratio in nutrient inputs from watersheds are well above 16:1, which tends to drive the aquatic ecosystems towards phosphorus limitation. In contrast to lakes, estuaries receive nutrients both from upstream watersheds and from ocean waters. The ocean waters are frequently phosphorus rich and somewhat depleted in nitrogen (relative to the Redfield ratio). This is one of the reasons that estuaries may be more prone to nitrogen limitation.

A variety of processes within an ecosystem can change the availabilities of nitrogen and phosphorus. Of particular importance for phosphorus is the adsorption to sediment particles. This lowers concentrations of dissolved inorganic phosphorus, and therefore makes phosphorus limitation more likely. The presence of competing ions in seawater makes adsorption less in estuaries than in freshwaters, and inorganic phosphorus that is adsorbed to suspended sediment particles in rivers is largely desorbed and becomes soluble in estuaries as the salinity increases. This tends to make phosphorus limitation less likely (and nitrogen limitation more likely) in estuaries than in freshwater ecosystems (within the constraints set by the inputs of nitrogen and phosphorus, and the influences of other biogeochemical processes).

Both nitrogen fixation and denitrification can have large influences on the availability of nitrogen in aquatic ecosystems. Briefly, nitrogen fixation by planktonic cyanobacteria is an important process in many lakes that helps to alleviate nitrogen shortages and can contribute to phosphorus limitation in freshwaters, providing the deficit of nitrogen availability to phosphorus is not too large. In stark contrast, nitrogen fixation by planktonic cyanobacteria seldom, if ever, occurs in even strongly nitrogen-limited estuaries at salinities greater than 10 parts per thousand. This is probably a result of the high sulfate concentrations in seawater interfering with the uptake of molybdenum by planktonic cyanobacteria in estuaries; molybdenum is required for nitrogen fixation. It is interesting to note that sulfate levels are sometimes high and sometimes not in inland saline lakes. As a result, nitrogen fixation is a major process in some saline lakes but not in others. In saline lakes where nitrogen fixation occurs, the process helps to alleviate nitrogen shortages and maintain phosphorus limitation, while high sulfate lakes without significant nitrogen fixation are often nitrogen limited.

Scientists who study nutrient limitation in lakes have used a variety of approaches, and this has contributed to the ongoing debate about the prevalence of phosphorus and nitrogen limitation (Howarth and Marino, 2006; Paerl et al., 2016; Higgins et al., 2018). Often, researchers will use short-term bioassays. In this approach, nitrogen, phosphorus, or some other element is added to water samples in bottles and any change in phytoplankton biomass or productivity over a few days to a week is noted. While this can provide very useful information, the approach has many difficulties. One of the greatest of these is that the time frame may not allow for some important biogeochemical processes, such as nitrogen fixation, to occur. In experiments with nutrient additions to

whole lakes over growing seasons and years, researchers have demonstrated that temporary shortages of nitrogen that result from fertilizing with phosphorus and nitrogen at ratios below 16:1 can be alleviated by planktonic nitrogen fixation, and that the lakes remain phosphorus limited over these longer time frames. But such a response would not be observed in a short-term bioassay, which might instead suggest nitrogen limitation. The nitrogen limitation would in fact be only a short, transient feature.

A less ambiguous way to study nutrient limitation has come from longer-term, whole-lake experiments and experiments with large tanks or bags designed to mimic important components of the ecosystem over time periods of a growing season or longer (mesocosm experiments). Such experiments have clearly shown a prevalence for phosphorus limitation in moderately productive lakes and for nitrogen limitation in estuaries in the temperate zone.

The ratio of nitrogen to phosphorus can also be used to infer nutrient limitation in aquatic ecosystems. However, seldom if ever do scientists have direct information on the ratio of available nitrogen to phosphorus, so inferences are made from data on inorganic, dissolved nutrients or data on total nitrogen and phosphorus. For the reasons discussed above, the ratio of dissolved inorganic nitrogen to phosphorus cannot unambiguously indicate nutrient limitation by a particular nutrient, when close to the Redfield ratio of 16:1. But ratios of more than 1000:1 are common in many lakes, clearly indicating phosphorus limitation in these lakes. And the inorganic nitrogen to phosphorus ratio in estuaries is often less than 1:1, which indicates strong nitrogen limitation. For most lakes, the ratio of total nitrogen to total phosphorus is considerably less than the ratio of inorganic dissolved nitrogen and phosphorus, although typically greater than the Redfield ratio of 16:1. Based on statistical analyses across lakes, limnologists have suggested that when the total nitrogen to total phosphorus ratio is less than 29:1, nitrogen may be more important than phosphorus in regulating phytoplankton biomass (Dolman et al., 2016). However, this has not been independently verified with long-term experimental data.

Human acceleration of the nitrogen cycle

Human activity has altered the nitrogen cycle more than that of any other major element on Earth (Vitousek et al., 1997; Galloway et al., 2004). Prior to the industrial and agricultural revolutions, the vast majority of reactive nitrogen on the planet was created by bacterial nitrogen fixation, and this rate of creation was balanced over geological time by denitrification. Now the creation of nitrogen by humans to produce synthetic nitrogen fertilizer through the Haber–Bosch process exceeds the rate of natural fixation on the continents. This process was not invented until 1909 and did not see widespread production until after World War II, but in the years since 1960, synthetic nitrogen fertilizer has come to dominate agriculture and has helped power the green revolution that has allowed the human population to expand to over 7.9 billion people. The inadvertent creation of reactive nitrogen during fossil fuel combustion also adds to the global nitrogen cycle.

The influences of human activity on the nitrogen cycle vary across the regions of the globe. Because of the high chemical reactivity and high biological demand for nitrogen, most forms of reactive nitrogen (i.e., nitrogen other than N_2 gas) do not cycle globally, but rather at the scale of large regions. The natural rates of nitrogen fixation in terrestrial ecosystems are much higher in the tropics, whereas more of the fertilizer use and fossil fuel combustion to date has occurred in temperate regions. This has started to change somewhat in recent decades as fertilizer use and fossil fuel combustion increase in South Asia and tropical South America. Nonetheless, to date the largest changes in nitrogen cycling have occurred in the temperate zone in Europe, the United States, and China. The flow of nitrogen in large rivers in these areas has increased 15-fold or more due to human activity, with much of this increase occurring since 1980 in Europe and the United States and since 2000 in China.

Globally, the use of synthetic nitrogen fertilizer has driven most of the increase in nitrogen cycling. This is also clearly the case in many regions, including the Mississippi River basin (Fig. 3; Howarth et al., 2021). However, in some regions such as New England in the northeastern United States, the combustion of fossil fuel has been a larger contributor. This fossil fuel combustion leads to pollution of the atmosphere with oxidized nitrogen compounds. Their deposition onto the landscape contributes to the flux of nitrogen to aquatic ecosystems. Much of the nitrogen is deposited onto forests, which retain a great deal of it, and some falls on urban and suburban lands, where retention is much less. The movement of nitrogen in animal feeds and in food for humans can also be significant in many regions. Note the large export of nitrogen in food and feed from the Mississippi River basin, a flux that exceeds the flow of nitrogen in the waters of the River itself, and the large import of nitrogen to New England in food and feeds (Fig. 3, Howarth et al., 2021).

One of the largest consequence on aquatic ecosystems of the human acceleration of the nitrogen cycle has been the eutrophi cation of estuaries and other coastal waters. Eutrophication is the excess production of organic matter by phytoplankton and benthic plants and algae, and it has led to oxygen-deprived waters (anoxic and hypoxic zones, sometimes called “dead zones”) in many areas, as well as habitat degradation, loss of biotic diversity, and increased incidences and extent of harmful algal blooms. One of the world’s largest dead zones occurs every summer in the northern Gulf of Mexico, caused by the large flux of nitrogen down the Mississippi River.

Nitrogen has contributed to eutrophication in some freshwater lakes as well, quite likely including Lake Victoria in Africa and Lake Taihu in China (Paerl et al., 2016). However, in general nitrogen is less likely to cause eutrophication in freshwater lakes than in estuaries simply because nitrogen limitation of net primary productivity is less common in lakes. Nonetheless, some recent evidence suggests that toxic phytoplankton blooms may be aggravated in lakes by high levels of nitrogen, even when net primary production is severely phosphorus limited. The oligotrophic and mesotrophic Finger Lakes of New York State are clearly phospho-rus limited, as indicated both by experiments and ratios of inorganic nitrogen to phosphorus that are commonly greater than

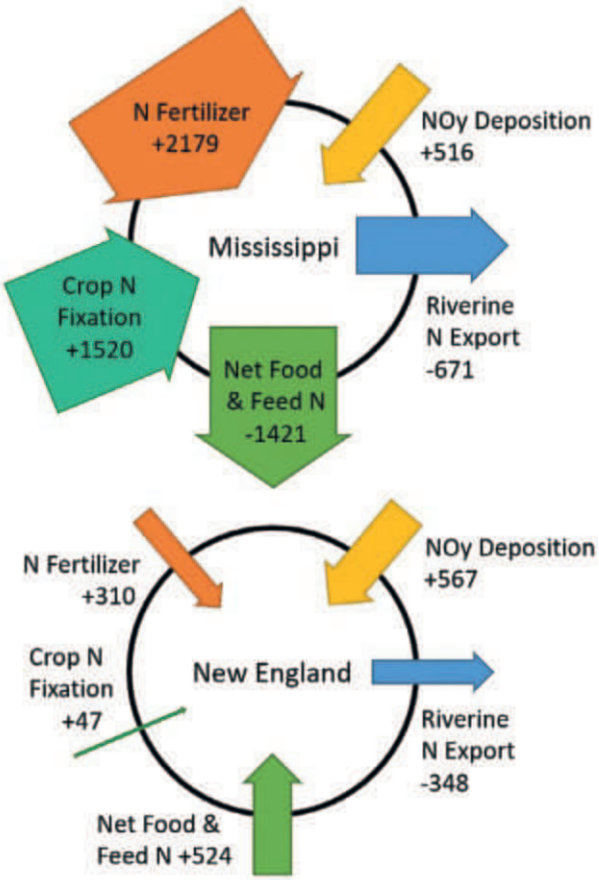

Fig. 3 Comparison of inputs of nitrogen to the landscape from human activity and exports of nitrogen in rivers, in kg nitrogen per square meter per year. Top shows the Mississippi River basin. Bottom shows all watersheds and rivers in New England. Note that the movement of nitrogen in food for humans and animal feeds is a net import in New England but a net export for the Mississippi River basin. Reprinted from Howarth RW, Chan F, Swaney DP, Marino RM, and Hayn M (2021). Role of external inputs of nutrients to aquatic ecosystems in determining prevalence of nitrogen vs. phosphorus limitation of net primary productivity. *Biogeochemistry* 154: 293–306.

1000:1. In recent years all of these Finger Lakes have experienced blooms of toxic cyanobacteria, often referred to as harmful algal blooms even though the cyanobacteria are not actually algae. One hypothesis for the occurrence of these blooms is that high nitrogen levels can promote higher concentrations of toxins such as microcystin in the cyanobacteria. The toxins can reduce grazing by zooplankton on the cyanobacteria, and thereby lead to a bloom with high cyanobacteria biomass even if the growth rate of the cyanobacteria is low due to low phosphorus. Some experimental evidence supports higher amounts of toxins when nitrogen levels are greater (Baker et al., 2018), although the connection to lower grazing and mortality has not yet been proven. In light of this hypothesis, cyanobacteria can be viewed to become a dominant part of the phytoplankton community in lakes under two conditions: when nitrogen levels are high and phosphorus levels are low to moderate, leading to highly toxic cyanobacteria that are not fixing nitrogen, and when nitrogen levels are low and phosphorus levels are high, which encourages nitrogen-fixing cyanobacteria (Fig. 4).

Another impact of accelerated nitrogen cycling on freshwater ecosystems comes from acid rain. Both sulfuric and nitric acids contribute to acid rain. Much of the focus historically has been on sulfuric acid, and that has led to some measurable progress in reducing sulfur emissions to the atmosphere. Reductions in NOx, the precursor for nitric acid, have been far less, and nitric acid is therefore growing as an overall source of acid rain. This nitric acid – which comes from fossil fuel combustion and is the same nitrogen deposition that contributes to nitrogen flows to estuaries – is the major source of acid rain now in some regions.

The deposition of ammonia gas and ammonium particles can also contribute to the acidification of inland waters. Most of the ammonia in the atmosphere comes from volatilization from agricultural sources, and particularly from large animal feedlot operations. Ammonia is a base, and so acts to raise the pH of precipitation. In this technical sense, ammonia counteracts acid rain. However, the ammonia and ammonium deposited onto terrestrial ecosystems or directly onto aquatic ecosystems can be nitrified to nitrate, as discussed above. This chemical transformation produces large quantities of acid – 1 mol of proton acidity generated for every mole of nitrate created from the oxidation of ammonia and 2 mol for every mole of nitrate created from the oxidation of ammonium ion. Consequently, the deposition of ammonia and ammonium also can contribute substantially to the acidification of inland waters.

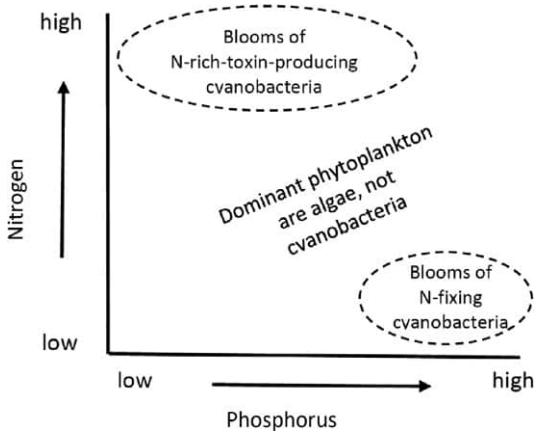

Fig. 4 In freshwater lakes, nitrogen-fixing cyanobacteria are favored under conditions when nitrogen availability is low and phosphorus availability is high, particularly when the N:P ratio is less than the Redfield ratio of 16:1 (lower right corner). Cyanobacteria may also be favored under conditions of low to moderate phosphorus but high nitrogen, although cyanobacteria will not fix nitrogen under these conditions. The high nitrogen may allow the cyanobacteria to produce nitrogen-rich toxins, thereby lowering their mortality rate from grazing by zooplankton (upper left corner).

Nitrate in drinking water for humans is also of concern, and a standard of 10 mg nitrate-N per liter is set in most of the world's nations, based on advice from the World Health Organization. Such a standard has existed since the early 1960s in the United States, and was originally set over concern about "blue-baby syndrome," a disease in infants where nitrate binds to hemoglobin in the blood, interfering with oxygen transport, and turning the blood blue. Studies over the past few decades have suggested that nitrate in drinking water poses many other health risks, including risk of a variety of cancers and a variety of developmental issues, and perhaps at levels below the drinking water standard. This topic has been much debated over the past 20 years, with some arguing that nitrate is a natural occurrence in saliva that the human body may actually manipulate to reduce bacterial infection. However, evidence shows a strong carcinogenic risk from nitrate in drinking water, probably due to the formation of nitrosomines, which are highly carcinogenic compounds. The best current evidence suggests a strong interaction between nitrate exposure and other dietary considerations: nitrate in vegetables such as spinach seems to pose little risk, while nitrate in drinking water combined with a high red-meat and low vegetable and fruit diet poses a major risk. Nitrate in drinking water at levels well below the current drinking water standard can pose a risk, in association with poor diet. Unfortunately, many of the drinking water sources in the world – including the developed world – exceed the current drinking water standard, and concentrations of nitrate in drinking water are rising (Townsend et al., 2003).

Nitrogen poses health risks beyond those of direct toxicity or carcinogenicity from nitrate, to both humans and natural animal populations. The toxicity of ammonia to aquatic animals is well known and is a major problem in waters heavily polluted from sewage or animal wastes. A more subtle aspect is the indirect effect of nitrogen on animal vectors that carry disease. For example, parasitic diseases of amphibians can increase markedly as eutrophication proceeds: nutrient pollution (probably phosphorus) in freshwaters in temperate-zone areas can lead to increased parasite releases from snails, which are an intermediary host, and cause massive disease in frogs and salamanders. The disease-causing organism is closely related to schistosomiasis, a major disease for humans in many tropical areas. An increase in snail populations as a result of nitrogen-based eutrophication in tropical reservoirs and lakes could lead to a similarly large increase in schistosomiasis. The temperate-zone studies on amphibian disease show an increased risk of disease resulting not only from an increase in snail populations as eutrophication progresses, but also a huge increase in the release of parasites from each snail. In another study, malaria has increased in some coastal areas of Brazil due to nitrogen-induced increases in eutrophication in mangrove swamps leading to increased abundances of mosquitoes that carry the malaria parasite.

One aspect of the human acceleration of the nitrogen cycle demands particular attention: the gas nitrous oxide (N_2O) presents severe challenges to the global environment. Laughing gas, as it is sometimes called, is an effective pain-killing drug sometimes used by dentists. It is also a long-lived gas in the Earth's atmosphere, with a residence time estimated at 120 years. Concentrations are rising rapidly. The gas catalyzes the destruction of ozone in the stratosphere, and increasingly nitrous oxide is responsible for ozone holes that allow excessive UV–B radiation to penetrate to the Earth's surface. Nitrous oxide is also a major absorber of infra-red energy, and therefore is a potent greenhouse gas that contributes to global warming. The Intergovernmental Panel on Climate Change considers nitrous oxide to be nearly 300-fold more powerful than carbon dioxide in terms of its long-term effect on global warming. Nitrous oxide is produced as a leakage-produce of both nitrification and denitrification. The rapid increase in the concentration of this gas in the atmosphere is clearly a side effect of the global acceleration of the nitrogen cycle by human activity.

Glossary

Anoxic Oxygen-free, lacking oxygen.
Autotroph An organism that fixes carbon dioxide (CO_2) and converts it into organic matter; photoautotrophs use light as the energy source to fix the carbon dioxide; photo-autotrophs include plants, algae, cyanobacteria, and other photosynthetic bacteria that use reduced substances such as hydrogen sulfide rather than water as an electron donor; chemo-autotrophs do not use light but rather use the energy released from oxidizing reduced chemical substances to fix carbon dioxide.
Benthic In or on bottom sediments.
Cyanobacteria Photosynthetic bacteria, often called "blue green algae"; these organisms can use fixed nitrogen in the environment and many, but not all, species are also capable of fixing atmospheric N_2.
Denitrification A bacterial respiration process that takes place in the absence of oxygen; nitrate is converted to N_2 gas through a series of steps involving nitrogen oxides.
Diazotroph Microorganisms (bacteria and archaea) that can fix atmospheric N_2 into a biologically available form of nitrogen such as ammonia.
Eutrophication The process of increased growth and production of algae and other plant life in an aquatic ecosystem in response to excessive nutrient inputs.
Heterocyst A specialized, thick-walled non-photosynthetic cell that is the site of nitrogen fixation in many species of cyanobacteria.
Heterotroph An organism that gains its energy for life's processes by consuming organic carbon compounds produced by autotrophic organisms. All animals, all fungi, and many bacteria are heterotrophs; animals and many fungi and bacteria consume the organic matter by respiring it to carbon dioxide, using oxygen as the electron acceptor; some bacteria use other electron acceptors instead, such as nitrate or sulfate; and some bacteria and fungi gain energy through fermenting organic matter, where no inorganic electron acceptor is used and instead electrons are transferred from one type of organic molecules to another.
Nitrogen fixation The process of converting molecular N_2 to reactive, biologically available forms.
Nitrogenase The enzyme that catalyzes the fixation (reduction) of N_2 to NH_3.
Nutrient limitation The condition where the rate of growth and production of biomass by photoautotrophs is less than maximum owing to a lack of one or more nutrients, usually phosphorus or nitrogen.
Oxic Having oxygen present.
Planktonic Living in the water column of an aquatic ecosystem and largely dependent upon motion of the water for movement.
Primary production The creation of organic biomass by living organisms, using simple inorganic molecules (water, carbon dioxide, nutrients) and light or chemical energy.
Prokaryotic Describing an organism that lacks a cell nucleus or other organelles bound by membranes; bacteria and archaea are prokaryotes.
Salinity The content of dissolved salt and other minerals in water, usually used in the context of ocean waters or salt lakes; salinity is generally reported in units of parts per thousand, or grams of dissolved salts per kilogram (or liter) of water.
Stereochemistry The aspect of chemistry relating to the spatial arrangement of atoms within molecules. Stereochemistry is important in the reactivity of molecules.

Introduction to biological nitrogen fixation in aquatic systems

Nitrogen fixation is the bacterial process whereby molecular N_2 gas is converted to reactive, biologically available forms of nitrogen. The vast majority of nitrogen on Earth is present as molecular N_2, and is not available to living organisms other than those that can fix nitrogen for growth. Before the advent of the agricultural and industrial revolutions, biological nitrogen fixation was the only significant process creating new nitrogen to support fixation of carbon dioxide into energy-rich organic matter (primary production) in Earth's ecosystems. It is an ancient process, having evolved more than 3 billion years ago. Since nitrogen is an essential element for life as well as one of the two macro-elements frequently limiting primary productivity in ecosystems (along with phosphorus) at the global scale, the process of nitrogen fixation is essential for life (Vitousek and Howarth 1991).

In nature, the ability to fix atmospheric N_2 into a form of reactive nitrogen that can be used by organisms is limited to a specialized group of prokaryotes (diazotrophs) that use an enzyme (nitrogenase) to catalyze the reaction. There is a wide variety of these organisms, including bacteria that use organic carbon (heterotrophs), and bacteria that fix inorganic carbon dioxide (CO_2) into biomass (autotrophs). The autotrophs include photosynthetic cyanobacteria, so named because of the blue-colored photosynthetic pigment they contain to capture light energy, other photoautotrophs (such as the purple sulfur bacteria that use hydrogen sulfide rather than water as the reducing agent in photosynthesis), and chemo-autotrophic bacteria that use inorganic chemical energy rather than light energy. The latter two types of nitrogen-fixing bacteria only live in environments hostile to most organisms whereas cyanobacteria can thrive in a wide range of aquatic habitats and have mechanisms which help them grow and persist during periods of adverse environmental conditions (Carr and Whitton, 1982). Nitrogen-fixers can either live freely in the environment, or symbiotically in association with other organisms. The cyanobacteria that are capable of fixing atmospheric N_2 have a unique ecological role in aquatic ecosystems, as they are the only group of organisms on Earth that can fix both inorganic carbon and nitrogen in an oxic (oxygen-containing) environment.

In inland waters heterotrophic bacteria, and cyanobacteria (primarily from the order Nostocales) are responsible for most of the nitrogen fixation that occurs. The rates of nitrogen fixation and the resulting nitrogen input to an ecosystem from this process vary greatly among lakes and other inland water bodies. In general, when biological nitrogen fixation is an important contributor to the nitrogen economy of an aquatic ecosystem, high rates of nitrogen fixation by cyanobacteria living in the plankton of the water column are the primary reason. Cyanobacteria and other autotrophic bacteria living in the benthos (sediments) or in assemblages attached to surface substrate of shallow water bodies, marshes, and streams can also fix nitrogen at high rates and provide a locally important source of nitrogen to the communities they support. Benthic nitrogen fixation by photoautotrophs in very low-nutrient lakes where light can penetrate to much of the bottom area can constitute a significant source of nitrogen to these systems. Because cyanobacteria can thrive in a wide range of aquatic habitats and have the unique ability to fix N_2 while carrying out oxygenic photosynthesis, most of this chapter is devoted to a discussion of cyanobacterial nitrogen fixation in inland water environments. Nonetheless, nitrogen fixation by heterotrophic bacteria is fairly ubiquitous in sediments and can be significant in the nitrogen cycle of some aquatic ecosystems.

Before considering the rates of biological nitrogen fixation in inland waters and general factors which influence this process, it is useful to understand a bit about how nitrogen fixation is estimated in natural systems. The most commonly used method remains the acetylene reduction assay, introduced in the late 1960s by Ralph W.F. Hardy and colleagues (Capone, 2019). This relatively simple and highly sensitive technique indirectly assays nitrogen fixation by measuring the conversion of acetylene gas, a structural analog for N_2, to ethylene gas. The reactions that reduce N_2 gas to ammonium (fixed reactive N) and reduce acetylene to ethylene are both catalyzed by the nitrogenase enzyme present in all organisms capable of biological nitrogen fixation. It is necessary to assume a fixed relationship between acetylene reduced and N_2 fixed by the enzyme. Variation in this ratio due to physiological and environmental factors is the primary source of uncertainty in estimating field N_2 fixation rates using the acetylene reduction method, although sampling and incubation techniques can also affect measured rates. Nitrogen fixation can be also assayed directly by measuring the incorporation of a stable isotopic form of N_2 (^{15}N) into biomass (Wannicke et al., 2018), or by measuring the change in dissolved N_2 in a sample over time relative to a biologically inactive tracer (Kana et al., 1994). The latter measurement allows a direct estimate of N fixation when the microbial process of denitrification is insignificant, such as in a fully oxic water column, and an indirect estimate when both processes are present such as in sediments (An et al., 2001).

Rates of biological nitrogen fixation vary tremendously across the wide range of aquatic ecosystems where measurements have been made. In addition to the variation and uncertainties inherent in the methodologies used, a number of environmental factors acting at levels from the cellular up to the ecosystem and the region act to influence the rates and relative importance of nitrogen fixation in different inland water environments. Nonetheless, some patterns and generalities have emerged. This article is intended as a summary of these concepts, and not as an exhaustive review of the literature on nitrogen fixation in inland aquatic environments.

Nitrogen fixation by heterotrophic bacteria in sediments

Heterotrophic bacteria fix nitrogen in virtually all sediments. The rates reported for the sediments in lakes and estuaries tend to be low to moderate, from 0.002 to 0.3 g N m^{-2} $year^{-1}$ (Howarth et al., 1988a). Such rates are low compared with those mediated by cyanobacteria in many lakes or rates by heterotrophic bacteria found in many terrestrial ecosystems. Nitrogen fixation rates are

generally higher when the organic matter content of the sediment is greater. In marine and freshwater ecosystems where vascular plants are present (including marshes, swamps, bogs, and submerged macrophyte and seagrass beds) nitrogen fixation rates in the sediments are more variable, and can be much higher than in unvegetated sediments in similar environments. For Temperate Zone systems measured rates generally range from 0.5 to 4 g N m^{-2} $year^{-1}$ (Howarth et al., 1988a; Scott et al., 2008), values which are more typical of many terrestrial systems. Nitrogen fixation rates in the sediments of seagrass beds in subtropical and tropical coastal water bodies are often higher than in temperate systems, and range from approximately 1 to 20 g N m^{-2} $year^{-1}$ (Howarth et al., 1988a). The higher rates of fixation in wetlands and seagrass beds as compared with unvegetated lake or coastal marine sediments are probably a result of the greater availability of labile organic matter associated with the plants as a substrate to fuel the process. Although rates of nitrogen fixation are fairly similar in saltmarshes and freshwater wetlands, the resulting nitrogen is a much more significant input to freshwater systems because the latter are often much more closed systems. For example, nitrogen fixation was estimated to contribute 1–2% of the total nitrogen input to a salt marsh in New England (United States), as compared with 60% of the nitrogen input to a freshwater bog in the same region (Howarth et al., 1988a).

In sediments, the microbial process that counters nitrogen fixation as a nitrogen input is denitrification, where fixed inorganic nitrogen is converted back to a gas and lost from the system. Rates of denitrification also tend to increase with greater organic matter in sediments, and so the processes of nitrogen fixation and denitrification tend to vary in parallel. Denitrification rates are generally found to be similar to or greater than heterotrophic nitrogen fixation rates in aquatic ecosystems (Seitzinger, 1988). As a result, sediments of inland aquatic ecosystems tend to either show no net nitrogen flux out to the overlying water or serve as a net nitrogen sink annually despite heterotrophic nitrogen fixation, although recent work in estuarine sediments suggests the net balance of the two processes fluctuates temporally in response to changing conditions (Newell et al., 2016). In some wetlands as well as lakes and estuaries where light penetrates to the bottom there can be additional nitrogen fixation associated with sediments owing to the activity of autotrophic nitrogen-fixing bacteria on the surface sediments (see "Nitrogen Fixation by Benthic and Epiphytic Cyanobacteria" later in this chapter).

The nitrogenase enzyme that is essential for nitrogen fixation is readily poisoned by oxygen. Oxygen seldom penetrates into sediments below the first millimeter or two, and so does not inhibit nitrogen fixation by heterotrophic bacteria in most sediments. On the other hand, when oxygen is present in an environment, it may severely constrain nitrogen fixation by these bacteria. For example, essentially no nitrogen fixation by heterotrophic bacteria occurs in the oxygenated water columns of lakes, probably because of the deleterious effect of oxygen on nitrogenase activity. Some nitrogen fixation is associated with heterotrophic bacteria on leaf litter and other organic matter aggregates in streams where decomposition lowers oxygen in microzones, but rates are typically quite low, again perhaps due to the high level of oxygen in flowing water.

Nitrogen fixation is considered energy-intensive relative to many other biological processes, as it requires breaking a N—N triple bond using a specific metalloenzyme complex. As such, the process of synthesizing nitrogenase and reducing N_2 to create a source of fixed nitrogen for growth is often viewed as energetically "expensive" to the organism when compared with the uptake of fixed inorganic nitrogen present in the environment, or the synthesis of other cellular compounds. However, this appears not to be the case for N_2 fixation by heterotrophic bacteria in anoxic (no oxygen present) sediments. Moderate to high rates occur in the presence of elevated concentrations of ammonium (NH_4^+) typically present in porewaters as a result of decomposition and remineralization. Since bacteria can readily assimilate the ammonium and thereby have a plentiful supply of nitrogen, the fact that they also fix N_2 indicates that it "costs" them little to do so. However, ammonium at high levels has been shown to inhibit the rate of nitrogen fixation in some sediments, perhaps keeping these rates lower than otherwise might occur (Howarth et al., 1988b). As discussed later, nitrogen fixation by cyanobacteria and particularly those most commonly found in the plankton of inland waters, may be a much more energy-expensive process to the organisms, in part because of the need to build and maintain structures that protect the nitrogenase enzyme from deactivation by oxygen produced during photosynthesis.

Nitrogen fixation by planktonic cyanobacteria in freshwater lakes

Nitrogen fixation by planktonic cyanobacteria varies greatly among lakes, and rates are related to the overall nutrient (trophic) status. Rates of N_2 fixation typically range from 0 to 0.003 g N m^{-2} $year^{-1}$ in oligotrophic (very low-nutrient) lakes, from 0.01 to 0.1 g N m^{-2} $year^{-1}$ in mesotrophic lakes, and from 0.2 to16 g N m^{-2} $year^{-1}$ in eutrophic (highly enriched) lakes (Howarth et al., 1988a; Higgins et al., 2018). Planktonic nitrogen fixation is generally not an important term in the nitrogen budgets of oligotrophic and mesotrophic lakes, and contributes less than 1% of the nitrogen inputs to most of these ecosystems. On the other hand, nitrogen fixation can be very important in the nitrogen economy of eutrophic lakes, with studies showing from 5% to 86% of the total nitrogen load to the ecosystem from this source.

The most important species of planktonic cyanobacteria that fix nitrogen in lakes belong to the genera *Anabaena*, *Aphanizomenon*, and *Nostoc*, which can rapidly reproduce and form large blooms (high biomass) under optimal conditions (Carr and Whitton, 1982). These species form long chains or filaments of cells, which can differentiate to allow photosynthesis to occur in most cells (vegetative) and nitrogen fixation to occur at the same time, in specialized, non-photosynthetic cells called heterocysts (Fig. 1). Heterocysts form in response to low intracellular concentrations of nitrogen, as a result of low availability of nitrogen in the environment. The heterocysts have a thick wall that protects nitrogenase from oxygen; this adaptation allows nitrogen fixation to occur in fully oxic environments. The energy necessary for nitrogen fixation comes from carbon fixed in the photosynthetic cells, which is transferred to the heterocysts. To support the energy required for nitrogen fixation, many photosynthetic cells are needed per one heterocyst cell.

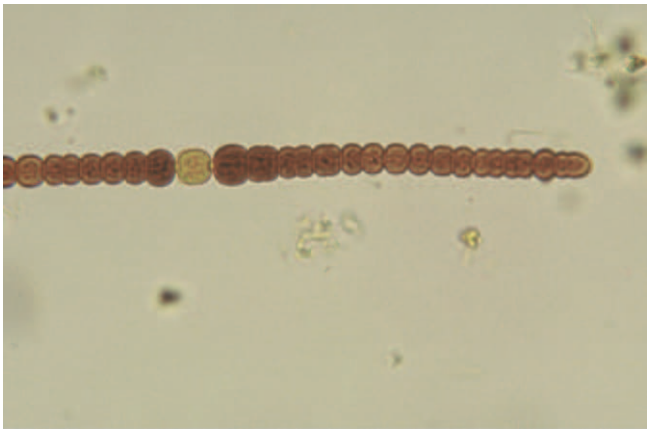

Fig. 1 Photograph of an *Anabaena* filament with heterocyst, stained for contrast. Heterocyst appears yellow, vegetative cells are orange-brown. Courtesy of Colleen Kearns, Cornell University.

Heterocysts develop in regularly spaced intervals of vegetative cells. Rates of both cyanobacterial growth and nitrogen fixation are generally higher when there are at least 15–20 vegetative cells per heterocyst cell (Stal, 2015). Filamentous cyanobacteria can be very sensitive to grazing: zooplankton can quickly shorten chains (and thereby reduce the number of photosynthetic cells available to support nitrogen fixation in a heterocyst) both by breaking chains into pieces and by eating along the end of a chain (Chan et al., 2006). As a result, grazing by zooplankton can constrain the development of a cyanobacterial bloom in nitrogen-depleted waters, by limiting nitrogen fixation and so nitrogen availability for further growth (Howarth and Marino, 2006). Significant reduction in cyanobacterial abundance by some types of zooplankton and filter-feeding bivalves has been observed in some inland waters, although many nitrogen-fixing cyanobacteria species often contain toxic chemical compounds as a protection against grazing. These defensive compounds may be less of a factor for grazers in the early stages of a cyanobacteria bloom, when filaments are developing and available nutrients and energy are needed for producing more vegetative cells rather than such accessory protective compounds. Also, some of the pigments in cyanobacteria cells at this stage of growth contain nitrogen-rich amino acids, making the cells a potentially high-quality food source. In addition to the ecological factors such as grazing that influence the extent of planktonic cyanobacterial growth and nitrogen fixation, there are other chemical and physical factors recognized to be important (Howarth et al., 1988b). These factors include light and the related parameters of turbulence and mixing depth, and the availability of essential macro-nutrients nitrogen (N) and phosphorus (P) and essential trace metals (iron, Fe and molybdenum, Mo). Other characteristics of the system, such as pH or dissolved organic carbon concentration, can interact with one or more of the primary factors to influence cyanobacterial population dynamics. The relative importance of any one factor in controlling nitrogen fixation in a water body varies depending on physical, biogeochemical, and ecological factors, as depicted in Fig. 2.

In contrast to nitrogen fixation by heterotrophic bacteria in anoxic sediments, nitrogen fixation by planktonic cyanobacteria appears to be an energetically more expensive process for the cells. Most of the energy cost of fixation is not in the catalysis of the reaction per se but rather in synthesizing and then protecting nitrogenase from oxygen, and perhaps the cost of assimilating trace metals that are required for nitrogenase in its predominant form: iron and molybdenum. The biological availabilities of both these metals are likely to be much greater in anoxic sediments than in an oxic water column (Howarth et al., 1988b). For iron, the greater availability under anoxic conditions in large part simply reflects the higher solubility of reduced iron compared to oxidized iron. For molybdenum, the chemically stable form found under oxic conditions in the pH range of most natural waters is molybdate. This anion can be difficult for bacteria to assimilate because of its close similarity in effective size and stereochemistry to the sulfate anion. The latter is far more abundant in inland waters, particularly in estuaries and some saline lakes. As such, the cellular uptake system needs to be more selective for molybdate, which likely requires more energy for synthesis than a lower affinity transport system (Marino and Howarth, 2016). In anoxic environments, molybdenum is present in different chemical forms, which may be more biologically available.

It is most advantageous to planktonic cyanobacteria to invest energy in heterocyst and nitrogenase synthesis to obtain nitrogen via the nitrogen fixation process when other sources of available nitrogen for growth are low. Further, even when concentrations of inorganic nitrogen are low, nitrogen fixation by planktonic cyanobacteria is not likely to occur if the N:P ratio of inorganic nitrogen and phosphorus in the environment is well above that needed for synthesis of phytoplankton biomass (the so-called Redfield ratio of 16:1, moles N to mole P, after Alfred Redfield, the scientist who first described this relatively constant relationship in oligotrophic ocean waters). Under these conditions, the growth of the cyanobacteria is more limited by phosphorus than by nitrogen. Nitrogen-fixing cyanobacteria generally have a high overall requirement for phosphorus (Carr and Whitton, 1982), and the biomass of planktonic cyanobacteria in freshwater lakes is often positively correlated with high concentrations of phosphorus in the water. The highest rates of nitrogen fixation are typically found when available nitrogen concentrations are low, available phosphorus concentrations are high, and the molar N:P ratio is below 16:1.

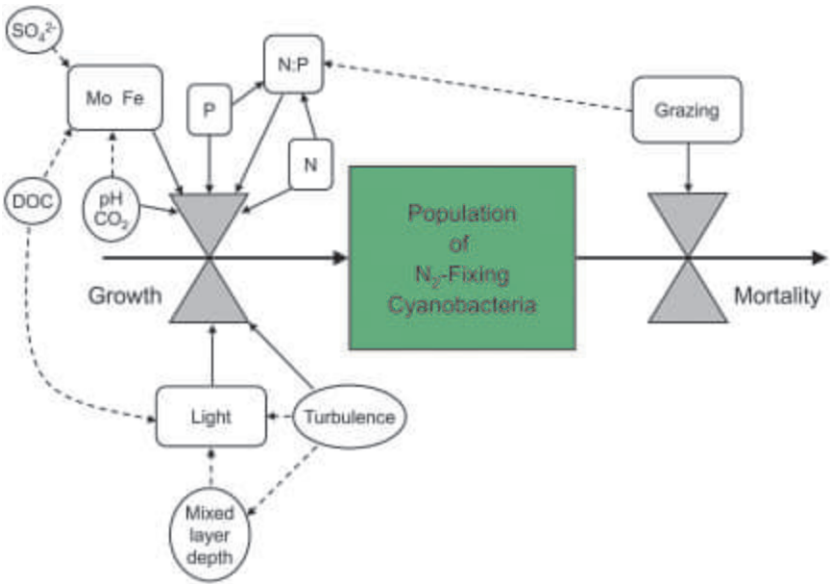

Fig. 2 Schematic representation of the factors that control growth and N_2 fixation by cyanobacteria in the plankton of lakes and estuaries. Dashed lines indicate indirect effects by acting to alter the availability of the direct factor; DOC is dissolved organic carbon; SO_4^{2-} is the sulfate anion.

In a series of classic experiments that began in the 1970s at the Experimental Lakes Area in Canada, David Schindler and colleagues demonstrated that planktonic nitrogen fixation can help maintain phosphorus limitation of net primary productivity in eutrophic lakes (Schindler, 1977; Higgins et al., 2018). For several years, they fertilized a lake with nitrogen and phosphorus, with an N:P ratio of total inputs of 32:1 (by moles). Under these conditions, phytoplankton growth is phosphorus-limited and sufficient dissolved inorganic nitrogen is present to meet the needs of the phytoplankton. No cyanobacteria were observed in the plankton. Then the experimental protocol was changed, reducing the nitrogen inputs while leaving the phosphorus input unchanged, with the N:P ratio of total inputs was 14:1. This was expected to induce a slight limitation of nitrogen to phytoplankton growth, but this did not occur. Rather, large populations of planktonic cyanobacteria grew in the lake and fixed a sufficient quantity of nitrogen such that net primary production in the lake remained limited by phosphorus. However, in some highly P-enriched lakes when the N:P ratio is very low, planktonic N fixation cannot fully alleviate the nitrogen deficit (Paerl et al., 2015; Hayes et al., 2019).

Nitrogen fixation by planktonic cyanobacteria in saline waters

Many of the world's lakes are composed of saline waters. These lakes typically occur in arid or semi-arid regions and have no drainage outlet. As a result, salt accumulates over time due to evaporation, and the salt content and composition of these types of lakes is quite variable. Nitrogen-fixing planktonic cyanobacteria are common in many of these lakes, and sometimes fix nitrogen at very high rates. Surprisingly, high rates have been observed even in oligotrophic (i.e., very low nutrient) salt lakes. For example, nitrogen fixation by cyanobacteria in Pyramid Lake, Nevada, United States, was measured as $2\ g\ N\ m^{-2}\ year^{-1}$, a rate more characteristic of eutrophic than oligotrophic freshwater lakes. In some years, nitrogen fixation is estimated to contribute roughly 80% of the total nitrogen input to Pyramid Lake (Howarth et al., 1988a). However, nitrogen-fixing cyanobacteria are not present in the plankton of many saline lakes even when conditions seem optimal—primary production is limited by nitrogen, concentrations of nitrate and ammonium are low, concentrations of dissolved inorganic phosphorus are high, and the N:P ratio is well below the Redfield ratio of 16:1 (Marino et al., 1990).

The controls on nitrogen fixation in saline lakes have received relatively little study, but the chemistry of the lakes is one major factor explaining variation in rates of nitrogen fixation. The specific dissolved substances that dominate the salinity in salt lakes vary greatly. In some saline lakes, sulfate is the dominant anion, while in others, chloride, carbonate, or other anions dominate. Growth and nitrogen fixation by planktonic cyanobacteria can be adversely affected by the high concentrations of sulfate found in some lakes because of an inhibition of molybdenum uptake, as discussed earlier. Thus, nitrogen-fixing cyanobacteria are most likely to be abundant in the plankton of salt lakes where the sulfate concentration is low. Salinity itself does not appear to be a constraint on growth and nitrogen fixation until salt concentrations reach very high levels (50–70 g per liter or more, about 1.5–2 times seawater levels) (Marcarelli et al., 2006).

Nitrogen-fixing cyanobacteria are present in the plankton of some estuarine ecosystems as well, although they are surprisingly rare, and generally are found to be significant only when the salinity is less than 10 parts per thousand (the salinity of open ocean

seawater is approximately 35 parts per thousand). Much of the Baltic Sea and its estuaries have a salinity below 10 parts per thousand, and nitrogen-fixing cyanobacteria are often present in high abundances (Moisander et al., 2003). A few other estuaries have reported cyanobacteria that persist at higher salinities, but these are ecosystems that tend to experience wide changes in salinity over the season; the cyanobacteria blooms typically originate during times when there is high freshwater inflow and the salinity is at or near zero parts per thousand, and then persist for some time as the salinity increases (Marino et al., 2006). Note that nitrogen-fixing cyanobacteria such as *Trichodesmium* that are commonly found in oligotrophic, warm, oceanic waters can be advected onto continental shelf regions and contribute new nitrogen (Mulholland et al., 2012) but are not significant nitrogen fixers in estuaries. For the vast majority of estuaries that have been studied, including all those in North America and in Europe outside of the Baltic Sea, nitrogen-fixing cyanobacteria have not been reported at salinities much above 8–10 parts per thousand (i.e., mesohaline and saline systems). This is a marked contrast with freshwater lakes, as many higher salinity estuaries typically have nutrient inputs and conditions that strongly promote nitrogen limitation of phytoplankton (Howarth et al., 2021).

What processes act to exclude nitrogen-fixing cyanobacteria from the plankton of most estuaries? Part of the answer again lies with sulfate, the second most abundant anion in seawater. Sulfate is a conservative constituent of seawater and estuarine waters, and so the sulfate concentration varies in direct proportion to the overall salinity. The concentrations of sulfate found in mesohaline and saline estuaries can significantly inhibit molybdate assimilation by heterocystous cyanobacteria. This is not an absolute constraint on nitrogen fixation, but does make molybdate uptake energetically costly by requiring more specificity (higher affinity) in the transport system, and therefore can negatively affect the growth rate of the cyanobacteria (Marino et al., 2003). Experimentally measured maximum growth rates for heterocystous planktonic cyanobacteria isolated from estuarine systems tend to be an average of four times lower than those for the same genera from freshwater systems (Marino et al., 2002).

As discussed earlier, heterocystous cyanobacteria growth can also be susceptible to grazing by zooplankton, because of the need to have enough photosynthetic cells per heterocyst in a filament to support differentiation and nitrogen fixation. A slower growth rate increases this vulnerability to grazing and is a negative feedback to the overall rates of production of cyanobacterial biomass and nitrogen fixation. Experiments have demonstrated that when grazing by zooplankton is suppressed in saline estuarine waters, heterocystous cyanobacteria can grow in the plankton and fix nitrogen, even when they are not observed under natural (and nitrogen-limited) conditions (Chan et al., 2006). The interaction of sulfate-induced slow growth rate and grazing by zooplankton is an important factor acting to exclude blooms of nitrogen-fixing cyanobacteria from the plankton of saline, nitrogen-depleted estuaries.

Nitrogen fixation by benthic and epiphytic cyanobacteria

When sufficient light reaches the bottom of an aquatic ecosystem to support photosynthesis, benthic nitrogen-fixing cyanobacteria frequently occur. This is true in both freshwater and saline inland waters, and in streams, particularly where current velocities are low and so hydrodynamic disturbance to the mats is minimal. There is relatively little information on nitrogen fixation by cyanobacteria in streams, however, the conditions most conducive to high rates appear to be similar to those in other freshwaters: low inorganic nitrogen availability and high phosphorus, high light, and warmer water temperatures (Marcarelli et al., 2008). In addition to free-living heterocystous cyanobacteria typically found in the benthic and periphyton communities of streams under favorable conditions, there are a few species of diatoms that have cyanobacteria capable of fixing nitrogen living within their cells (endosymbionts). Nitrogen fixation in stream ecosystems is generally patchy and influenced by microhabitat characteristics like substratum type in addition to the nutrient and seasonal environmental factors mentioned above. As such, nitrogen fixation is usually only important locally in river ecosystems.

In freshwater lakes, rates of nitrogen fixation by benthic cyanobacteria tend to be fairly low and range from 0 to 0.3 g N m^{-2} $year^{-1}$ (Howarth et al., 1988a). Rates are frequently higher in oligotrophic lakes than in mesotrophic and eutrophic lakes, since the light intensities at the sediment surface tend to be higher owing to lower phytoplankton productivity and lower concentrations of dissolved organic substances that attenuate light. Benthic nitrogen fixation by cyanobacteria generally constitutes a small proportion of the nitrogen budget of mesotrophic and eutrophic lake ecosystems, but fixation may be important in oligotrophic lakes. For example, benthic nitrogen fixation by cyanobacteria contributes an estimated 6% of the total nitrogen inputs to Mirror Lake (New Hampshire, United States) and 32% of the total nitrogen inputs to Lake Tahoe (California and Nevada, United States) (Howarth et al., 1988a). Some studies have found that grazing on benthic cyanobacteria can reduce nitrogen fixation, although often the effect is small. Other studies have shown a stimulative effect from grazing, sometimes because the light availability to the cyanobacteria increased as overlying sediment and competing phototrophic organisms are removed, or because the supply of phosphorus increased.

Rates of nitrogen fixation associated with marine and saline lake cyanobacterial mats can be very high, ranging from 1 to 75 g N m^{-2} $year^{-1}$ (Howarth et al., 1988a) The nitrogen fixation rates measured at the high end of this range occur in tropical marine environments and are some of the highest reported for any type of ecosystem globally. High rates of nitrogen fixation (10–30 g N m^{-2} $year^{-1}$) have also been reported associated with cyanobacterial mats in constructed wetlands and in salt marshes in both England and the Northeastern United States (Scott et al., 2008; Howarth et al., 1988a). However, these well-developed cyanobacterial mats are usually fairly limited in area, and so nitrogen fixation is generally not an important term in the overall nitrogen budgets of the larger ecosystems in which the mats exist. The factors that lead to the sometimes extremely high rates of nitrogen fixation in coastal marine cyanobacterial mats remain poorly known, but reducing conditions within the mats may result in chemical species of iron and molybdenum that are more readily available to the cyanobacteria, as well as limit oxygen

inactivation of nitrogenase. Thus, as with heterotrophic fixation in anoxic sediments, the energetic cost of the fixation to these cyanobacteria may be low. Such physiologically favorable conditions, combined with high light in the mat environments, likely support high rates of nitrogen fixation.

Nitrogen fixation by cyanobacteria also occurs in seagrass beds, an important coastal marine habitat. These cyanobacteria grow as epiphytes on seagrass leaves and on surface sediments in between the grasses. The seagrass leaves provide a high surface area substrate in the photic zone for the autotrophic N fixers, and overall fixation rates can sometimes be quite high. The conglomeration of organic material that accumulates on seagrass leaves in nutrient-rich estuarine systems can also support some heterotrophic nitrogen fixation in anoxic microzones, though when both light and dark fixation are assayed, higher rates are generally found in the light. In the sediments of these systems, it is not clear whether nitrogen fixation by autotrophic nitrogen fixers is more significant per unit area than that of heterotrophic bacteria. The relative contribution of each to the overall nitrogen economy of the beds likely depends on a number of factors including seagrass growth patterns and overall biomass, water column depth and clarity, nitrogen and other nutrient availability, and other bacterial processes in the sediments which influence nitrogen fixation, such as sulfate reduction.

Conclusions

The process of biological nitrogen fixation is carried out exclusively by a relatively few species of prokaryotes, capable of living in a very wide diversity of aquatic conditions. In most inland waters where biological nitrogen fixation is an important component of the nitrogen economy of the ecosystem, the fixation occurs in either the sediments or the water column, and is fueled either directly (cyanobacteria) or indirectly (heterotrophic species) by light energy. Heterotrophic bacteria fix nitrogen in virtually all lake and estuarine sediments, at low to moderate rates relative to cyanobacteria. Sediment nitrogen fixation is generally higher when the organic matter content of the sediment is greater, and is often balanced or exceeded by nitrogen losses through the microbial process of denitrification. Nitrogen fixation by benthic (sediment and mat) and epiphytic autotrophs can be high under optimal conditions of light and nutrient availability and thereby is important to the local environment of the organisms. However, the area of this type of habitat is limited in most inland waters and so such fixation usually constitutes only a small portion of the total nitrogen input to the ecosystem. An exception is oligotrophic lakes, where nitrogen fixation by benthic cyanobacteria can be a significant overall nitrogen input.

Nitrogen fixation by planktonic cyanobacteria varies greatly among lakes and is generally not of great importance in the nitrogen budgets of oligotrophic and mesotrophic lakes, but can be very important in the nitrogen economy of eutrophic lakes where phosphorus is often present in excess of nitrogen. Heterocystous species of cyanobacteria are the major nitrogen-fixers in both freshwater and saline lakes and estuarine environments. There is a marked contrast in the significance of these N-fixing organisms in the plankton of freshwater versus estuarine systems; when similarly nitrogen-limited, large blooms are often observed to occur and act to alleviate nitrogen deficits in freshwater, but rarely if ever in estuaries. This is in part owing to a greater inhibitory effect of sulfate, present in much higher concentration in estuaries and some saline lakes than in freshwaters, on molybdate uptake. Molybdenum is necessary for synthesis of the most abundant and efficient form of the enzyme nitrogenase which is essential for biological nitrogen fixation, and thus for growth on N_2. Slower growth leaves filamentous cyanobacteria more susceptible to control by grazing and limits development of blooms that can contribute significant nitrogen to an aquatic system via fixation. Several additional chemical, physical, and ecological factors and interactions also influence the extent of cyanobacterial growth and fixation of "new" nitrogen in inland waters. As population and land use pressures around inland waters increase and nutrient enrichment of these systems accelerates, along with changing and intensifying climate patterns, the relative constraints on this important biological process may shift. Current management strategies for controlling eutrophication and problematic algal blooms may need to be re-examined and altered as a result (Conley et al., 2009).

Biodiversity of Inland Waters

AP Covich, University of Georgia, Athens, GA, United States

This is a update of AP Covich, Biodiversity of Aquatic Ecosystems, in *Encyclopedia of Inland Waters*, edited by GE Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00200-3.

This article was reviewed for the *Encyclopedia of Inland Waters*, Second Edition by Section Editor Lars Rudstam.

Glossary

Biodiversity A measure of the number of species and their relative abundances in an assemblage or region, together with the genetic composition and the phylogenetic relationships represented by the community.
Dominance A measure of the degree to which species in a community deviate from equal abundance, i.e., degree of inequality in abundance.
Endemic species Species that live in a specific location, which may either be small (e.g., a specific lake or spring) or large (a specific continent).
Facilitation The concept that some species can enhance the effectiveness of other species in terms of their complementary ecosystem functions.
Functional group Species that have the same or very similar role in ecosystem processing of organic matter (e.g., primary producers, herbivores, predators, or decomposers).
Hydraulic connectivity The degree of linkage among surface and subsurface waters for a particular geographic zone or drainage basin.
Redundancy The concept that species that may partially substitute for one another within a functional group to sustain an ecosystem process.
Species richness The number of species in an ecological community; species richness is one aspect of biodiversity.

Introduction

The astounding diversity of species found among inland waters has attracted a great deal of interest since Hutchinson (1959) asked, "Why are there so many species?" How does it happen that inland waters comprise only 0.01% of the Earth's total amount of water and cover only 0.8% of the Earth's surface, yet these ecosystems support approximately 6% of all described species?

No single factor determines the biodiversity of inland waters. However, one explanation for this remarkable diversity is the high potential for isolation of inland waters across a wide range of temperatures and salinities. These isolated populations can evolve various adaptations to avoid their competitors and predators and increase their chances for coexistence with others species. Because isolated ecosystems are not easily colonized, endemic species can evolve and adapt to specific habitats over many generations resulting in large number of species in the geologically oldest inland waters (Brooks, 1950; Schön and Martens, 2004; Hampton et al., 2018). Many of the endemic species in inland waters occur in lakes that originated more than 100,000 years ago and some of these species-rich ancient lakes have persisted over millions of years (Albrecht et al., 2020a).

The degree of isolation can change over time. In coastal rivers and lakes, some marine-derived species adapted to freshwater as they continued to migrate back to coastal waters to complete their life cycles. But fragmentation of coastal rivers can isolate populations during periods of sea-level change which can result in speciation but also extinctions (e.g., Dias et al., 2014; Miura et al., 2020). Similarly, lakes and ponds are affected by major floods and severe droughts that alter regional hydrologic linkages and change connectivity among these systems. In general, major differences in the age and origins of inland water ecosystems as well as adaptations for dispersal and tolerance of variability in key environmental factors, along with human impacts all can interact to determine species distributions and, therefore, biodiversity of inland waters.

Measuring biodiversity and its use as indices of the environment

Numerous methods are used to measure freshwater species diversity and to document the number of species lost. The earliest measures were based on lists of species that occurred in different locations ("species richness"). Additional measures such as "evenness" or relative abundance of species are also useful and both species richness and evenness are combined in the commonly used Shannon-Wiener index of diversity. Species richness, evenness and the observed log-normal distributions of species abundance were recognized early as having important biological attributes that could be analyzed mathematically (Fisher et al., 1943; Simpson, 1949). These early studies generated new interest in the ecological conditions that caused some species to be rare while others were relatively abundant in samples from different locations (Magurran, 2004).

Measures of biodiversity are also used as indices of environmental quality including those based on freshwater algal, fish, or benthic macroinvertebrate species (Bandeira et al., 2013). Indices based on diatom species richness and evenness were among the first to rely on extensive datasets on species and dominance distributions relative to changes in salinity, acidity, and nutrients as well as flow conditions for monitoring water quality (Patrick and Palavage, 1994). Among macrophytes, early studies showed that species of charophytes were especially intolerant of high nutrient concentrations, especially dissolved phosphorus (Hutchinson, 1975; Lambert and Davy, 2011). Changes in distributions of submerged macroalgae (such as charophytes) and aquatic mosses, are now widely used to monitor rates of eutrophication in deep lakes where increased densities of phytoplankton, especially cyanobacteria, can decrease light penetration and lead to the elimination of macrophytes (Ecke, 2018). Because many taxonomic groups of aquatic insects have extremely high numbers of widespread genera with different levels of tolerance for organic pollution, they also are widely used to measure water quality. Increases in relative abundance of some of these taxa indicate high concentrations of dissolved oxygen and good water quality. For example, the EPT density index is based on the observed relative abundances of the insect orders Ephemeroptera (E), Plecoptera (P) and Trichoptera (T) compared to the total number of individuals of all aquatic insect orders in the samples. High relative abundance of EPT taxa in a sample indicates good water quality based on high levels of dissolved oxygen and low concentrations of toxins (Valente-Neto et al., 2018; Goncharov et al., 2020). The ratio of the number of native to non-native species is also used to measure water quality and habitat condition ("ecological integrity") of freshwaters (Ruaro et al., 2020). Multi-metric indices include environmental as well as biotic factors for regional and nation-wide studies of habitat suitability and water quality (Bolding et al., 2020). These metrics integrate changes in key chemical and physical factors that can affect biotic distributions over a range of time scales. However, many threats to native species losses are not effectively included in these metrics because populations and individuals of species can differ in their responses to toxins (Collen et al., 2014; Cadmus et al., 2019; Taddei et al., 2021).

Biodiversity of major groups of plants and animals

Here, a brief overview of some of the most diverse groups of aquatic organisms illustrates general patterns of biodiversity in inland waters. These examples show that evolutionary history is critical for understanding how diverse communities have developed and how species interact in complex food webs. This summary also provides some insights into the natural and anthropogenic processes that influence species richness and species distributions across inland waters.

Primary producers and decomposers

The number of species in major groups of plants and animals in inland waters differs greatly on a regional basis. For example, there are 12 major groups of algae with more than 770 genera (many with numerous species) known to occur in North America. These diverse groups of algae differ in their nutrient and light requirements as well as their fundamental cell biology. Distinctions among these groups reflect differences in their modes of photosynthesizing and tolerances for different ranges of salinity and water temperatures (Wehr et al., 2015). Most algae are well adapted for wide dispersal by birds and other animals. Along with other freshwater species, there are concentrations of endemic algal species in the photic zone of some very old, deep lakes (e.g., Boedeker et al., 2018). Worldwide, the most diverse group is the green algae (chlorophytes) with over 400 genera and thousands of species in inland waters. Many of these species live in open waters as planktonic (floating) species while benthic species grow attached to surfaces (rocks, sediments, larger plants, and animals). Most species of green algae are free-living but some are parasitic or endosymbiotic (living inside animal species such as freshwater sponges and hydra). The green flagellated algae occur in a wide range of habitats including ponds, lakes, rivers, as well as ice and snow. This group of flagellates includes about 100 genera (44 in North America) and over 1000 species. A single genus, *Chlamydomonas*, has more than 400 species worldwide. Other green algae lack flagella and are typically planktonic. There are approximately 200 genera and thousands of species, the most commonly known genus of chlorophytes is *Chlorella*. Some groups of green algae have large cells and are macroscopic (e.g., charophytes such as *Chara* and *Nitella*). Many species form filamentous colonies of small single cells. The microscopic diatoms constitute another highly diverse and widely distributed group of algae characterized by cell walls composed of silica and can be unicellular or form multicellular colonies. Some species live on hard and soft surfaces; others remain suspended, floating in open waters.

Some other major groups of primary producers, such as "blue-green algae" (cyanobacteria) and euglenoids are sometimes classified differently because of their unique cell biology. Both cyanobacteria and euglenoids photosynthesize and are considered algae by many biologists. Currently, 'blue-green algae' are considered as bacteria, in part because they lack a nucleus. Cyanobacteria are among the earliest life forms on Earth and formed extensive layered rocks of calcium carbonate (stromatolites) as early as

3.5 billion years ago. Cyanobacteria can adapt to wide range of salinities and temperatures (e.g., Iniesto et al., 2021) and include about 120 genera in North America. Many of these species are important because they fix atmospheric nitrogen. Blooms of these organisms cause taste and order problems in water treatment processes and some species produce toxins. Euglenoids have flagella and can move in water. There are 800 named photosynthetic euglenoids in 13 genera worldwide. Another algal group, the dinoflagellates, has distinct flagellar morphology and pigmentation with about 35 genera in North America. Some species produce distinct cysts that are adapted for dispersal and persistence in sediments. A few species are toxic and known to cause serious water-quality problems. Freshwater red algae comprise about 180 species and some species of *Batrachospermum* can dominate low-nutrient, spring-fed streams (Necchi Jr., 2016). Brown algae are the least diverse, with only six freshwater genera and seven species worldwide (many more species are marine). They grow primarily on rocky surfaces in streams and lakes.

The aquatic fungi and bacteria are very widespread and play essential roles in breaking down organic matter (dead leaves, wood, and dead organisms). On a global scale, these microbes are essential for processing dead organic matter and recycling carbon in freshwaters (Tiegs et al., 2019). Different microbes provide food for many types of consumers (detritivores), especially aquatic insects and juveniles of many other groups. There are approximately 600 species of freshwater fungi with about 340 ascomycetes and 300 deuteromycetes. The environments, only 10 species occur in inland waters. Chytridiomycetes have about 1250 species but most are terrestrial or marine (Shearer et al., 2007). Freshwater chytrids degrade chitin, cellulose, and lignin. One species, *Batrachochytrium dendrobatidis*, is known to parasitize and kill certain types of amphibians. This species, along with other factors, contributes to large-scale declines in some frog populations where tadpoles are infected with chytrid fungi (Barnum et al., 2021).

A high diversity of aquatic vascular plants (macrophytes such as littoral submerged, floating, and emergent vegetation) provides important food, cover, and structure in many inland waters across a wide range of latitudes and altitudes (Alahuhta et al., 2020). Some species of aquatic mosses grow in bright light in shallow waters on rocky substrata of rivers and other species grow in low-light levels in deep, clear lakes (e.g., 20 species of *Fontinalis*). Other species (e.g., *Sphagnum*) live in bogs with relatively acidic waters low in nutrients. Ferns and liverworts occur primarily in vernal pools along with a high diversity of other plants capable of growing in habitats with fluctuating water levels. Aquatic vascular plants include 88 families and over 2600 species of angiosperms with a few groups of gymnosperms in wetlands and several types of aquatic ferns (Chambers et al., 2008). The 'horsetail' or 'scouring rush' (*Equisetum fluviatile*) is widely found in wetlands and riparian zones; it is related to the earliest land plants that predate the flowering plants (angiosperms and gymnosperms). Other familiar shoreline plants are flowering plants such as cattails (e.g., *Typha latifolia*), sedges (e.g., *Carex stricta*), rushes (e.g., *Juncus canadensis*), and papyrus (*Cyperus papyrus*). Submerged plant species are especially diverse in persistent habitats with optimal conditions for growth and reproduction such as clear water and stable water levels. Floating species are well adapted to variable water levels and can shade out submerged macrophytes and algae. Floating plants typically have roots that can take up dissolved nutrients in the water but are not anchored to the sediments, unlike many of the submerged and emergent species that are rooted in the sediments. Floating ferns (e.g., *Azolla*, *Salvinia*) and flowering species (e.g., *Trapa*, *Eichhornia*) can cover the surface of lakes and reservoirs, resulting in decreased fisheries and increases in mosquito and snail vectors of human diseases. For example, the water hyacinth (*Eichhornia crassipes*) is a native of South America and was initially distributed as an ornamental plant. Now it is widely distributed in warm waters and can contribute to limiting boat traffic and to major declines in fisheries as it did in Lake Victoria, West Africa, following deoxygenation of the waters. Duckweed (*Lemna*) is another example of problematic floating species and is the smallest flowering aquatic plant. Duckweed grows quickly in nutrient-rich waters and is widely used as a plant bioassay for laboratory toxicological studies. Dense populations of *Lemna* have created numerous problems for water intakes and cooling systems. Major 'blooms' of duckweed have created spirals of massive plant production repeatedly in Lake Maracaibo, Venezuela, a very large coastal lake, where petroleum production is concentrated. Submerged invasive species, such as the widespread *Hydrilla verticillata*, can dominate some warm-water lakes and create problems for fisheries and boating especially when they are not consumed by native herbivores (Langeland, 1996; Shivers et al., 2018).

Aquatic animals

The estimated number of known freshwater animal species exceeds 100,000, and more are being discovered each year, especially in tropical ecosystems. The greatest species diversity in inland waters occurs among the invertebrates. Collectively, they provide a wide array of food for many aquatic and terrestrial consumers, including humans. Their ecological roles and habitat preferences are generally well understood but vary in response to environmental conditions (Thorp et al., 2015). Aquatic insects are the most species-rich group; their estimated abundance varies greatly among families. Dipterans (true flies) are extremely diverse and widespread (Courtney and Cranston, 2015). This order includes 30 families and some 7000 species just in North America with more than 45,000 species globally. One species-rich family Chironomidae (midges) has more than 300 genera and more than 4000 species. Chironomids occur on all continents, including the Antarctica, and on most large oceanic islands. These species live in streams, lakes, and wetlands, and some species occupy wet dead wood. Beetles (Coleoptera) are also extraordinary diverse; however, only 5% of the coleopteran species are aquatic. Even so, this order has about 12,000 aquatic species, similar to the diversity of the caddisflies Trichoptera but lower than the Diptera (Yee and Kehl, 2015). Some species of beetles are highly effective predators. For example, *Dytiscus* spp. inject their prey with digestive enzymes that liquefy and digest a wide range of prey sizes and types. Dysticid "diving beetles" include 4200 species in 175 genera and are worldwide in distribution. Other predatory species occur among the 900 species in 11 of the 36 families of gyrinid beetles. Aquatic beetles can control mosquito larvae in temporary habitats and generally can affect colonization by other aquatic insects (Pintar and Resetarits Jr., 2020). A unique mode of feeding occurs among elmid beetles that bore into submerged dead wood that increases microbial breakdown and nutrient recycling

(e.g., Valente-Neto and Fonseca-Gessner, 2011). Unlike in marine waters, there are relatively few invertebrate groups that have evolved means to feed on dead wood. However, some tropical species of catfishes have microbiomes that allow them to digest wood and other foods (McDonald et al., 2019).

Other aquatic insects that are widely distributed in a many different types of inland waters include the odonates (dragonflies and damselflies) with more than 5680 species. Most of the species occur at low latitudes, especially in the neotropical and oriental tropics. The larvae have developed specialized modes of feeding while in the aquatic phase of their life cycle. Their extendible jaws and complex visual system are especially effective at capturing their prey that range from small invertebrates to tadpoles and small fishes (Kalkman et al., 2008). Another adaptation among the larvae of *Aeshna palmata* is their use of abdominal movements to lure their prey within striking distance (Edgehouse and Brown, 2014). These odonates have not evolved morphological "fish lures" as described for some freshwater mussels (Sietman et al., 2018) or turtles (Drummond and Gordon, 1979), but their behavior is effective in attracting some of their invertebrate prey.

Other less diverse groups are used to compare water quality besides the many species of aquatic insects. Globally there are about 1100 freshwater species of Oligochaeta (Timm and Martin, 2015). Some oligochaetes live in sediments and on submerged plants, insects and bryozoans, snails and sponges (Brinkhurst and Gelder, 2001; Corbi et al., 2005). There is high diversity in Lake Baikal with about 190 species of oligochaetes and more than 70% are endemic and have distinct niches in this extremely deep, well-oxygenated lake (Martin et al., 2019). The largest family (Tubificidae) has about 1000 species. These "blood worms" have oxygen-retaining blood (hemoglobin). *Tubifex tubifex* is found in organic-rich, fine sediment that accumulate in highly eutrophic waters characterized by low dissolved oxygen. They are used as indicators of excessive nutrient inputs that increase organic production leading to excessive decomposition and low dissolved oxygen. Some are freeze-dried and sold as aquarium food for tropical fishes. *Tubifex* can also serve as critical links in the parasite life cycle of *Myxobolus cerebralis* that causes whirling disease in some species of salmonid fishes (Nehring et al., 2016), causing regional economic losses from decreased recreational fishing.

Macroinvertebrates that provide other ecosystem services such as biofiltration include the freshwater sponges (and the bivalves described below). Sponges often attach to hard surfaces and form colonies, while filtering suspended particles in clear lakes and streams. Some species of sponges have evolved to live in extreme environments such as salt lakes and caves. Unlike marine habitats, inland waters have relatively few species of sponges (Van Soest et al., 2012). There are 45 genera with 219 acknowledged freshwater species with the highest diversity in Neotropics with 65 species in 23 genera (Manconi and Pronzato, 2007). Some of the largest and more diverse sponges occur in Lake Baikal (Kenny et al., 2019). Other endemic species live in several other ancient lakes such as Tanganyika, Malawi, Ohrid, Tiberius, Poso, Titicaca and Tana. In contrast, *Spongilla lacustris* is widely distributed and its green colonies contain symbiotic algae (zoochlorella and yellow-green algae) also found in hydra. Closely associated insect species are the spongilla flies (*Climacia* and *Sisyra*), caddisfly larvae (*Ceraclea*), and chironomid midge larvae (*Xenochironomus xenolablis*), which use sponges as protective cover and food.

The Mollusca account for more than 6000 freshwater species (Böhm et al., 2020). There are more than 1200 species of freshwater bivalves in 19 families. The largest family of mussels is the Unionidae, which has 674 species (Graf and Cummings, 2007, 2015). Many of these species are important for biofiltration and biomonitoring but are at risk of extinction (Vaughn, 2010, 2018). Part of the vulnerability of some species is based on their complex life cycles that require dispersal by fishes. Some mussels have species-specific connections with certain fish species that disperse the larvae. The female bivalve releases small larvae (dart-like glochidia) that attach as parasites on fish gills during a period of larval development and dispersal. A few mussel species have evolved a 'mantle flap' of tissue that resembles a prey item that lures the host fishes closer and into range of release of the glochidia by the female mussel as the fish attacks the lure. For example, *Lampsilis reevesiana* is a mussel that uses a lure resembling a small fish (Fig. 1) and attracts smallmouth bass and rock bass as dispersal agents. If these fish are rare or absent, the life cycle of the mussels are disrupted. Overharvesting, water pollution, water diversions and dam construction continue to threaten populations of native mussels. Bivalves also create major ecological problems. Invasive species (e.g., Asian clam *Corbicula fluminea*, zebra mussel *Dreissena polymorpha*, quagga mussel *Dreissena rostriformis bugensis*) have spread widely through lakes and rivers in North America with a

Fig. 1 A female 'broken ray' mussel (*Lampsilis reevesiana*) with a modified mantle flap of tissue that resemble a small fish. The mussel moves the flap to attract fish hosts to disperse larval mussels. From: www.pearl-guide.com/forum/pearl-books-resources/1137-unio-gallery.html.

cascade of effects resulting from their filtering. Declines have occurred among open-water zooplankton and some bottom-dwelling molluscan and crustacean species. Other bottom-dwelling species have increased as a result of changes in the sediments produced by these bivalves (Vaughn, 2010).

Gastropods are also very diverse with 4800 species worldwide and more than 600 species of freshwater snails in 15 families in North America. Some species of freshwater snails have evolved from intertidal marine species and others from terrestrial progenitors (Strong et al., 2008). Thin-shelled snails are widespread and well adapted for dispersal, while the thicker-shelled species are more restricted in their dispersal in ability (Pyron and Brown, 2015). Most species live in shallow waters and are often associated with littoral macrophytes where they graze on attached algae. Spatial gradients of snail distributions are well studied in the exceptionally clear waters of Lake Baikal where 148 gastropod species are known to occur and 78% of them are endemic. There are 80 endemic species between 20 and 30 m that are abundant. The number declines with depth and 39 endemic species are found deeper than 100 m, below the photic zone; only a few species occur at depths greater than 500 m (Sitnikova, 2006). Other variables also determine snail distributions. For example, endemic limpets that are found in deep hydrothermal vents and oil seeds in Baikal (Sitnikova and Shirokaya, 2013; Stelbrink et al., 2015). Unique endemic limpets occur in insular lakes in Sulawesi (Indonesia) where at least three species of planorbid limpets (*Protancylus*) live exclusively as epizoans on endemic pachychilid gastropods (*Tylomelania*). These limpets brood their young beneath their outer mantle, a type of parental care that is distinct among lacustratine pulmonate snails (Albrecht et al., 2020b).

In general, snail morphology and life histories vary greatly in ancient lakes and rivers where endemic species evolved distinct adaptations. Most species in recently formed freshwater habitats have relatively small, smooth, thin shells. Although thin-shelled snails are well adapted for rapid growth and wide dispersal, they are less adapted to avoid shell-breaking predators (Covich, 2010). For example, several endemic freshwater snails such as *Tiphobia horei* (Fig. 2) have evolved in Lake Tanganyika in the African Rift Valley, the second oldest and deepest lake in the world (Livingstone, 2003). Their shells are characterized by sharp spines that are

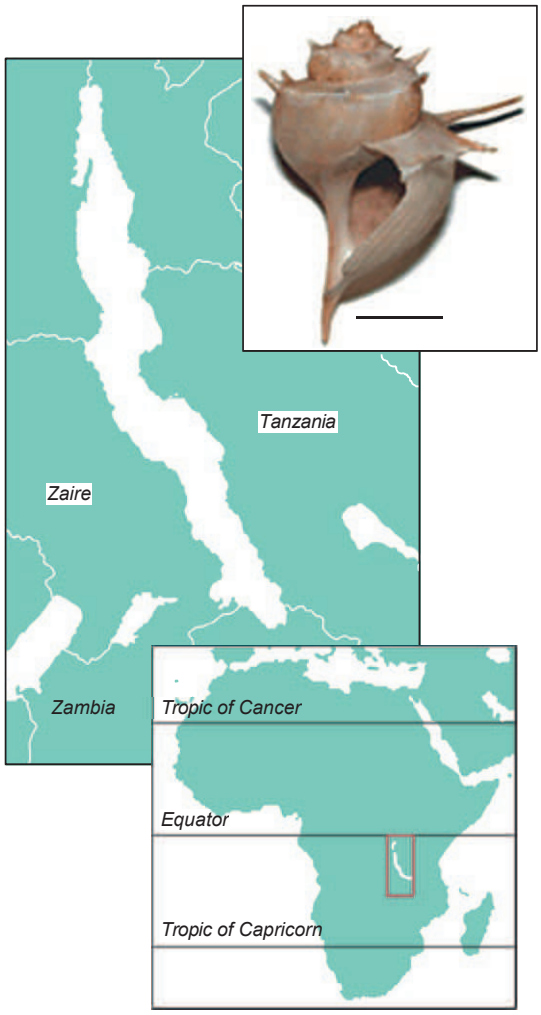

Fig. 2 A deep-water snail, *Tiphobia horei*, from Lake Tanganyika with spinose shell adapted to avoid predation by shell-breaking fishes. From: Livingstone DA (2003) Global climate change strikes a tropical lake. *Science* **301**: 468–469. The 1 cm scale indicates that these thin spinose shells are relatively large for freshwater gastropods.

anti-predator adaptations as often occurs among species of marine snails (Vermeij, 2019). These spinose shells have developed apparently in response to specialized shell-breaking cichlid fishes and crabs in this ancient lake (Marijnissen et al., 2008). Several near-shore snail species of *Lavigeria* in Lake Tanganyika grow into a size refuge once they are larger than 15 mm in shell length and spend more time on various surface substrata during the day. Predatory crabs are unable to break these large shells. Consequently, the snails are able to graze efficiently in the brightly illuminated microhabitats. In these well-lit waters, the snails accumulate a thick cover of algae that grows on their shells, creating a symbiotic snail-epibiotic algal relationship (Lukens et al., 2017). Another example of complex inter-relationships in this ancient lake occurs among one of the many cichlid fish species, *Telmatochromis temporalis*. This fish has two size morphs. The smaller individuals protect their eggs by laying them in empty snail shells of *Neothauma tanganyiicense* that occur in light brown sandy sediments. Individual fish among this dwarf morph change their color when moving across the sand from a pale to a dark color after they enter the shells seeking cover and protecting the eggs (Takahashi, 2019).

The Crustacea constitute another large group with about 10,000 species. Many are abundant and have key roles in freshwater ecosystems (Covich, 2015; Thorp et al., 2015). Crustaceans include a wide range of sizes of organisms from large river shrimp, such as *Macrobrachium carcinus*, which as adults are the size of marine lobsters, to smaller organisms such as cladocerans, copepods and ostracods. The cladocerans ('water fleas' such as *Daphnia magna*) include about 80 genera with some 4000 species. These crustaceans are also well adapted for wide dispersal by forming resistant stages, which are transported by birds and other animals. Most species are grazers on planktonic algae, while others are benthic and feed on sediments and algae growing on larger aquatic plants. Copepods are other important planktonic and benthic grazers. Harpacticoid copepods include about 300 species, calanoid copepods about 575 species, and cyclopoid copepods about 490 species in freshwaters. Some of the cyclopoids are parasitic on fishes. These zooplankton are often very abundant seasonally and many species have adapted to avoid fish predators by migrating into deep waters during daylight hours. The ostracods are small, mostly bottom-dwelling consumers with a worldwide distribution in inland waters with more than 2000 species in about 200 genera (Smith et al., 2015). Only a few ostracod species swim into open waters. Most species consume algae and dead organic matter (detritus). Some species are commensal and attach to the carapace of crayfishes. Ostracods live in a wide range of lakes, ponds, vernal pools, and caves, with some specialized species being restricted to saline waters while others are only found in calcium-rich waters or in small pools ('tanks') of bromeliads growing on tropical trees. Like other small crustaceans, these species are passively dispersed long distances by animals. However, most ostracod species are distributed in a single zoogeographic region and many species are endemic (Martens et al., 2008). For example, ostracods have evolved high concentrations of endemic species in ancient lakes such as Baikal (Schön et al., 2017) and Tanganyika (Schön et al., 2014).

The amphipods occupy a wide range of habitats from exceptionally deep lakes to ponds, vernal pools, and caves. There are some 1870 species and subspecies of amphipods; high concentrations of species are found in Lake Baikal (Siberia), Lake Titicaca (Peru), Tasmania, and the southeastern United States. For example, the amphipod *Acanthogammarus godlewskii* is one of the many unique species in Lake Baikal. It has sharp lateral spines that serve as effective adaptations to avoid cottid fish predation (Fig. 3). This crustacean species is one of more than 260 species of amphipods in 50 genera in Lake Baikal. Spinose armature also evolved among amphipod species in Lake Titicaca, apparently in response to predation by some of the endemic cyprinodontid killifish (*Orestias* spp.).

From: Czaja A, Estrada-Rodríguez JL and Romero-Mendez U (2015) A new species of the genus Mexipyrgus Taylor, 1966 (Caenogastropoda: Truncatelloidea: Cochliopidae) from late Holocene spring deposits in Viesca, Coahuila, Mexico. *Nautilus* **129**: 163–168.

There are only about 70 freshwater species of the largely marine group of mysid or opossum shrimps. They are highly mobile and remain out of sight during daylight hours to avoid visual predators such as large fishes. Species in the *Mysis relicta* group are large zooplankton that undergo vertical migrations to limit their exposure to fish predators, others are littoral species that hide under rocks or among plants during the day. Mysids are omnivores and can be important predators on smaller zooplankton. Non-native mysid species were intentionally introduced in some lakes to enhance salmonid fisheries production but the unexpected cascade of changes was often detrimental to sustaining stable food webs (Ellis et al., 2011; Ricciardi et al., 2012). Because of their ability to migrate daily into a deep-water refuge, mysids are well adapted to exert major impacts on zooplankton prey populations and can compete with fish that feed on zooplankton (Gal et al., 2006).

Decapods are among the most diverse groups of crustaceans. For example, the total worldwide number of described crayfish species is over 640, and they are concentrated in two centers of diversity (Crandall and Buhay, 2008). The first is the southern Appalachian Mountains and the southeastern United States, where crayfish occur in subsurface waters as well as in small streams, rivers, lakes, wetlands, and springs. In all of North America there are over 340 crayfish species. The second center of diversity is located in southeast Australia where the largest freshwater crayfishes (*Astacopsis gouldi*) occur in Tasmanian rivers and are reported to weigh over 6 kg and live for 40 years. The Murray River crayfish (*Euastacus armatus*) is another very large Australian species that has evolved a spinose carapace (hard exoskeleton or shell) and large chelae (claws).

Crabs also occur in inland waters and have strong claws that can crush a wide range of animal prey, fruits, and nuts; their diversity is especially high in Neotropical, African, and Asian waters. Over 1300 species of freshwater crabs complete their life cycle independently of marine environments (Yeo et al., 2008; Cumberlidge et al., 2014). For example, some marine-derived species of freshwater crabs are known to have expanded their dispersal into coastal rivers during cycles of sea-level expansion and contraction throughout the Pleistocene. The diversity among species of *Parathelphusa* was not driven only by these regional fluctuations but was complexly connected with earlier dispersal events to rivers and ancient lakes in parts of southeast Asia (Klaus et al., 2013; Poettinger and Schubart, 2014). Some freshwater crabs are semi-terrestrial (amphibious) and link aquatic and terrestrial ecosystems. Freshwater crab species have evolved numerous endemics on large, isolated islands such as Madagascar, with six genera. The co-evolution of crabs and snails is widely documented in mainland and insular freshwaters (von Rintelen et al., 2004; Schubart and Ng, 2008; Marijnissen et al., 2009; Covich, 2010).

Freshwater shrimp also evolved from marine ancestors as they adapted physiologically and behaviorally to moving upstream into large coastal rivers, headwater streams, and lakes (De Grave et al., 2008; Bauer, 2013). Insular habitats have relatively high diversity of endemic species as in Madagascar. New species continue to be found among Indonesian insular lakes in Sulawesi (von Rintelen et al., 2020; Klotz et al., 2021). One endemic species of atyid shrimp (*Caridina spongicola*) found shelter and food in freshwater sponges and another species (*Limnocaridina iridinae*) associates with a bivalve species (*Iridina* sp.) in Lake Tanganyika (Zitzler and Cai, 2006; von Rintelen et al., 2007). Many inland waters of China are occupied by unique species of shrimps. Lake Tanganyika and the Amazon River basin also have unique endemic genera of shrimps.

Some benthic macroinvertebrates are associated with complex feeding behavior and numerous species interactions such as the many types of leeches. They are active predators and ectoparasites found in association with a wide range of larger invertebrate and vertebrate species. They are prey for many species such as fishes, snakes, salamanders and some invertebrate predators (Govedich and Moser, 2015). Leeches (Hirudinida) occur globally, except in Antarctica, with over 400 species in 91 genera in wetland, stream and lake habitats. Two ancient lakes, Siberian Lake Baikal and Balkan Lake Ohrid, each have 10 endemic species (Sket and Trontelj, 2008). The leech fauna of Lake Baikal consists of a total of 28 species. These species parasitize endemic amphipods and other species; for example, *Baicalobdella* infects sculpin fishes (Kaygorodova and Sorokovikova, 2014). Leeches affect the health of host species by causing ulceration, hemorrhage, and inflammation. Leech attachment sites can open the host to bacterial and virus infections as well as transmit trematodes, cestodes, nematodes and parasitic flagellates.

Several groups of invertebrates are among the smaller and often unnoticed species. Rotifers are microscopic, multicellular animals sometimes called 'wheel animalcules,' based their rings of cilia that appear to rotate like spinning wheels in the microscope. Rotifers are very abundant, functionally important consumers, and comprise about 2000 species. A single tropical lake can contain more than 200 species, while fewer species are often encountered in temperate-zone lakes, springs, vernal pools and ponds (Segers, 2008; Brown et al., 2020). They are primarily filter-feeding herbivores and detritivores, although a few species are predators and some are parasitic. Size and shape of some species is modified by the presence of predators (induce spine formation) and by their diet (vitamin E induces larger individuals). Most rotifers live as solitary, planktonic individuals but some species are attached (sessile) to plants, rocks, and other hard surfaces and about 25 species are colonial. Rotifers are prey for larger zooplanktonic species of insects and crustaceans.

Other small invertebrates include the approximately 1300 species of free-living freshwater flatworms (Planaria or Turbellaria). Most species live in crevices of well-oxygenated sandy, stony or muddy sediments in rivers and lakes or on macrophytes leaves and roots while some are found in streams that flow through caves. Flatworms can switch from living in the littoral zone to living in the open water depending on the relative risk to predation and to food quality (Dumont et al., 2014). Some planarians (triclades) are cannibalistic while others are predatory on zooplankton or on oligochaetes, chironomids, amphipods and other benthic invertebrates. A few species are ectosymbionts that live on crustaceans, snails, insect larvae and turtles where they ingest algae and small prey suspended by the host-generated turbulence (Noreña et al., 2015). Triclads are widely known for their ability of regenerate and are used in laboratory studies where identical individuals are useful to test responses to various manipulations independent of genotype. Some species of *Girardia* have well-studied life cycles, distributions, and ecology because they are enteric

parasites and create health concerns for humans relative to drinking untreated stream water. *Girardia tigrina* was introduced to Europe and *Girardia dorotocephala* was introduced to Hawaii from North America (Sluys et al., 2005).

The free-living nematodes are additional micro-metazoans that live in sediments of many inland waters (Poinar Jr., 2015). They range over a wide range of sizes and can occur at high densities (>1 million individuals per m^2). Along with other meiofauna they provide essential roles in nutrient cycling and in benthic food webs (Traunspurger, 2013; Majdi and Traunspurger, 2015). Some feed on bacteria and algae while others are predators and all are subject to predation by other groups of meiofauna, benthic macroinvertebrates, and some vertebrates (Abebe et al., 2008; Hodda et al., 2009). Nematodes are another group that evolved relatively high numbers of species in Baikal with about 65% of the more than 100 species considered as endemics (Naumova and Gagarin, 2019).

Another widely distributed group are the small "water bears" or tardigrades. Their common name derives from their movement behavior and use of multiple claws on their legs to hold on to surfaces, especially aquatic mosses and other macrophytes. Videos of their walking demonstrate interesting jumps and quick moves along with their slow forward motion. Those living in freshwaters are well adapted to a broad range of temperatures that allows them to survive in freezing conditions, intense UV radiation, complete desiccation in very dry environments, and even exposure to vacuum pressure in outer space. Although some species commonly reproduce parthenogenetically, many other species produce resistant eggs during periods of stress that also allow for local and regional dispersal (Nelson et al., 2015; Schill, 2019).

Because of their size, and often their important economic value, vertebrate distributions are generally more completely documented than invertebrate distributions. There are more than 20,000 known vertebrate species in inland waters, including nearly 18,000 species of freshwater fishes (Lévêque et al., 2008; Su et al., 2021). More than 1600 fishes are known just from the Amazon River basin (Albert et al., 2020). Other major concentrations of fish diversity occur in the Congo River (Stiassny et al., 2011) and in the Mekong River (Chea et al., 2017). In the African Rift Valley Lakes, remarkable species 'flocks' have apparently evolved in isolation from other lakes during prolonged dry periods. Approximately 250 cichlid species evolved in Lake Tanganyika, more than 800 in Lake Malawi and some 500 in Lake Victoria. Very rapid evolution of endemic cichlids is known from Central American crater lakes in Nicaragua. Hybridization can greatly increase the genetic and phenotypic diversity of cichlid flocks and result in important differences in morphology, feeding behavior and coloration. The extraordinary diversity of cichlids indicates the importance of understanding appropriate spatial and temporal scales in analyzing rates of speciation (Genner et al., 2007; Meier et al., 2017; Rometsch et al., 2020).

Turtles are another widespread, diverse group of vertebrates that play important roles in food webs of inland waters (Stanford et al., 2020). Their potential for long life and variations in life-cycle traits and local spatial distributions (e.g., seasonal movements and home ranges) are well known from studies that have recaptured marked individuals (e.g., Sexton, 1959, 1995) or used radio tracking to define travel patterns (Rowe, 2003). There are interesting differences among their life histories in that some species have indeterminate growth while others do not. Females among many species are known to reproduce late in life. For example, female Blanding's turtles (*Emydoidea blandingii*) can increase their reproductive output after 65 years of age by slowing their growth rates and allocating more energy to reproduction (Congdon et al., 2003). Turtles feed on many types and sizes of plants and animals as they mature. These ontogenetic shifts in diet increase the potential for coexistence among age classes. Among the unique fauna are the alligator snapping turtles (*Macroclemys temminckii*) in southern US that evolved a lingual lure that is moves to attract fish prey (Drummond and Gordon, 1979). This use of "fish lures" is very different from the way mussels attract fish to serve as dispersal agents (Fig. 1), but demonstrates the complexity of species interactions in diverse food webs. Many turtles are at risk from habitat fragmentation, pollution and overharvesting in many areas, especially in tropical waters where human population growth is threatening their future (Rhodin et al., 2018).

Global patterns of biodiversity in inland waters

One limitation in understanding patterns in global biodiversity is that hypotheses regarding the formation of species assemblages in various kinds and ages of inland aquatic habitats often are based on information from a limited subset of well-studied species. Another limitation is the incomplete geological, environmental, and historical information in many regions, especially from tropical inland waters. Even so, the examples in the previous sections regarding the highly uneven distribution of the number of species in different major groups of freshwater organisms demonstrate some biogeographic distributions that provide insights about speciation and the potential loss of species from centers of diversity. The dispersal ability of different groups is also important. Species of plants and invertebrates that are adapted for inland waters have generally evolved some means of dispersal. Many have resistant stages (seeds, hardened egg capsules, etc.) that allow for transport and colonization as well as persistence in "seed banks" that can regenerate populations (species "resurrection" from lake sediments) when favorable conditions occur (Hairston and Fox, 2009). The "ubiquity hypothesis" proposed for the smallest organisms (algae, bacteria, fungi, and some small invertebrates) suggest that those species are widely and uniformly dispersed (Fenchel and Finlay, 2004; Fontaneto and Hortal, 2013). The presence of such species in a given waterbody reflects current environmental conditions rather than isolation and dispersal. It is clear that some species have stages in their life histories that allow them to become inactive during stressful conditions (e.g., Vyverman et al., 2010). Other species such as fishes, turtles, and mammals (e.g., beavers, otters, raccoons) are excellent swimmers while some are strong flyers (e.g., wading birds, some insects). Thus, many species can disperse over long distances during some periods of their life cycle or in response to environmental change.

Unlike most marine and terrestrial ecosystems, the biodiversity of inland waters is generally independent of latitude. Fish distributions are an exception with a clear latitudinal gradient of more species in the tropics (Lévêque et al., 2008; Leroy et al., 2019; Miller, 2021; Su et al., 2021). In general though, the biodiversity of the major groups of invertebrates does not follow latitudinal trends or has a single explanation for predicting species assemblages (e.g., Dumont, 1994; Gillooly and Dodson, 2000; Les Eyzies and de Ciencias Biologicas, 2013). This lack of a latitudinal pattern is a result of the highly isolated nature of many inland waters and their varied types of geological origin (such as glaciation, tectonic activity, and dissolution of limestone).

Freshwater biodiversity generally reflects the major differences in the geological origins and ages of inland waters. However, because of the great variation in persistence of inland aquatic habitats, there is no single physical variable that adequately predicts how many species of any taxonomic group will share a given habitat. Some inland water habitats dry out completely every year, while others remain permanently wet. The large flowing rivers, deep lakes, and extensive wetlands frequently are colonized by dispersing species. These ecosystems can have many endemic species that coexist and coevolve in spatially distinct habitats over millennia. Dispersal, colonization, and local extinction explain a community's natural species composition over time.

It is clear that system age is important. Most inland waters can be considered temporary in a geologic sense in that they can eventually fill with sediments, dry out, or change physically and chemically in other ways over geological and historical time scale. For example, the North American Great Lakes took their present form during the last glacial retreat, only some 12,000 years ago. However, there are some very old lakes with remarkable species. Lake Baikal is the deepest (>1600 m maximum depth) and oldest lake in the world with an exceptionally long geologic history (more than 25 million years old) and extremely low nutrient concentrations. Lake Baikal contains 20% of the Earth's freshwater and has maintained one of the highest biodiversity found in any inland water with a large number of endemic species in several different groups. Shifts in Baikal's many complex environmental gradients over its long geological and evolutionary history affected the evolution of this unique biota; biota that is threatened by ongoing effects of climate change and landuse (Timoshkin et al., 2016; Hampton et al., 2018). Other lakes that are millions of years old are Tanganyika, Malawi, Victoria, Ohrid, Biwa, and Titicaca and the early dispersal of some groups to these isolated sites led to evolution of unique species and species "flocks." These ancient inland waters have attracted intensive research on the mechanisms of speciation (Schön and Martens, 2004; Hampton et al., 2018). In general, fluctuations in lake levels from climate-changes and paleohydrology over millions of years have created numerous endemic species in ancient lakes. For example, the evolution of species "flocks" and many endemic species of diatoms, gastropods, amphipods and fishes in Lake Titicaca resulted from regional changes in evaporation-precipitation ratios that altered water levels and sizes of several lakes with internal drainage (endorheric) throughout the central Andean high plateau (Jurado-Rivera et al., 2020; Zapelloni et al., 2021). Other ancient lakes, like Lakes Tanganyika and Malawi are especially well known for the large concentrations of endemic cichlid fishes. This is also true for Lake Victoria, but this lake is not as old and may have been affected by drought during the Pleistocene, which lowered the level of this lake, possibly accelerating the rate of evolution among the highly diverse cichlid fishes in perhaps just 15,000 years. However, short-term changes from recently introduced species have altered the diversity of native species in Lake Victoria. Population reductions of endemic cichlids followed the introduction of the Nile perch (*Lates niloticus*) in the 1950s; an introduction intended to increase sport fisheries and commercial harvests. Unfortunately, concentrations of endemics that have evolved from a single ancestral line can be vulnerable to rapid novel environmental changes such as introductions of non-native species as in Lake Victoria or the warming of surface waters and earlier melting of ice cover as is occurring in Lake Baikal (Njiru et al., 2010; Hampton et al., 2018).

Most of the 10 largest rivers are also ancient, highly diverse ecosystems. The Amazon River is the largest and has by far the highest mean annual discharge and drainage area. This basin also contains the largest number of freshwater fish species and has a high species richness of crustaceans and many other taxa. Other large tropical rivers such as the Congo (Stiassny et al., 2011) and Mekong (Chea et al., 2017) also have unique fish species diversity as a result of their complex channel networks, high-velocity barriers, and seasonal connections to large wetlands that provide numerous types of habitats. The evolution of different species in large rivers can result from isolation of habitats by very deep channels with complex rapids and by exceptionally high current velocities that separate populations on one side of the river from populations on the other side (e.g., Markert et al., 2010). Isolation also occurs from differences in flows and substrata associated with rapids (Hrbek et al., 2018) as well as by adaptations for traversing steep waterfalls (e.g., Hongjamrassilp et al., 2021; Ebner et al., 2021).

Additional insights about species diversity and biogeography are based on species that live in extreme environments of temperature and salinity as well as in dark caves, deep groundwaters, springs, and intermittent habitats (Gibert et al., 2009; Pipan et al., 2020). These species demonstrate a wide range of unique evolutionary adaptations that illustrate the physiological limits to distributions in very different habitats (Benvenuto et al., 2015; Baxter and Zalar, 2019). For example, brine shrimp (*Artemia*) dominate in hypersaline waters that few other species can tolerate, and are highly productive in those lakes. Their life cycle includes production of "resting eggs" that can withstand low-saline conditions until the environment is again appropriate for the eggs to hatch (e.g., Barnes and Wurtsbaugh, 2015). Many other well-studied examples are known from a wide range of salinities of inland waters in arid central Australia and South America (e.g., Bayly, 1993). Isolated springs in arid regions have large numbers of endemic species that are threatened by increased frequencies of drought and diversion of groundwater (e.g., Shepard, 1993; Box et al., 2008).

Biodiversity in freshwater habitats on islands provides opportunities to evaluate the importance of age as well as area and isolation of freshwater habitats relative to source areas (Arnott, 2009; Covich, 2009; Burress et al., 2018). Well-adapted species colonize these insular habitats either by dispersal from other freshwaters or by adapting to freshwaters from near-shore marine habitats. For example, in the south Pacific, Lake Wisdom is a deep crater lake on a recently formed volcanic island that is known to be younger than nearby Lake Dakataua, another caldera in West New Britain, Papua New Guinea. More species of aquatic plants and

aquatic invertebrates are found in the older lake but there are some similar species in both lakes. These shared species were most likely transported by birds and includes similar species on other nearby islands (Ball and Glucksman, 1980). Crater lakes can also be linked to springs and small streams flowing from the lakes. These small streams can function as corridors for movements among molluscan, decapod, insect, turtle, salamander and fish species, allowing for relatively rapid colonization of the lakes from marine-derived species that have adapted to low salinities in coastal rivers.

Hydrologically isolated lakes, springs and wetlands are similar to oceanic islands in that only species with special adaptations can colonize them. The duration of isolation may allow evolution of distinct endemic species, especially in arid regions where long distances separate potential sources of dispersal. Speciation may result in species flocks in permanent springs, ancient rivers, and deep lakes. Radiation (extensive development of new species) of some taxa can occur rapidly. For example, gastropod speciation is well documented in both large, ancient ecosystems and in small streams, springs, and groundwater habitat. Rapid radiations of some amphipod and gastropod species are apparently the result of micro-geographic isolation resulting from changing water levels during periods of rapid shifts in precipitation and the isolated nature of many spatially distinct small habitats. Genetic analyses are increasingly demonstrating the importance of these modes of speciation. High diversity of endemics and accumulation of species from both this process of speciation and slow rates of colonization from other regions can create distinct 'hot spots' of regional biodiversity. One of the most extensively studied clusters of spring-fed lakes and rivers occurs in the Chihuahuan Desert in northwest Mexico. The ecoregion contains a high concentration of endemic species that resulted from a long series of fluctuations in rainfall and groundwater levels (Czaja et al., 2015, 2020). Endemic species of fishes, turtles, shrimps, snails and an exceptionally high diversity of cyanobacteria have evolved in a complex food web. Some of the Mexican species of snails have sculptured shells that lower their risk to fish predation (Fig. 3).

Overall, there is a general relationship between size, age, geomorphology, and hydrology that influences species diversity of inland waters. However, unlike marine and terrestrial ecosystems, latitudinal diversity gradients are lacking for many groups of freshwater plants and animals, in part due to the high diversity of Baikal and other very old, deep lakes outside the tropics.

Loss of biodiversity

The highest rates of extinction in recent decades have occurred among freshwater species. These rates of loss are several times greater than those of terrestrial species or marine species. Inland water species are increasingly threatened from pollution, overharvesting, as well as dams and reservoirs that block dispersal corridors and that change natural flow regimes (Winemiller et al., 2016). Pollution and siltation have increased rates of extinction and loss of diversity through habitat degradation or complete elimination of some freshwater habitats. Recent increases in global transport of nonnative species are also changing distributions of some intentionally and accidentally introduced species from aquaculture, sport fisheries, and aquarium trades (Ricciardi, 2007; Havel et al., 2015). The impacts of these losses are further compounded by the negative effects of many invasive species and increased appropriations of freshwater for human needs at the expense of native species (Dudgeon, 2020; Rico-Sánchez et al., 2020). Loss of native freshwater species is a major concern because of the ethical values associated with preserving native species in protected areas and the value of native species for human use as well as for scientific study of evolutionary and ecological processes.

Although many species are well studied in inland waters, a large number remain taxonomically, ecologically, and behaviorally incompletely or entirely unknown, especially in tropical regions (Dudgeon, 2020). These major gaps limit our current understanding of the long-term impacts of species losses in aquatic ecosystems and the ability to predict sustainable production of ecosystem services. Most ecologists expect that rapid shifts in community composition will likely result in loss of important ecosystem processes and related ecosystem services (Covich et al., 2004). Once one species is locally or globally extinct, other species may not be adequate substitutes for the lost species in sustaining ecosystem processes. Partial species replacement or 'compensation' can occur in some cases for short periods of time (e.g., Frost et al., 1995), but complete, long-term functional replacement is unlikely because most native species have adapted to a lengthy history of different, and sometimes extreme, environmental changes. Consequently, assumed substitutability of "substitute species" in a particular functional group is unjustified without long-term studies (e.g., Lake et al., 2000). Loss of key species can not only affect short-term nutrient cycling but also diminish fisheries production (McIntyre et al., 2007) and sever connections among freshwater and terrestrial ecosystems (Naeem et al., 2012). Many decades of research have demonstrated that biodiversity in inland waters has economic value and a variety of ecological and social values (Heal et al., 2005; Heino et al., 2021). Despite this recognition, the remarkable biodiversity of species in inland waters is increasingly in need of protection and effective management to sustain essential ecosystem services (Dudgeon et al., 2006; Reid et al., 2019; Stanford et al., 2020). Much more information is needed on global distributions of species and their function in the ecosystem (Collen et al., 2014).

Populations in Inland Waters

Matthew P Hare and Lars G Rudstam, Department of Natural Resources and the Environment, Cornell University, Ithaca, NY, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor, Lars Rudstam.

Glossary

Carrying capacity, K The maximum population size of a given species that can be sustained by a specific environment. It is an attribute of the environment where the population exists.

Demographically correlated populations Two or more groups of individuals with correlated vital rates (survival, fecundity) or population growth rates over time.

Dispersal/migration These two words are used as synonyms as is the convention in population genetics. Both terms refer to the movement of individuals away from their birth place. Demographic consequences of that movement depend on intraspecific and ecological interactions after dispersal whereas evolutionary consequences depend on interbreeding after dispersal.

Effective population size, N_e In small populations genetic drift causes greater random changes in allele frequencies between generations than it does in large populations. However, the census number of adults is relatively uninformative about the strength of drift because demographic factors such as skewed sex ratio, high variance in reproductive success, and fluctuations in census population size over time can all increase genetic drift for a given census population size. If we consider an imaginary, demographically "ideal" population that has none of these factors enhancing genetic drift, then N_e = the size of the ideal population that would experience drift as strongly as the observed focal population. For the theoretical ideal population N_e = census N, but in most real populations N_e is 5–10 times lower than census N.

Evolutionarily correlated populations Two or more groups of individuals with correlated patterns of gene frequency variation over time.

Gene flow (effective migration, mN_e) Genes travel as a function of dispersal, but only get passed on to the next generation and generate "gene flow" if an immigrant interbreeds. Thus, gene flow is an evolutionary process. The per generation rate of gene flow is the product of the migration rate, m, and genetically effective population size of the receiving population, N_e.

Genetic drift Random changes in allele frequencies between generations due to finite population size. The alleles in a cohort of offspring are a sample from the previous (parental) generation. Chance differences in survival and reproduction contribute to sampling error. Smaller populations experience stronger genetic drift.

Intrinsic rate of increase, r (instantaneous rate of increase) The difference between instantaneous birth and death rates. A parameter in the logistic growth equation that indicates the per capita growth rate per unit time.

Logistic population growth A sigmoid population growth model that describes the exponential increase at low population size and decreasing rate of population growth as the population approaches its carrying capacity.

Metapopulation A set of spatially discrete populations that exchange migrants and in which some extinction and recolonization of habitat patches occurs. The term is often used more loosely as any spatial array of subpopulations that exchange migrants to some limited degree. If there is enough connectivity to make the subpopulations demographically correlated then the whole system is a population, not a metapopulation.

Phylogeography The use of molecular markers (e.g. DNA variation) to trace the extended genealogy within and among populations of a species to understand demographic history and evolution of the populations.

Introduction

"Population" refers to a group of individuals of the same species that interact more with each other than with other individuals of that species. Such a general definition serves well in many contexts, but any deeper investigation tends to be from a particular perspective shaped by specific questions. To understand population dynamics and persistence probabilities an ecologist might focus

on competitive or facilitative interactions in the context of predation and disease, whereas a demographer is focused on immigration and emigration and their effects on the life table and population growth. Similarly, an evolutionary lens puts focus on reproductive interactions of residents and immigrants and the impact of gene flow on random population genetic changes (genetic drift), the deleterious consequences of inbreeding, and how these processes interact to affect adaptive potential. Because different kinds of interactions are more important for various questions about a population, the definition of population boundaries might differ across studies, especially when physical boundaries that limits distributions are fuzzy.

In freshwater aquatic systems there is often a discrete landform that imposes population boundaries - a lake shore or watershed perimeter. Neither of these boundaries are necessarily absolute, that is able to contain a closed population (no immigrants; entirely self-recruiting). Lakes and ponds typically have inlet and outlet connections and watersheds can connect at their downstream junction. Nonetheless, for many species these landforms enforce a discrete population structure with relatively few migrants. At the other end of the spectrum are macrogeographic watersheds containing semi-continuously distributed species. Is the entire watershed a population? In these cases interactions are quantitatively greater and qualitatively different within local habitats than across distances much greater than the average dispersal distance. It is in these less discrete contexts that useful population definitions often depend on the question being asked, and as a consequence there are many definitions that have been applied.

The working definition of a population is also important for conservation and management. Leaving aside the reality that political jurisdictions often impose population definitions for the purposes of conservation, restoration or management of harvest, it is critical that management plans properly account for the ecological, demographic and evolutionary forces that affect population dynamics.

For an operational definition it is useful to focus on process rather than pattern because habitats are dynamic, and population boundaries vary as a function of habitat. Population abundance and spatial distribution are patterns that might suggest where one population ends and another begins. Demography entails the processes wherein individual traits like fecundity and survival (vital rates), along with immigration, emigration, and habitat quality, determine the local trajectory of population size change. If populations on two adjacent habitat patches change in synchrony, then the pattern suggests one population occupies both habitat patches. If we find that the species has a growing population in one habitat patch and is declining in the other, the two habitats have different populations and the demographic process lens helps identify the scale at which distinct management actions may be needed. Similarly, if two populations have different gene frequencies, that is a pattern that implies evolutionary differentiation and the need to manage the populations separately.

In this chapter we follow others in arguing for distinct definitions of demographic and evolutionary populations (Waples and Gaggiotti, 2006; Cooper and Hurd, 2019). We will address demographic and evolutionary population definitions conceptually first, and then address operational metrics for delineating populations.

The ecological population paradigm

Demographic and ecological processes often are considered together under an "ecological population paradigm." Thus, many definitions have focused on proximity and interactions; "A group of individuals of the same species that co-occur in space and time and have an opportunity to interact with each other" (Waples and Gaggiotti, 2006). Boundaries have been conceptualized as defining the spatially most inclusive set of individuals for which the rate of intraspecific interactions is much higher within the grouping than across groupings (Millstein, 2010). Others have emphasized the degree of immigration and emigration over some time period (Cooper and Hurd, 2019) in defining the population. The key feature of a population under the ecological paradigm is that population dynamics, i.e. births and deaths, are determined locally within an ecologically cohesive group. Unfortunately, very little theory has been developed to guide expectations for how low the immigration rate, m, needs to be to maintain independence of the group's population dynamics from that of surrounding populations. Hastings (1993) used coupled 2-population deterministic models to demonstrate a complex relationship between dispersal rate and the independence of local population dynamics. The analysis suggested a strong dependency of results on the intrinsic rate of population growth for intermediate migration rates, but in general $m < 0.1$ (10% immigration per generation) led to independent population dynamics (Hastings, 1993). However, White et al. (2011) found a substantial amount of coupling at $m = 0.1$ between the demography of two populations when one was experiencing strong harvest pressure. More work is needed; it may be premature to use $m < 0.1$ as a threshold for identifying discrete management units (Palsbøll et al., 2007).

The evolutionary population paradigm

Whereas competition and perhaps cooperation within a shared niche are the currency of cohesion under the ecological paradigm, the degree of evolutionary independence for a population is determined by a different kind of interaction - reproduction - and the source and magnitude of gene flow. Genetic drift is the random genetic change that occurs within and between generations. It shifts allele frequencies with unpredictable directionality at a rate that is the inverse of population size. Genetic drift reduces genetic variation within populations and causes differentiation among populations that may lead to populations evolving into new reproductively isolated species.

Recent and contemporary processes have effects on populations that are overlayed and intertwined with phylogeographic history. In particular, natural selection often generates spatial variation in organismal traits so dramatic that it shapes our perception of deep population divisions, as often reflected in subspecific taxonomy. In fact, however, adaptive traits can evolve relatively quickly compared to the deep history generating phylogeographic structure. Also, strong natural selection can maintain adaptive differences between populations even when a considerable amount of gene flow connects them (Lenormand, 2002; Richardson et al., 2014). Genomic studies are showing how portions of a genome that contribute to local adaptive trait variation can have lower realized gene flow than other regions of the genome (Martin and Jiggins, 2017). Thus, the degree of evolutionary correlation among subpopulations, and the implications for population definitions, often vary across the genome for a given history of migratory exchange and diversifying selection. Although genomics is being harnessed in ever more efficient ways to probe this complexity and interpret it in terms of evolutionary processes relevant to population management, this chapter primarily focuses on the more inevitable and predictable process of gene frequency differentiation caused by genetic drift.

Aspects of demography can alter the rate of genetic drift for a given population size (e.g., sex ratio, variance in reproductive success), so drift theory is based on an index of population size that accounts for these variables - the genetically effective population size or N_e. Leaving aside the N_e details (see glossary), a small reproductively cohesive group will experience more random genetic change per generation than a large group. The rate of gene flow can be thought of in terms of the proportion of immigrants per generation, m, but unlike the demographic rate m, only immigrants that reproduce contribute to gene flow so the evolutionary parameter refers to *effective* migration. Evolutionary process, and more specifically the degree of evolutionary independence of a population, are determined by the product of effective population size (N_e) and the immigration rate (m).

The number of effective migrants per generation (mN_e) is related to the degree of evolutionary independence, leading to disparities in the degree of evolutionary and demographic consequences for low levels of exchange. It can be surprising how few effective migrants are sufficient to maintain genetic homogeneity among spatially discrete populations compared to maintaining demographic homogeneity. With some simplifying assumptions, the theoretical turning point between evolutionary independence (leading to local fixation or loss of alleles at migration-drift equilibrium) vs. reproductive cohesion (maintaining genetic homogeneity among subpopulations and minimizing local allelic diversity losses) occurs at $mN_e = 1$. This led to the "one migrant per generation" rule in conservation biology describing the level of exchange desired to prevent evolutionary isolation. Mills and Allendorf (1996) examined some genetic and nongenetic factors that complicate applications of this rule and suggested that $1 < mN_e < 10$ provides a more generally useful quantitative threshold for exchange rates above and below which evolutionary correlations are more predictable.

Comparing the ecological and evolutionary paradigm

The ecological and evolutionary paradigms provide different definitions of a population because, for a given spatial pattern of average dispersal for individuals inhabiting fragmented habitat, demographic correlations trend toward zero at smaller concentric scales than evolutionary genetic drift correlations (Fig. 1). This process-based difference is sometimes used to posit ecological exchangeability when the demography of a species is correlated between two habitat patches, or evolutionary exchangeability if gene flow levels have prevented genetic drift from fixing different alleles in the two patches (Templeton, 1989). In practice, this distinction is sometimes aligned with management or policy goals with demographically correlated patches of individuals representing the minimum possible spatial "management unit" whereas criteria for "evolutionary significant units" focus on measures of evolutionary independence (Crandall et al., 2000).

Discrepancies in the demographic and evolutionary impacts of migration can cut both ways. As a result of mate choice or aspects of local adaptation it is possible to have immigration that influences demography (e.g. through competition) but has little to no gene flow effect. For example, demographic effects might be expected for a pair of cryptic species (species that are difficult to distinguish based on phenotype, yet are unable to interbreed) that diverged in isolation but are intermingling in secondary contact. Reproductive barriers would minimize evolutionary consequences of this secondary contact but mate choice confusion or competition for resources could occur. Discrepancies in the opposite direction might be more common. if there are no reproductive barriers and low rates of exchange ($1 < mN_e < 10$) between two patches, demographic correlations might be weak despite a potent evolutionary homogenizing force countering differentiation by genetic drift.

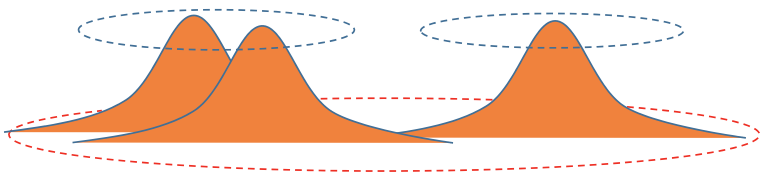

Fig. 1 Orange distributions represent dispersal kernels, the distribution of dispersal distances from a central point. The kernels are centered on adjacent habitat patches. Overlap between kernels depicts demographic connection. More overlap contributes to demographic correlations (left, one encompassing dashed circle). Less overlap may maintain a connection but promote demographic independence (separate dashed circle at right). The red dashed circle represents evolutionary processes and the larger spatial scale at which evolutionary exchangeability is maintained because fewer effective migrants are sufficient to counter differentiation by genetic drift.

Waples and Gaggiotti (2006) in their excellent simulation-based examination of population distinctness concluded that typical high resolution genetic studies can reliably discern allele frequency differentiation due to genetic drift, even with number of migrants as high as 25 per generation. This would be consistent with 10% exchange ($m = 0.1$) among constant size subpopulations with $N_e = 250$, implying that under some conditions genetics can resolve fine scale differentiation among "populations" that are likely to be demographically correlated. The prospects for management applications are high if high-resolution genetic data, when coupled with a careful spatial sampling design, can be used to estimate both contemporary m (the migration rate at the time of sampling, including both "effective" and non-effective migrants) and a long-term average effective migration (mN_e, Cayuela et al., 2018). In the remainder of this chapter we give some examples of populations and compare demographic and evolutionary population paradigms.

Simple populations – A collection of individuals in a defined space

A population can consist of a collection of individuals that are both demographically and evolutionary distinct. For such populations, there are no issues with different definitions based on demography and ecology versus genetics and evolution. Some populations even consist mostly of individuals with the same genotype. Examples include several macrophytes that reproduce vegetatively and where a large number of individuals within a lake may be part of the same clone (e.g. common reed *Phragmites* and eelgrass *Vallisneria*). Other groups such as cladoceran and rotifers may also have populations consisting of a limited number of clones. These zooplankton species reproduce parthenogenetically during most of the year and only produce males and reproduce sexually at the end of the growing season. Such populations consist of several coexisting clones that dominate at different times, representing evolutionary changes in the population. This can lead to eco-evolutionary feedbacks (De Meester et al., 2019). For example, early spring clones reduce phytoplankton abundance during the spring clear water phase, resulting in improved conditions for less edible cyanobacteria which in turn lead to changes in the *Daphnia* population toward clones that are able to feed on cyanobacteria (Schaffner et al., 2019).

Standard population dynamics equations describe how the number of individuals in a population are related to birth and death rates and the effect of population size on these rates (Fig. 2A). These standard equations for logistic population growth are fundamental to population dynamics theory and described in all standard ecological textbooks (e.g. Gotelli, 2008). Attributed to Malthus, Lotka and Volterra, these equations show how a single population that is not resource-limited initially increases exponentially. As the population size increases resources per individual decline, birth rates decline, and the population eventually cease to increase (birth rates = death rates) at its carrying capacity. This population growth model works well to describe population size response after colonization of a new habitat. As an example, the quagga mussel (*Dreissena rostriformis bugensis*), like its congener the zebra mussel (*Dreissena polymorpha*), are considered aggressive invaders in aquatic systems, each capable of changing the physical structure of the lakes they colonize (Higgins and Vander Zanden, 2010; Karatayev et al., 2015). Quagga mussels were first detected in Oneida Lake, New York USA in a marina in 2005 and 4 years later, the species reached densities of 5800 m^{-2}, or over 1 trillion individuals in the 207 km^2 lake (Hetherington et al., 2019). This tremendous population increase is partly due to the large number of free-swimming larvae (veligers) produced by these mussels; one female mussel may produce 1 million larvae in a year. At the same time, zebra mussels declined from 5800 m^{-2} in 2007 to 400 m^{-2} in 2011, showing an almost complete replacement of one invader by a new invader (Hetherington et al., 2019). Zebra mussel density ranged from 2600 to 7600 m^{-2} from 1995 through 2008, suggesting that ~6000 m^{-2} represents the carrying capacity of these mussel in Oneida Lake. The observed increase of the quagga mussel population was well described by a logistic growth equation with an intrinsic rate of growth (r) of 3.0 and a carrying capacity K of 6000 m^{-2} (Fig. 3A). The carrying capacity varied somewhat among three areas of the lake (example from hard bottoms in Fig. 3B) which may be related to different bottom structure and bathymetry in different parts of the lake. Even so, the similarity in the population growth trajectory throughout the lake suggests that the quagga mussels in Oneida Lake can be considered one population.

These standard population dynamics equations are the basis not only for predicting population development, but also for predator-prey interactions, competition, and harvest management (Gotelli, 2008). Of interest to inland waters is the large body of theory developed in fisheries (Beverton and Holt, 1957; Quinn and Deriso, 1999; Walters and Martell, 2004) in parallel with the development of theory in population ecology. The fisheries-based theory led to concepts such as stock-recruitment functions, surplus production models, and maximum sustainable yield, the latter predicting the maximum harvest rates possible without decreasing the population size (Fig. 2B). This occurs at the highest rate of increase in the logistic growth curve, often at a population size about half the density of an unfished population at carrying capacity.

This theory of population dynamics assumes that the individuals within the population can be considered equivalent. This is of course a simplification. For starters, a population consists of individuals of different age, and age may be related to size and fecundity. For fish, larger females produce more eggs, but also potentially eggs of higher quality (Chambers and Leggett, 1996). Many aquatic animals have juvenile and adult stages that differ in habitat use and diets. For example, the mussels discussed above have free swimming larvae (veligers) that live in the open water and are transported by currents whereas the adults are benthic and often attached to substrates. In addition to age, individual size is important. Fish larvae are orders of magnitude smaller than the adults and have dramatically different interactions with their environments, including being prey for their larger conspecifics (Fuiman and Werner, 2002). Cannibalism can be the most important source of mortality of young fish, leading to population cycles (Parker-Stetter et al., 2007; De Roos and Persson, 2013). Therefore, population dynamics depends on size structure, and

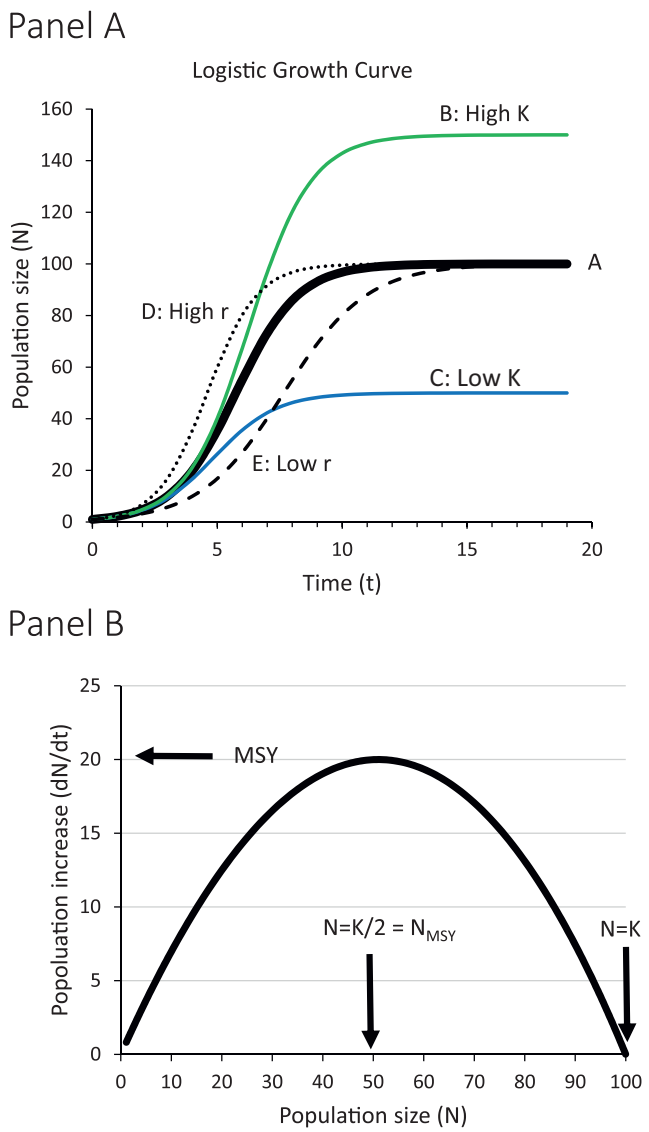

Fig. 2 Population growth according to the logistic growth equation: $N_t = K/(1 + [K\text{-}N_0)/N_0]e^{-rt})$. N_t is the population size at time t, K is carrying capacity, N_0 is the population at time 0, r is the intrinsic rate of increase. Panel A depicts the population increase for different carrying capacity (K) and intrinsic growth rate (r). Curve A has K = 100 and $r = 0.80$. Curve B and C show the effect of increasing K to 150 (curve B) and decreasing K to 50 (curve C). Curves D and E shows the effect of increasing r to 1.00 (curve D) and decreasing r to 0.60 (curve E). Panel B shows the rate of increase of the population (dN/dt) as a function of population size for curve A in panel A. dN/dt = rN (1-N/K). Maximum rate of population increase occurs when the population size is half of the carrying capacity (N = K/2 = 50 in this model). This maximum population increase at half the unfished population size is the maximum rate at which this population can be harvested without declines in the population (maximum sustainable yield, MSY).

incorporating such structure in population models has been an active area of research for some time (DeAngelis and Gross, 1992; De Roos and Persson, 2013).

Populations are also collections of individuals that differ along some trait continuum even at the same size and age. Some of these differences are due to genetics, others arise from the plasticity of individual form when residing in different environments. For example, Eurasian perch (*Perca fluviatilis*) are known to develop different morphology depending on whether these fish are in the littoral or pelagic zone of a lake. Littoral perch have a deeper body and larger fins and mouth than the more slender perch caught in the pelagic zone (Svanbäck and Eklöv, 2002). The more streamlined pelagic fish have more zooplankton in their diet than the littoral deeper bodied individuals. Interestingly, common garden experiments showed that most of these morphological differences in Eurasian perch were due to phenotypic plasticity and not genetic differences (Svanbäck and Eklöv, 2006), although genetics does influence the capacity to express environment-specific forms and this capacity may differ among sexes and individuals (Höök et al., 2021). Thus, the perch population should be considered one population that consist of individuals with forms representing a continuum of a given trait (here body depth and gape size). Individual differences in diet choice and ability to grow on different food resources has also been observed in other fish species such as roach (*Rutilus rutilus*, Faulks et al., 2015), yellow perch (*Perca*

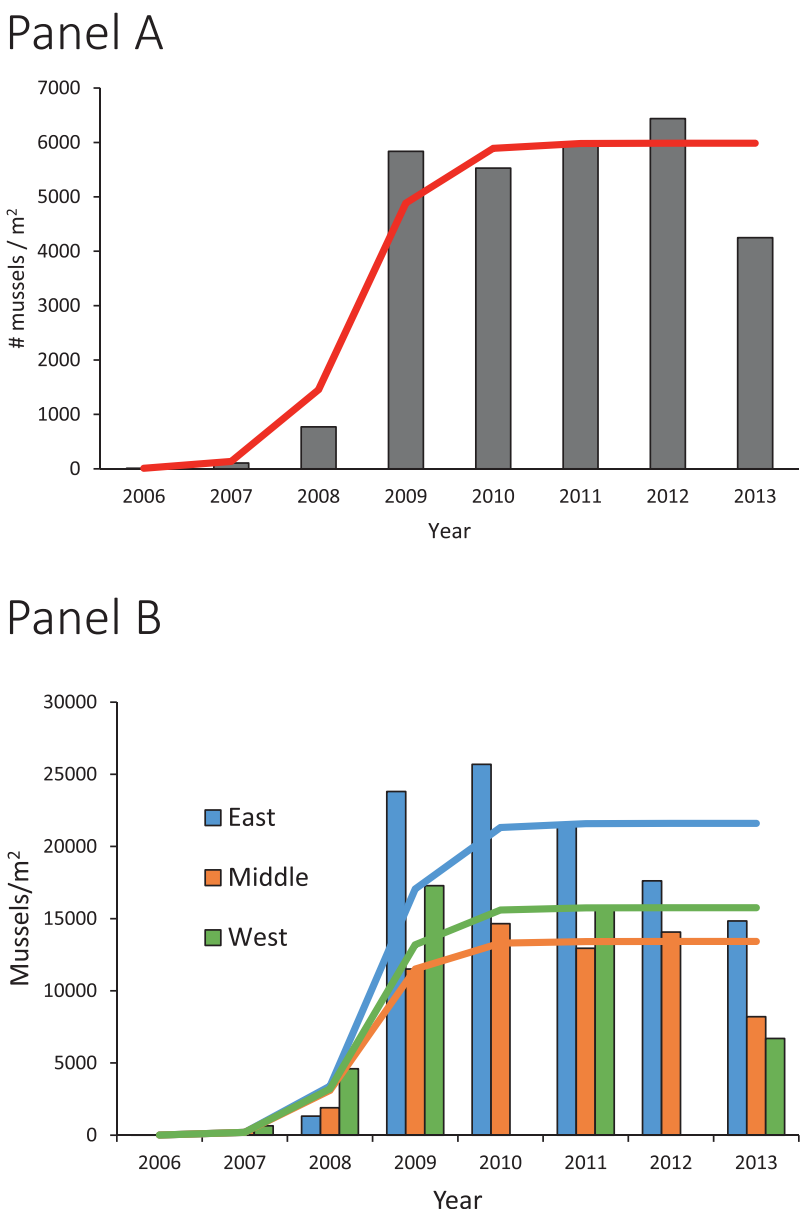

Fig. 3 Population increase of quagga mussels (*Dreissena rostriformis bugensis*) in Oneida Lake, New York follows a logistic growth curve with an intrinsic annual rate of increase of 2.6 and a carrying capacity of 6000 ind/m^2 (Panel A). Quagga mussels were first detected in Oneida Lake in 2005, and increased to between 10,000 and 25,000 ind/m^2 by 2009, an increase from a few individuals in 2005 to one trillion (1.2×10^{12}) individuals in the lake by 2009, 4 years later, exemplifying the population explosion possible in highly fecund organisms. Carrying capacity varied somewhat in different sections of the lake. The intrinsic rate of increase on hard substrate was 3.0, and the regional carrying capacity was 21,500 ind/m^2 in the eastern part of the lake, 13,400 ind/m^2 in the middle part, and 13,800 ind/m^2 in the western part (Panel B). The differences in carrying capacity likely reflect differences in substrate, although the samples depicted here are all from bottom with rocks and stones. Densities on other substrates were lower. The similarity in the increase in numbers in the different parts of this 207 km^2 suggest that the quagga mussels in this lake can be considered one population. In deeper, stratified lakes, the quagga mussels residing in deep water have a different morphotype with longer siphons and slower growth rates than the quagga mussels in shallow water leading to different population growth rates in these habitats (Karatayev et al., 2018). Oneida Lake data from Hetherington et al. (2019).

flavescens, Fetzer et al., 2015) and largemouth bass (*Micropterus salmoides*, Post, 1993) as well as in *Daphnia* (Schaffner et al., 2019), frogs and gastropods (Bolnick et al., 2003). Indeed, increased niche breadth in generalist species following release of interspecific competition may be due to increased difference between individuals rather than increased niche breadth of each individual (Bolnick et al., 2007). Thus, both populations dynamics and food web interaction models based on an average individual may not be sufficient to describe the dynamics of a heterogeneous population (Bolnick et al., 2003; Persson and DeRoos, 2003). The need to account for individual differences in population models led to the development of individual-based models that could account for a range of individual traits within populations (DeAngelis and Gross, 1992). At the extreme, within population differences between

morphotypes can lead to the development of distinct subpopulations and likely speciation over time. A classic example is the divergence of morphotypes of artic charr (*Salvelinus alpinus*) in Lake Thingvallavatn, Iceland into a benthic dwarf form, a benthivore, an open water planktivore and an open water piscivore (Sandlund et al., 1992).

A complex population – The brook charr

The brook charr (*Salvelinus fontinalis*) is a broadly distributed species that shows population distinctions at many spatial scales. The term "population" might reasonably be used at any of these hierarchical levels. The species inhabits cold water streams and lakes from the southern Appalachian Mountains of the U.S. to the watersheds of Labrador, Canada. The first order pattern of population subdivision, detected with genetic markers, coincides with regional river basins that likely differed in their post-Pleistocene recolonization timing and/or source. Allozyme data were used to distinguish Brook charr from the Allegheny, Hudson & Delaware, and St. Lawrence River basins (Perkins et al., 1993). Similarly, microsatellite markers revealed a broad regional pattern of subdivision among Labrador Brook charr consistent with hypothesized distinct Pleistocene refugial sources (Pilgrim et al., 2012). These studies illustrate how phylogeographic patterns across major portions of a species range can be used to infer historical processes shaping the distribution of genetic variation, sometimes revealing deep intraspecific genetic disjunctions that are not apparent phenotypically.

In brook charr, life history distinctions are a good example of trait-based population differentiation driven by natural selection and/or plastic responses to environmental variation. Across its geographic range, brook charr either live and breed in lakes, live and breed in streams, or are born in streams but migrate into a lake or ocean for a portion of the life cycle before returning to a stream for reproduction (anadromy). These life history traits, often associated with distinct morphologies, are a reasonable basis for distinguishing "populations," but the relative importance of trait inheritance vs phenotypically plastic responses to environment is typically ambiguous without intensive research. This is why understanding ecological and evolutionary exchangeability between these life history populations is challenging. For example, nonmigratory and migratory populations are sometimes sympatric, with a difficult to distinguish combination of genetic and environmental factors triggering one strategy or the other in individuals (Thériault and Dodson, 2003). The morphological variation associated with these life histories is moderately heritable (Varian and Nichols, 2010), meaning that both genetic and environmental factors contribute to population variation in the trait, and natural selection can induce an adaptive response. Thus, situations likely occur where demographic exchange is substantial between life history populations, but immigrants have maladaptive traits relative to locals and little of the exchange is evolutionarily effective (i.e., immigrants typically transmit no genes).

One of the fascinating aspects of brook charr population structure is that it extends down to extremely local levels in some continuous habitats where no dispersal barriers are known. Genetic drift theory applied across a continuous species range generates expectations for the amount of evolutionary independence to expect across different geographic distances. At spatial scales smaller than a certain limit, determined by population density and the distribution of dispersal distances, genetic variation will be spatially homogeneous (panmixia). At spatial scales above single generation average dispersal distances, and after an equilibrium is established between gene flow homogenization and genetic drift differentiation, pairwise levels of genetic differentiation will be positively correlated with geographic distance. The panmictic scale is sometimes referred to as a genetic neighborhood (Wright, 1946) whereas the broader pattern fits an 'isolation by distance' model in which the slope of the relationship between spatial separation and differentiation is steeper when average dispersal distances are shorter. Isolation by distance is a very common pattern to find in species that have not had major colonization, population expansion, bottleneck or fragmentation events over the last 100s to 1000s generations (thus having reached an approximate equilibrium between dispersal and genetic drift). In freshwater systems, panmictic genetic neighborhoods might be found at the level of tributaries, as is the case for brook charr, or entire watersheds, depending on the historical and contemporary levels of gene flow. Practical management decisions are simplified if the population genetic pattern coincides with a larger landscape feature (watershed). In this case a watershed population boundary suitably reflects both demographic and evolutionary processes and there is little controversy. In brook charr, where there is a dire need to manage population viability in response to the synergistic stressors of degraded water quality, introduced competitors, and climate change (Hudy et al., 2008), their population biology in streams often leads to very fine scale evolutionary differentiation of breeding populations at the level of single tributaries despite some demographic interdependence among adjacent tributary and mainstem reaches.

Several detailed studies have revealed these tributary distinctions in stream-dwelling brook charr (Kanno et al., 2014; Kazyak et al., 2016) using both demographic and genetic methods for estimating population sizes and connectivity. In a study of brook charr in two tributaries and the interconnecting mainstem reach, methods of detecting fish movements revealed symmetric exchanges between mainstem and tributaries by close to a third of individuals. In contrast, genetic sibship data revealed substantial movements of mainstem fish into tributaries to breed but gene flow in the reverse direction and between tributaries was rare (Kanno et al., 2014). Later genetic analyses capable of inferring the long-term realized impact of gene flow on allele frequency differentiation indicated that gene flow was sufficient to homogenize the mainstem with one of the tributaries but not the other, and revealed higher levels of differentiation ("cryptic" metapopulation structure) among these very closely spaced tributaries (Whiteley et al., 2017). Levels of genetic differentiation were surprisingly high given the amount and pattern of detected exchange, suggesting some combination of movements unrelated to reproduction, natal homing, and reduced reproductive success in non-natal fish relative to local residents.

Because brook charr have exchange rates seemingly sufficient to generate correlated demography, yet the genetic differentiation among tributaries conclusively demonstrates evolutionary independence, this species provides an excellent case study for comparing these two paradigms. Perhaps unsurprisingly, what brook charr studies reveal is the inadequacy of a population paradigm focused on spatially correlated demography or ecological exchangeability when habitat heterogeneities significantly impact vital rates in age-, season- and site-specific ways. For example, variation in stream flow rate and temperature were found to differentially affect brook charr vital rates in mainstem vs. tributary habitats, and these dynamic differences in habitat quality are not independent of movement patterns (Letcher et al., 2015). Also, system-wide tests of association among habitat features and genetic connectivity (riverscape genetics) can reveal spatial variation in population exchange that informs a more functional understanding than would a classification system defining populations (White et al., 2020). The typical genetic differentiation of brook charr at the tributary level in many areas frustrates management planning premised on identifying and prioritizing distinctiveness because it focuses on the isolation implied by genetic differences and the population viability risks inherent in isolation. In this species there is an underlying metapopulation structure - meaning an interconnected network of populations - with spatial and life cycle components that respond to environmental fluctuations differently such that the entire system is more resilient than the local evolutionary isolation implies. Ultimately, metapopulation theory may provide a more productive framework for managing species such as brook charr than trying to identify and manage discrete populations.

Knowledge gaps/future work

- For conservation and management of populations there are increasingly diverse ways of assessing population relationships from both a demographic and evolutionary perspective. For example, genetic parentage analysis on wild samples can provide inferences similar to mark and recapture methods of abundance estimation, but also contribute to landscape scale assessments of long term gene flow.
- Genomics can be used to survey the spatial patterns of genetic variation within and among populations and to identify genes that are responding to environmental stressors. Although this chapter focused on non-adaptive processes defining populations, genomics provides an important lens focused on local adaptation, the capacity for evolutionary responses, and the eco-evolutionary feedbacks shaping those responses.
- Geneflow, migration, and adaptative traits of individuals need to be better integrated into our understanding of population dynamics.
- Despite powerful ways that genetics informs conservation and management, it remains a mostly academic venture with less application than is warranted.

Metapopulations in Inland Waters

Kasey C Pregler, Emily K Chen, and Stephanie M Carlson, Department of Environmental Science, Policy, and Management, University of California, Berkeley, CA, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Lars Rudstam.

Glossary

Assisted gene flow Physically moving individuals among populations/patches to increase and maintain genetic diversity.
Demographic rescue Moving individuals from one population to another population to increase population size and buffer against demographic stochasticity.
Dispersal Movement of individuals to different patches outside of their home and migratory range.
Emigration Permanent dispersal of individuals out of a patch.
Extirpation/local extinction A species that no longer exists within a specific location (e.g., a patch) but still exists elsewhere.
Genetic rescue Moving genetic diversity from one population to another population to increase the fitness of the receiving population.
Immigration Dispersal and establishment of individuals into a new patch.
Inbreeding depression Loss of fitness due to reproduction/breeding between closely related individuals.
Iteroparity Ability to have multiple reproductive events over the course of an individual's lifetime.
Lentic Standing waterbodies (e.g., lakes and ponds).
Lotic Moving water (e.g., streams and rivers).
Matrix The unsuitable habitat that surrounds the mosaic of patches.
Metapopulation Spatially structured populations with asynchronous dynamics connected by dispersal.
Mosaic A collection of habitat patches across the landscape that comprise the metapopulation.
Occupancy Presence of a species within a patch.
Patch Discrete, suitable habitat for a self-sustaining population.
Recolonization Immigration of individuals into an uninhabited patch that was previously extirpated.
Rescue effect Extirpation of population is prevented due to immigration from outside individuals.
Sink An unproductive patch or population that is dependent on immigration to persist.
Source A productive patch or population that is self-sustaining and produces individuals that disperse to other patches.
Stochasticity Fluctuations due to chance. Stochasticity (chance) exists in the environment and in a population's demographics. Environmental stochasticity is the unpredictability in environmental conditions, whereas demographic stochasticity are random fluctuations in population size due to birth and death rate dynamics.
Stock Many harvested fish populations are characterized by stock structure, that is, sub-species structure where component units are defined for purposes of management and often correspond to a population or subpopulation.

Introduction

Many populations of species occur in dynamic environments that vary over time, where demographic and environmental stochasticity can affect population dynamics (May, 1974). Often demographic information is studied for individual species and sites, but the study of a population in isolation may lead to only a partial understanding of its ecology. Early attempts at understanding population dynamics often used simple models that assumed population closure, where emigration and immigration are not considered. The role of dispersal was later acknowledged to influence population dynamics where the movement of

individuals among populations was important for persistence of nearby local populations (Brown and Kodric-Brown, 1977). A collection of multiple, interacting populations is termed a "metapopulation," in which local extinction and recolonization depend on the dispersal of individuals among discrete habitat patches, i.e., suitable areas surrounded by a matrix of unsuitable habitat (Levins, 1969). In other words, a metapopulation is an assemblage of many local populations where ecological processes take place at two scales, both local and regional.

There are several origins of the idea that natural populations in larger regions consist of discrete local populations connected by dispersal and that species persistence depends on a balance between local extinctions and recolonizations. While Levins (1969) is credited with coining the term "metapopulation theory," he wasn't the first to consider local extinctions and recolonizations of extirpated or vacant habitats. The earliest known concept of metapopulation processes is attributed to Nicholson and Bailey (1935) who noted the importance of local extinctions and recolonizations to maintaining parasite-host dynamics (Hastings and Harrison, 1994). Biologists like Sewall Wright (1940) considered the evolutionary implications of discrete patch structure. Andrewartha and Birch, (1954) emphasized the importance of local extinctions and recolonizations to the distribution and abundance of species. Around the same time as Levins' metapopulation theory appeared, MacArthur and Wilson (1967) published the theory of island-biogeography to predict species richness of vacant island habitats that were recolonized by dispersal from a mainland.

Levins' metapopulation model assumed identical populations where local habitat patches were the same size and quality, and equally connected to one another. However, real-world examples are often more complex, and Levins' theory proved too simplistic to accurately capture metapopulation dynamics (Hanski, 1989, 1991, 2001). Later both theoretical and empirical studies recognized the importance of differences among populations and further investigated the underlying ecology and evolutionary biology of these dynamics. Indeed, it is now well-appreciated that metapopulations are dependent on the spatial complexity of both local and regional dynamics where the size, arrangement, number, and distance among patches can influence population dynamics (Campbell Grant, 2011). Moreover, metapopulation dynamics do not remain static; population demographics and habitat can change over time.

For a classic metapopulation, Hanski et al. (1995) outlined four criteria that must be met. The first is that populations within a metapopulation occur in discrete patches that are separated from each other by unsuitable habitat (i.e., the matrix). Separation from neighboring populations allows for each population to act independently. The second criteria is that there must be some asynchrony in dynamics among populations. A complex of populations with asynchronous dynamics is less likely to experience simultaneous population declines and local extinction events. Third, there must be some dispersal of individuals to other patches so populations within a metapopulation are connected. Dispersal is critical to the existence of a metapopulation because it allows for unoccupied patches to be recolonized and for declining populations to be rescued from extirpation due to a demographic subsidy, a phenomenon known as the rescue effect (Brown and Kodric-Brown, 1977). Lastly, local populations are not large enough to persist on their own (or else they could be considered single populations). While Hanski outlined these criteria for classic metapopulations, other metapopulation types have been described with slight variations on these assumptions. For example, in mainland-island and source-sink metapopulations, a given local population may be highly persistent (Harrison and Taylor, 1997).

Despite the popularity of metapopulation theory in the literature, it continues to be challenging to empirically document given the amount of labor required for the long-term monitoring of multiple populations. Metapopulation theory first focused on terrestrial systems (Levins, 1969) and later expanded to marine and freshwater systems. Given that freshwater habitats are embedded within the terrestrial landscape, species' populations within a region are often spatially structured (Falke and Fausch, 2010; Erõs and Campbell Grant, 2015; McCullough et al., 2019), suggesting the potential for metapopulation dynamics to emerge.

Overview of freshwater metapopulations

The spatial discreteness of freshwater habitats in combination with environmental variability and disturbance regimes leads to spatially structured populations that can be characterized by metapopulation theory (Falke and Fausch, 2010). Lentic systems can align with the classical conception of metapopulation patches as islands, where discrete populations can exist in individual lakes, ponds, and wetlands which can be insular with populations isolated from each other by land (Fig. 1A), or occur in whole networks connected by streams and wetland habitats (Fig. 1B) (Meerbeek and Weber, 2020). Metapopulations can also arise within a single lake when species exhibit philopatric behavior (i.e., returning to natal habitat for reproduction) which can contribute to spatial structuring of local populations (Hayden et al., 2011). Discrete populations can also occur in streams, which are arranged in hierarchical dendritic patterns where the network topology of river and stream systems creates habitat and matrix patches with distinct abiotic characteristics (Erõs and Campbell Grant, 2015). The presence of natural and anthropogenic barriers can limit movement among habitats within this branching network, also contributing to spatial structure. Metapopulation structure occurs at different spatial scales within stream networks. For larger and more motile species, discrete populations may be distributed across tributaries of a watershed (Fig. 1C), whereas the metapopulation structure for sessile and small-bodied species may exist within reaches of a stream (Fig. 1D).

Freshwater species take advantage of numerous connectivity types among freshwater habitat patches (Fig. 1) and many species use a diversity of habitats across their life histories at various spatial and temporal scales (Schofield et al., 2018). Strictly aquatic species such as fish can move along stream corridors to access different tributaries within a watershed. Ephemeral and perennial wetlands and streams can connect lakes and ponds and act as corridors for aquatic species (Daniels et al., 2008; King et al., 2019). Semi-aquatic species (e.g., invertebrates, amphibians) may use both aquatic and terrestrial connections (McCullough et al., 2019).

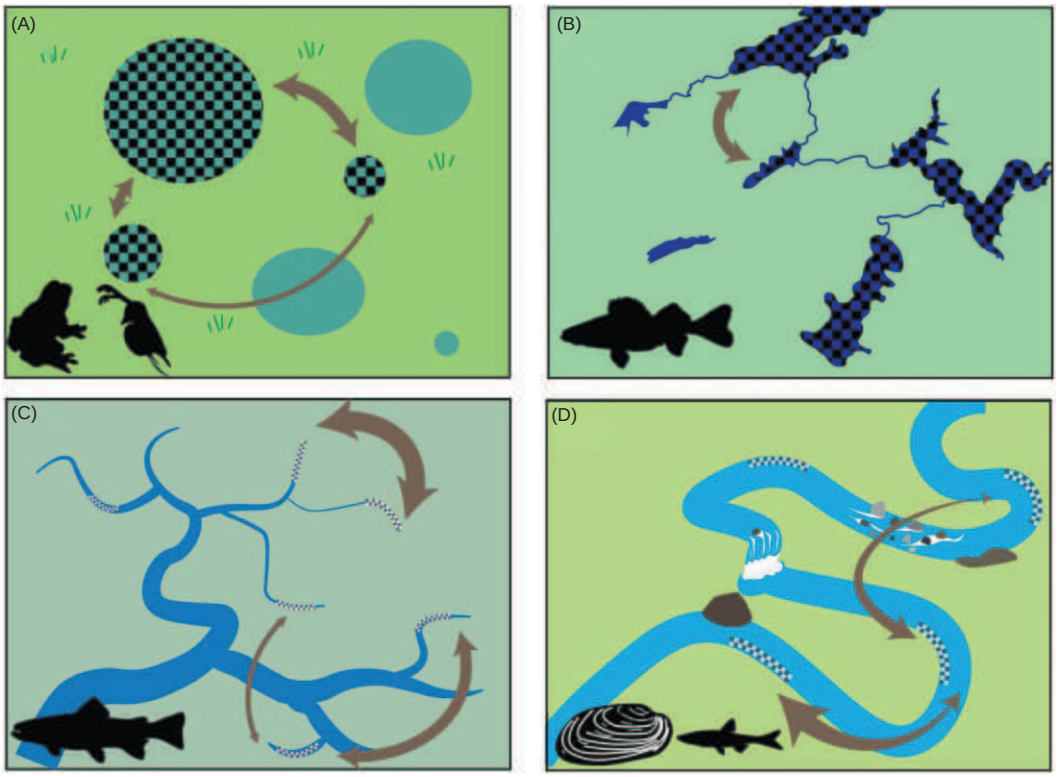

Fig. 1 Examples of spatial structure and degree of dispersal in various aquatic metapopulations. Metapopulation dynamics can exist between (A) insular ponds for semi-aquatic species, (B) lakes connected by inflows and outflows, (C) tributaries of a watershed, and (D) reaches of a single stream. Checkered areas indicate occupied patches. Arrows indicate dispersal, with arrowhead size signifying the dispersal rate between populations.

Many invertebrates and amphibians use freshwater habitats for breeding and juvenile rearing, with adults dispersing among patches overland or aerially (Bohonak and Jenkins, 2003; Semlitsch, 2008).

Thus, aquatic habitats can be characterized by discrete patches with varying degrees of connectivity, suggesting the potential for metapopulation dynamics to emerge. Unclear, however, is whether metapopulation dynamics are common among freshwater taxa. Syntheses are helpful for addressing this question. For example, a review of >50 journal articles and theses on amphibian metapopulations by Smith and Green (2005) revealed that the majority of studies (74%) did not test the key assumptions necessary to demonstrate the existence of classical metapopulation structure as outlined by Hanski (i.e., habitat patches support local breeding populations, patches are not too isolated to prevent recolonization via dispersal, local dynamics are sufficiently asynchronous to make simultaneous collapse unlikely, and no single population is large enough to ensure long-term survival). Even so, the review did identify some cases of pond-breeding amphibians functioning as metapopulations.

For example, a study by Sjögren (1991) explored local extinction and recolonization dynamics along an isolation gradient for pool frogs (*Rana lessonae*). In this system, reproduction is confined to distinct water bodies, which allowed researchers to closely monitor population size, survival, and dispersal rates. Local extinctions were likely to first occur at patches greater than 1 km from breeding populations. Neighboring ponds within 300 m of breeding populations were more likely to receive immigrating individuals and had a decreased risk of extirpation due to a rescue effect.

As an example from riverine systems, Koizumi (2011) summarized nearly a decade of research on a Dolly Varden (*Salvelinus malma*) metapopulation in the Sorachi River basin, Japan. While a few self-sustaining Dolly Varden populations were found within large tributaries, the majority of populations were small with fewer breeding individuals. They found that populations were largely independent and observed asynchronous dynamics across tributaries. The author concluded that these local populations should persist as long as some degree of connectivity was maintained among the tributaries to allow dispersal and recolonization.

Other syntheses also recognized critical next steps in addressing metapopulation dynamics in freshwater habitats. For example, Falke and Fausch (2010) reviewed 31 riverine fish papers published from 1995 to 2008 that investigated metapopulation dynamics. They noted that while authors framed their paper in the context of metapopulation theory, only the simplest of models were applied. Few papers included in their review incorporated the realisms of freshwater ecosystems in their models. As was recognized in early terrestrial metapopulation studies, spatial and temporal dynamics can also play an important role in the structuring of metapopulation dynamics in freshwater ecosystems. The following sections describe more realistic considerations of both spatial and temporal processes in freshwater ecosystems when applying metapopulation theory.

Local and regional dynamics in freshwater metapopulations

Local

Habitat size, quality, and heterogeneity can all influence local dynamics and extinction risk. In general, larger habitats are associated with larger populations and lower local extinction risk. However, habitat quality can greatly influence dynamics. For example, Suhonen et al. (2010) explored local extinction risk of dragonfly and damselfly populations in Finnish streams, ponds, and lakes and found that local extinction risk is generally elevated in low-quality habitats relative to high-quality habitats, consistent with source-sink theory. Moreover, species with narrow geographic ranges were more likely to go locally extinct in local patches compared to widely distributed species. Briers and Warren (2000) also noted that habitat quality can influence reproductive success and populations can have patch-specific probabilities of persistence in their study of breeding amphibians. Habitat quality and heterogeneity also influenced a wetland metapopulation of round-tailed muskrats (*Neofiber alleni*) in a study by Schooley and Branch (2007). The authors found that differences in the presence and density of the muskrat's food source, maidencane grass (*Panicum hemitomon*), resulted in spatially autocorrelated "neighborhoods" of high-quality and low-quality patches across the wetland.

Regional

The arrangement of patches relative to each other influences the amount of dispersal, a process necessary for recolonization, demographic rescue, and gene flow. The distance between patches and the degree of connectivity through the matrix are key factors that shape a metapopulation's regional dynamics (Hanski and Gaggiotti, 2004). For example, Sjögren's (1991) metapopulation study of pool frogs (*Rana lessonae*) inhabiting ponds at the northern edge of the species range in Sweden demonstrated how the distance between ponds was an important factor influencing extinction and occupancy. Fagan (2002) demonstrated how altered connectivity and fragmentation in dendritic stream networks can decrease metapopulation persistence given the diversity of fragmentation that can take place (e.g., both natural and anthropogenic).

Beyond distance and degree of connectivity, larger patch networks (e.g., those with a greater number of patches) are more likely to persist longer compared to smaller networks (Campbell Grant, 2011). Additionally, the position of patches within the network can lead to some patches being disproportionately important to metapopulation dynamics relative to others. For example, species in streams and rivers with limited dispersal capabilities may only disperse downstream through drift (Mari et al., 2014). In this common scenario in rivers, upstream habitat patches can be important sources for recolonization of downstream patches. For example, Sousa-Santos et al. (2014) found that for a threatened cyprinid metapopulation, (*Anaecypris hispanica*) recolonization primarily occurred in a downstream direction due to this fish's limited dispersal ability. The authors emphasized that if connectivity to the upstream patches became lost or if the upstream populations were extirpated, it could be detrimental to the long-term persistence of the metapopulation. The arrangement of patches can also impact metapopulation dynamics in lentic habitats. To explore the importance of patch position in pond habitats, Holmes et al. (2020) excavated experimental ponds, where a subset of these ponds were stocked with zooplankton (*Daphnia pulex*), and explored how the location of the stocked ponds influenced metapopulation dynamics. The authors found that centrally located ponds acted as a stepping stone for surrounding neighboring patches. Removal of these central ponds increased the risk of metapopulation extinction.

Temporal aspects of metapopulations

While advances were made in accounting for the importance of spatial patterns for metapopulation functioning, earlier models assumed that these patterns were stationary over time. In reality, just as populations experience temporal turnover due to local extinctions and recolonizations, the same is true of habitat patches and the uninhabitable matrix. Both habitat patches and the surrounding matrix can experience environmental variability, disturbances, habitat loss, and succession (Stelter et al., 1997; Keymer et al., 2000; Amarasekare and Possingham, 2001) which can vary in their timing, duration, and frequency.

Patch number and quality can also vary among years, and this shifting mosaic of habitat can influence local dynamics and extinction risk (Reigada et al., 2015). For example, Briers and Warren (2000) found that temporal variation in habitat (e.g., mud percentage cover) influenced the local extinction risk of notonectid backswimmers in small, artificial ponds in the United Kingdom. Directional habitat change can also influence occupancy and local extinction risk. For example, Skelly et al. (1999) studied a community of pond-breeding amphibians in Michigan, United States, which had been surveyed earlier between 1967 and 1974. The authors reported that forest succession negatively impacted breeding amphibians, through its effect on pond hydroperiod and canopy cover. Many ponds that supported pond-breeding amphibians in the early survey period were ponds that dried in summer during the later survey period, limiting their potential for all but those with the most rapid development.

Additionally, temporal variability can connect and disconnect habitat patches over time. Freshwater habitats have varying degrees of permanence, where some streams are perennial and flow year long, others are temporary and periodically go dry. Lentic habitats can also be ephemeral or temporary where ponds are wetted for only a portion of the year. Mediterranean-type rivers are characterized by a flow regime of fall-winter floods and summer droughts. These seasonal fluctuations can result in streams reduced to a series of disconnected pools where surface flows often cease entirely. Drought periods can be responsible for population

fragmentation and extirpation, and the movement of individuals during periods of connectivity allows extirpated regions to be recolonized. Similar disturbance dynamics are observed in dryland rivers in Australia that have low and unpredictable annual rainfall where metapopulation patches are prone to frequent extirpation due to drying. Huey et al. (2011) found that persistence of metapopulation structure depended on dispersal events during periods of connectivity for two species of fish (*Macquaria ambigua* and *Tandanus tandanus*) and a crustacean (*Macrobrachium australiense*). These dispersal events were critical to maintaining gene flow and genetic integrity due to the high frequency of extirpations and bottleneck events that isolate populations during dry periods.

Temporal macroscale interactions can occur where regional climate and weather patterns (e.g., temperature and precipitation) interact with local habitat to affect metapopulation dynamics. Griffiths et al. (2010) noted that inter-annual variation in rainfall can interact with local hydrology and influence the hydroperiod of temporary ponds. Fluctuations in rainfall can result in the water level of nearby ponds to vary asynchronously and affect the survival of amphibians such as crested newts (*Triturus cristatus*). Crested newts hibernate in terrestrial soil in winters and breed in temporary ponds in spring. Adult survival ranged from 25% to 80% over the 12 year study period, where low adult survival was associated with mild winters that resulted in warmer temperatures and more rainfall. The authors speculated that the changes in precipitation altered the local habitat to the point of affecting the crested newts' physiological needs. Warmer winter temperatures potentially disrupted winter hibernation causing individuals to use more energy. Since newts respire both across their skin and using lungs, wetter soils during hibernation could have also negatively impacted respiration, further contributing to lower survival and reproductive failure. The majority of patches experienced reproductive failure across most years—but a single successful patch with asynchronous dynamics relative to the other patches served as a source patch which allowed the metapopulation to persist.

Whether or not species' metapopulations persist ultimately depends on how their timing of dispersal and reproduction events correspond with landscape temporal structure (Reigada et al., 2015). The next section explores how species traits can be suited to these spatially and temporally variable environments.

Metapopulation persistence across space and time—species traits

In order for metapopulations to persist, species must be able to cope with both spatial and temporal variability. Spatial dispersal that connects populations within a larger metapopulation is a critical feature of metapopulation functioning, serving to rescue populations and reduce global extinction risk. Life history variation within populations—such as iteroparity or age complexity and overlapping generations—can also influence metapopulation functioning by generating asynchronous dynamics and reducing the probability of synchronous collapse.

In fact, many spatially structured populations have life history traits that spread extirpation risk across time and space (Buoro and Carlson, 2014). As an example, many harvested fish species are composed of multiple populations that differ in their dynamics. Such population diversity has consequences for resource flows to fishing communities via the portfolio effect, wherein the variability in the dynamics of the complex is lower than the variability in constituent populations, as exhibited in Bristol Bay sockeye salmon (*Oncorhynchus nerka*) (Schindler et al., 2010). Maintaining multiple populations that differ in their dynamics buffers the fishing community against stock fluctuations due to environmental variation and change (Hilborn et al., 2003; Schindler et al., 2010). Life history diversity that contributes to asynchronous dynamics could reflect local adaptations to environmental conditions (e.g., variation in spawn timing that reflects temperature variation, Lisi et al., 2013) or plasticity. Regardless, this population diversity reduces local extinction risk and stabilizes resource flows to consumers like fishers and predators (e.g., bears).

Environmental stochasticity can be an important driver of life-history evolution where iteroparous species may skip a breeding season if environmental conditions are unfavorable. Recent research has found this true in an amphibian metapopulation where among-year variability in pond characteristics resulted in life history variation in yellow-bellied toad (*Bombina variegata*) populations (Cayuela et al., 2019). The probability to skip breeding was higher in ponds with more variable hydroperiods. Similarly, a diversity of freshwater invertebrate species (including zooplankton, and odonates) can experience diapause, where development in offspring embryos is suspended during periods of unsuitable environmental conditions, such as drought (Bohonak and Jenkins, 2003). Long-lived and iteroparous freshwater fish species can also spread risk across multiple generations. Species that use multiple habitat types across their life histories, such as in diadromous species like salmonids, face multiple sources of risk across both time and space. Multiple cohorts in the ocean stage can compensate for reproductive failure in the freshwater stage. Spreading risk through space and time contributes to the resilience of a metapopulation and its ability to persist through disturbance and changes in the environment to some extent.

Anthropogenic impacts and conservation implications

To the extent that a particular freshwater taxon exists as a population of populations connected by dispersal, metapopulation theory has relevance for its management and conservation. Humans have dramatically changed landscapes in ways that have implications for metapopulation processes.

Habitat quality, size, and connectivity can all be altered by human disturbance, affecting metapopulation dynamics both at the local and regional scale (Fig. 2). Elimination or degradation of patches reduces connectivity and potentially persistence of whole metapopulations. Increased water use, sedimentation, and pollution can lower the quality of or eliminate patches, leading to a

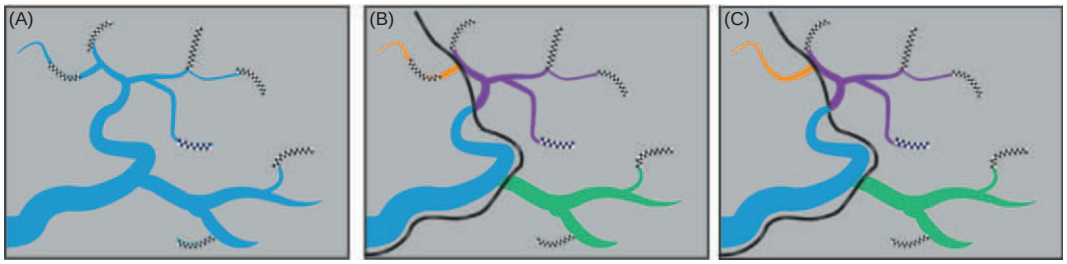

Fig. 2 Human disturbance can alter habitat quality, size, and connectivity and put metapopulation patches at increased risk of extirpation. For example, panel (A) shows a metapopulation within an intact watershed, with checkered areas signifying occupied patches (e.g., fish). In panel (B), a road (black line) is constructed across the watershed that blocks passage for fish between tributaries. The metapopulation patches are now fragmented into three regions (orange, purple, and green), resulting in some patches becoming extirpated (orange patch in panel (C)). Figure adapted from webinar by Jackson S (2006) *Ecological Considerations for Road Design at River and Stream Crossings [Webinar]*. US Forest Service. http://www.fsl.orst.edu/geowater/PEP/PEP_eco_consider.html (Accessed on 22 January, 2021).

reduction in capacity and a greater separation of populations by unsuitable habitat spaces. For example, historic strip mining and impoundments increased sedimentation and created large bodies of lentic waters, respectively in the Warrior River Basin, Alabama (Dodd, 1990). These human uses of the landscape led to large stretches of unsuitable habitat for stream-dwelling species such as the threatened flattened musk turtle (*Sternotherus depressus*), not only reducing available habitat but also increasing the distance of separation for remaining populations.

Barriers in rivers such as dams and culverts fragment populations and block dispersal between populations (Morita and Yamamoto, 2002). Individuals in isolated and small fragments have higher risks of extirpation because of disturbances, genetic drift, and environmental and demographic stochasticity (Shaffer, 1981). Anthropogenic alterations (e.g., dams) can lead to the permanent isolation of habitat patches and populations, which in turn has consequences for metapopulation persistence. Sink populations that typically inhabit smaller patches and are dependent on immigrants are especially vulnerable to extirpation from reduced connectivity (e.g., after a barrier is created). For example, in Hokkaido, Japan, white-spotted char (*Salvelinus leucomaenis*, resident and anadromous) were extirpated from upstream habitats after dams blocked connectivity, suggesting upstream populations are sink habitats that rely on immigrants to persist (Morita and Yamamoto, 2002). Although small sink populations are most dramatically affected by barriers, source populations and the metapopulation as a whole are also placed at greater risk of local extinction due to the lack of gene flow and the decreased potential for genetic and population rescue (Letcher et al., 2007).

Taken together, these anthropogenic impacts increase the risk of local extinction and often conservation intervention is needed to restore natural metapopulation processes. Restoring habitat patches and/or restoring connectivity among existing patches are strategies for reducing local extinction risk. Local habitat restoration in streams and rivers such as setting-back levees to expand floodplain patches and adding wood to re-configuring channels to create high quality pool habitats all hold potential for increasing the number and/or quality of habitat patches. Similar efforts within wetland ecosystems involve restoring existing wetland habitats (e.g., via dredging to improve drainage or removal of invasive vegetation to improve habitat quality) or creating new wetlands to mitigate pervasive wetland degradation and destruction. A synthesis by Brown et al. (2012) suggests that the restoration and creation of wetlands can be effective tools for increasing amphibian species richness and abundance, and that restored and created sites are as suitable as reference wetlands for supporting a suite of amphibians. A study by Lehtinen and Galatowitsch (2001) highlights that recently restored wetlands are rapidly colonized by amphibians, and that wetland size and spatial isolation were important predictors of species occupancy.

In addition to restoring or creating new habitat patches, enhancing connectivity can be an effective method of maintaining persistence of metapopulations if dispersal and/or gene flow are limiting. For example, restoring the natural hydrology and patterns of inundation and draining can influence connectivity and seasonal patterns of use by wetland-dependent species (Poff et al., 1997; Merenlender and Matella, 2013). More generally, restoration designs focused on connectivity vary by landscape and species of interest. Dams that inhibit connectivity can be circumvented by fish ladders and side-channels or be completely removed depending on their current function (Kondolf et al., 2006). Culverts that were previously designed to maximize hydraulic efficiency can be redesigned to facilitate movement of fishes between suitable habitats (Franklin and Bartels, 2012). A restoration design will no doubt affect the connectivity for species differently depending on life history, swimming ability, and spatial distribution (Wilkes et al., 2019). It is therefore critical for restorationists to understand the ecology of the species of interest and have defined targets/goals to help restoration designs achieve their desired outcome and to evaluate the success of those designs through post-project monitoring.

While restoring connectivity is the ideal outcome, often this may not be feasible due to logistics and/or costs. In instances where barriers to connectivity cannot be reversed, creative solutions must be applied if natural dispersal is not possible, given that artificial barriers can impact the genetic structure of a metapopulation. Permanent isolation can lead to the cessation of gene flow, resulting in a decrease in genetic diversity and an increase in inbreeding. These changes can lead to reduced fitness of the population and a greater risk of local extinction. Assisted gene flow in the form of translocations can help prevent the local extinction of small populations and can rescue populations from inbreeding depression and increase adaptive potential (Pavlova et al., 2015).

Translocations can rescue a population from local extinction by either increasing its size through demographic rescue or increasing population fitness by genetic rescue (Hufbauer et al., 2015; Whiteley et al., 2015). While demographic rescue can buffer against extirpation from stochastic events by increasing the number of individuals, genetic rescue can increase population fitness by reducing inbreeding.

The metapopulation approach is useful to conservation biology as it addresses restoring multi-scale processes to preserve dispersal and recolonization dynamics to minimize local extinction risk. Restoration and management efforts should focus on restoring and maintaining suitable habitat patches as well as connectivity among those patches. Careful consideration should also be given to maintaining habitat quality to increase survival of local populations. Moreover, maintenance of connectivity (or restoring connectivity) allows for dispersal and rescue effects to increase persistence of local populations and the metapopulation system as a whole.

Summary

In summary, it is evident that a diversity of freshwater systems can support spatially structured populations. The studies featured in this chapter highlight the importance of considering both spatial and temporal aspects of the environment when modeling metapopulation dynamics. Further synthesis efforts such as the one conducted by Smith and Green (2005) and Falke and Fausch (2010) are needed to better quantify the types and prevalence of metapopulation dynamics in freshwater habitats. Metapopulation theory has grown in relevance given the degree of habitat fragmentation and degradation observed in freshwater habitats that leads to human-induced spatially structured populations. In addition to understanding what regulates presence-absence and abundance of freshwater taxa, knowledge of dispersal, colonization, and extirpation rates is also required for successful conservation of spatially structured metapopulations.

Acknowledgments

The Ecological Niche in Aquatic Ecosystems

WM Lewis, University of Colorado, Boulder, CO, United States

This is an update of W.M. Lewis, The Ecological Niche in Aquatic Ecosystems, In Encyclopedia of Inland Waters, Edited by: Gene E. Likens, Academic Press, 2009, https://doi.org/10.1016/B978-012370626-3.00204-0

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Lars Rudstam.

Glossary

Competitive exclusion Elimination of one species population by another species population at a given location caused by competition between the two species.
Fundamental niche An ecological niche for a given species that is not restricted by competition with other species.
Niche All combinations of physical, chemical, and biological environmental attributes that are consistent with the sustained presence of a given species.
Niche overlap Components of an ecological niche for one species that are shared with those of another species.
Realized niche An ecological niche for a given species that is smaller than the fundamental niche because of competition from one or more other species.

Introduction

Niche, in everyday English usage, means a place or situation that is especially well suited to an individual or inanimate object. No doubt the word was used in this general way by ecologists before they began adapting its meaning to a more specific purpose, through the concept of ecological niche. Niche, defined ecologically, can be pronounced as a rhyme either with "rich" or "quiche."

J. Grinnell (1877–1939) was first to convert the niche in its generic sense to the niche as defined ecologically. Grinnell's ecological niche grew out of his observation, shared with other ecologists, that species are associated with specific ranges of environmental conditions that correspond to their spatial distribution in nature. Thus, Grinnell's niche was drawn from the idea that the persistence or success of a species in a given place is determined by a suite of environmental variables associated with that place.

Grinnell also explained that the distribution of a species within the range of environmental variables favorable to it is affected by the presence of other species. He drew the analogy of soap bubbles: a single bubble takes a symmetrical shape, but multiple bubbles are distorted as they press one upon the other. Thus, Grinnell foresaw the relevance of the ecological niche concept to the study of interspecific competition. In his classic book, *Principles of Animal Ecology* (1927), Charles Elton (1900–91) defined the ecological niche somewhat differently than Grinnell had (Elton 1927). He stated that the niche of an organism should be defined on the basis of processes rather than features of habitat. This was probably Elton's way of setting ecology apart from the dominant fields of taxonomy and natural history, which had emerged much earlier than ecology. Ecologists, according to Elton, want to understand the functions of organisms in relation to their environment and each other.

Ecological niche could have been a minor concept had it not been for the importance of interspecific competition in the development of ecology. In his studies of interspecific competition, G.F. Gause (1910–86), following the mathematically based predictions of V. Volterra (1860–1940), conducted experiments that demonstrated what became known as the "competitive exclusion principle." An example from Gause's work consists of an experiment in which two species of protozoan were held in a laboratory medium with a suspended food source (bacteria). Often one species declined to extinction, and thus was excluded from the habitat provided by the laboratory vessel. In some cases, two species coexisted because they showed reduced competition through differing adaptations. For example, one experimental contest of two protozoan species ended in coexistence because one species was adapted to feed on bacteria that had settled to the bottom of the vessel, whereas the other fed only on suspended bacteria. The general conclusion was that competition can exclude a competitor, but also coexistence of species can occur if competition involves the expression of differing requirements, i.e., differing fundamental niche dimensions.

Decades later, Hardin (1960) attacked the concept of competitive exclusion as a tautology, i.e., a self-evident truth. If so, the principle, while correct, would have little application to nature. It became increasingly clear as the study of competition progressed that different species, even if similar, do not occupy the same niche because they have different suites of adaptations; that environmental conditions change constantly, thus reversing competitive advantages from one species to another; and that environments in nature are heterogeneous spatially in a way that allows species appearing to be very similar to coexist indefinitely.

Ecologists now think in terms of niche overlap; the underlying scientific problem is to determine the degree of overlap that can produce strong competition. By wondering whether there may be empty niches in nature, Grinnell forecast modern thinking on the packing of apparently similar species together in a common environment such as the pelagic zone of a lake. Studies of population dynamics, viewed in large part through biological succession, also influenced the ecological concept of niche. In a famous paper entitled *Homage to Santa Rosalia*, G.E. Hutchinson (1903–91) pointed out that the pelagic zone of a lake or ocean is filled with dozens of species that have similar functions (e.g., all phytoplankton species in a given lake, or all herbivorous zooplankton species in a given lake, Hutchinson 1959). While the open water of a lake may seem similar to Gause's laboratory vessel, it is not. As Hutchinson pointed out, environmental conditions including temperature, nutrient availability, turbulence, and solar irradiance vary from week to week, allowing first one group of species to have an advantage, and then another. Competition in such a community does not go to completion because conditions are not stable.

Quantification of the ecological niche

The concept of ecological niche was modernized in 1957 by G.E. Hutchinson. One of Hutchinson's many gifts to the ecological sciences was his consistent use of quantitative tools in the formulation of ecological concepts. Such an approach opened new potential for old ideas, many of which had stalled in argumentation based on field observations and experiments. In essence, Hutchinson added a touch of something like physics to the rich mixture of taxonomy, natural history, population sampling, and field experiments that made up the bedrock of ecology in the first half of the twentieth century.

Hutchinson's idea of niche was that ecological space is defined by all environmental variables that have any influence on the welfare of a given kind of organism, including physical and chemical features as well as predation, parasitism, competition, and other biotic variables. Because more than three influential variables usually can be named for any kind of organism, the ecological niche space cannot be shown as a diagram or physical model; it has numerous ("*n*") dimensions, where *n* might not be known exactly but would be greater than 2 or 3. Hutchinson called the ecological niche defined in this way as an "*n*-dimensional hypervolume." The idea of dimensions exceeding three was unusual but not bothersome in 1957, by which time physicists had already conveyed at least to the science community that not only the three dimensions of space, but also time, a fourth dimension, define physical realities of the universe. Thus, conceptually, we may think of the ecological niche of a species as a hypervolume that has any number of dimensions, and all important factors affecting a particular species of organism are accounted for by it. With the *n*-dimensional hypervolume, Hutchinson generalized the idea of the ecological niche so that it would fit all species, regardless of the numbers or types of dimensions that might describe its requirements for persistence.

Elaborating on the *n*-dimensional niche concept, Hutchinson pointed out that there are actually two kinds of niches. The "fundamental niche," according to Hutchinson, is the *n*-dimensional hypervolume that could be occupied indefinitely by a species (Fig. 1). The "realized niche," in contrast, is the portion of the fundamental niche that can be occupied in the presence of other species that, by competition, allow the species to occupy only a portion of the fundamental niche.

It follows from Hutchinson's thinking that the realized niche is never greater than the fundamental niche and typically is smaller. Furthermore, the realized niche is site-specific. The realized niche of a weak competitor at a location with little or no competition could be quite large. On the other hand, the realized niche of the same species in a place with fierce competition could be small, even leading to the extirpation of the species population at that site.

It is clear from these examples that Hutchinson's redefinition of the niche offers many more possibilities than the earlier, simpler definitions. Like Grinnell's original concept, it invites a biogeographic interpretation and is based jointly on environmental variables and competition.

Current controversies surrounding the ecological niche concept

Analysis of competition and niche has moved in new directions over the last few decades (Hubbell 2001). Some ecologists have concluded that the niche has been overestimated as a determinant of community composition. S. Hubbell, for example, has proposed a "neutral theory of biodiversity and biogeography," one component of which is denial of the significance of niche for understanding the relative importance of a species at a given location. Hubbell's reasoning is that even species with very similar ecological requirements are sufficiently different to have offsetting advantages and disadvantages during competition. Thus, according to Hubbell, the distribution of species in relation to each other is much more a matter of chance than it is a reflection of the outcome of competition.

Modern analysis of the ecological niche has returned to some concepts that originated with C.S. Elton in the early twentieth century. As explained by Leibold (1995), the Hutchinsonian niche has as its basis the amount of environmental space that can be occupied by a species either with or without competition. In contrast, the earlier and simpler Eltonian concept is based conceptually

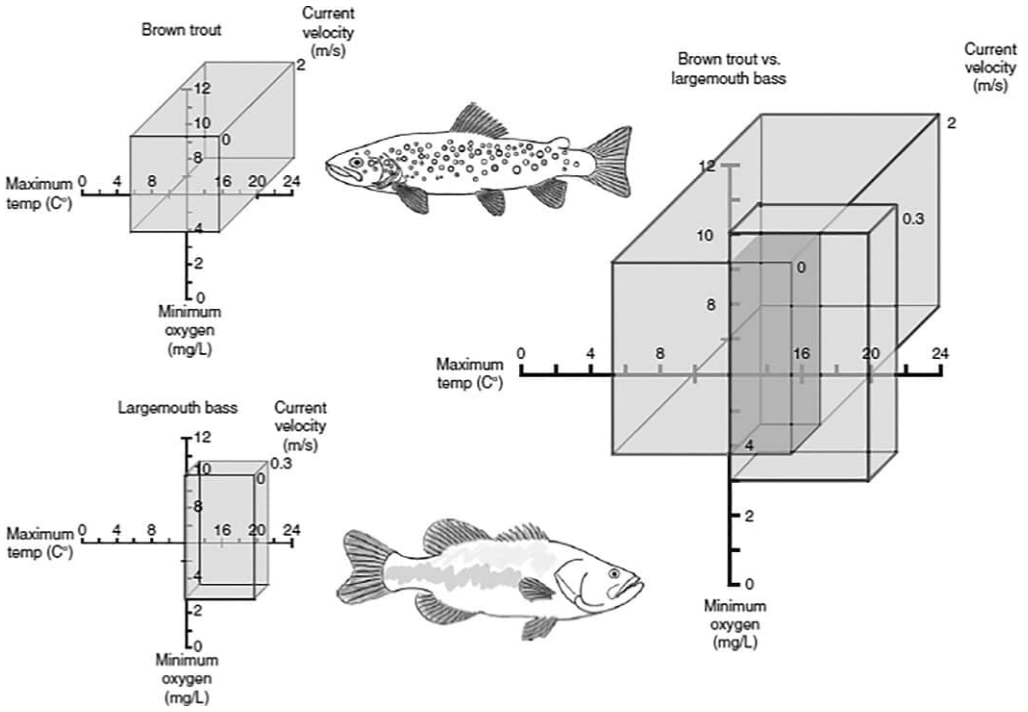

Fig. 1 A simplified depiction of niche space defined by three important environmental variables for a coldwater predator (brown trout, *Salmo trutta*) and a warmwater predator (largemouth bass, *Micropterus salmoides*). The fundamental niches are shown on the left, and their overlap is shown as the darkly shaded area on the right. More exact information on niche boundaries would most likely show the niche spaces as rounded and somewhat irregular rather than rectangular. The overlap shown on the right could lead to reduction of space (corresponding to the realized niche) for one or both species as a result of competition in a given ecosystem where the two species could occur together.

on the per capita effect (impact) that a given species has on the environment. The two concepts are related, but Leibold argues that a niche concept based on per capita effect leads to mechanistic (quantitative) analysis that is more realistic and therefore more productive.

Some ecologists also believe that the niche is a valuable determinant of species composition in communities of a given place, but they fault the original notions of niche for being overly vague about the means by which competition occurs. Chase and Leibold (2003) argue, as Hutchinson (1957) speculated, that the possibility of n dimensions for a niche is eclipsed by the likelihood that the distribution of a species is most likely defined by only two or three of the n dimensions. This re-examination of the Hutchinsonian model opens new possibilities for analysis because it presents the outcome of competition as a byproduct of a relatively small number of interaction types.

One further change in treatment of the ecological niche has been an increase in connectivity of the niche concept with other ecological concepts. Disturbance is one example; temporal changes at the ecosystem and community level explain why many species that might not coexist in a stable environment persist in an environment that is subject to constant change. Yet another example is the relationship between stability of an ecosystem or community and its number of species (species richness). The multiplicity of species occupying overlapping niches is viewed as a collective shock absorber that stabilizes ecosystems against externally induced change. Connection of the niche concept to a mechanistic understanding of ecosystems and communities insures that niche will continue to be a useful concept.

Aquatic ecological niches

Ecological niches are found in all types of ecosystems. At the level of concept or definition, there is no distinction between aquatic niches and terrestrial niches. Even so, aquatic environments are distinctive in that some (but not all) of the niche axes most likely to be important differ from those of terrestrial environments. Important dimensions of the ecological niche for aquatic organisms include temperature, dissolved oxygen, habitat structure, predation, and plant nutrients.

The range of temperature for aquatic ecosystems is much narrower than the range for terrestrial ecosystems because liquid water has a minimum temperature of 0 °C. Thermal thresholds are weak for phytoplankton and zooplankton, as shown by the distribution of species across wide ranges of latitude and elevation. Thermal thresholds are more important for large invertebrates and especially for fishes. For example, the family Salmonidae (salmon and trout) contains many species that are intolerant of waters

exceeding 15–20 °C. Similarly, perennially cool waters, such as montane or subarctic lakes, cannot sustain populations of many kinds of warmwater fishes, such as most species of the sunfish family (Centrarchidae).

Water holds only approximately 10 mg/L of oxygen at low temperatures and 6–7 mg/L at high temperatures. Thus, respiration can make water anoxic if it is not offset by photosynthetically produced oxygen or by contact of water with the atmosphere. High rates of respiration in water that is in contact with sediment, for example, can remove all oxygen from water in a matter of a few days.

Some aquatic environments are much more subject to oxygen depletion than others. Mountain streams of high gradient with low amounts of respiration are on one end of the spectrum, in that they have very little potential for oxygen depletion, whereas fertile lakes or wetlands, where there is much respiration and less efficient gas exchange with the atmosphere, show a much higher probability of oxygen depletion.

The distribution of organisms reflects in part their ability to tolerate oxygen depletion. Fishes, for example, show a wide range of tolerance to oxygen depletion. On one extreme are fishes that can obtain oxygen from the atmosphere (e.g., the tropical labyrinth fishes such as the betta, *Betta*) and fishes that have a small, upturned mouth capable of drawing oxygen from the top 1–2 mm of water in contact with the atmosphere (cyprinodont fishes, including the mosquito fish, *Gambusia*). Intermediate in tolerance are fishes that have no special means of obtaining oxygen, but have high physiological resistance to oxygen depletion (some catfishes, such as the bullhead, an ictalurid, *Ameiurus*, and the common carp, a cyprinid, *Cyprinus*). In contrast, other fishes are moderately or highly sensitive to oxygen depletion: trout and salmon, as well as largemouth bass (*Micropterus*), bluegill (*Lepomis*) and other sunfishes, and many others. Thus, the fish fauna of a particular waterbody reflects the likelihood of oxygen depletion. Invertebrates follow similar patterns. Aquatic larvae of midge species, for example, vary in oxygen tolerance, which explains their contrasting distributions in aquatic environments.

Habitat structure (cover) is a consistent component of most terrestrial environments; it is provided to a large extent by vegetation, which appears on all but the driest surfaces or on ice sheets. In contrast, the pelagic (open-water) environment of lakes provides no structure. Thus, organisms living in pelagic zones are specialized for living in an environment that lacks spatial stability and offers no refuge from predation. Variation in cover, ranging from the open waters of lakes and sandbed streams to richly vegetated littoral zones, vegetated wetlands, and rocky streams, offer a very wide range of possibilities for the niche axes that relate to habitat.

Limnologists and aquatic ecologists have shown repeatedly that predation has strong effects on the species composition of inland waters. Top predators are especially important in that they often remove or greatly suppress the abundance of their prey. Visual predators of lakes in particular may be much more efficient in eliminating their prey than would be the case in most other environments. In fact, some large invertebrates are unable to inhabit aquatic ecosystems that contain fishes. Small fishless lakes, for example, contain a rich abundance of large invertebrates that are not found in similar lakes that are stocked with fish. Thus, the niche dimension related to predation is critical to the distribution of many invertebrates.

Aquatic environments show an exceptional range of potential for producing autotroph biomass. Waters that have very low concentrations of nitrogen and phosphorus have production potential that falls well below that of any soil-based environment where moisture is present. In contrast, aquatic ecosystems with high concentrations of phosphorus and nitrogen have production potential for autotrophs that may be 1000 times higher than the least productive waters. Competition for nutrients is paramount in unproductive waters, which contain species having very high affinity for phosphorus and nitrogen. The most productive aquatic environments also support specialized taxa, but with different kinds of adaptations. Balance of nutrients may also be an important determinant of niche. For example, the nitrogen-fixing blue-green algae (heterocystous cyanobacteria) are, unlike other algae, capable of converting gaseous N2 to ammonia that can be used in making amino acids. When inorganic nitrogen is in short supply, these organisms are capable of continuing growth when other autotrophs cannot.

Conclusion

The ecological niche concept applies to all environments and should be seen as means of understanding the distribution and functional roles of species. Thus, ecological niche is a root concept for analysis of biodiversity, species distribution, ecosystem stability, and all other concepts that relate to the composition of communities. Critical niche dimensions of aquatic ecosystems provide some contrasts with terrestrial environments, and set the stage for comparison of aquatic ecosystems with other ecosystem types.

Glossary

Attack efficiency The number of successful attacks divided by the total number of (successful plus unsuccessful) attacks.
Encounter rate The number of encounters between a predator and an individual prey per unit of time. An encounter is thereby defined as the arrival of the prey in the space where the predator is in principle able to detect it (Jeschke et al., 2002).
Functional response The functional relationship between (on the y axis) the number of prey that a predator consumes per unit of time (i.e., consumption rate) and (on the x axis) the abundance or density of its prey (Holling, 1959a).
Inducible prey defenses A prey defense (as defined below) that is phenotypically plastic. Such a defense is only expressed if a cue for the presence of predators is present, such as a chemical signal.
Invasive species Species that have successfully completed the invasion process, i.e., they have been (i) intentionally or unintentionally transported by human action from their native range to a new range, have been (ii) released there or escaped into the wild, have (iii) established one or more self-sustaining populations there, and have (iv) spread substantially beyond their point(s) of release or escape (Blackburn et al., 2011; Jeschke et al., 2013).
Permanent prey defenses A prey defense (as defined below) that is constitutive. Such a defense is always expressed, even if no cue for the presence of predators is present.
Predation cycle The process that a predator consecutively goes through when successfully hunting prey, consisting of the following steps: search, encounter, detection, attack, capture; if the predator is hungry again, the next cycle starts, beginning with search, encounter etc. (Jeschke et al., 2008).
Predator An organism that consumes other organisms (the prey) in part or completely, with the following conditions: (i) the organisms it attacks are alive (difference to detritivory), and (ii) it consumes many organisms during its lifetime (difference to parasitism). Predators can be categorized into: true predators, which typically kill their prey, and grazers, which remove parts of their prey but do not usually kill them (modified after Begon et al., 2005).
Predator confusion effect If a predator confronted with a swarm of its prey is limited by its neuronal abilities, resulting in a reduced attack efficiency (Krause and Ruxton, 2002; Jeschke and Tollrian, 2007). Predator confusion is a special type of swarming effect.
Prey An organism that is consumed by a predator (as defined above).

Prey defense Behavioral, morphological, physiological or life-history adaptation leading to a reduced likelihood that prey is killed or otherwise harmed by a predator.
Swarming effect If a predator confronted with a swarm of its prey is less successful at one or more steps of the predation cycle as compared to when being confronted with individual prey. Predator confusion is an example of a swarming effect.

Introduction

Predation is a classic species interaction that has been investigated for a very long time. Conceptually, predation is a +/− interaction that benefits one side, the predator, and harms the other side, the prey. In brutal reality, of course, prey is often not just "harmed" but killed. That depends on the type of predator: True predators are those that typically kill their prey, whereas grazers remove parts of their prey but do not usually kill them (modified after Begon et al., 2005). Species that first come to mind when imagining a "predator" are true predators, for example piscivorous fish species such as northern pike (*Esox lucius*) or zander (*Sander lucioperca*). However, fish and invertebrate predators that consume zooplankton (e.g., three-spined sticklebacks *Gasterosteus aculeatus* or tadpole shrimp *Triops cancriformis*) are, as defined here, true predators as well, and so are some herbivores (e.g., waterfleas *Daphnia* spp. consuming algae). Examples of grazers, as defined here, are in the terrestrial realm cattle and sheep; in fresh waters, examples include ducks, geese and swans that partly consume macrophytes.

Parasitism is a +/− interaction as well, where the parasite benefits from the interaction and harms the host organism. So how do parasites differ from predators? First, parasites have a much closer relationship to their host than predators have to their prey. Second, while predators feed on many organisms during their lifetime, parasites only have a limited number of hosts during their life. And finally, parasites do not usually kill their host; this last point is only a differentiation from true predators, not from grazers.

This chapter provides an overview of key concepts related to predator-prey interactions and illustrates them with examples: (1) the predation cycle and its stages search, encounter, detection, attack and capture; (2) prey defenses and how they can be classified based on the predation cycle, thereby also comparing inducible with permanent prey defenses, looking at aggregation as a defense and prey responses against specific vs. multiple predators; (3) predator offenses; and (4) predator functional responses with a focus on classic mathematical predator-prey models. In the chapter's final section, we turn to more applied questions related to predation in the Anthropocene, outlining how (5) predator-prey interactions are affected by anthropogenic stressors as well as novel predators and novel prey organisms.

The predation cycle

The predation cycle is a conceptualization of the consecutive steps that a predator goes through when successfully hunting prey (Fig. 1). First, the predator searches for prey. That means for cruising predators like a zander or crayfish that they are actively moving around to find prey. For ambushing predators like northern pike or *Chaoborus* (phantom midge) larvae, "searching" means waiting for suitable prey to swim by: fish for the pike, zooplankton for *Chaoborus* spp.

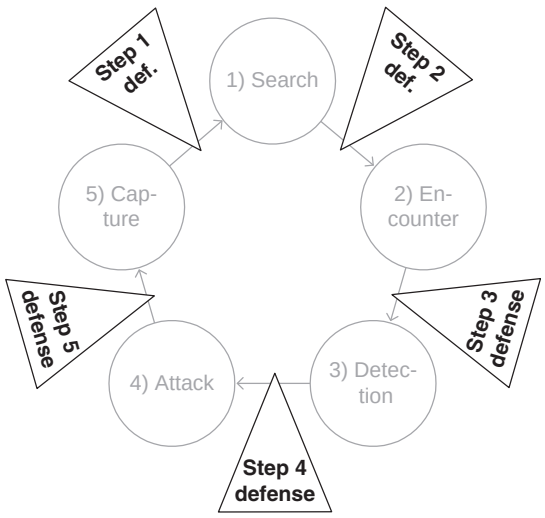

Fig. 1 The predation cycle consisting of the five steps search, encounter, detection, attack and capture. Prey defenses can be categorized according to the steps they interrupt.

Second, the predator encounters prey; that is, a prey item arrives in the space where the predator is, in principle, able to detect it (Jeschke et al., 2002). Again, such an encounter can be due to the active movement of a cruising predator and/or the movement of the prey, and strongly depends on the speed with which predator and prey move (Gerritsen and Strickler, 1977; Giguère et al., 1982). If the prey is immobile, e.g., a macrophyte, the predator obviously needs to move by itself in order to encounter prey.

Third, the predator detects prey. Predator species have different senses for prey detection. Many fish species, for instance, primarily rely on their eyes to detect their prey. They therefore hunt when and where light is sufficiently available. Other species, such as *Chaoborus* larvae, are mainly tactile predators that detect their prey, e.g., waterfleas, through their movement, leading to pressure gradients in the water. Chemical cues can also be very important for detecting prey, for example in catfish such as *Ictalurus punctatus*, which are sometimes called "swimming tongues" (Caprio et al., 1993).

Fourth, the predator attacks prey. Amazing organs and capabilities of predators have evolved, so that they can successfully transition through the predation cycle. At the same time, prey have evolved defense strategies to reduce the likelihood that they become a predator's next meal. Examples of such prey defenses and predator offenses are provided in the following two sections, so we only want to briefly mention here that well-known prey defenses reducing the likelihood of a predator attack are warning signals, such as bright coloration indicating toxicity.

Fifth and finally, the predator captures its prey. If it is still hungry or once it is hungry again, a new predation cycle starts.

Prey defenses

Prey defenses can be categorized according to different schemes. Here we outline (1) a classification based on the predation cycle, (2) inducible vs. permanent prey defenses, (3) aggregation as a defense and (4) responses against specific vs. multiple predators.

Classification based on predation cycle

Defenses are often classified according to the step of the predation cycle that they interrupt (Fig. 1). We outline such a classification in the following sub-sections, from step 1 to step 5 defenses, following Jeschke (2006) and Jeschke et al. (2008).

Step 1 defenses prevent search

Prey can prevent predators from searching, or increase the time period between a predator's last meal and its next search by way of: (A) Hardly digestible or toxic substances that increase predator digestion time and thus reduce the motivation to search for the next meal. In extreme cases, predators become sick or even die due to toxic prey substances. (B) Prey armor, weapons and flight behavior: they increase predator handling time, i.e., the time needed to attack, capture, and consume a prey individual.

Note that step 1 defenses are not advantageous for the consumed prey organisms themselves if they are killed by the predator. However, for prey of grazers (which only partly consume their prey), they can be beneficial on the individual level; macrophytes are a good example. Further, step 1 defenses can be evolutionarily adaptive in clonal prey such as *Daphnia* spp. (Fig. 2), or result from kin selection. Nonetheless, step 1B defenses are simultaneously and usually primarily step 5 defenses (see below).

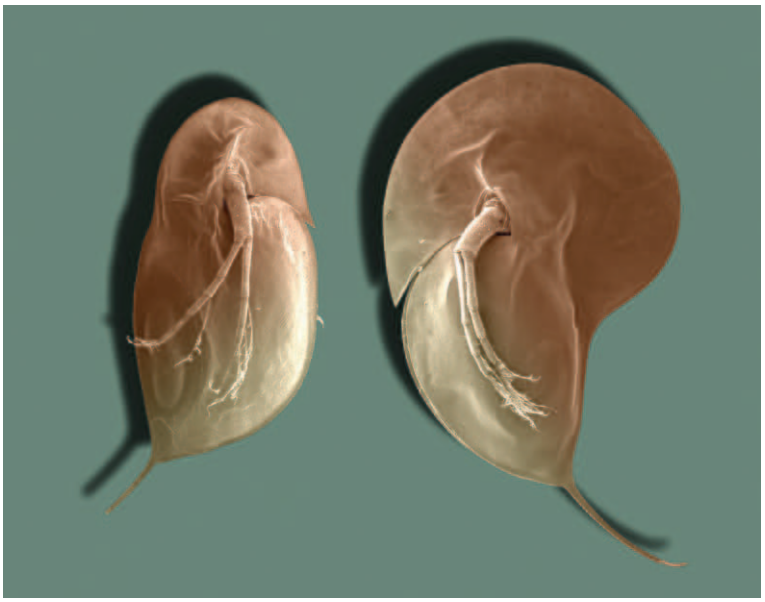

Fig. 2 *Daphnia longicephala* develop a large crest as an inducible step 1B, 5 defense which increases the handling time and reduces the attack efficiency of invertebrate predators (left: undefended morph, right: defended morph). © C. Laforsch.

Step 1 defenses are especially advantageous at intermediate prey densities: their effect is small at low densities, when predation rate is limited by other factors than handling or digestion time (namely by the encounter rate between predators and prey, the probability to detect and attack prey, and the probability that an attack is successful); at high prey densities, on the other hand, predation rate is limited by handling or digestion time, even if the prey are undefended (Jeschke, 2006). In other words, safety-in-numbers (also called the dilution effect, Hamilton, 1971) overrides the effect of step 1 defenses at high prey densities, making them unnecessary there.

Step 2 defenses prevent encounter

Defenses in this class prevent encounters with predators, i.e., prey are not within a predator's detection range. Examples are predator-avoidance strategies, such as hiding in refuges or diel vertical migration. The latter is performed by many aquatic invertebrates including *Daphnia* (Fig. 3): since visually hunting fish need light to successfully capture prey, they forage in the upper layers of the water body during the day. *Daphnia* can avoid them by spending the daytime in the lower layers of the water body and foraging for algae in the upper layers at night, when the fish are no danger due to the lack of light.

If prey move slowly or not at all, they also reduce the encounter rate with predators, especially when those predators move slowly or not at all themselves; the latter is true for ambush predators like northern pike or *Chaoborus* larvae (Gerritsen and Strickler, 1977; Giguère et al., 1982). A number of animals have evolved the ability to produce resting stages, e.g., *Daphnia* can produce resting eggs under unfavorable conditions. Although it might not be the foremost function of such resting stages, they can also serve as life-history defenses that avoid encounters with predators during periods of high predation risk.

Step 2 defenses are especially beneficial at low prey densities because the above mentioned dilution effect becomes stronger with increasing density and makes these defenses less advantageous under crowded conditions. The same is true for step 3, 4, and 5 defenses. Thus, defenses affecting the steps 2–5 are generally more beneficial at low than at high prey densities (Jeschke, 2006).

Step 3 defenses prevent detection

When being within the detection range of a predator, a prey individual can reduce the probability of actually being detected in several ways. Camouflage is the best known example of such a step 3 defense and is found in a vast number of animals, e.g., in mayfly, dragonfly or damselfly larvae (Ephemeroptera, Odonata). Freezing reduces the detection probability as well, and so does slow movement or sleeping—the latter is also a step 2 defense (see above).

Step 4 defenses prevent attack

Detected prey can avoid an attack by way of warning signals (aposematism), e.g., bright coloration as a sign of toxicity. Such warning signals are basically the opposite of camouflage, but are also widespread. Poison dart frogs (Dendrobatidae) and fire salamanders (*Salamandra salamandra*) are well-known examples. Aposematisms are often similar across prey species, so-called Müllerian mimicry, which increases recognition and avoidance by predators. Yet, warning signals offer opportunities for "cheating"

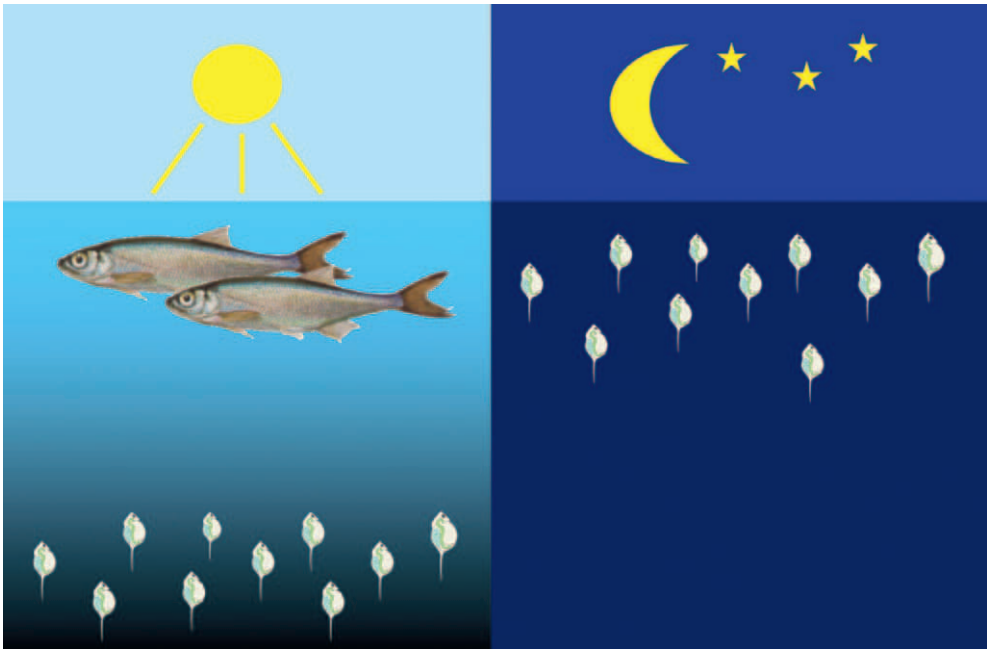

Fig. 3 *Daphnia* and many other planktonic species show diel vertical migration. During daylight hours (left side), they avoid the upper layers of the water body if they are populated by planktivorous fish during that time. At night (right side), the fish do not hunt due to the lack of light, so the *Daphnia* can migrate to the upper layers of the water body and forage for algae. Diel vertical migration avoids encounters with predators; it is an example of an inducible step 2 defense. © R. Tollrian.

species which are not poisonous but show the same appearance, so-called Batesian mimicry. A well-known example for insects are the black-and-yellow stripes of harmless hover flies (Syrphidae) resembling those of wasps and bees. An example for fish species is the appearance and behavior of juvenile grunt (*Pomadasys ramosus*) mimicking venomous juvenile leatherjacket (*Oligoplites palmeta*; Sazima, 2002). Finally, some prey species also warn acoustically. For instance, the tub gurnard (*Chelidonichthys lucerna*) produces sounds that resemble "grunts" when being confronted with a predator. These sounds are accompanied with visual warning signals—"raising of dorsal fin and spreading large and brightly colored pectoral fins" (p. 989 in Kasumyan, 2009).

Step 5 defenses prevent consumption

Defenses of this final category reduce predator attack efficiency, i.e., the probability that a predator attack is successful. Typical examples are flight behavior (most prey do that, unless they are immobile), armor (as in mussels, crayfish or *Daphnia*, Fig. 2), weapons (such as cnidocytes in cnidarians, Fig. 4; Tardent, 1995) and fighting. The latter is especially effective for grouped prey—for example, some fish species such as bluegill sunfish (*Lepomis macrochirus*) aggregate to mob predators away (Smith, 1992). Aggregated prey may also benefit from other swarming effects, as we further outline below.

Many aquatic predators are gape-limited and thus cannot mechanically handle prey beyond a certain size. For example, northern pike cannot ingest fish that exceed a certain height or breadth. Crucian carp (*Carassius carassius*) with a deep body are therefore effectively defended against this piscivore (Petersson and Brönmark, 1997). Similarly, *Daphnia* can allocate energy to growth instead of reproduction in order to outgrow the prey-size spectrum of *Chaoborus* larvae (Fig. 5), *Leptodora kindtii* and other gape-limited invertebrate predators. This energy-allocation strategy is also an example of a life-history defense (Fig. 6).

Step 5 defenses could in principle be further classified into defenses that prevent capture (e.g., flight) and those that prevent consumption (e.g., armor), but this distinction is often unclear. Recall that step 5 defenses also increase predator handling time, so they are also step 1B defenses.

Other classifications of defenses based on the predation cycle

Different authors have used different classification schemes of defenses based on the predation cycle, but they are largely similar. As in the above classification, defenses often fall into more than one category. This can be seen as a disadvantage, but it also expresses that many defenses function in several ways. Some classifications do not include defenses that prevent predators from searching (step 1 defenses according to the above terminology). For example, Edmunds (1974) divided defenses into primary and secondary ones, where primary defenses involve step 2, step 3 and step 4 defenses according to the above classification, and where secondary defenses equal step 5 defenses. Primary and secondary defenses have also been called pre- and post-contact defenses, respectively (Swift, 1992). Endler (1991) used the following categories: encounter defenses (= step 2 defenses); detection defenses (=step 3 defenses); identification defenses (= step 4 defenses); approach defenses and subjugation defenses (both together form the group of step 5 defenses); consumption defenses (similar to step 1 defenses).

Fig. 4 Charged and discharged cnidocytes. In addition to their offensive function as weapons for prey capture, they also defend cnidarians from being captured by predators and exemplify permanent step 5 defenses. © C. Laforsch.

Fig. 5 Phantom midge larvae (*Chaoborus* spp.) are gape-limited predators. © C. Laforsch.

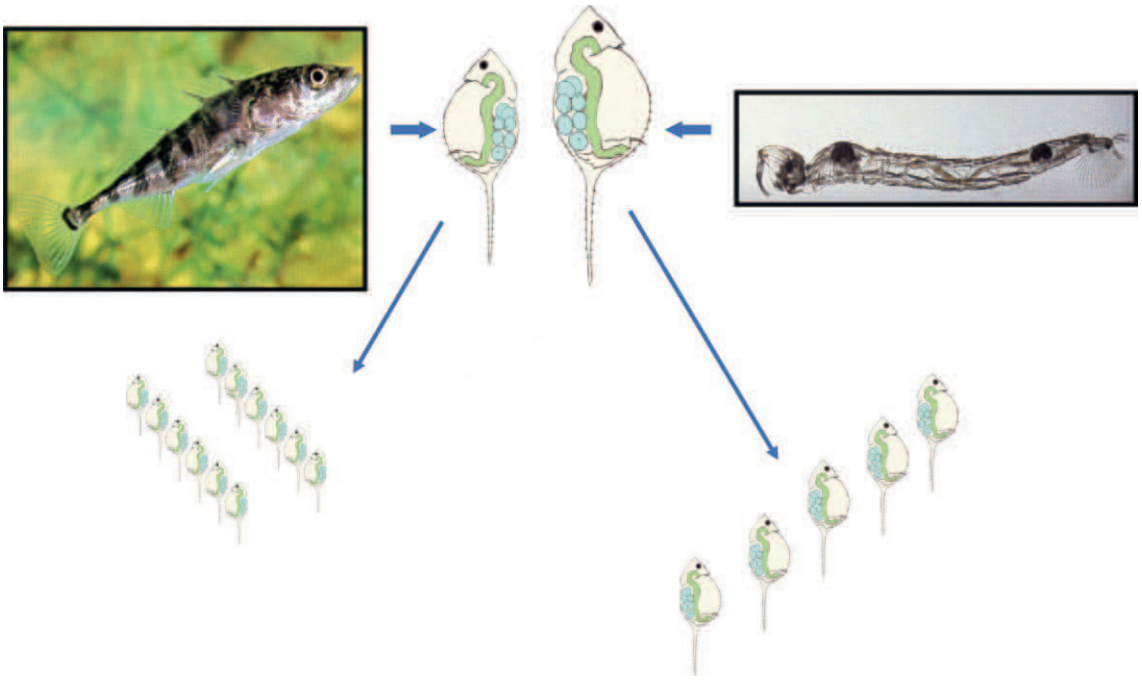

Fig. 6 *Daphnia* adaptively change their resource allocation between somatic growth and reproduction in response to cues from fish and gape-limited invertebrate predators (Stibor and Lüning, 1994). Fish consume larger size classes, so *Daphnia* invest less energy in somatic growth and more in reproduction if fish predation dominates. On the other hand, gape-limited invertebrate predators consume smaller *Daphnia*, so outgrowing their prey-size spectrum by investing much energy in somatic growth is an effective defense if invertebrate predation dominates. This resource-allocation shift is an example of an inducible step 5 defense that affects the prey's life history. © R. Tollrian.

Inducible vs. permanent prey defenses

Defenses can be permanent (i.e., constitutive) or inducible. The phenotypically plastic expression of defensive traits, i.e., inducible defenses, enables prey organisms to express a particular defense only if a reliable cue for a future attack is present (Tollrian and Harvell, 1999). Thereby, the organisms can minimize costs affiliated with the formation or maintenance of a defense when predation risk is low. Inducible defenses are an appropriate mechanism to cope with the variable hazard of a frequently changing predator spectrum. In the animal kingdom, inducible defenses are covering a taxonomic range from protozoans to vertebrates. The defensive traits range from behavior, morphology and life-history adaptations to the activation of the specific immune system of vertebrates. *Daphnia* show prominent examples of morphological plasticity triggered by chemical cues, so-called kairomones, released by predatory invertebrates and fish (reviewed by Tollrian and Harvell, 1999; Weiss and Tollrian, 2018; Diel et al., 2020). For example, elongated helmets, tail spines or crests have been shown to reduce predator-caused mortality (Fig. 2). Another example of inducible defenses is a deeper body shape of fishes, which is often an effective strategy against (gape-limited) piscivorous fish species (Petersson and Brönmark, 1997; Price et al., 2015).

Several factors have been identified that favor the evolution of inducible as opposed to permanent defenses: (1) the attacker has to have a variable but sometimes relevant impact; (2) the defense must be effective within a relatively short time, so lag phases can be avoided; (3) a reliable cue has to indicate the danger; and (4) costs have to outweigh the benefit of the defense during relevant periods of time (Tollrian and Harvell, 1999; Diel et al., 2020).

Aggregation as a prey defense

Aggregation can have several benefits. It can, for example, provide energetic benefits when swimming in a swarm as compared to swimming alone. It can also reduce the individual risk of being killed by a predator, simply because of "safety in numbers" (Hamilton, 1971). Such a dilution effect does not reduce the kill rate of the predator, but it is nonetheless a prey defense, as it reduces the likelihood that individual prey is killed or otherwise harmed by a predator.

There are also defenses where the kill rate of the predator is reduced. Such defenses are caused by swarming effects; here, a predator confronted with a swarm of its prey is less successful at one or more steps of the predation cycle as compared to when being confronted with individual prey. The following swarming effects can be discriminated:

- Early-warning or many-eyes effect: approaching predators are detected either with a higher probability or earlier by a prey swarm than by a single prey item (Pulliam, 1973; Godin et al., 1988).
- Encounter effect: the encounter rate with the predator is lower for aggregated than for individual prey (Englund and Harms, 2001).
- Confusion effect: a predator confronted with a swarm of its prey is limited by its neuronal abilities, resulting in a reduced attack efficiency (Krause and Ruxton, 2002; Jeschke and Tollrian, 2007). Empirical studies reviewed by Jeschke and Tollrian (2007) suggest that tactile predators and those visual predators that hunt highly agile prey frequently show a confusion effect, whereas visually hunting predators that focus on other prey do not usually have a reduced attack efficiency when being confronted with a swarm of their prey.
- Active defense effect: aggregated prey can defend themselves better actively than individual prey (Bertram, 1978).
- Clogging effect: if the filters of filter feeders clog in case of highly abundant food particles (Harbison et al., 1986).
- Toxin accumulation effect: predators suffer from an accumulation of prey-specific toxins (Halbach and Halbach-Keup, 1974).

All of these effects can lead to a reduced foraging success of the predator when prey aggregate. It is important to realize, however, that some predators can also benefit from prey aggregations. In particular, filter feeders such as *Daphnia* spp., silver carp (*Hypophthalmichthys molitrix*) or flamingos typically have a higher foraging success when encountering prey swarms (unless their filters clog), as their foraging strategy is optimized for prey aggregations.

Responses against specific vs. multiple predators

At first glance, some of the above-described defenses seem to be general defenses against predators per se. For example, the just mentioned swarming behavior will work against a large number of predators, not only one predator species. Similarly, some genera such as *Daphnia* enlarge their body size or the length of their appendages in the presence of many predation threats (Tollrian and Harvell, 1999; Weiss and Tollrian, 2018; Diel et al., 2020). A detailed look, however, reveals that this is only a rough approximation.

In many cases, defenses are evolutionarily tailored towards specific predators. Just recently, Kruppert et al. (2017) unraveled the mechanisms behind such a specific response in *Daphnia pulex* and *D. longicephala*: both species alter their carapace in the presence of their main predator, *Chaoborus* spp. and backswimmer *Notonecta* spp., respectively. While the former crushes its prey with its mandibles and needs to force it through the mouth opening (Schremmer, 1950; Kruppert et al., 2019), the latter pierces its prey's carapace and imbibes the externally digested, liquified innards (Dahm, 1972). While *D. longicephala* enhances the lamination of the layers of chitin fibrils forming its carapace cuticle, resulting in enhanced puncture resistance against *Notonecta*'s proboscis, *D. pulex* enhances lamination as well as carapace thickness, resulting in enhanced puncture and bending resistance, which complicates crushing and ingestion by *Chaoborus* spp.

Nevertheless, a variable impact is key for the evolution of inducible prey defenses, as mentioned above. Otherwise, the defense would evolve permanently. Such a variable impact does not necessarily result from fluctuations in one predator's abundance. More likely in nature are predator successions or varying predator regimes accompanied by fluctuating selectivity for different prey morphs.

Therefore, one-on-one interactions with a single threat are possibly rare in nature. Most of the time, the life of prey organisms may be jeopardized by a multitude of predaceous species, or predators in different life stages (Scharf et al., 2000). Such multipredator-prey-systems can be categorized as either functionally equivalent, functionally inverse or functionally diverse (Herzog and Laforsch, 2013). Depending on the system, a behavior, life history or morphology that is advantageous against one threat may be disadvantageous against another. Defenses that evolved via diffuse coevolution and function as a multitool against different predators are accordingly extremely useful. Again in *Daphnia*, we find two very impressive examples of such multitool defenses: *D. cucullata*'s helmet provides efficient defense against *Cyclops*, *Chaoborus* and *Leptodora* predation, acting on different ontogenetic stages and via different mechanisms (Laforsch and Tollrian, 2004), while the helmet formation in *D. lumholtzi* reduces predation rate in the presence of fish as well as *Chaoborus* (Engel et al., 2014). Interestingly, even seemingly very different morphological defenses can have a shared benefit, as for example in *D. barbata* (Herzog and Laforsch, 2013). This species is able to form different morphotypes against different predators, the tadpole shrimp *Triops* and backswimmer *Notonecta*. The defense against *Notonecta* was shown to be as advantageous against *Triops* as the specific defense, but not vice versa, even though there was still a small benefit compared to undefended individuals. Apart from the obvious costs of e.g., delayed reproduction, material investment into morphological structures or altered locomotion speed, the costs of being defended against the "wrong threat" are reduced through multitool-defenses.

Similarly, a defense against predators may have an additional benefit. For example, diel vertical migration (see above) in zooplankton is regarded as an avoidance strategy against visually hunting predators during daytime. However, it has been shown that an additional benefit in several *Daphnia* species is the avoidance of damage imposed by UV-radiation (Leech and Williamson, 2001; Rhode et al., 2001). A defense adjusted to the main threat(s) with an efficacy also against co-occurring dangers should therefore lead to the highest gain in fitness.

Predator offenses

While defenses are important for prey to protect themselves against predators, offenses are important for predators to avoid starvation. Similarly to prey defenses, predator offenses can be classified according to the steps of the predation cycle they affect (Jeschke, 2006).

Step 1 offenses reduce the time between the end of one predation cycle and the beginning of the next one, i.e., when the predator starts searching for its next meal. Examples of such offenses are physiological adaptations that reduce predator digestion time, or morphological adaptations that reduce handling time. Extreme cases are some filter feeders, such as *Daphnia*, with a morphology that allows them to simultaneously handle and search for (i.e., filter) food.

The benefit that a predator has from such step 1 offenses in terms of an increased consumption rate is particularly high at high prey densities (Jeschke, 2006). On the other hand, step 2–5 offenses, which are outlined in the following paragraphs, have a maximum effect at intermediate prey densities; this is because their effect is overridden at very high prey densities, where consumption rate is mainly determined by digestion time or, depending on the predator, handling time (Jeschke, 2006; see also the following section on predator functional responses).

Step 2 offenses increase the encounter rate with prey, for instance by means of an increased foraging speed or an enlarged encounter volume. Cruising predators, such as zander, benefit from such an offense. Long-distance senses are another example.

Step 3 offenses increase the probability that a predator detects prey it has encountered. Senses with high spatial resolution, such as sharp eyes or elaborated mechanosensillae as in *Notonecta* (Mail et al., 2018) are good examples of such an offense.

Step 4 offenses increase the probability that a predator attacks prey it has detected. This is particularly relevant in connection with aggressive, toxic or in other ways dangerous prey: if the predator is at least partly protected against such prey, it is more likely to take the risk and attack it.

Finally, step 5 offenses increase the likelihood that a predator attack is successful. Attack efficiency can, for example, be increased by a high acceleration when prey is attacked: northern pike have been reported to have an astonishing strike acceleration of 55 m/s^2 (Schriefer and Hale, 2004). Another good example is the explosive discharge of cnidocytes in cnidarians (Fig. 4; Tardent, 1995).

Predator functional responses

The functional response of a predator describes the relationship between the number of prey it consumes per unit of time and the abundance or density of its prey (Solomon, 1949; Holling, 1959a). This is another classic concept related to predation and highly important for several fields of research, for example for behavioral, physiological and evolutionary ecology, as functional responses and corresponding models capture key elements of foraging ecology (cf. Stephens and Krebs, 1986), digestion and fitness-related factors (e.g., the survival of prey). Given that functional responses epitomize the density-dependence of trophic relationships, they

are also highly important for predicting population dynamics whenever two or more trophic levels are present in a food web, which is of course almost always the case under natural conditions.

What do functional responses graphically look like? While predator consumption rate typically shows a monotonic increase with prey density, the exact shape of this increase varies and has been categorized into three main types (Fig. 7; Holling, 1959a; Jeschke et al., 2004): in type II functional responses, consumption rate shows a curvilinear increase; in type III functional responses, the increase is sigmoid; and in type I functional responses, the increase is linear until a threshold prey density is reached, beyond which consumption rate remains constant. For each of these three types, a dome-shaped variant is possible where consumption rate does not monotonically increase with prey density, but instead declines at high densities (Fig. 7; type II dome-shaped, type III dome-shaped, type I dome-shaped; Jeschke et al., 2004).

The most frequently observed type of functional response is the type II. This is particularly true for non-filter feeders. Reviewing 814 individual functional responses measured in 235 empirical studies, Jeschke et al. (2004) found for non-filter feeders (n = 449 studies) a frequency of 77% for type II, 13% for type III, 8% for dome-shaped functional responses and 3% for type I. For filter feeders, though (n = 365 studies), the type I was most frequent with 37% of the functional responses, followed by type II with 29%, type III with 25% and dome-shaped functional responses with 13%.

Functional responses have not only been measured for several decades, there also exist quite a number of functional response models (reviewed in Jeschke et al., 2002). The most influential model has been Holling's (1959b) classic disc equation:

$$y = \frac{a \cdot x}{1 + a \cdot b \cdot x}, \tag{1}$$

where y is consumption rate, a is predator success rate, x is prey density and b is predator handling time (Holling used a slightly different notation). Predator success rate a can be derived from the predation cycle, as it is the product of (i) encounter rate, (ii) the probability that the predator detects prey it has encountered, (iii) the probability that the predator attacks prey it has detected and (iv) attack efficiency. Similarly, predator handling time b is the sum of the time needed (1) to capture a prey item (including time wasted for unsuccessful attacks) and (2) to consume a prey item (Jeschke et al., 2002).

Predator consumption rate is at low prey densities mainly determined by predator success rate—and thus, by its components representing the different transitions in the predation cycle. At high densities, however, it is mainly determined by digestion time and handling time, more specifically by the longer of the two processes (digestion or handling), at least under circumstances where predator satiation and thus digestion are relevant. Most predators need more time to digest than to handle their prey (Jeschke et al., 2002), thus their long-term maximum consumption rate depends on their physiological digestion capacity. Short-term maximum consumption rates, where satiation does not kick in, can be higher—these are usually determined (in other words: limited) by handling time.

Handling and digestion time are also the reason why a type II functional response has a curvilinear shape: with increasing prey density, the predator spends an increasing amount of time handling and digesting prey; thus, the curve increasingly flattens. A key point here is that predators showing type II functional responses can typically either search for or handle prey, but they cannot do both simultaneously; this is also an assumption underlying Holling's disc equation. Other predators, which can search for and handle prey simultaneously (e.g., filter feeders such as *Daphnia* spp.) frequently show a type I functional response which does not flatten with an increase in prey density; here, consumption rate increases linearly to a certain point at which satiation kicks in and abruptly limits consumption rate. Type III functional responses result from a density-dependent effect. For example, if a given prey

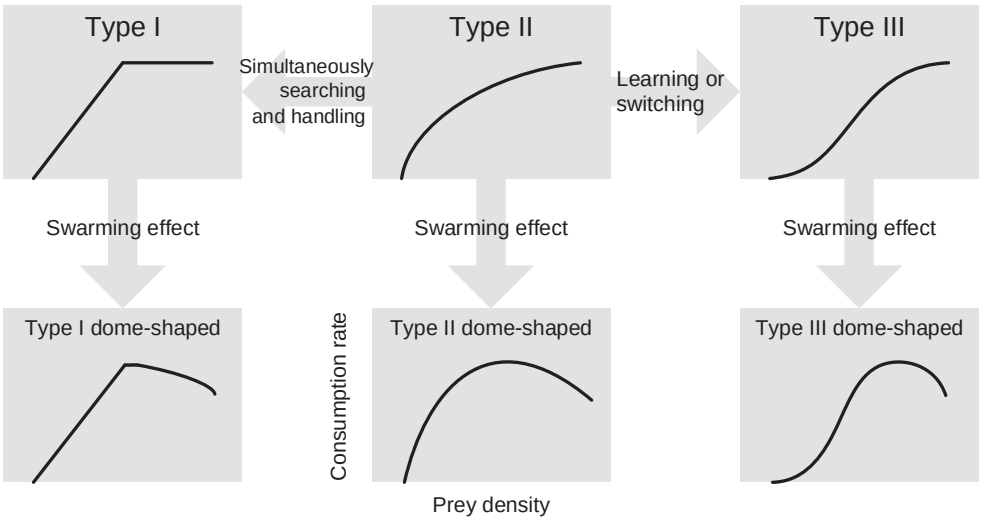

Fig. 7 Different types of functional response. Modified after Jeschke, J. M., Kopp, M., Tollrian, R., 2004. Consumer-food systems: why type I functional responses are exclusive to filter feeders. Biological Reviews 79, 337–349.

species reaches a high density and predators learn to better detect (e.g., through developing a search image) or more efficiently attack this prey, then success rate *a* increases with prey density; this, in turn, leads to a sigmoid shape. Similarly, some predators switch from a sit-and-wait to a cruising foraging tactic when prey density increases (reviewed by Helfman, 1990), which also leads to a type III functional response. Finally, dome-shaped functional responses result from swarming effects, which are characterized by a reduced success rate at high prey densities (see above).

Predator-prey interactions in the Anthropocene

How anthropogenic stressors affect predators and prey

At least since the industrial revolution, anthropogenic activities (see Fig. 8) have massively impacted freshwater ecosystems and predator-prey interactions within those systems. Due to space limitation, we can only highlight some of these anthropogenic stressors here.

Private and industrial disposal of pharmaceuticals and personal care products (PPCP) (number 1 in Fig. 8) combined with the inability of sewage plants to remove all these compounds have been found to lead to residues of these often water-soluble chemicals in waterbodies, where they can affect freshwater organisms (Kreke and Dietrich, 2008; Hedgespeth et al., 2014). For example, drugs can mimic infochemicals, disrupt signal production/transduction pathways or interfere in other ways with the chemical communication of predator and prey organisms (Van Donk et al., 2016). Specifically, the antidepressants fluoxetine, venlaflaxine and bupropion, which are selective serotonin reuptake inhibitors (SSRIs), were found to slow down the escape behavior of larval fathead minnows (*Pimephales promelas*) (Painter et al., 2009). Sertraline, another SSRI, was found to decrease the feeding rates of Eurasian perch (*Perca fluviatilis*) consuming *Daphnia magna* (Hedgespeth et al., 2014).

Anthropogenic stressors derived from intensive agriculture (number 2 in Fig. 8), such as pesticides and nutrient input, can impact freshwater predator and prey organisms even more strongly. The rotifer *Brachionus calyciflorus* was found to express increased transgenerational costs, i.e., a reduced population growth rate, for its morphological defenses against its predator, the rotifer *Asplanchna girodi*, when exposed to the pesticide Methamidophos (Heine-Fuster et al., 2017). The indicated study further showed that pesticides might even affect future generations. A pesticide-related increase of the costs for predator-induced defenses was also found in *D. magna* preyed on by the brown trout (*Salmo trutta*) during exposure to Imidacloprid (Pestana et al., 2010). Furthermore, the authors detected that the pesticide compromised the predator-induced life-history defenses of the daphnids. The functional

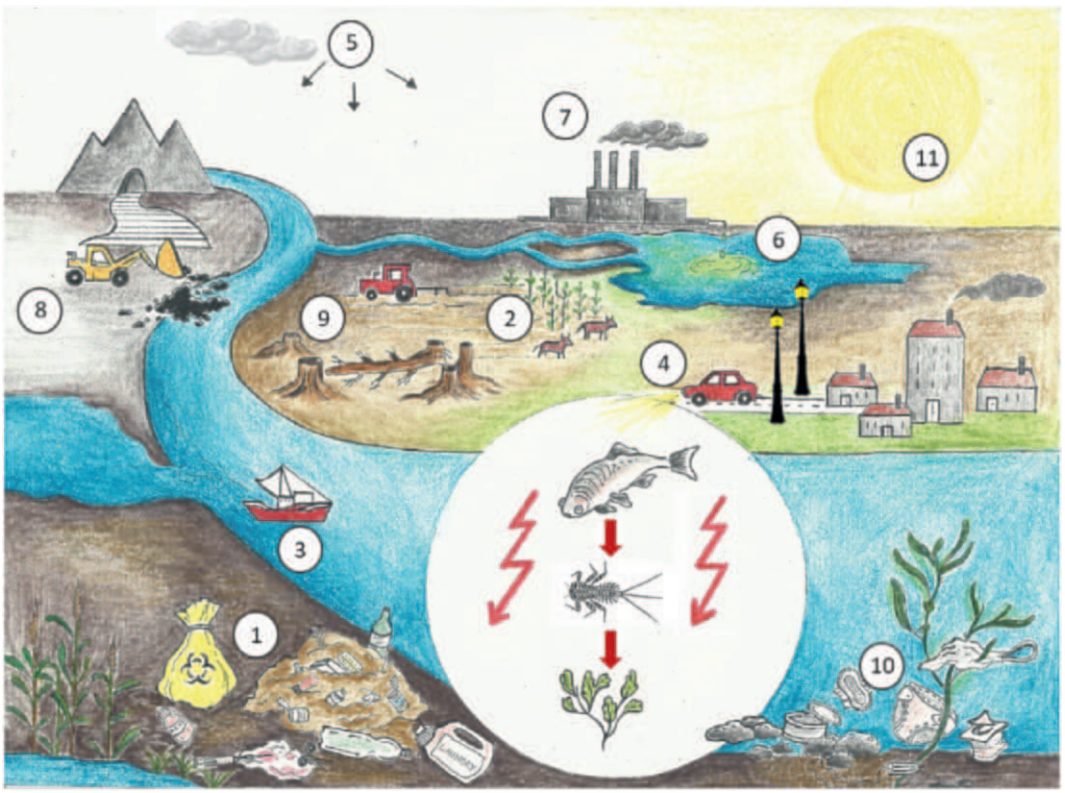

Fig. 8 Examples of anthropogenic stressors for freshwater bodies: (1) pharmaceuticals and personal care products, (2) intensive agriculture, (3 + 4) transportation, (5) acidification, (6) artificial light at night, (7) industrial manufacturing, (8) mining, (9) logging, (10) particulate contaminants, (11) climate change. Details on each stressor are provided in the main text, where we also outline the important, yet insufficiently understood, integrated effects of multiple stressors.

mechanism behind the pesticide-related changes is supposedly the inhibition of acetylcholinesterase, leading to an increased duration and strength of neurotransmission (Heine-Fuster et al., 2017). This changes the activity of the affected animal and also likely leads to life-history changes. Additionally, this effect can be transferred onto coming generations by the inhibition of acetylcholinesterase in the developing oocytes. Especially since *Daphnia* is a keystone genus in a multitude of freshwater bodies, this reaction to pesticides potentially leads to negative consequences for the communities in these ecosystems.

Further, there are a number of stressors related to transportation, for instance via waterways (number 3 in Fig. 8) or roads (number 4). Enhanced levels of salinity, which can be caused by road salt, were found to weaken life-history defenses of *D. pulex* against *Chaoborus americanus* (Liu and Steiner, 2017). Road salt can also cause a mobilization of heavy metals from roadside soils (Schuler and Relyea, 2018). When the combination of these chemicals arrives in adjacent water bodies, e.g., through precipitation, the toxicity of heavy metals is likely to rise as well, and trophic interactions can be strongly compromised. Another example for a transportation-related stress factor is noise. The European minnow (*Poxinus phoxinus*) reduces its attack rate and shows specific stress-related behavior when confronted with motorboat noise (Hanache et al., 2020). Resulting from the combination of aerial pollution through transportation, e.g., via cars, and industrial burning of fossil fuels, acidification (number 5 in Fig. 8) can impair predator-prey interactions as well. For instance, rainbow trout (*Oncorhynchus mykiss*) and brook charr (*Salvelinus fontinalis*) were found to have a reduced detection capability and responsiveness to conspecific alarm cues in reaction to small amounts of sulfuric acid, which is a known chemical substance associated with acidic rain (Leduc et al., 2004). The effect of acidification on freshwater fish may be related to a chemical change in the alarm cue and/or the inhibition of the chemosensory pathway (Leduc et al., 2013). In addition, transportation often requires artificial lighting (number 6 in Fig. 8), which can distort diel rhythms of organisms. Becker et al. (2013) also indicate that light pollution is in some areas likely to induce top-down trophic pressure on freshwater communities, through attracting prey organisms at night, which in turn allows predatory fish to hunt at night. Of course, transportation is not the only reason for artificial light at night—others are, for example, an increased security, or aesthetic or commercial reasons. Finally, transportation can lead to the arrival of invasive species that affect resident predator and prey organisms (see below for details).

Industrial manufacturing (number 7 in Fig. 8) and mining (number 8) can also affect predator-prey interactions, particularly due to an increase in the concentration of heavy metals in aquatic systems. For example, copper was found to affect the neckteeth induction in *Daphnia pulex*, possibly due to an inhibited kairomone reception pathway or an impaired neckteeth induction (Hunter and Pyle, 2004). Clements et al. (1989) found copper to increase the predation risk of caddisflies under predation pressure by the stonefly *Paragnetina media*. The authors attributed this partly to a suspected behavioral change of the prey organisms. A further chemical anthropogenic stressor for some freshwater predator-prey interactions is acid mine drainage. Hogsden and Harding (2012) highlighted fundamental alterations in the food-web composition and interactions in affected streams. They outlined that the reduced primary production in these water bodies is followed by an absence of herbivores, making invertebrates the top predators of these communities' food webs, as fish are rather lost due to acidification.

Logging (including removing trees including their roots, which is called whole-tree harvesting, WTH; number 9 in Fig. 8) can also affect predator-prey interactions in freshwater bodies. Trees act, in combination with base cation pools in the ground, as chemical buffers in many ecosystems. Through WTH, base cations are withdrawn from the soil, which can lead to a critical reduction in cation input into nearby water bodies (Watmough et al., 2003; Cox et al., 2018). When faced with reduced calcium concentrations, *D. pulex* are less capable of morphologically defending themselves against *Chaoborus* spp. (Riessen et al., 2012). Logging can also increase sediment input and turbidity, impeding fish and other visually oriented predators and prey. For example, increased turbidity was found to reduce the reactive distance of foraging rainbow trout (*Oncorhynchus mykiss*, Barrett et al., 1992) and coho salmon (*Oncorhynchus kisutch*, Berg and Northcote, 2011).

Some of the above-mentioned activities (numbers 1, 2, 3, 4, 7 in Fig. 8) additionally produce particulate contaminants (number 10), such as nanoparticles or plastic debris, as a novel suite of environmental stressors. Trotter et al. (2019) found plastic waste to negatively impact induced morphological and life-history defenses of *D. longicephala* against the predatory backswimmer *Notonecta glauca*. The plastic waste seems to adsorb kairomones emitted by *N. glauca*, thus reducing the amount of detectable infochemicals for *D. longicephala*. Any misperception of predator composition or density can have consequences on the population level and may even affect the whole food web.

The final stressor we are highlighting here is climate change (number 11 in Fig. 8), which is caused by a multitude of anthropogenic activities including those mentioned above. Grigaltchik et al. (2012) found that warm-acclimated Australian bass (*Macquaria novemaculeata*) interacting with eastern mosquitofish (*Gambusia holbrooki*) as prey launch more attacks and have a higher overall hunting success than cold-adapted individuals. However, the speed and number of attacks declined at very high temperatures, whereas the escape speed of mosquitofish increased, leading to an advantage of the prey at high temperatures. Solely rising pCO_2 levels without changing temperatures was also shown to have the potential to disrupt predator-prey-interactions, e.g., in *Daphnia* (Weiss et al., 2018). This variation in species reactions to temperature and rising pCO_2 levels illustrates how predator-prey interactions can be affected by climate change.

It is even more complicated when integrating the above anthropogenic activities and resulting stressors, plus those we did not outline here. This is a pressing task for science, as the diversity and magnitude of stressors has rapidly increased in the Anthropocene (Steffen et al., 2015; Waters et al., 2016). Moreover, while real ecosystems are faced with many anthropogenic stressors simultaneously, studies combining them are rare (Mazor et al., 2018). Based on a functional response approach and focusing on the copepod *Lovenula raynerae* preying on mosquito larvae (*Culex pipiens*), Cuthbert et al. (2019) found interacting effects of salinization

and warming on predator-prey interactions. Even more integrative studies are needed to better understand the combined effects that multiple stressors have on freshwater systems.

Novel predators and novel prey

Novel organisms are those organisms that have either been introduced by humans beyond their native range (non-native species, also called alien species), have expanded or shifted their range due to climate change (range-expanding species, also called neonatives, Essl et al., 2019), have recently emerged as new pathogens (emerging pathogens), have been modified genetically (GMOs) or even been created synthetically (synthetic organisms), typically by building their genomes with short DNA sequences called "BioBricks" (Jeschke et al., 2013). Novel organisms can heavily affect freshwater (and other) systems (e.g., Pyšek et al., 2020), and we here focus on the impacts of non-native predators and prey on resident prey and predators, respectively.

First, non-native predators can affect native prey species in various ways. Such impacts are often particularly strong if the prey species is evolutionarily naïve to the archetype represented by the predator—in other words, if the prey species lacks eco-evolutionary experience (Saul and Jeschke, 2015). Some prey species cannot detect cues from non-native predators (Carthey et al., 2017). For example, when exposed to the invasive red-eared slider turtle (*Trachemys scripta* elegans), three out of four European tadpole species did not reduce their swimming speed. They did, however, swim more slowly when exposed to native predatory turtles (Polo-Cavia et al., 2010). Furthermore, prey species can be poorly defended against novel predators (Weis, 2011). The introduction of the predatory spiny water flea (*Bythotrephes longimanus*) led to a decrease in many cladoceran species, because it preys on small instars of daphnids, whereas the native predator *Leptodora kindtii* preys only on later instars (Branstrator, 1995; Barbiero and Tuchman, 2004). Another invasive invertebrate predator is the freshwater amphipod *Dikerogammarus villosus*, called the "killer shrimp." Compared to native species, *D. villosus* consumes more prey (approximately one-third of their body weight per day) and feeds on other amphipod species as well as on fish larvae, which can lead to cascading effects in the food web (Krisp and Maier, 2005; Casellato et al., 2007).

Second, non-native prey have been shown to defend themselves against native predators in various ways, e.g., by way of habitat change, novel secondary metabolites or morphological defense structures (Bollache et al., 2006; Schultz and Dibble, 2012; Engel et al., 2014). These defenses can have strong impacts on resident predators, especially if they are novel for the community, so that the resident predators lack eco-evolutionary experience in interacting with such prey (Saul and Jeschke, 2015). For example, the invasive amphipod *Gammarus roeseli* has spines on the back, whereas the native *Gammarus pulex* shows no such morphological defenses (Bollache et al., 2006; Copilaș-Ciocianu et al., 2020). Another example is the invasive waterflea *D. lumholtzi*, which is known for its unique head and tail spines that serve as effective protection against both invertebrate and vertebrate predators (Kolar and Wahl, 1998; Engel et al., 2014).

These direct impacts of non-native predator and prey species often lead to indirect effects on other organisms and can restructure entire food webs (David et al., 2017). Continuing with the example of *D. lumholtzi*, if fish species cannot feed on these heavily armored daphnids, they may preferentially consume and thus reduce the density of native zooplankton species (Kolar and Wahl, 1998). It is also possible that biological invasions lead to new trophic interactions in already disturbed ecosystems. The invasive zebra mussel (*Dreissena polymorpha*), for instance, is a prey species of the invasive round goby (*Neogobius melanostomus*; Ray and Corkum, 1997). In Lake Erie, the round goby is in turn consumed by the native water snake *Nerodia sipedon insularum* (King et al., 2006). While this is as such beneficial for this endemic and threatened snake species, the gobies form a more contaminated diet than the snake's previous prey species (Fernie et al., 2008).

Conclusions

Predation is a classic topic for researchers investigating the ecology of freshwater organisms. Accordingly, countless studies have been published on predator-prey interactions in inland waters. In this chapter, we provided an overview of important long-standing concepts related to predators and their prey. We also outlined how predator-prey interactions are affected by the multitude of human actions in the current era, as this is a research topic where many pressing questions lack adequate answers. Work that is currently being done in this context draws on classic predation studies. A good example is the concept of predator functional responses and corresponding mathematical models (see above). This work, which was initiated in the mid-20th century (Solomon, 1949; Holling, 1959a,b), is the foundation of a fruitful line of research that is now investigating biological invaders and their interactions and impacts in the ecosystems where they were introduced (e.g., Dick et al., 2014; Cuthbert et al., 2019; Dickey et al., 2020; Linzmaier and Jeschke, 2020).

Knowledge gaps

- Many aspects of predation are better investigated in terrestrial than in aquatic systems.
- Carnivorous plants, such as *Utricularia* and *Aldrovanda*, can be quite important freshwater predators (Poppinga et al., 2017; Horstmann et al., 2019), but so far fly under the radar of most freshwater ecologists.

- Predator-prey-interactions are rarely mechanistically understood, which impairs our capability to make adequate predictions for their future dynamics, especially when being faced with anthropogenic stressors.
- Many anthropogenic stressors (e.g., most synthetic chemicals; Bernhardt et al., 2017) are rarely or not at all investigated. This is partly due to some of the stressors' novelty, but also due to topical research biases (cf. Jeschke et al., 2019).
- Our understanding of multi-stressor effects has remained even more limited.
- Similarly, there is a lack of knowledge about the impacts of non-native species in freshwater systems and how they change through time.
- There is even less knowledge about the impacts of other novel organisms (particularly genetically modified and synthetic organisms, see Jeschke et al., 2013) on predator-prey interactions and food webs in inland waters.

Acknowledgments

Some text and figures of this chapter were taken from Jeschke et al. (2008); these parts (text mainly in sections "Classification based on predation cycle" and "Inducible vs. permanent prey defenses", and Figs. 1–6) were revised and updated where appropriate. The other parts of the current chapter were freshly written and created. We thank Lars Rudstam and Thomas Mehner for the invitation to contribute this chapter and for helpful comments and suggestions. JGPD acknowledges financial support from the German Environmental Foundation (DBU; AZ 20017/509).

Parasites in Aquatic Food Webs: How and Why Environmental Gradients Influence Epidemics and Their Implications

Spencer R Hall, Department of Biology, Indiana University-Bloomington, Bloomington, IN, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Lars Rudstam.

Glossary

"Health herds" Reduction of disease prevalence by predators of hosts.
Clearance rate The proportion of habitat from which food resources are removed by a consumer-host (foraging sense) or the rate at which infected or exposed hosts are returned to the susceptible class due to immune-mediated killing of parasites (immunological sense).
Dilution Reduction of parasite prevalence by another host species via "encounter reduction" or "host regulation" mechanisms.
Epidemic An outbreak marked by a rapid increase of the number (or proportion) of hosts infected with a parasite.
Exposure Contact of susceptible hosts with a parasite; a first stage of disease transmission.
Host A species (victim) in or on which a parasite (enemy) grows.
Parasite A species that grows in or on its host (victim). They attack one host per life stage.
Predator A species (enemy) that attacks more than one prey (victim) in its life stage.
Propagules Infectious particles produced by a parasite, often distributed environmentally.
Reproductive ratio, R_0 The number of new infected hosts produced by a given infected host. It is a ratio of gains to losses of the life stages of the parasite. When $R_0 > 1$ the number of infected hosts increases over time in the population leading to an epidemic.
Susceptibility The probability that host becomes infected (or "exposed") given contact with infectious hosts or propagules.
Transmission Transfer of parasites to a new susceptible host.
Virulence Depression of a fitness component (fecundity, survival) of a host due to infection.

Introduction

Textbooks for aquatic ecologists often skip over or skimp on diseases of aquatic organisms and host-parasite interactions. This omission seems strange. After all, over the decades, aquatic ecologists have produced and perfected some of the finest models of species interactions in all of community ecology. For instance, lake biologists have championed concepts such as trophic cascades, resource competition and limitation, trophic heterogeneity, ontogenetic niche shifts, stage-structure and biomass overcompensation, density- and trait-mediated indirect effects, ecological stoichiometry, cryptic eco-evolutionary dynamics, and the like (Mittelbach and McGill, 2018). Furthermore, aquatic ecologists have developed and tested these models, with experiments and field observations, yielding great successes. Yet, those models have rarely been extended to include aquatic parasites (Johnson and Paull, 2011; Okamura and Feist, 2011) even though outbreaks in aquatic ecosystems can spread quickly and become very large (i.e., become an "epidemic") and profoundly influence host populations. In addition, parasites infect hosts embedded in food webs that aquatic ecologist so expertly characterize. Hence, one might imagine a future in which parasites become more integrated into our theories for aquatic ecosystems. Such a future would address questions such as: what are the core components of disease spread in aquatic ecosystems? What habitat and ecological factors influence when epidemics start and how big they get? How does disease alter community and ecosystem outcomes? What are the major sources of heterogeneity governing these outcomes?

In this article, I hope to encourage such integration via two steps. First, the integration must focus on the relevant natural history (Lafferty and Kuris, 2002). That natural history must identify the key sources of heterogeneity that influence disease epidemics

(Poulin, 2007). I consider three key sources here: variation of the parasite's life history (epidemiological); intra-specific variation in hosts themselves (stoichiometric, genetic, and stage-structured); and variation in the food web players (competitors, predators, and resources) that influence host-parasite dynamics. I discuss 12 examples centered on the host-resource interaction (a key difference from generic models of diseases of humans). I make this choice because aquatic organisms often strongly influence their resources (Shurin et al., 2002), and the subsequent feedbacks involving resources then reverberate into host-parasite dynamics.

Second, I focus on the environmental gradients and traits influencing disease spread using a case study of disease in the plankton (Hall et al., 2010b). I take the system, abstract some sources of heterogeneity (for the sake of brevity here), and translate its natural history into the language of equations. The payoff yields an organized inventory of the traits governing the gains and losses of parasites, in both propagule and infected host forms, that determines the size of epidemics. In particular, I use the net reproductive ratio, R_0, which determines the start of an epidemic ($R_0 > 1$) and often correlates with epidemic size (e.g., maximal prevalence of infection [proportion infected]). With that framework, I link environmental gradients to those traits (Lafferty and Holt, 2003). For instance, some environmental gradients (like resource quality and quantity, other non-dynamic resources, and toxins) can influence propagule production, therefore epidemic size. Others (like temperature) influence transmission (Shocket et al., 2018a). I propose that environment-trait connections can be captured using models of energy (and material) flow through individual hosts (i.e., using dynamic energy budget models: Cressler et al., 2014; Hall et al., 2009b). Then, I connect two more environmental gradients (dissolved organic carbon and refuge size) to losses of parasites. Those losses can emerge directly (by reducing damage from solar radiation: Overholt et al., 2012; Shaw et al., 2020) or indirectly (by governing density of the food web players that themselves influence epidemics). Finally, I illustrate how parasites themselves influence the traits of hosts, and those traits then shape epidemics. Specifically, I show three cases (foraging depression, fecundity-transmission tradeoffs, and allocation to males) that then alter the density, genetic composition, and sexual makeup of host populations.

Combined, this case study provides one potential roadmap for aquatic ecologists in the future. Using mathematical models, it shows how one might connect key parts of natural history and environmental gradients to the traits that determine the causes and consequences of disease epidemics. Such frameworks should prove extremely useful when looking to explain and predict how aquatic ecosystems will change in the future.

Some types of host-parasite systems (via 12 modules)

Before commencing, some definitions and illustrations seem mandatory. First, a parasite (enemy) infects one host (a victim) during a particular life stage (following Lafferty and Kuris, 2002): in contrast, predators attack more than one victim. Then, different forms of parasites exert varying effects on host fitness. Important aquatic microparasites (e.g., viruses, bacteria, fungi, and protists) include *Plasmodium* which causes malaria in birds, the VHS virus (Viral Hemorrhagic Septicemia, infecting fishes), and the oomycete *Aphanomyces astaci* (the devastating plague of crayfish worldwide: Martín-Torrijos et al., 2021). Important macroparasites include the trematodes causing schistosomiasis in humans and limb deformities in frogs (*Ribeiroia*). Some of these parasites use multiple hosts (like blood flukes [Echinostomatids] that move between snails and vertebrates, and the cnidarian parasite that uses oligochaetes before causing whirling disease in salmonids). Others spread by propagules that swim (e.g., chytrids that infect phytoplankton: (Kagami et al., 2007); the *Vibrio* bacterium that causes cholera in humans) or are simply passive particles in the water (viruses that infect phytoplankton: Biggs et al., 2021). Many of these examples—and a whole array of others not touched on here—pose important concern to aquaculture, conservation of species (e.g., chytridiomycosis in amphibians), and human health alike (see Tables 1 and 2 of Johnson and Paull, 2011 for an excellent overview).

To sample just a bit of diversity of host-parasite interactions in aquatic systems, I consider 12 different "modules" (simple compartment) models. These 12 models exemplify how host-parasite interactions in aquatic systems occur within food webs by considering the interactions with other species. These highly simplified representations capture the sometimes strong interactions that influence disease spread and community ecology alike. They have a long tradition in both community and disease ecology (Hudson et al., 2002), and they provide a template with which to evaluate individual host-parasite systems of interest in freshwater systems.

To start, let us focus on a baseline model of a susceptible host (S), an infected host (I), and a resource (A; Fig. 1A). Interactions of just these three players fuse the central role of hosts as participants in disease spread (leading to new infections) and as consumers of resources (and therefore influencing production, partitioning of biomass among trophic levels, nutrient cycling, etc.). To that template, I then layer on (at least) three forms of relevant heterogeneity.

- *Epidemiological heterogeneity* (Fig. 1B–F): For instance, one can add more realistic host-parasite epidemiology, illustrated via five examples. A parasite may produce exposed but not yet infectious classes, but others could spread via environmentally-transmitted propagules, trophic transmission (i.e., as one host consumes another infected hosts), and production of propagules from dead hosts. Multiple parasites may also compete for hosts, possibly yielding coinfection.
- *Intraspecific heterogeneity of hosts* (Fig. 1G–I): Then, intraspecific variation of hosts themselves provides a second important form of heterogeneity. Hosts and their resources can vary in their body composition (stoichiometry), in stage structure (e.g., juvenile vs. adults which may compete for a resource), and in genotype. Because transmission can vary with composition, stage, and genotype, each of these sources of intraspecific heterogeneity can strongly influence disease dynamics and spread.

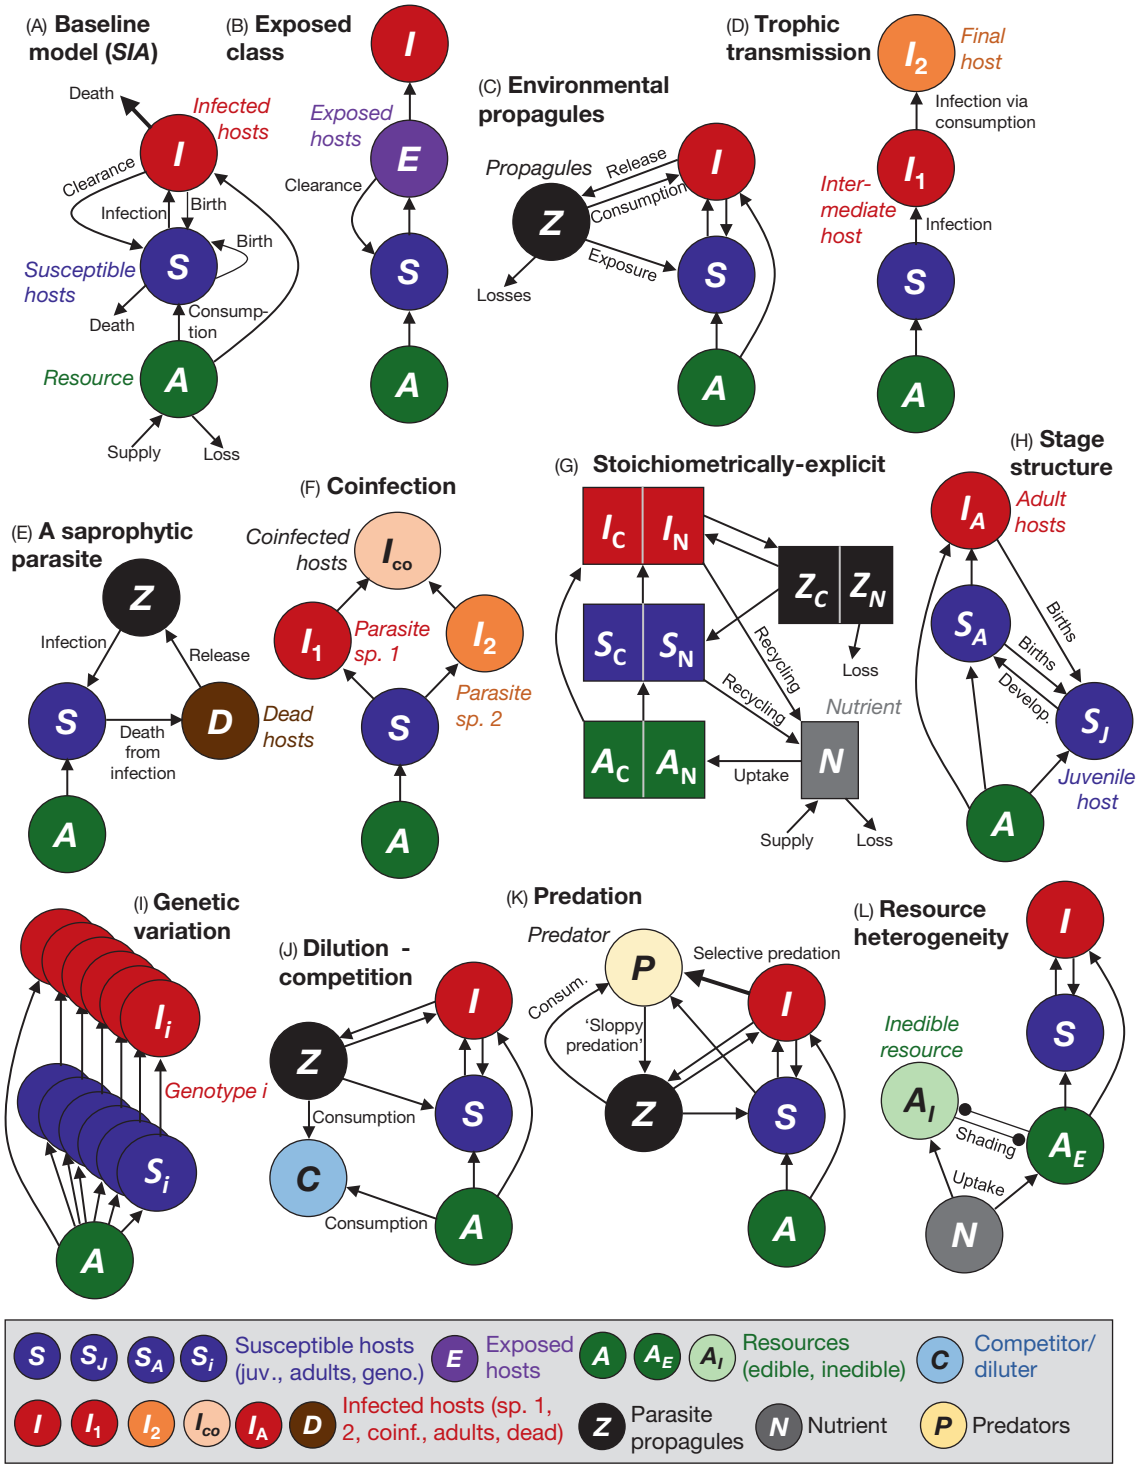

Fig. 1 Some types of host-parasite interactions in aquatic food webs—an illustration with 12 different modules. (A) *Baseline SIA model:* A baseline susceptible-infected model, with flows in an out of these host compartments labeled explicitly (see text; some of these flows are dropped in diagrams that follow). An explicit resource is added. *Five variations with epidemiological heterogeneity.* (B) *Exposed class*: Addition of an exposed class, where immune systems of the host can clear infection before hosts become infectious (i.e., able to spread parasites to new hosts). (C) *Environmental propagules*: Addition of a propagule class, where infectious hosts either shed propagules in the aquatic environment continuously or upon death. (D) *Trophic transmission,* where parasites move from intermediate hosts to final hosts via trophic (feeding) interactions. (E) *A "saprophytic" parasite*: Saphrophyte-like parasites first kill hosts very quickly, then consume corpses to release propagules. (F) *Co-infection*: Some aquatic parasites can coinfect their hosts, but exclusion or priority effects (alternative stable states) are also possible. *Three forms of intraspecific heterogeneity of hosts*: (G) *Stoichiometric composition*: Aquatics hosts and their resources and parasites can vary in their stoichiometric body composition (e.g., carbon:nutrient ratio), enabling tracking of nutrient recycling and losses. (H) *Stage structure*: Many aquatic hosts progress through ontogenetic life stages (e.g., juvenile to adult). Parasites can differentially infect those stages (e.g., only adults). (I) *Genetic variation:* Both hosts and parasites can vary genetically in traits governing epidemics. *Three forms of food web heterogeneity: (J) Dilution-competition:* Other host species can consume propagules ("encounter reduction") and shared resources ("host regulation"). (K) *Predation*: Predations can selectively prey upon infected hosts, release propagules via "sloppy predation," and directly consume propagules. (L) *Resource heterogeneity*: Inedible resources and epidemics can interact via shared nutrient pools.

- *Food web heterogeneity* (Fig. 1J–L): Finally, host-parasite interactions exist embedded within food webs. For instance, host species vary in resistance to parasites, predation can alter epidemiology, and disease might alter competition among heterogeneous resource species.

These three forms of food web heterogeneity combine into a suite of interactions that influence and are shaped by epidemics in aquatic systems.

Baseline (SIA) model: Direct transmission with a resource (Fig. 1A)

In a baseline model of disease in aquatic systems, susceptible hosts (S) consume resources (A), following their foraging biology (i.e., functional responses and assimilation efficiency). Without disease, they convert that consumed food into (susceptible) offspring, and they die at some background rate. But, when susceptible hosts contact infected hosts (I), they become infected themselves. If transmission is horizontal (i.e., no mother to offspring [vertical] transmission), infected hosts produce susceptible offspring (perhaps at a reduced rate). Immune systems might successfully clear infection and an infected host revert back to a susceptible host. But if the infections are not cleared, the host likely die at some enhanced rate. Hence, infection can exact virulent effects on fecundity (including up to complete castration by e.g., brood parasites or via physiological manipulation causing gigantism) and/or survival (by increasing death rate). Note that resources are also supplied and lost via production ecology familiar to freshwater ecologists.

This seemingly simple three dimensional (S, I, A) view of aquatic disease can capture a diverse array of dynamical properties (Anderson and May, 1991). For instance, it can delimit environmental conditions, via controls on nutrient supplies, that bound the fundamental niche of a parasite. For instance, for directly transmitted parasites, a minimal threshold host density, S_i^*, might be needed to ensure that an epidemic can start. If the resource-host (A-S) system provides sufficiently high host density [e.g., this "boundary" density, S_b^*, exceeds S_i^*], then an initial infected host could yield more than one new infection (i.e., $R_0 > 1$). If host density is too low, perhaps in an oligotrophic system, epidemics may not be possible. Once an epidemic starts, the *SIA* system can capture a diverse array of dynamics. For instance, prevalence of disease and density of infected hosts could increase along eutrophication gradients (if eutrophication increased carrying capacity of the resource: Johnson et al., 2007). Both resource density and infection status could alter key traits (feeding, fecundity, mortality). Via those traits, the disease epidemic could then cause a trophic cascade (higher resources, fewer hosts: Buck and Ripple, 2017). Alternatively, it could unleash a hydra effect (yielding higher resources and more hosts, named for the mythical beast: Penczykowski et al., 2022; Schroder et al., 2014). Both possibilities seem more likely in aquatic systems, where hosts can strongly depress resources. Higher resource density could then interact with (parasite modified) functional responses of the grazer (type II or type III [as in *Daphnia:* Uszko et al., 2015]) to stabilize or destabilize host-resource interactions (Hurtado et al., 2014). Hence, while simple, the *SIA* baseline model captures a rich array of dynamical possibilities. Furthermore, it helps explain fundamental issues of production, allocation of biomass among trophic levels, and dynamics of freshwater systems.

Epidemiological heterogeneity #1: An exposed class, E (Fig. 1B)

Many freshwater parasites (e.g., flatworms, nematodes, fungi, bacteria) undergo different life stages within their host. Such life history prompts addition of an exposed host class (E) that retains the ability to clear infection. However, eventually those exposed hosts can become infectious (e.g., by producing a terminal stage propagule). At this stage, immune systems may or may not succeed in clearing infection (as shown in the diagram: Stewart Merrill et al., 2021). For instance, once *Daphnia* produce infectious propagules of the focal fungus (described below), infection is irreversible, and the host will die from infection.

Epidemiological heterogeneity #2: Environmentally distributed propagules, Z (Fig. 1C)

A highly relevant class of parasites produce infectious propagules within the bodies of infected hosts. Then, those propagules are released continually (e.g., by shedding from guts) or upon host death (i.e., "obligate killers" or parasitoids: Lafferty and Kuris, 2002). Some infected hosts release massive numbers of propagules following physiological manipulation by parasites that redirect energy away from reproduction (castration) and towards growth (gigantism, e.g., in fish, snails, water fleas: Hall et al., 2007a; Cressler et al., 2014). While in the water column, these propagules can actively swim to contact hosts (often by penetrating the host body) or become consumed by foraging hosts. In that latter case, exposure to parasites interweaves intimately with foraging biology (i.e., it can become proportional to "clearance rate" [in the foraging rate rather than immunological sense]: Hall et al., 2007c). Once consumed, those propagules successfully infect with some susceptibility (infectivity) probability. However, while inhabiting the free-living water column, those propagules can suffer very high loss rates from various environmental factors (such as solar radiation and sinking: see below) while infected hosts (and other species) may consume them. Simultaneously, production of propagules can depend strongly on resource density (e.g., many hosts produce more propagules when feeding on richer resource quality; Cressler et al., 2014). As a result, this *SIZA* system creates additional mechanisms by which aquatic environments and resources shape disease spread.

Epidemiological heterogeneity #3: Trophic transmission & complex life cycles (Fig. 1D)

Once they infect their first host, certain parasites with complex lifecycles can then move into other hosts. In the example illustrated, parasites infect a first intermediate host (I_1). Often, these parasites reproduce to large numbers asexually before they become consumed by a second host. That consumption may be mediated by a morphological or behavioral modification that enhances consumption (mortality) of the intermediary host or hosts. Once they enter their final host (here, I_2), those parasites typically

engage in sexual reproduction to complete their life cycle (Johnson and Paull, 2011). Combinations of environmental stages and multiple hosts might best describe these complex life cycles. For instance, in a typical three-host life cycle of a trematode worm, an initial snail hosts might consume worm eggs. Those eggs hatch, undergo several life stages asexually within the host, and then exit via a swimming stage (cercariae). This stage then infects the second intermediary host (e.g., a frog) and produces a life stage that encysts (metacercariae). Once a final host (bird) consumes that host, eggs are produced by sexual reproduction, completing the life cycle.

Epidemiological heterogeneity #4: Production of propagules from carcasses (Fig. 1E)

Some aquatic parasites (e.g., oomycete parasites of *Daphnia*) quickly kill their hosts (Wolinska et al., 2008). Hence they exact extremely high virulence. Then, they produce propagules from the body of the dead host. These parasites act differently than mere saprotrophes (i.e., organisms that feed on decaying matter)—they do indeed infect and kill their hosts. However, because they kill so quickly, they can defy easy detection in nature. Instead, they might act as stealthier, unnoticed sources of mortality for aquatic hosts.

Epidemiological heterogeneity #5: Competition and coinfection (Fig. 1F)

Multiple aquatic parasites can disperse in the environment, and they can potentially co-infect hosts. For instance, a host infected with parasite species 1 (I_1) could become infected with parasite species 2 after contact with an individual hosting that parasite (I_2), yielding co-infection (Clay et al., 2020). Co-infected hosts, in turn, can suffer higher virulent effects. That interaction could also lead to competitive exclusion or alternative stable states (priority effects). In the latter case, parasites successfully invading first can gain an advantage that prevents invasion of other parasites into hosts.

Intraspecific host heterogeneity #1: Stoichiometric body composition (Fig. 1G)

Although such theory remains quite underdeveloped, a fully stoichiometric disease model might prove quite illuminating. Imagine that the resource (A) is an autotroph that uptakes a nutrient (N) for growth. It might have flexible stoichiometric content (i.e., plastic carbon:nutrient, or C:N ratio in its tissues), driven by environmental resource supply (e.g., incident light, nutrients, depth) and losses (from dilution, grazing sinking, etc.: Hall et al., 2007b; Sterner and Elser, 2002). Variation in such content can influence assimilation efficiency of susceptible hosts, thereby modulating density of hosts and disease transmission. Once infected, parasites could shift the C:N content and/or assimilation efficiency of hosts, potentially altering (speeding up, slowing down, altering ratio) of nutrients recycled relative to susceptible hosts (Frost et al., 2008; Narr and Frost, 2016). Furthermore, production of propagules (having their own C:N content) could depend upon quantity but also stoichiometric quality of resources. For instance, some propagules (e.g., viruses, bacteria) might demand higher nutrient supply (due to higher C:N content). Yet, propagule release from dead hosts could speed up nutrient recycling (e.g., in algal-virus systems). Alternatively, loss of propagules of parasites from the water column could yield a nutrient sink during epidemics. Hence, a fully stoichiometric model reveals how parasites could modify sources and sinks of nutrients in aquatic systems. They may also alter classical limnological relationships (like ratios of total phosphorus to chlorophyll *a* of algal autotrophs) in underappreciated ways.

Intraspecific host heterogeneity #2: Stage structure (Fig. 1H)

Many hosts in aquatic systems develop through distinct and even intricate life stages (de Roos and Persson, 2013). In this simplest case, host offspring first move through a juvenile stage, then mature into adults. Adults, in turn, produce offspring that enter the juvenile class. Through that ontogeny, hosts increase in body size and may even shift habitat. Yet, juveniles and adults may compete for resources. In that latter case, the parasite may target one life stage solely or preferentially (the example drawn illustrates attack solely on adults). Such ontogenetic asymmetry in infection, via virulence on mortality, feeding, and maintenance, could introduce or magnify asymmetry in energetics. If true, parasites could shift stage structure of hosts (i.e., partitioning of individual or biomass among stages) and even trigger counter-intuitive phenomenon like biomass overcompensation (when the stage infected increases in biomass: de Roos and Persson, 2013; Preston and Sauer, 2020). Such fusion of stage-structured resource theory with disease lies at a largely unexplored conceptual frontier, yet likely applies to many aquatic disease systems.

Intraspecific host heterogeneity #3: Genetic variation (Fig. 1I)

Aquatic hosts and their parasites often vary genetically in key epidemiological traits. For instance, the genetics of successful infection may require particular combinations of host and parasite genotypes (i.e., the "matching alleles" patterns famously shown in *Daphnia*-bacteria (Luijckx et al., 2013) and snail-trematode systems (Koskella and Lively, 2009)). Additionally, hosts may vary in other defensive traits that confer differential resistance to infection (via e.g., lower exposure while feeding, gut defenses) and clearance of infection (via variation in immune killing). Furthermore, those same traits granting resistance advantages may come with costs to fitness via other traits. For instance, some hosts become exposed to propagules while acquiring resources for growth and reproduction (Hall et al., 2007c). In those cases, traits granting higher fecundity (e.g., faster feeding rate) may also yield lower resistance (due to higher exposure: Hall et al., 2010a). As a result, the combination of parasite and resource densities could determine selection pressure upon hosts (as they influence the benefits and costs of resistance, respectively). That selection pressure can act quite strongly on hosts that reproduce clonally (asexually)—but, due to tradeoffs, natural selection might favor higher or lower resistance. The subsequent response of natural selection, in turn, can influence the size of epidemics (i.e., prevalence of

infection and density of infected hosts) and shape the fate of the density hit that populations face during epidemics. Indeed, rapid evolution could even alleviate severe density suppression endured by hosts during large epidemics (via "cryptic dynamics": Yoshida et al., 2007).

Food web heterogeneity #1: Dilution-competition (Fig. 1J)

Hosts in aquatic ecosystems inevitably interact with other species that share resources and/or interact with the parasite. Consider first a species, *C*, that only competes for the resource that also fuels the disease epidemic (in the *SIZA* system). Two interacting features emerge. First, disease that targets a superior competitor (i.e., one having a lower minimal resource requirement, A^*) could open realized niche space that allows an otherwise inferior competitor to persist (because disease increases the A^* of the system past the minimal requirement of the competitor). In this way, parasites could facilitate coexistence of the two consumers (Grover, 1997). Yet, once they enter, these competitors can suppress density of hosts. That 'host regulation' mechanism can reduce size of epidemics (Strauss et al., 2018). As a result, these competitors act as disease "diluters." Alternatively, disease could undermine coexistence of the competitors, exacerbating the harm to hosts caused by the competitors. In yet another variation, other host species might only consume, remove, or otherwise provide a sink for parasite propagules (Johnson et al., 2013). If they strongly resist infection, such consumption elicits the "encounter reduction" mechanism of disease dilution. However, if they can become infected, these other species may experience epidemics themselves via a process called "disease spillover." In aquatic systems with generalist, unselective feeders (e.g., mussels, snails, *Daphnia*) as host, these two mechanisms can become intertwined. In these cases, the net interaction of encounter reduction and host regulation can prove helpful to hosts (via disease dilution). Alternatively, it can end disastrously (where competitors fail to control epidemics but still exert strong competitive harm: Strauss et al., 2015). Hence, dilution-competition systems can truly explain a wide range of dynamics.

Food web heterogeneity #2: Predation (Fig. 1K)

Predators can also strongly shape disease dynamics. Consider four possibilities. First, predators may prey selectively upon infected hosts. That possibility seems particularly likely when infection transforms hosts into more obvious prey to visually-oriented predators (like fishes) or changes behavior or habitat use. In these cases, predators can reduce disease via "healthy" herd mechanisms (Duffy et al., 2005; Hall et al., 2005). Second, predators may disperse propagules of parasites via "sloppy feeding" (i.e., *Chaoborus* larvae feeding upon *Daphnia*). This mechanism might particularly benefit parasites that otherwise face a habitat trap if dead, infected hosts sink away before releasing propagules (Cáceres et al., 2009). Third, predation upon hosts might trigger trophic cascades. Those cascades can reduce disease epidemics (via lower host density) or amplify them (if higher resources enhance propagule production via "cascade fueling": Smith et al., 2015). Fourth, predators might directly consume free-living propagules of parasites (thereby acting as diluters via "encounter reduction": Orlofske et al., 2015). Hence, depending on the foraging biology of the predators (selective, sloppy, on propagules or hosts) and the response of resources (fueling), predators could reduce or catalyze disease spread in aquatic systems. And of course, as aquatic ecologists know well, predators can exert non-consumptive effects on host behavior, physiology, and habitat use (Peacor and Werner, 2001). All of those factors might also shape disease epidemics (e.g., Decaestecker et al., 2002). Hence, in aquatic systems, predators can strongly influence aquatic communities and disease epidemics alike.

Food web heterogeneity #3: Resource heterogeneity (Fig. 1L)

In a final example, we could imagine disease epidemics altering competition among resource species. For instance, an edible autotroph resource (A_E) might compete superiorly for a nutrient with an inedible resource (A_I: Grover, 1997). By controlling density of autotrophs, grazing by hosts could enable coexistence between hosts (by indirectly meeting the nutrient needs of inedible species). However, in one scenario, a disease epidemic could reduce this control of grazers over the superior resource competitor. In this case, epidemics would reduce freely available resources, shrinking realized niche space for the inedible species. Such a scenario might influence the probability or magnitude of blooms of inedible autotrophs. Of course, parasites of inedible autotrophs might regulate or even end such blooms (not illustrated here, but famously shown in a diatom-chytrid system: Kagami et al., 2007). Hence, disease might directly or indirectly influence the likelihood of algal blooms. Much theory remains to be developed at this interface of basic and applied aquatic disease ecology.

Dynamics of epidemics in aquatic systems: A case study of environmental gradients, traits, and outcomes in the plankton

Overview: For a given host-parasite system, how can aquatic ecologists understand the drivers of epidemics? How can they connect environmental gradients, habitat structure, and food web players to the start, magnitude, and consequences of those outbreaks? A case study of disease spread in plankton illustrates a useful path forward (Fig. 2). To make this case, we first must meet the system, both conceptually and dynamically (in the language of a model). That model organizes several sources of heterogeneity that influence the components of disease spread. It also provides an index (R_0) that nicely highlights both the gains and losses of parasites. With that tool, we can then see how environmental gradients enhance components of gains, by influencing transmission rate and propagule production (Fig. 3A). Furthermore, those drivers of gain focus on energetics of hosts (as part of a "host condition" hypothesis). We can envision such connections using a dynamic energy budget model (Fig. 3B). Then, other (possibly correlated) environmental gradients can shape losses of parasites, directly (via mortality on propagules) or indirectly (by shaping

S and A in their disease free state

Fig. 2 *A model for a planktonic disease system: a case study.* Links between environmental gradients in aquatic ecosystems, traits that govern disease spread, and the outcome of epidemics can be illustrated with a pelagic example in freshwater lakes. (A) *Natural history, simplified:* The freshwater grazer *Daphnia dentifera* hosts the virulent fungus *Metschnikowia bicuspidata* while competing with other zooplankton (e.g., *Ceriodaphnia* sp.) for phytoplankton resources and while falling prey to predators such as larvae of the phantom midge (*Chaoborus* sp., shown) and fishes (not show). (B) *A mathematical model for that disease system*: It tracks gains and losses of susceptible (*S*) and infected (*I*) hosts, propagules of the fungus (*Z*), and the resource (*A*). For simplicity, density of the predator and diluter-competitors are fixed parameters. (C) *An index of disease spread: R_0, the reproductive ratio*: The mathematical model predicts key aspects of the epidemic such as R_0. When R_0 exceeds 1, epidemics can begin in a disease-free system. This index is a ratio of gains to losses of both the propagule class (yellow shading) and the infected class (orange shading).

predation and host composition: Fig. 4). Finally, parasites themselves can alter traits of hosts (such as foraging rate, tradeoff structure among genotypes, and allocation to sex (Fig. 5). Via these traits, parasites can then influence density, trait evolution, and sexual dynamics of their host.

*A model for planktonic disease system—A case study (*Fig. 2*)*

A well-studied example of planktonic disease illustrates how drivers of environmental gradients, community composition, and heterogeneity of disease traits all collide to modulate the size of disease epidemics. This intersection happens in the open waters (pelagia) of small, north-temperate, dimictic (stratified) lakes during autumn in the Midwestern United States (Hall et al., 2010b). The focal host is the grazer *Daphnia dentifera*, a crustacean waterflea (S). This host is famous for at least three ecological roles: it can strongly graze edible forms of phytoplankton resources (A) and compete with other species (C) for those resources; it provides an important food source for fishes and invertebrate predators, particularly larvae of the phantom midge *Chaoborus punctipennis* (P); and it recycles nutrients. While it reproduces asexually during most of the summer and autumn seasons, the host creates a sexual diapausing egg (after producing males) that create temporal dispersal. It also serves as host to a fungus (the yeast *Metschnikowia bicuspidata*). Hosts become exposed to the parasite while eating propagules (ascospores) distributed in the water column. If the fungus successfully penetrates the gut of the host, it undergoes several life stages (which, in principle, could be cleared by the immune system). However, once these exposed hosts produce propagules, these hosts are irreversibly infected (I: Stewart Merrill et al., 2021). For simplicity, we collapse the E into the I stage here. Upon host death (sped up by infection), bodies of infected hosts can release up to 100,000 or more propagules (Hall et al., 2009a,b). If they enter the water column, those propagules then continue the epidemic.

A relatively simplistic mathematical model of this system can pinpoint the key traits underlying disease spread. An example model described below tracks dynamics of susceptible (S) and infected (I) hosts, both of which consume a resource (A) that fuel production of parasite propagules (Z). The predator (P) and diluter-competitor (C) are simply treated here as parameters (but could be modeled more explicitly and dynamically).

Production of susceptible hosts and the infection process—dS/dt

To start an epidemic, the parasite requires enough hosts to infect and produce parasites. Hence, the ecological factors shaping host and resource density apply. Density depends on per capita births, $e\ fs(A)\ A$, where e is conversion efficiency (governed by, e.g., digestion resistance, stoichiometry, etc.) and $fs(A)$ is "clearance" in the foraging rather than immunological sense (governed by, e.g., *Daphnia*'s type III functional response—so a function of resource density, body size, and traits like maximal feeding rate that can itself vary among genotypes and depend upon chemical cues from other species, temperature, etc.). These hosts then die, at some background rate (d_S) and predation (where predators, P, feed at linear rate f_P here). On top of that ecology, we can then layer in the epidemiology: these hosts also become infected at a transmission rate determined by both exposure and susceptibility. Hosts contact propagules, Z, proportional to their foraging clearance rate. Once exposed, hosts become infected with some susceptibility, u. This parameter has a quantitative genetic component. It also likely depends on a variety of other factors (e.g., gut thickness, rearing [maternal effects], Shocket et al., 2018b; Stewart Merrill et al., 2021). Finally, infected hosts can contribute to susceptible hosts via birth, assuming horizontal transmission (from propagule to susceptible host), and recovery from infection (following immune clearance parameter c). Births depend on foraging rate of infected hosts, which itself can be diminished ($f_I < f_S$), and any further fecundity depression due to virulence (where $\rho = 1$ means no additional depression while $\rho = 0$ indicates complete castration [as for the bacterium *Pasteuria*]). In the particular case study, horizontal infection slows feeding but does not depress fecundity too much ($\rho \approx 0.8$).

Production of infected hosts and parasite propagules, dI/dt and dZ/dt

To continue with an epidemic, parasites must grow and produce propagules that re-enter the environment. Hence, production of infected hosts (dI/dt; Eq. 1.B, Fig. 2B) follows the increase from new infections, $u\ f(A)\ Z\ S$, and losses at a rate elevated from background by virulence of the parasite ($d_S + v$), immune clearance (c), and predation (where $\theta > 1$ indicates selectivity on infected hosts). Then, in the propagule production equation (dZ/dt; Eq. 1.C; Fig. 2B), spores are released at a yield times a rate. The yield is $\sigma(A)$, a function of resource density in the environment, A. In the focal system, this function increases monotonically: hosts with higher (edible) resource density (but especially higher resource quality) produce more propagules. Then, that yield is released when hosts die due to virulence ($d_S + v$). Predators, P, with "sloppy feeding" can also release a proportion of propagules (γ) when preying (at rate $\theta\ f_P$). In the planktonic example, sunfish predators release some viable spores that likely do not return to the water column (so $\gamma \approx 0$: Duffy, 2009) while phantom midge large release about half into the epilimnion (upper water column) at night (Cáceres et al., 2009).

Then, losses of propagules stem from both biotic and abiotic sources. First, susceptible hosts, S, consume them (given their foraging clearance rate, $f_S(A)$). That route leads to exposure and possible successful infection. However, infected hosts, I, also consume them (at clearance rate $f_I(I)$). Quite importantly, other more resistant or completely resistant hosts, C, also remove them (at their own foraging clearance rate $f_C(C)$). Via this consumption, these hosts (such as *Ceriodaphnia* sp. and *Daphnia pulicaria*) enact the "encounter reduction" mechanism of dilution (Strauss et al., 2018). Finally, here, the other courses are lumped into a d_Z rate. This term can capture much germane abiotic biology. For instance, solar radiation (ultraviolet [UV] but even photosynthetically active [PAR] light) can damage propagules quite significantly (Overholt et al., 2012; Shaw et al., 2020). Furthermore, if mixing is limited, propagules that cannot swim may sink out of the water column. Hence, factors shaping penetration of solar radiation

(incident levels, dissolved organic carbon [DOC], background turbidity, phytoplankton density, water column depth) and physical mixing in the water column (wind shear, night-time cooling, stratification strength, depth)—all key limnological factors—could influence this vital loss rate of parasites.

Production of resources, the fuel of epidemics, dA/dt

To finish out this model, we must not forget phytoplankton resources, the fuel of epidemics (dA/dt; Eq. 1D; Fig. 2B). Resources power production of both hosts and their competitors but also of parasites. Primary production, $r(A)\,A$, is presented here as some generic function, but one which aquatic ecologists have spent decades describing (i.e., as functions of nutrient supply, uptake kinetics, internal nutrient storage, light intensity, sinking, etc.). Indeed, a more detailed model might include flexible nutrient content, plastic defenses (like digestion resistance), etc. Then, both susceptible, S, and infected, I, hosts consume those resources. Diluter-competitors also can share this resource (particularly when hosts are generalist filter feeders). Through this indirect exploitative mechanism, these diluter-competitors can reduce disease prevalence (through a "host regulation" mechanism). On the other hand, the epidemic can disadvantage hosts in the competition (by increasing their minimal resource requirement). Hence, this resource competition dimension complicates the role of diluter-competitors: they might reduce disease prevalence but also severely depress host density during epidemics (as can happen in the focal system). Yet, these interactions almost certainly abound in aquatic systems (e.g., with other plankton, snails, mussels, tadpoles, etc.).

Pulling the pieces together: An index of disease spread, R_0 (the reproductive ratio, Eq. 2)

With production of all players described, the model can predict dynamics of epidemics in aquatic systems. An overview of all such dynamics exceeds the scope of this article, but some immediate insights flow from an expression the net reproductive ratio, R_0 (Eq. 2, Fig. 2C). This quantity governs the success ($R_0 > 1$) or failure ($R_0 < 1$) of an epidemic to start. In the focal plankton system, that start date falls somewhere in the late summer to late autumn months. The R_0 quantity often (but not always) increases with disease prevalence (proportion infected). It can be derived using mathematical techniques well-known to epidemiologists (i.e., the Next Generation Matrix method: Diekmann et al., 2010). Helpfully, following this calculation, R_0 can be written as a ratio of gains (numerator) to losses of propagules (yellow shading) and infected hosts (orange shading; Fig. 2C). Hence, factors enhancing release of propagules and transmission rate catalyze disease spread; those strengthening losses undermine it. Furthermore, tension can arise between components of spread. For instance, predation might reduce host density (S) before epidemics begin. All else equal, lower density suppresses disease spread (lowers R_0). However, through a trophic cascade (indirect release of resources), release of propagules could increase, thereby catalyzing it (higher R_0). Fortunately, parameterized equations provide the machinery needed to mediate a tug of war among factors. Furthermore, they provide the opportunity to map environmental factors to traits to disease spread. To illustrate, we can focus on environmental drivers driving gains and losses.

*Tension between gain components and the host condition hypothesis (*Fig. 3*)*

The focal planktonic system reveals how environmental drivers of disease spread can operate through traits linked to gains for the parasite. Those gains appear in the numerator of the R_0 expression. However, environmental gradients can pull these traits in opposing directions. To illustrate, consider three environmental drivers: quality and quantity of a dynamic resource (phytoplankton: Civitello et al., 2015; Hall et al., 2009a), a non-dynamic resource (potassium: Civitello et al., 2013), and sublethal doses of a toxin (copper; Fig. 3, top three rows: Civitello et al., 2012). Higher resource quantity/quality can reduce transmission rate (through contact/foraging clearance mechanisms) but increase both host growth and propagule production within infected hosts. In experiments and in the field (among lakes), the net result is larger epidemics with richer resource environments. Hence, the response of parasite production matters most (top row). This framework recapitulates with the non-dynamic resource potassium (second row). In experiments, potassium enrichment has no effect on exposure but does stimulate host growth. In mesocosms and the field, higher potassium levels led to higher propagule production and large epidemics. In contrast, sublethal doses of copper increased feeding rate (hence transmission) but depressed host growth and parasite production. In mesocosms, copper reduced epidemics (third row). Integrating among all three stories, the links between gradient and parasite production, mediated through host growth, reigned supreme. Yet, a thermal example provides a counterpoint. Specifically, warmer temperatures (from 15 °C to 25 °C) speed up transmission rate, via both faster feeding (exposure) but also a rearing effect (i.e., propagules produced in warmer conditions infect more readily: Shocket et al., 2018b). Meanwhile, production of propagules responds unimodally yet fairly flatly to temperature (despite that host growth increases considerably with warming). The net result: because warmer temperatures enhance the transmission rate, "warmer is sicker" (Shocket et al., 2018a).

An energetic framework can likely capture key components of this tug-of-war between traits governing gains (Fig. 3B). Consider, for instance, the dynamic energy budget (DEB) model. In this model of an individual host, food is consumed, and via assimilation, converted into an energy reserve (with recycling of waste). This reserve, in the typical model, is then allocated (utilized) to growth of structure (body mass and length) and production of offspring with payment of associated metabolic costs. Because DEB models hinge on body size, the rate of maximal resource consumption increases with size. While initially developed with *Daphnia* in mind, this model successfully captures growth and fecundity of a variety of organisms, using one currency (e.g., energy) or multiple ones (e.g., adding in phosphorus). Parasites then intercept this flow of energy at some point: as shown, parasites take from the reserve before it is utilized (Hall et al., 2009b). Through this energy theft, parasites can exact virulent costs on growth and fecundity and shorten lifespan (e.g., by starving hosts internally). Additional features added to the model could capture other life history. For instance, parasites can reduce foraging rate beyond mere stunting of growth (through "anorexia": Strauss et al., 2019). They can also

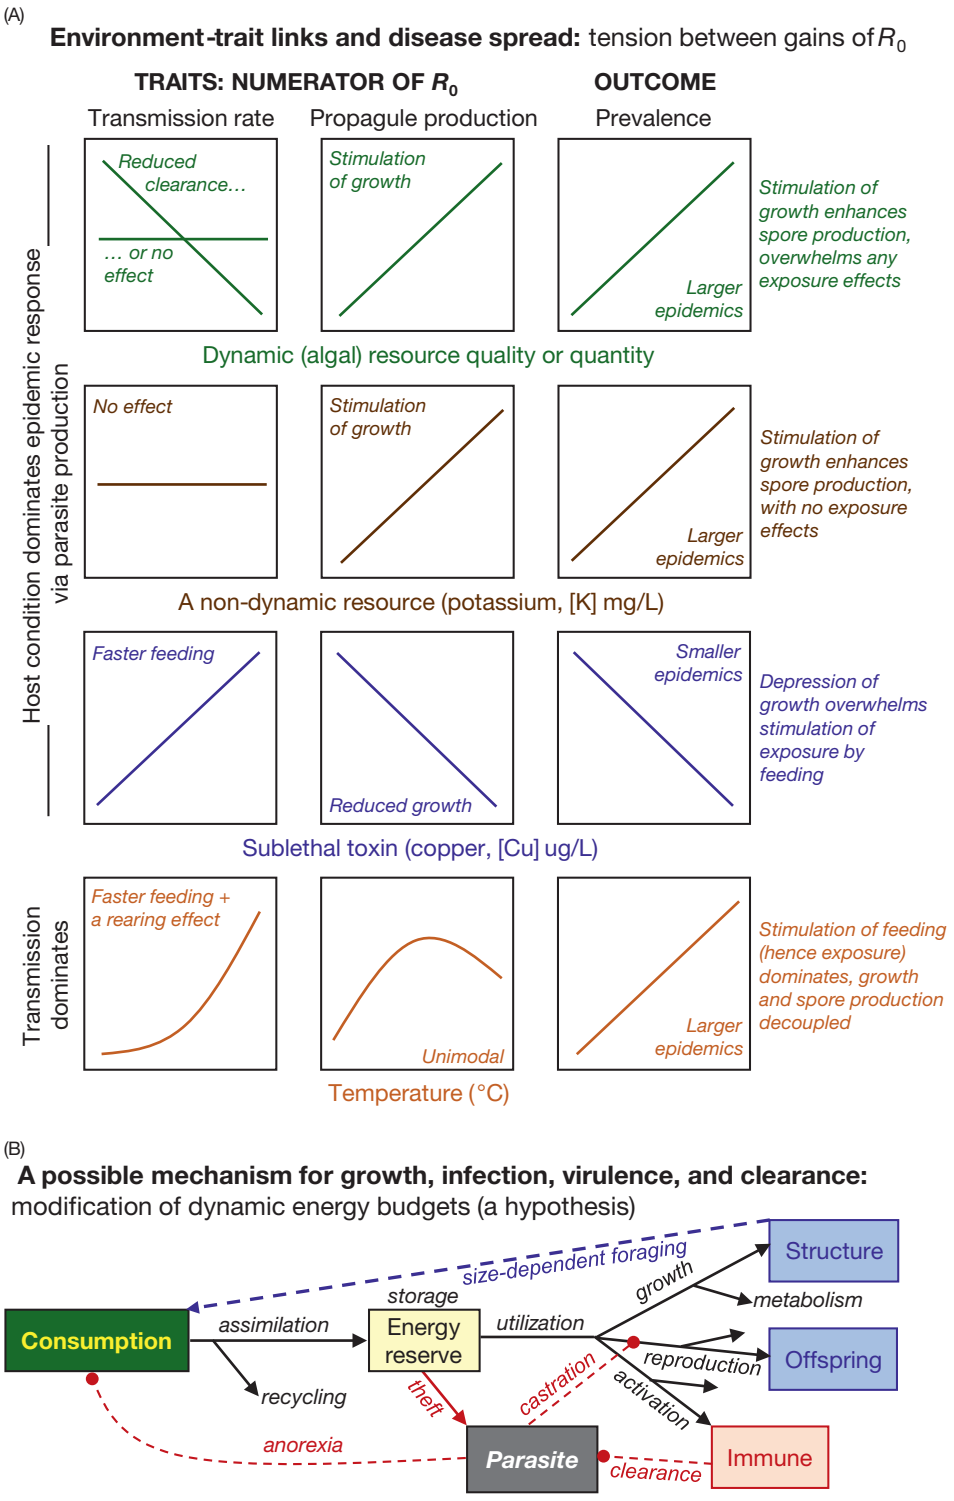

Fig. 3 *Tension between components of disease spread and the host condition hypothesis.* (A) *Environmental-trait links to disease spread and tension between gains of R_0.* Three examples—a dynamic resource, a non-dynamic resource (potassium), and a sublethal toxin—illustrate how these environmental factors can influence both transmission rate and/or production of parasite propagules, perhaps even in opposition. All three highlight the supremacy of the propagule production trait—epidemics increase or decrease in size depending on how the environmental factor affects this trait. However, the thermal example provides a counter-point: warmer temperatures lead to larger epidemics ("warmer is sicker") by strongly increasing the transmission rate trait. (B) *A possible mechanism for growth, infection, virulence, and clearance: modification of dynamic energy budgets (the host condition hypothesis).* These environment-trait-outcome connections can be captured by models of energy and nutrient flow within individual hosts. Here, in a typical dynamic energy budget model, consumed energy is assimilated into an energy reserve, then utilized for growth of structure, production of offspring, and payment of associated maintenance and other metabolic costs. Then, parasites can steal energy, reduce feeding (through "anorexia"), and alter allocation away from reproduction (causing castration and possibly gigantism).

alter allocation of utilized energy reserve away from reproduction and towards growth (producing [possibly transient] gigantism: Hall et al., 2007a). Finally, some representation of immune function (such as hemocyte cells) could be layered in, enabling clearance (via killing) but also present an energetic loss (Cressler et al., 2014).

This framework becomes pertinent to the focal planktonic examples because it provides a mechanism for the "host condition hypothesis." Any factor increasing energy flow into hosts (e.g., better phytoplankton resources, more potassium) can increase both energy reserve and host growth. Hence, this fungal parasite has a larger body to fill with propagules, and that large body provides energy at faster rates (through faster feeding). Alternatively, any toxin (like copper) that increases metabolic costs (e.g., for detoxification) would decrease size, hence energy input and space to pack parasites. Additionally, a thermally explicit version of this model might explain decoupling of host growth and production of propagules with warmer temperatures (particularly if thermal scaling of the traits governing energy acquisition and use differ between host and parasite). Finally, the model could help predict transmission rate, particularly once realistic forms of immune clearance are added. Other factors, like digestion resistance via gut passage time mechanisms can enhance realism for both resource quality and infection dimensions (Hall et al., 2012). Yet, much work remains on such frameworks.

*Environmental gradients and abiotic and biotic losses of parasites (*Fig. 4*)*

The focal planktonic system also illustrates how environmental gradients can influence losses of parasites, both in the free-living propagule and infected host stages. Through these effects, they also influence epidemic size (Fig. 4A). These factors feature in the denominator of R_0. The example gradients here, dissolved organic carbon (DOC) and refuge size (i.e., oxygenated waters below the thermocline) shape both abiotic and biotic losses. For instance, solar radiation proves highly damaging to propagules distributed in the water column. As a result, propagule loss rate (m_Z) increases in lakes with lower concentration of dissolved organic carbon (Fig. 4B, panel (i)). Hence, epidemics tend to start earlier in the autumnal season (more incident UV) and can become larger in browner lakes (i.e., "browner is sicker"). Additionally, lakes with higher dissolved organic carbon have more midge predators (ii).

Furthermore, deeper lakes with larger thermal refuges (that last longer when stratified) also have more midges (iii) and sometimes have higher density of a diluter-competitor (*D. pulicaria*). Typically, this species has left the water column before epidemics commence (hence is not drawn here: but see Penczykowski et al., 2014). Conversely, lakes with smaller thermal refuges tend to have higher realized predation intensity from visually oriented sunfishes (like sunfish: (iii); all of below from Strauss et al., 2016). Those visually oriented predators increase frequency of smaller-bodied species (esp. *Ceriodaphnia* sp). that act as diluter-competitors by consuming spores (iv). These fishes tend to selectively prey upon infected hosts ($\theta \gg 1$) since infection turns ordinarily translucent hosts more opaque (v)) but release few if any viable propagules into the water column ($\gamma \approx 0$). As a result, they act like "healthy herds" predators: higher realized predation intensity by fishes leads to smaller epidemics. Conversely, midge predators feed differently (by mechano-sensory mechanisms), often in the epilimnion at night. As a result, they are not selective upon infected hosts ($\theta \approx 1$) but do release propagules into habitat that where they can readily contact new hosts to infect ($\gamma > 0.5$). If that release occurs in darker lakes (lower loss rate) and avoids sink-out of infected hosts before propagule release, these 'predator spreaders' can increase epidemic size.

The case studies then illustrate two general points that should apply broadly across aquatic disease systems. First, some environmental gradients will facilitate epidemics by reducing abiotic losses (from damage, sinking, flushing, etc.) Second, those same or other environmental gradients can change community composition of the suite of predators and diluter-competitors with which hosts interact. Depending on foraging biology of the predators (e.g., degree of selectivity on infected hosts and diluters, release of propagules, etc.), increases in their density may lower disease ("health herds") or increase it ("predator spreaders"). Then, third, note how densities of these factors influence losses can also indirectly shift components of the gains. For instances, trophic cascades caused by predators could increase resource density (hence propagule production)—but, then again diluter-competitors may control resources and prevent the cascade. Finally, predators can influence other components of host biology that also shape disease spread. For instance, selective predation on juveniles can shift populations towards adults. If parasites more easily infect adults, they may help spread disease via shifts in stage structure. Hence, environment gradients that influence losses can act in straightforward but also in more intricate ways interwoven within food webs.

*Some other connections between traits and epidemic outcomes (*Fig. 5*)*

The focal parasite itself can change key traits that then influence the density or composition (genetic or stage) of its host. Three examples illustrate this point.

(i) *Foraging depression and cascades* vs. *hydras*: In this first case, parasite propagules in the environment depress foraging of hosts (Fig. 5A). This sensitivity to propagules can depend upon host genotype (i.e., some respond more sensitively than others: Strauss et al., 2019). However, this plasticity of foraging can create a trait-mediated indirect effect that leads to higher host density during epidemics of virulent epidemics (via a "hydra effect"; Fig. 5B; Penczykowski et al., 2022). The causal chain starts with an increase in resource density caused by the epidemic. That increase can boost production of the resource (if the host strongly controlled it). Then, both foraging depression and mortality influence per capita resource consumption at equilibrium. Since host density hinges on a ratio of production to per capita consumption (at equilibrium), models predict parasite-driven trophic cascades (more resources, less hosts) at low carrying capacity of the resource (e.g., more oligotrophic systems). However, the potential for hydras (more resource, more hosts) arises in more eutrophic conditions (Penczykowski et al., 2022). Hence, the parasites can initiate trait-mediated indirect effects that then influence allocation of biomass among trophic levels.

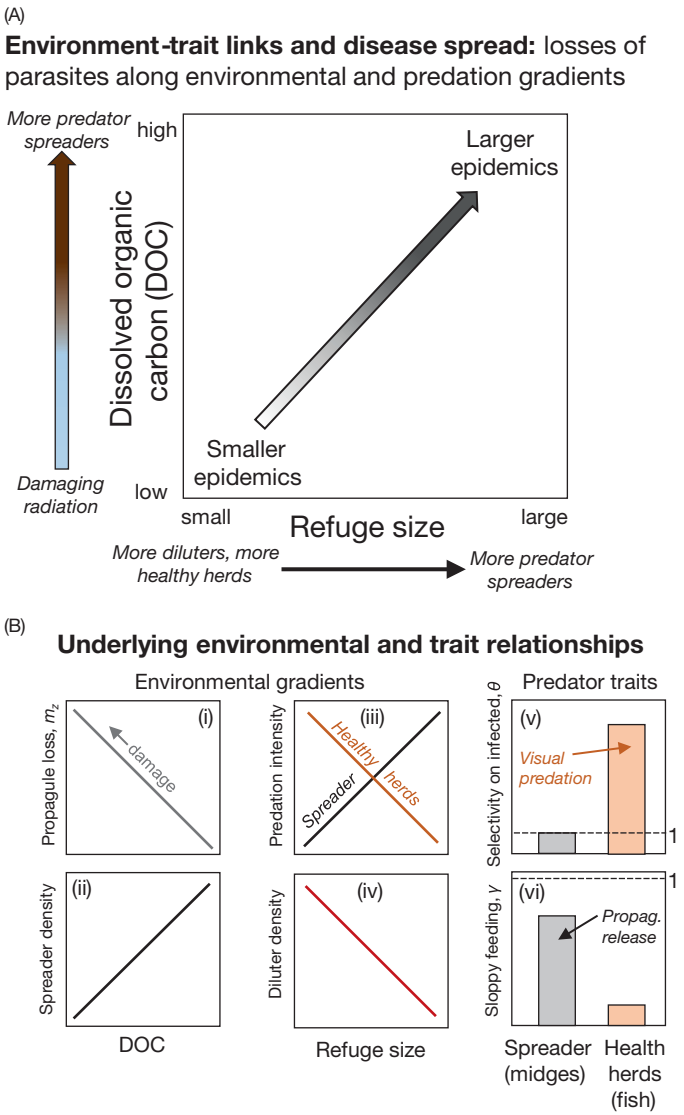

Fig. 4 *Environmental factors influencing losses of parasites.* (A) *Environment-trait links and disease spread: losses of parasites along environmental and predation gradients.* In the focal plankton system, two environmental gradients (dissolved organic carbon [DOC] and refuge size) influence losses of parasites both directly and indirectly. Therefore, both modulate the size of epidemics. (B) *Underlying environmental and trait relationships.* (i) Higher DOC protects propagules from damaging solar radiation, but (ii) also correlates with higher density of midges that spread disease. Then, larger size of thermal refuge (i.e., thickness of oxygenated water column below the thermocline) creates gradients of predators with different traits and diluter-host composition that influence epidemics indirectly. The two major predators, in turn, vary in two key traits. Fishes act like "healthy herds" predators (reducing disease) because they (iii) selectively prey upon infected hosts but (iv) release few propagules back to the water column. Midges, in contrast, do not selectively consume infected hosts (v) but release half or more of the propagules back into the epilimnion at night (vi).

(ii) *Fecundity-transmission tradeoffs and evolution of resistance:* In a second example, clonal genotypes of the host can trade off fecundity and transmission rate. In this relationship, more fecund genotypes resist infection less while less fecund ones better resist infection (Fig. 5C; Hall et al., 2010a). Such a relationship arises in the focal system because both traits depend on feeding rate (i.e., fast feeders consume more propagules while consuming more phytoplankton resources). This covariance of traits then influences evolution of resistance and feeding rate traits during epidemics (Fig. 5D; Duffy et al., 2012). Under certain conditions, hosts rapidly evolve higher resistance to the virulent fungus. In others, hosts can rapidly evolve higher susceptibility (because fast feeding becomes the fittest strategy during epidemics). In this later situation, such an evolutionary response can paradoxically trigger large declines of host density during epidemics. Hence, connections between traits that influence epidemics and consumer-resource interactions can shift trait distributions and host abundance.

(iii) *Allocation decisions and the stage and sexual structure of host populations—the example of males*: In the third example, disease epidemics can shift allocation of a host population towards production of males (Hite et al., 2017). In the focal host-parasite

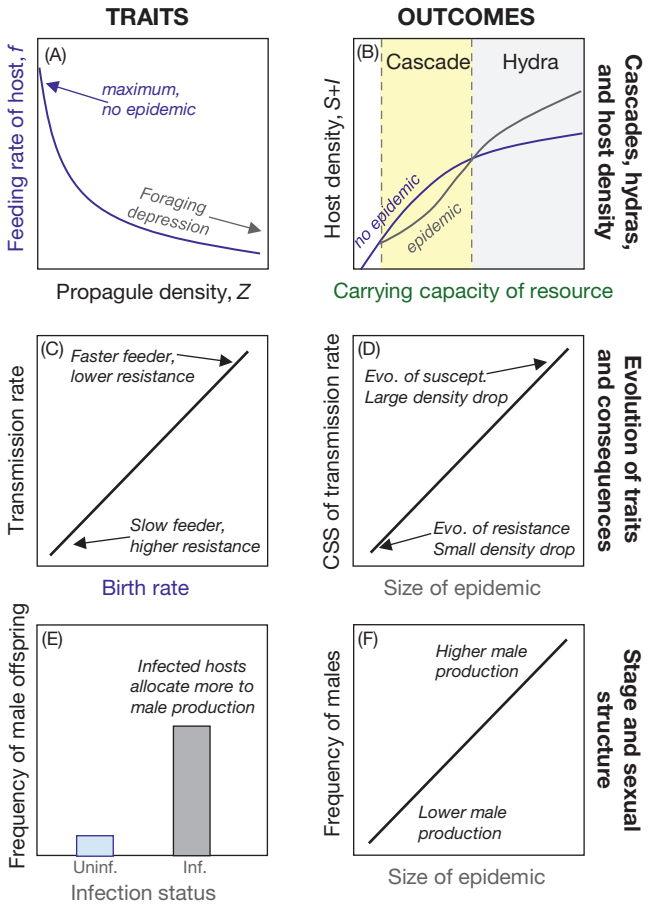

Fig. 5 *Three other connections between parasites, host traits, and the outcomes of epidemics. Foraging depression and the cascade-hydra gradient*: (A) Propagules reduce foraging rate of hosts. (B) Through that trait, epidemics can cause trophic cascades (more resources, fewer hosts: more likely at lower carrying capacity of resources). They can also trigger "hydra effects" (more resources, more hosts: higher carrying capacity). *Fecundity-transmissions tradeoffs and the evolution of hosts during epidemics*: (C) Through connections to the feeding rate trait, hosts with high fecundity (while uninfected) tend to have less resistance to infection. The tradeoff strongly influences (D) whether hosts (often rapidly) evolve more resistance to infection or lower resistance. The eco-evolutionary outcome can reduce or magnify depression of host density during epidemics. *Allocation to males and stage/sex structure of host population*: (E) Infected hosts allocate more reproduction to males. (F) Subsequently, during larger epidemics, the frequency of males in the host population increases.

system, individual infected females produced more male offspring. (These males were not more resistant to infection). As a result, lakes (and mesocosms) with larger epidemics become composed of a higher percentage of males during late autumn. Hence, parasites can influence allocation of host populations to production of males (sex) during epidemics.

Conclusions

Despite what textbooks may lead us to believe, parasites feature prominently in aquatic food webs. Once we embrace this interesting dimension of aquatic ecosystems, how can we characterize them, understand the factors that modulate epidemic size, predict the consequences for host populations, and link them to the food webs? This article proposes a two-part approach. First, we must understand the natural history of the host-parasite interaction. Epidemiological books teach us some of the basics—for instance, transmission as the transfer of infection upon contact between host and parasite. But then, the biology of the organisms themselves can require modeling of more details. Indeed, three categories of heterogeneity almost certainly must be considered (e.g., epidemiological, intraspecific, and food web architecture). Hence, in order to characterize the community ecology of an aquatic disease we must embrace these forms heterogeneity. With this focus, we can model disease spread.

The second part of the approach connects that model to environmental gradients that so profoundly shape aquatic communities. A planktonic host-parasite case study illustrates some examples. First, a mathematical model can capture the gain-loss processes that influence the start, magnitude, and implications of fungal epidemics in zooplankton hosts. Then, that model connects environmental gradients to these traits influencing gains and losses. Some environmental gradients (e.g., resources, toxins, temperature) more strongly influence gains of parasites, either by influencing transmission rate (especially via exposure [feeding rate]) or production of parasite propagules. Then, other environmental gradients most strongly influence the losses of

parasites, either directly or via species that themselves strongly shape the size of epidemics. Of course, parasites themselves can influence traits of hosts that then determine the magnitude and scope of epidemics in aquatic ecosystems. Three examples (foraging depression, fecundity-transmission tradeoffs, and allocation to males) illustrate how aquatic parasites can alter density, genetic composition, and sexual/stage structure of host populations.

Once we identify and characterize the important host-parasite interactions, we then can predict how they influence inland waters in a changing climate. For instance, perhaps a "browner world is a sicker world" in lakes: increased concentration of dissolved organic carbon into otherwise clearer lakes may remove direct constraints on parasites and/or facilitate interactions with species that spread them. Additionally, warmer conditions may exacerbate epidemics ("warmer is sicker") if they more strongly influence traits governing disease spread (like transmission rate) than enhance the food web factors that constrain epidemics (like "healthy herds"-type predators: Hall et al., 2006). These and other similar questions remain tractable for aquatic ecologists once they embrace relevant heterogeneity inherent in the host-parasite system, then link (changing) environmental gradients to those sources of heterogeneity. Though these steps, aquatic ecologists can create predictive theories for disease epidemics within aquatic food webs in a changing world.

Research gaps

Looking to the future, several directions arise. In freshwater aquatic communities:

1. What are the major drivers of the start of disease epidemics? What combination of physical, environmental, immunological, and ecological factors trigger their start ($R_0 > 1$), and which of them inhibit epidemics ($R_0 < 1$)?
2. How will climate change alter these factors? For instance, will enhanced browning or warmer lead to larger disease epidemics? Could more variable climatic conditions trigger them? Does pollution with nutrients and/or chemicals further modify conditions for epidemics?
3. Once they begin, in what (understudied and likely underappreciated) ways do parasites alter the ecology of their aquatic hosts? How do they shift stage structure, genetic diversity, sexual characteristics, density and production, etc., of their hosts?
4. Then, beyond the host, to what extent do disease epidemics influence freshwater ecosystems? To what extent do they alter primary production, cause trophic cascades or hydras, modify nutrient cycling (as sources or sinks), interact with algal blooms, shift community composition, and/or influence energy and material flow up food webs?

These questions and more await future discovery in the study of freshwater systems.

Light as an Ecological Resource☆

Dina M Leech[a] and Sönke Johnsen[b], [a]Department of Biological and Environmental Sciences, Longwood University, Farmville, VA, United States; [b]Department of Biology, Duke University, Durham, NC, United States

This is an update of D.M. Leech, S. Johnsen, Light, Biological Receptors, in Encyclopedia of Inland Waters, Edited by Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00073-9.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Lars Rudstam.

Glossary

Brownification An increase in the yellow-brown color of inland waters, caused mainly by inputs of dissolved humic matter of terrestrial and wetland origin, which absorbs solar radiation strongly in the short wavelength part of the visible spectrum.
Chromophore A molecule that absorbs light. As a component of photoreceptors, the chromophore is often retinal (i.e., vitamin A1 or A2).
Eutrophication The process by which a body of water becomes enriched in dissolved nutrients, such as phosphates, that stimulate the growth of aquatic plant and bacterial life, usually resulting in the depletion of dissolved oxygen.
Opsins A group of proteins made light-sensitive through their chemical bond with a chromophore. The amino acid sequence of an opsin protein, combined with the type of chromophore, determines the absorption spectrum of a visual pigment.
Photopigment A chromophore bound to an opsin protein. Photopigments are classified by their wavelength of maximum absorbance.
Photoreceptor A sensory neuron that contains chromophores bound to opsin proteins within their membranes and thus responds to light. Examples include rod and cone cells in the eyes of vertebrates.
Spectral tuning Adaptive shifts in the absorption spectra of photopigments, aligning peak spectral sensitivity with the predominant wavelengths available in a particular environment.

☆*Change History*: October 2021. DM Leech and S Johnsen as requested, Leech and Johnsen have rewritten the chapter from a broader perspective to discuss all wavelengths of light, not just UV radiation. References are included. Further reading has been revised to match updated text. Relevant websites have been updated. Tables 1 and 2 are new to this edition. Figs. 1, 2, and 6 were retained from the previous chapter. Figs. 3–5 & 7–10 have been added.

Introduction

Light energy has bathed the Earth since its formation ~4.5 billion years ago, even at depth in underwater environments. It is therefore unsurprising that most species have evolved the ability to capture light and utilize it as an ecological resource. Beyond its conversion into chemical energy by primary producers, light—via photoreception— enhances the fitness of organisms in numerous ways, ranging from habitat selection, foraging, and mate choice to the setting of biological clocks. What is somewhat surprising is that the basic mechanism of light capture, or photoreception, is similar across all three domains of life: Bacteria, Archaea, and Eukarya. This suggests that photoreception is an evolutionarily old trait. Often, with only small modifications at the molecular level, species adapt, or spectrally tune, to light in their environment. Nevertheless, benefits of photoreception must be balanced with potential costs, such as exposure to damaging solar radiation. In the present chapter, we briefly describe the properties of light in freshwater environments and the structure and function of photoreceptors used to capture light. We discuss the visual and non-visual uses of photoreception by a wide diversity of taxa as well as possible tradeoffs. We further highlight how recent, human-induced alterations in the underwater light environment, including eutrophication, brownification, and artificial lighting (or light pollution), affect inland waters. We conclude with knowledge gaps that require future research.

The underwater light environment

Light in freshwater ecosystems primarily originates from the Sun and is both absorbed and scattered as it penetrates through water. As a result, downwelling irradiance decreases with depth, with shorter and longer wavelengths attenuating more rapidly than the wavelength of peak transmission (generally between 470 nm (blue light) and 550 nm (green light)). In clear, oceanic water, absorption by the water itself is the primary source of light attenuation. However, particulate and dissolved organic matter are typically the dominant contributors to light attenuation in freshwater ecosystems. Increased phytoplankton biomass attenuates light as a result of both scattering and absorption, particularly in the visible range (400–700 nm). In systems with moderate-to-high dissolved organic carbon (DOC) (>3 mg L^{-1}), UV and blue wavelengths (<450 nm) are attenuated rapidly, and the underwater light field shifts towards longer wavelengths (>550 nm), while in systems with low DOC (<3 mg L^{-1}), shorter wavelength radiation penetrates farther, and UV and blue wavelengths are more prevalent. In 1996, 25% of the lakes in North America were estimated to have 1% attenuation depths (the depth to which 1% of surface irradiance remains) greater than 4 m for 320 nm UV-B radiation and greater than 10 m for 380 nm UV-A radiation (Williamson et al., 1996). However, more recent data from the United States Environmental Protection Agency's National Lakes Assessment Program suggest that the percentage of clear, blue lakes in the US is declining (i.e., 46% of lakes in 2007 to 28% in 2012) while the percentage of murky lakes is increasing (i.e., 24% of lakes in 2007 to 35% in 2012), due to continued inputs of nutrients and organic matter from the terrestrial watershed (Leech et al., 2018). In turn, these changes in water color dramatically affect light penetration depth, intensity, and spectral characteristics (Levine and MacNichol, 1982; Fig. 1).

Additionally, solar elevation, cloud cover, and turbidity influence light availability at depth by affecting either surface light or the depth to which surface light can penetrate (Kirk, 2010). In shallow, relatively clear waters, the reflectance of bottom substrates can have a significant effect on the light environment. For rivers and streams, canopy cover and riverbed topology must also be considered (Julian et al., 2008; Heaston et al., 2017).

Together, these differences in light intensity and spectral composition create potential "light niches." For example, relative quantities of UV radiation can be greater during crepuscular periods (i.e., dawn and dusk) compared to daylight hours due to the increasing proportion of high-UV skylight in the total irradiance (Fig. 2). Twilight hours may therefore provide a temporal niche for predators with UV vision, enhancing target–background contrast and potentially silhouetting prey (Cronin and Bok, 2016), while clear waters near the surface may provide a spatial niche, with relatively more available UV radiation compared to deeper depths. The relative abundance of UV radiation, compared to visible light, is highest in the horizontal and downward lines of sight, representing up to 40% of the total photons in clear oceanic surface waters (Johnsen, 2012). In both cases, UV radiation can serve as a short-range private communication channel for organisms with UV vision because it is absorbed and scattered more than most visible wavelengths.

While bioluminescence is an important source of light in the ocean, it is extremely rare in fresh waters. Only one genus of adult freshwater bioluminescent animal has been identified, the freshwater limpet-like snail *Latia*. It consists of four species that reside in clean, fast flowing streams in New Zealand (Shimomura et al., 1972; Ohmiya et al., 2005). In contrast, bioluminescence has been widely observed in marine taxa, from bacteria to sharks (Widder, 2010; Johnsen, 2012). The reason for the lack of bioluminescence in fresh waters remains unknown.

Biological photoreceptors

Structure and function

Photoreceptor proteins have been observed in all domains of life, including rhodopsins, phytochromes, xanthopsins, cryptochromes, phototropins, and BLUF or "sensors for blue-light using FAD" proteins. In archaea, bacteria, and eukaryotes, photoreceptors often consist of a chromophore bound to an opsin protein, and together, they are referred to as a rhodopsin, photopigment,

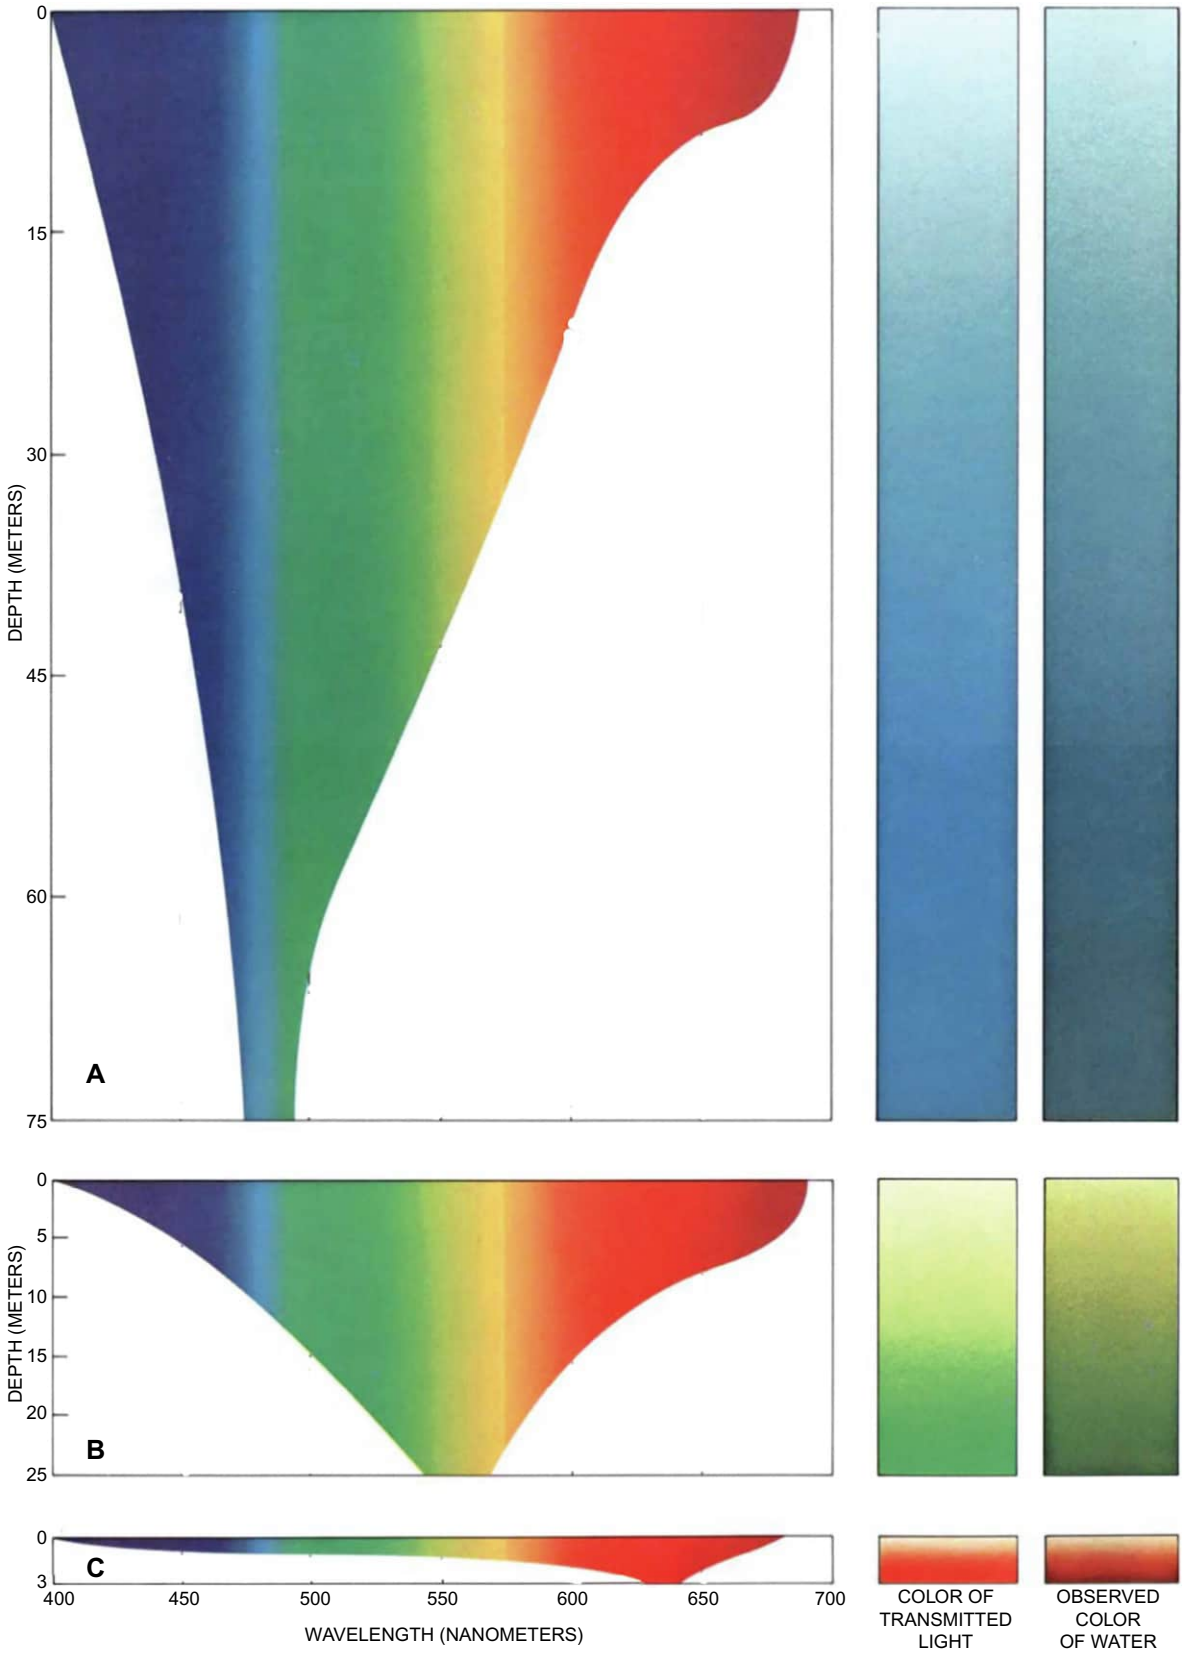

Fig. 1 Transmission of light by water is dependent on the color or wavelength of the light. In clear oceans and lakes (A) the light becomes increasingly monochromatic and blue as its path length increases. In fresh water that carries green organic matter (B) light at all wavelengths is absorbed more quickly than it is in clear water, but the light becomes greener with path length. In rivers, swamps and marshes that carry large amounts of the products of plant and animal decay (C) absorption is rapid and the spectral distribution of the light shifts to the red. Such waters are called black because the human eye is relatively insensitive to light at long wavelengths; a less anthropomorphic name would be infrared water. The depths given for the maximum penetration of light are typical, but they vary widely. Reproduced with permission from Levine J and MacNichol E (1982). Color vision in fishes. *Scientific American* 246: 140–149.

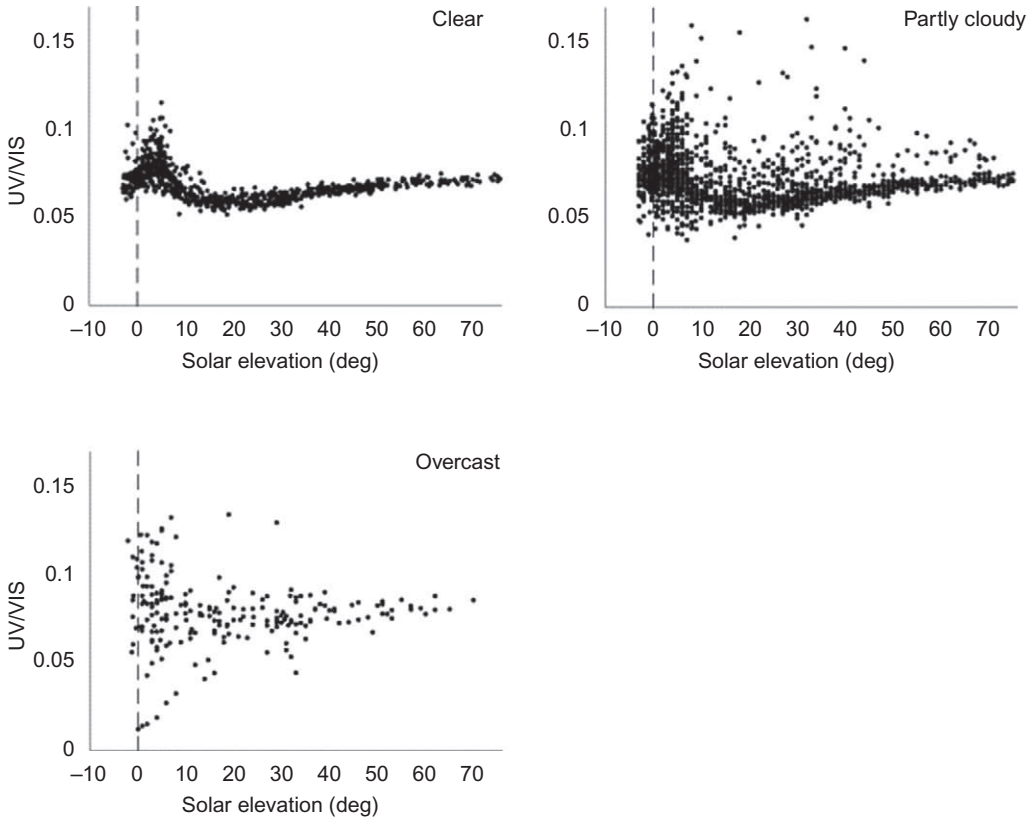

Fig. 2 Ratio of UV (300–380 nm) to visible light (380–780 nm) as a function of solar angle under clear, partly cloudy, and overcast conditions. A total of 2600 spectra were measured from the roof of the University of Granada's Science Faculty (Granada, Spain, 37_110N 3_350W, elevation 680 m) from February 1996 to February 1998 using a LI-1800 spectroradiometer (LI-COR Bioscience, Lincoln, NE, United States) fitted with a cosine-corrected receptor. Measurements were taken at all solar elevations greater than -4^{o} and in all weather except for rain or snowfall. Data were collected at 5 nm intervals from 300 to 1100 nm. Data are courtesy of Dr. Javier Hernandez-Andres at the University of Granada in Spain.

or visual pigment (Fig. 3). Each photopigment absorbs light most efficiently at a specific wavelength based on the amino acid sequence of the opsin protein and its interaction with the chromophore. Most often the chromophore is either 11-cis-retinal (A1) or 11-cis-dehydroretinal (A2) although other chromophores have been identified. Opsin proteins are more diverse and are divided into two major groups: Type I opsins, or microbial opsins, found in archaea, bacteria, algae, and fungi, and Type II opsins, or animal opsins, found only in metazoans (Table 1).

Both microbial- and animal-opsins are seven-transmembrane-helix receptor proteins (Ernst et al., 2014). Yet interestingly, despite their similarity in protein tertiary structure, Type I and II opsins are believed to have evolved through convergent evolution, given the lack of homology in their amino acid sequences (Ernst et al., 2014). Organisms often possess multiple opsin genes that allow them to measure and compare light intensity across a broader spectrum (Fig. 3). For example, five general families of opsins are observed across a diversity of aquatic taxa, including the rod opsin RH (blue-green sensitive, 460–530 nm) and four cone opsins: SWS-1 (ultraviolet sensitive, 355–450 nm), SWS-2 (shortwave sensitive, 415–480 nm), MWS (mid-wavelength sensitive, 470–530 nm), and LWS (long-wavelength sensitive, 495–570 nm) (Table 2).

For single-celled organisms, photoreceptors most often occur as simple cell membrane receptors; however, advanced ocular structures are found in some species. For example, warnowiid dinoflagellates have a light-sensitive ocelloid that is similar to the camera-like eyes of multicellular organisms (Hayakawa et al., 2015), and cells of the freshwater cyanobacterium *Synechocystis* act like lenses, focusing light to a single point inside the cell (Schuergers et al., 2016). In animals, photoreceptors are often associated with eyes, which can allow for color vision and detailed image formation. However, extraocular photoreceptors are commonly found throughout the body (e.g., pineal gland, brain, nerves, and skin), serving important non-visual functions (Cronin and Johnsen, 2016).

Eyes and color vision

Eyes are unique to animals and vary in complexity from simple eyespots that can only detect shadows to camera-like and compound eyes with detailed color vision. The evolution of eye complexity generally correlates with a species' visually guided behaviors

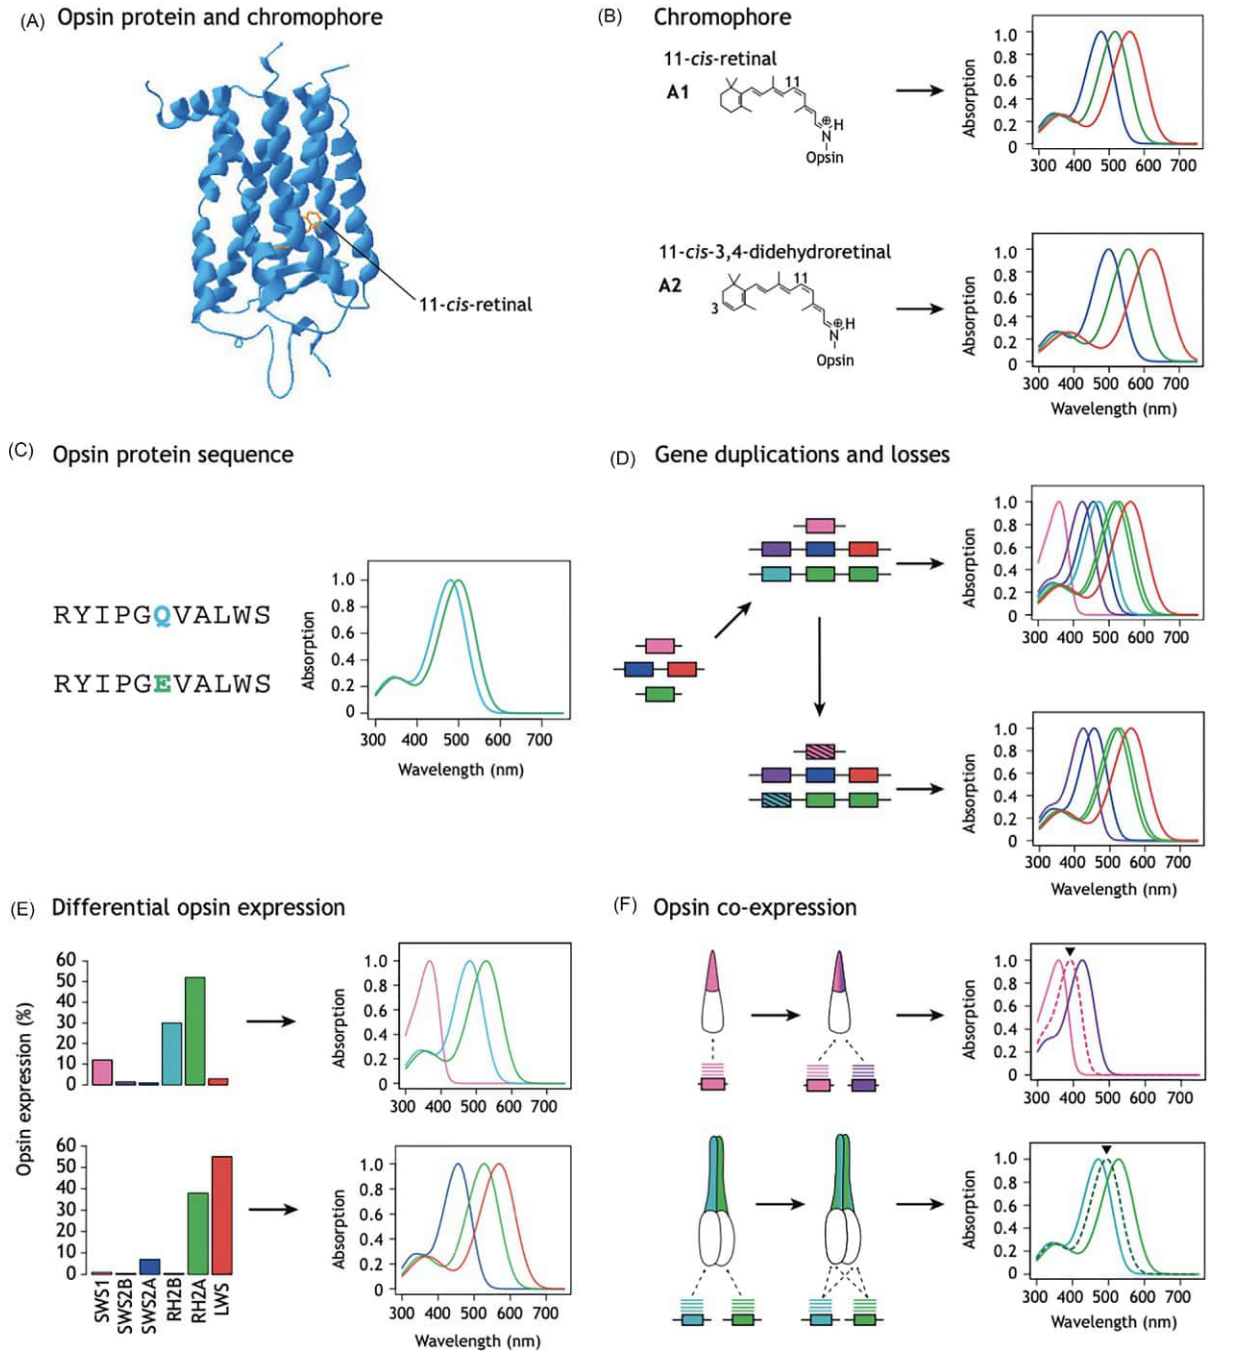

Fig. 3 Mechanisms affecting visual pigment sensitivities, including changes to opsin genes and the retinal chromophore. (A) Photoreceptor sensitivities are set by visual pigments, which are composed of chromophores (yellow) and opsin proteins (blue). Several different mechanisms can alter sensitivities (shown by absorption spectra for each visual pigment) including: (B) shifts between vitamin A1- and A2-derived chromophores; (C) changes to opsin amino acid residues; (D) opsin gene duplications and losses, with duplicate genes acquiring new function (e.g., violet versus blue) and some duplicates subsequently being lost (shaded); (E) differential opsin expression (shown as % total cone opsin); and (F) co-expression of multiple opsins with co-expression possible both in single cones (top) and double cones (bottom). Opsin genes are color coded as SWS1 (pink), SWS2B (violet), SWS2A (blue), RH2 (blue-green to green) and LWS (red). From Carleton KL, Escobar-Camacho D, Stieb SM, Cortesi F and Marshall NJ (2020) Seeing the rainbow: mechanisms underlying spectral sensitivity in teleost fishes. *Journal of Experimental Biology* 223: jeb193334.

(Land and Nilsson, 2012; Nilsson, 2013). Non-directional photoreception, such as monitoring ambient light intensity as a depth gage or to set a circadian clock, requires simple light sensing structures while high resolution vision, needed to detect, pursue, and communicate with others at relatively long distances, requires more complex structures (Fig. 4). In vertebrates, eyes consist of a cornea and lens to collect and focus light combined with a retina of photoreceptors that absorb and thus detect light. These retinal photoreceptors include rods, which aid in low-light vision, and cones, which permit color vision.

Table 1 Summary table of common Type I and Type II opsins and their general location and function.

Opsins	*Location*	*Known functional roles*
Type I: present in archaea, bacteria, and algae		
Bacteriorhodopsin	Cell membrane	Photosynthesis; proton pump
Bacterial sensory rhodopsins	Cell membrane	Ion-pump; proton-pump; phototaxis
Channelrhodopsins	Cell membrane	Ion channel; phototaxis
Halorhodopsin	Cell membrane	Chloride pump; phototaxis
Proteorhodopsin	Cell membrane	Ion and proton pumps
Type II: present in animals (excluding sponges)		
C-opsins (Ciliary)	Eye, brain, skin, pineal organ, sperm, heart, kidney, liver, blood vessels, placenta	Vertebrate vision, ranging from non-directional light sensors to high resolution image formation and color vision; entraining circadian rhythms; body color change; photorelaxation of blood vessels
Cnidops (Cnidarian opsins)	Eye, neuropil (jellyfish)	Entraining circadian rhythms; gamete release
R-opsins (Rhabdomeric)	Eye, brain, skin, pineal, blood vessels, sperm	Invertebrate vision; entraining circadian rhythms
Go/RGR	Eye, brain, spinal cord, pineal, skin, sperm, tube feet	Photoisomerases; regulate retinoid traffic

Not an all-inclusive list. Based on information from Ernst et al. (2014) and Leung and Montell (2017).
New functional roles continue to be discovered.

Animals must express multiple opsins with varying wavelengths of peak absorption in order to see color. Some have simple color vision with only two types of cone photoreceptors (dichromacy) while others see a broader color spectrum as tri- or tetra-chromats; the latter of which generally possess UV vision (Cronin and Bok, 2016). Invertebrates are generally dichromats or trichromats, often with one UV sensitive photopigment (Land and Nilsson, 2012). Among vertebrates, fishes show the greatest diversity for detecting color, with more colorful fishes displaying increased chromacy (Marshall and Vorobyev, 2003). That said, many freshwater, predatory fishes are dichromatic, with color vision centered on red and green wavelengths, such as adult largemouth bass *Micropterus salmoides* (Lythgoe, 1979; Mitchem et al., 2019).

Spectral tuning

The ability to adjust to spectral changes in the optical environment is advantageous. This spectral tuning is accomplished in several ways, over both short- and long-time scales (i.e., days to generations). Natural selection acts on opsin genes that vary in amino acid sequence to allow for light absorption across the visible solar spectrum, from the ultraviolet to near-infrared. Interestingly, even single amino acid changes may cause up to 75 nm shifts in spectral sensitivity, depending on the location and proximity/interaction with the chromophore (Carleton et al., 2020). In addition, switching the chromophore from vitamin A1 (retinol) to A2 (3,4-didehydroretinol) shifts peak absorbance to longer wavelengths. This is often seen in amphibians, crustaceans, fishes, and insects on a behavioral and/or seasonal basis as the dominant wavelengths of their light environment change (Fig. 5; Enright et al., 2015). Interestingly, the adult American bullfrog has A1-based photopigments in the lower portion of the retina and a mixture of A1- and A2-based pigments in the upper portion, corresponding to its time spent at the air-water interface (Enright et al., 2015). The fact that sea lamprey display A1 to A2 chromophore shifts suggests that this trait may have evolved during the Cambrian period, approximately 500 Mya (Morshedian et al., 2017). In animal eyes, changes in the shape and pigmentation of the lens can also affect the wavelength of peak light absorbance. For instance, retinal UV sensitivity is only possible if the ocular media are UV transparent and UV- and blue-sensitive photoreceptors are present (Cronin and Bok, 2016).

With the increasing use of molecular techniques in visual ecology, we have learned that species can down- and up-regulate opsin genes within their genome based on environmental conditions. For example, African cichlids possess seven opsin genes in their genome but generally only express three to four (Carleton et al., 2020). Gene expression differs among cichlid species inhabiting surface versus benthic habitats, clear versus turbid lakes, as well as at different life history stages within a species (Fig. 6). More recently, regulation of opsin gene expression has been demonstrated on finer time scales. Killifish (*Lucania goodei*) transferred from clear to tannin-stained waters, and vice versa, were shown to spectrally tune by altering opsin gene expression within 1–3 days (Fuller and Claricoates, 2011). This suggests that spectral sensitivity and tuning are more plastic than previously thought. Differential expression of opsin genes within a species' genome is hypothesized to permit expansion into varied habitats, as seen in the highly invasive western mosquitofish *Gambusia affinis*. This species also possesses seven cone opsin genes (i.e., one *sws1*, two *sws2*, one *rh2*, and three *lws*), with gene expression for short-wavelength *sws1* and *sws2* being higher in larval stages compared to adults (Chang et al., 2020). More information is needed to understand the role of spectral tuning in invertebrates. The water flea *Daphnia pulex* contains the largest number of opsin genes reported thus far, with 46 opsin genes encoded in its genome. Based on molecular phylogeny, 27 of these genes are related to vision; however, their functional role, including possible involvement in spectral tuning, is unknown (Colbourne et al., 2011).

Methodology includes behavioral assays, electroretinogram (ERG), microspectrophotometry (MSP), suction pipette electrodes (SPE), and identification of RNA sequences in genetic databases. Dashed lines indicate the absence of a particular group of photoreceptors. The asterisks indicate that a photoreceptor is present, but the peak absorbance was not reported because photoreception was determined by behavior experiments or molecular evidence from genetic sequence databases. In some cases, sources focused on cone photoreceptors and not rods. We indicate these with NR for not reported. Based on our survey, fishes are extensively studied but more research is needed to identify specific peak absorbances for invertebrate photoreceptors.

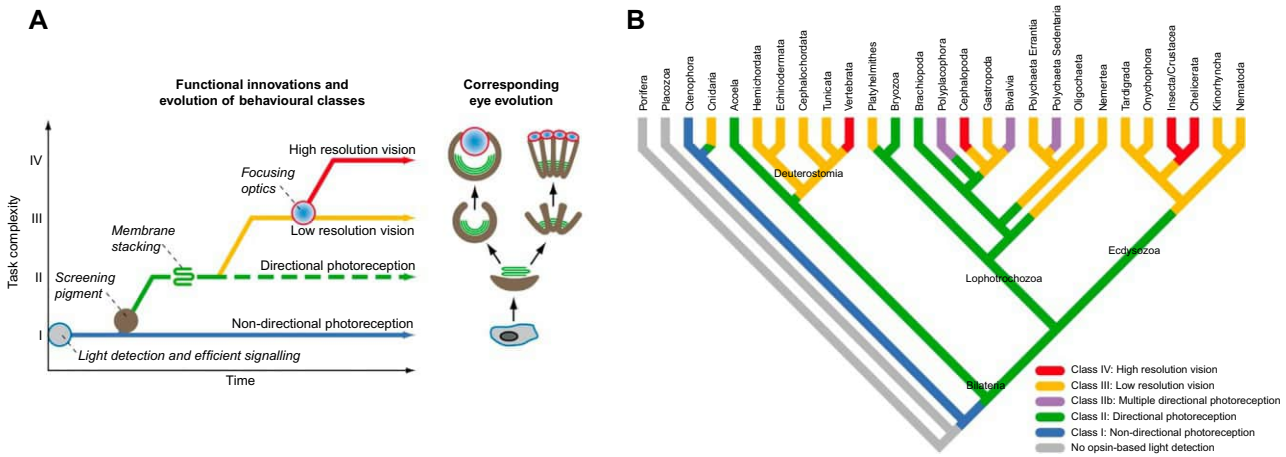

Fig. 4 Behavior and the evolution of the eye. (A) Schematic illustration of the evolution of photoreceptive behaviors on a vertical scale of task complexity, with the position of major functional innovations indicated. The line for directional photoreception is dashed to indicate that class II tasks may become superfluous by the evolution of class III tasks, whereas the other classes remain relevant after a higher class has evolved. Eyes capable of class IV tasks can still handle class III tasks. The corresponding receptor/eye morphologies are shown to the right. Note that compound and single chambered eyes are principally different solutions, suggesting independent transitions from class II to class III. (B) The classes of photoreceptive tasks plotted on a metazoan phylogeny. Reproduced from Nilsson DE (2013) Eye evolution and its functional basis. *Visual Neuroscience* 30: 5–20.

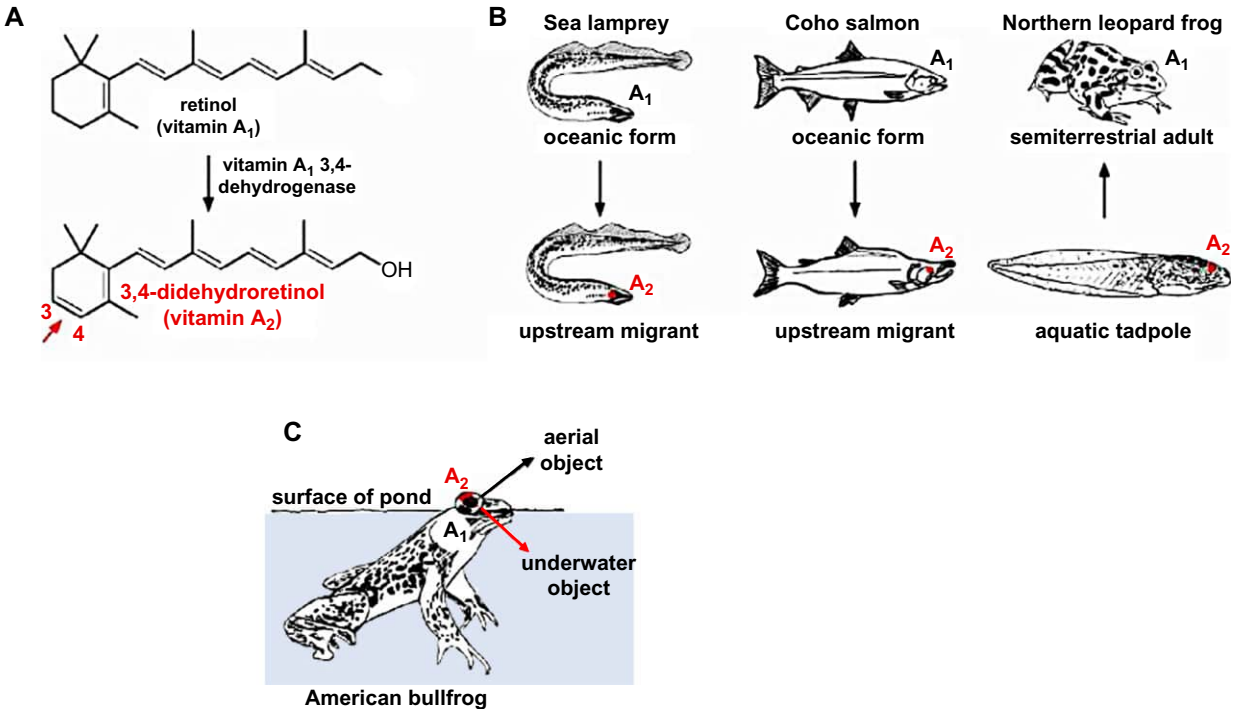

Fig. 5 Examples of chromophore switching. (A) The conversion of retinol (vitamin A1) to 3,4-didehydroretinol (vitamin A2) underlies the rhodopsin-to-porphyropsin switch. (B) This vitamin A1 to A2 switch is widely used by a variety of vertebrates and can be deployed at key stages of the life cycle: e.g., during upstream migration in sea lamprey (*Petromyzon marinus*) and Coho salmon (*Oncorhynchus kisutch*) and upon metamorphosis in amphibians such as the Northern leopard frog (*Lithobates pipiens*). (C) The American bullfrog (*Lithobates catesbeianus*) often sits at the water's surface and possesses exclusively A1-based visual pigments in the ventral retina and a mixture of A1- and A2-based visual pigments in the dorsal retina, possibly facilitating downward vision into murky, red-shifted water. Modified from Enright JM, Toomey MB, Sato SY, Temple SE, Allen JR, Fujiwara R, Kramlinger VM, Nagy LD, Johnson KM, Xiao Y, How MJ, Johnson SL, Roberts NW, Kefalov VJ, Guengerich FP and Corbo JC (2015). Cyp27c1 red-shifts the spectral sensitivity of photoreceptors by converting vitamin A1 into A2. *Current Biology* 25: 3048–57.

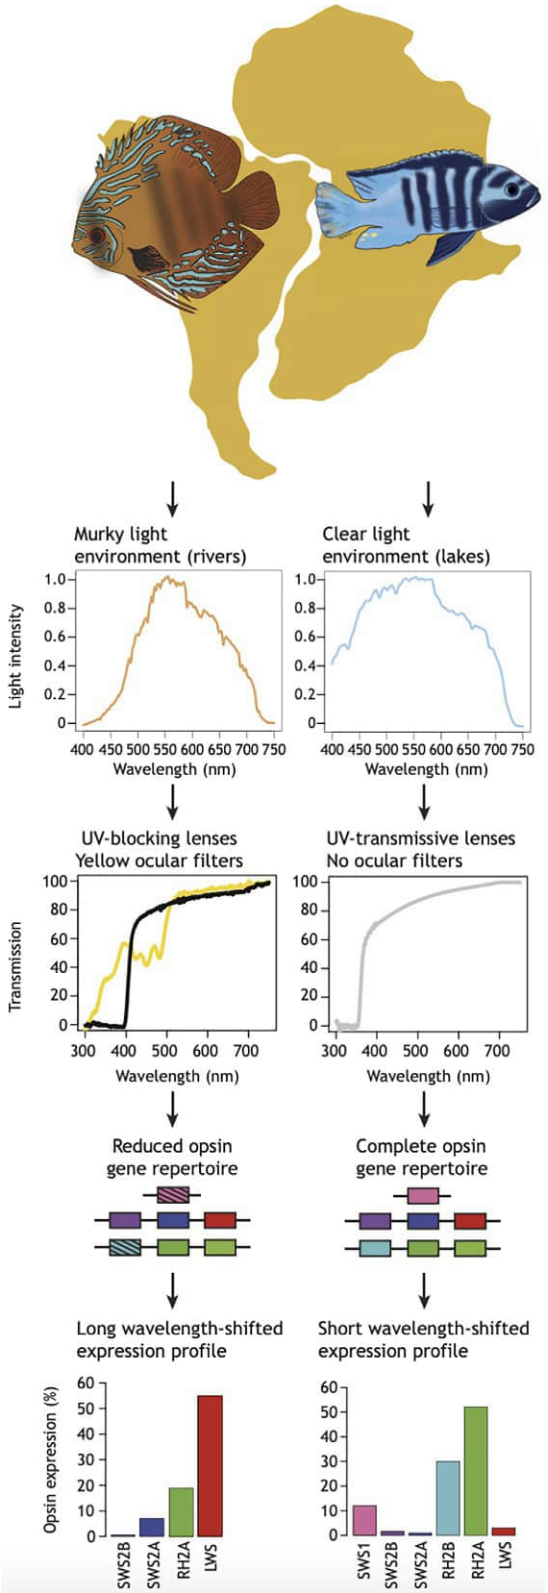

Fig. 6 Visual system divergence in cichlids. Cichlids have adapted to different rivers and lakes on different continents. African rivers and lakes may be quite clear, leading to a diverse array of opsin genes that detect a broad spectrum of light. South American waters are often murkier, such that cichlids have lost a number of shorter wavelength opsins. South American cichlids have also acquired yellow cornea and lens filters, perhaps to reduce the transmission of scattered light in the murkier waters. References cited within text. From Carleton KL, Escobar-Camacho D, Stieb SM, Cortesi F and Marshall NJ (2020) Seeing the rainbow: mechanisms underlying spectral sensitivity in teleost fishes. *Journal of Experimental Biology* 223: jeb193334.

Adaptive significance of photoreception

The conversion of light to chemical energy by primary producers is arguably the most important example of light as an ecological resource. However, light perception also conveys valuable spatial and temporal information that can enhance an organism's fitness. Visually, light helps organisms to select optimal habitats and mates, find food, and avoid predators. Non-visually, light aids in setting biological clocks as well as regulating other physiological functions, like proton and ion pumps in microbes. Here, we briefly describe the adaptive significance of photoreception in a wide diversity of freshwater taxa.

Visual functions

Diel vertical migration

In aquatic ecosystems, an organism's position in the water column can mean life or death. Light works as an effective depth gage, varying in intensity and spectral quality as it travels downward through the water column. By comparing differences in the quantity and quality of light with depth, species respond with positive or negative phototaxis. One of the most interesting behavioral responses to sunlight is the phenomenon of diel vertical migration (DVM). Large zooplankton, like the cladoceran *Daphnia* spp., the cyclopoid *Mesocyclops* spp., and the phantom midge larvae *Chaoborus* spp., often exhibit deep migrations during the day to darker depths in the water column (Lampert, 1989; Hayes, 2003). In turn, smaller zooplankton, including rotifers and copepod nauplii, remain in the surface waters during daylight and migrate to the deeper waters at night to avoid predation or competition with larger zooplankton. Many factors, including temperature and food availability, have been proposed to explain these patterns in fresh waters; however, predation by visually feeding fish is typically identified as the primary factor inducing DVM (Lampert, 1989; Hayes, 2003). Nevertheless, in high-UV systems, ultraviolet radiation may induce downward, diel vertical migrations in freshwater zooplankton, even in the absence of predators (Leech and Williamson, 2001; Williamson et al., 2011; Fischer et al., 2015).

Avoidance of damaging solar radiation

A wide diversity of aquatic taxa display avoidance behaviors to damaging solar radiation, particularly UV radiation and short wavelength blue light. In algae, exposure to high intensities of sunlight can bleach pigments critical to photosynthesis. Negative phototactic responses have been detected in protists, like the freshwater ciliate *Blepharisma japonicum*, which swims away from wavelengths of UV-B but swims towards yellow light (580 nm) (Lenci et al., 1997). Within filamentous cyanobacterial mats, individual cells of *Microcoleus chthonoplastes* were shown to migrate to greater depths in response to increased UV-B exposure (Bebout and Garcia-Pichel, 1995). Interestingly, in the cyanobacterium *Chlorogloeopsis*, a UV-B photoreceptor regulates the production of shinorine, a photoprotective compound (Portwich and Garcia-Pichel, 2000; Singh et al., 2008).

The zooplankter *Daphnia magna* is positively phototactic to wavelengths of visible light (421–600 nm) and negatively phototactic to UV radiation (260–380 nm), with maximal sensitivity at 340 nm (Smith and Macagno, 1990). Field experiments in high-UV lakes have also demonstrated a strong negative phototactic response to UV radiation in *Daphnia* as well as calanoid

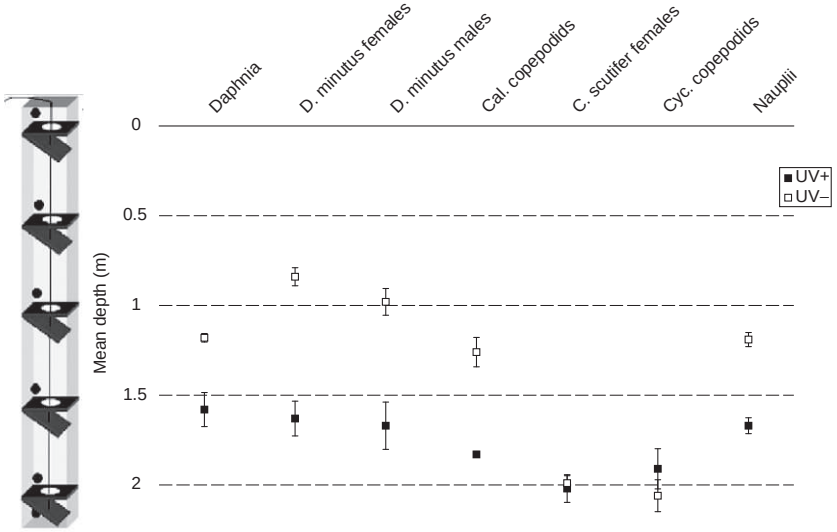

Fig. 7 Mean depths of zooplankton in the presence and absence of UVR at the surface of Lake Giles, Pocono Mountains, PA, United States. Error bars represent standard errors. Zooplankton were placed in 2.2 m long acrylic columns that were either UV-transparent or UV-blocking columns (shown to the left). Columns were suspended from 0 to 2 m between 9:00 p.m. on 20 June to 10.30 a.m. on 21 June 2001. At the end of the experiment, the trap doors were closed and the number of species in each section was counted. Species included the cladoceran *Daphnia catawba*, the calanoid copepod *Diaptomus minutus*, and the cyclopoid copepod *Cyclops scutifer*. Copepod nauplii represent both calanoids and cyclopids. Note the deeper distribution of the Daphnia and calanoid copepods in the presence of UVR. *C. scutifer* is a cold-water species that typically inhabits the deeper waters of Lake Giles during both the day and night. Therefore, their deep distribution in both the UV+ and UV− treatments is expected.

copepods (Fig. 7; Leech et al., 2009; Fischer et al., 2015). Zooplankton with increased photoprotective compounds, such as carotenoids, melanin, and mycosporine amino acids, are often less responsive to shorter-wavelength radiation (Rautio and Tartarotti, 2010). More recently, negative phototactic behaviors in response to UV exposure have been observed in benthic species, such as the planarian *Schmidtea mediterranea* (Paskin et al., 2014) and the leech *Hirudo* spp. (Jellies, 2014). Little or no behavioral responses were observed when exposed to visible light (Jellies, 2014; Paskin et al., 2014).

Differences in the spawning depths of yellow perch (*Perca flavescens*) in a high-versus a low-UV lake suggest that they also avoid exposure to UV radiation (Williamson et al., 1997; Huff et al., 2004). Comparable results have been reported for nest building in bluegill sunfish *Lepomis macrochirus* (Olson et al., 2006). This is particularly interesting because adult perch and sunfish lack UV-sensitive cones, unlike larval stages. Vertical distribution patterns differ for larval vendace (*Coregonus albula*) occupying the surface waters of clear versus brown Finnish lakes (Ylönen et al., 2005). Larvae in clear lakes were deeper on sunny days compared to cloudy days. Laboratory experiments with larval zebrafish have linked retinal UV photoreceptors in larval zebrafish to UV avoidance behaviors (Guggiana-Nilo and Engert, 2016). In contrast, zebrafish larvae swim towards light with wavelengths >400 nm (Guggiana-Nilo and Engert, 2016).

Predator avoidance

As described above, exposure to visible light serves as a proximate cue for zooplankton to move deeper, which ultimately aids in avoiding visual predators. Similar behaviors are seen in streams, whereby macroinvertebrates drift downstream during twilight or dark hours to presumably avoid visual predators while searching for improved habitat conditions (Nanam et al., 2015). In both cases, invertebrates are required to distinguish changes in light due to time of day from changes due to variations in canopy- or cloud cover (Ringelberg, 1999; Schloss and Haney, 2006). Vertical and horizontal migrations in response to light levels are dampened in the absence of predator cues, such as kairomones, suggesting an integration of light and olfactory stimuli to properly execute the behavior (Ringelberg, 1999).

Light can also help prey avoid direct contact with predators. "Shadow responses" are associated with rapid changes in behavior, such as altered swimming speed/direction or body contraction, due to sudden reductions in light intensity. In larval zebrafish, shadow responses appear early in development (i.e., ~70 h post hatch), supporting its importance to survival (Easter and Nicola, 1996). Sessile or sedentary organisms also exhibit shadow responses. For example, the oligochaete *Lumbriculus variegates* resides in the littoral zone of ponds with its tail segments positioned above the sediment and horizontal at the air-water interface to facilitate gas exchange. Rapid escape responses are exhibited when exposed to moving shadows or abrupt decreases in light intensity (Drewes and Fourtner, 1989). In planktonic organisms, shadow responses appear to be more common in marine zooplankton compared to freshwater (Buskey et al., 1987). However, ectoparasitic copepods are an exception, which rather than predator avoidance, use shadow responses as a means to locate their fish hosts swimming overhead (Poulin et al., 1991).

Foraging

Simultaneously, adequate light levels are required for visual predators to locate and strike at prey. In aquatic ecosystems, fish are most often the top predators, preying on zooplankton, macroinvertebrates, and/or other fishes. The eyes of visually feeding fishes are adapted to both the environment as well as prey type (Caves et al., 2017; Fig. 8). Fishes that inhabit darker waters have a higher portion of rod photoreceptors and depend on differences in light intensity to locate and capture prey while fishes inhabiting brighter waters often possess 2–5 cone photoreceptor types in addition to their rod cells, permitting color vision and higher visual acuity, or the ability to resolve spatial detail. In teleost fishes, visual pigments within the cone cells often correspond to the background illumination, with blue-shifted pigments in fishes inhabiting clear waters and red-shifted pigments in those inhabiting tannin stained blackwaters (Lythgoe, 1979; Carleton et al., 2020). Objects at depth that differ in spectral reflectance from the illumination spectrum will thus appear darker than the background (Fig. 9).

UV photoreceptors are also thought to enhance prey contrast for visual foragers. Zooplankton prey, such as *Daphnia* and *Leptodiaptomus*, often contain compounds that absorb UV-A and short-wavelength blue light (e.g., carotenoids, melanin, and mycosporine-like amino acids (MAAs)). While these compounds block UV radiation, they may also make zooplankters appear darker than the background (Cronin and Bok, 2016). In addition, zooplankton also scatter light and may appear lighter or darker depending on the direction of illumination as well as the organism's shape and refractive index. Scattering and absorption of UV radiation in tissues is often higher than that of longer-wavelength visible light, giving predators with UV vision a possible advantage in certain viewing geometries. In laboratory experiments, larval fish within the genera *Lepomis*, *Micropterus*, *Perca*, and *Oncorhynchus* caught more prey and had longer pursuit distances in the presence of UV radiation (Loew et al., 1993; Browman et al. 1994; Leech et al., 2009; Novales Flamarique, 2016). In some cases, fish fed better under UV-A alone than under visible light at the same energy. Predation rates of African cichlids *Metriaclima* spp. feeding on *Artemia* spp. were greater for species with UV sensitivity than those without, suggesting that UV vision can provide an adaptive advantage (Jordan et al., 2004).

Nevertheless, other studies have detected no effect of UV radiation on foraging, including laboratory experiments with the guppy *P. reticulata* (White et al. 2005; Zukoshi et al., 2018), juvenile bluegill L. *macrochirus* (Leech and Johnsen, 2006), and freshwater three-spine sticklebacks *Gasterosteus aculeatus* (Rick et al., 2012). In field experiments conducted in Patagonia, Argentina with rainbow trout (*Oncorhynchus mykiss*), the removal of UV wavelengths from solar radiation had no effect on the number of prey eaten or on prey preference (Rocco et al., 2002).

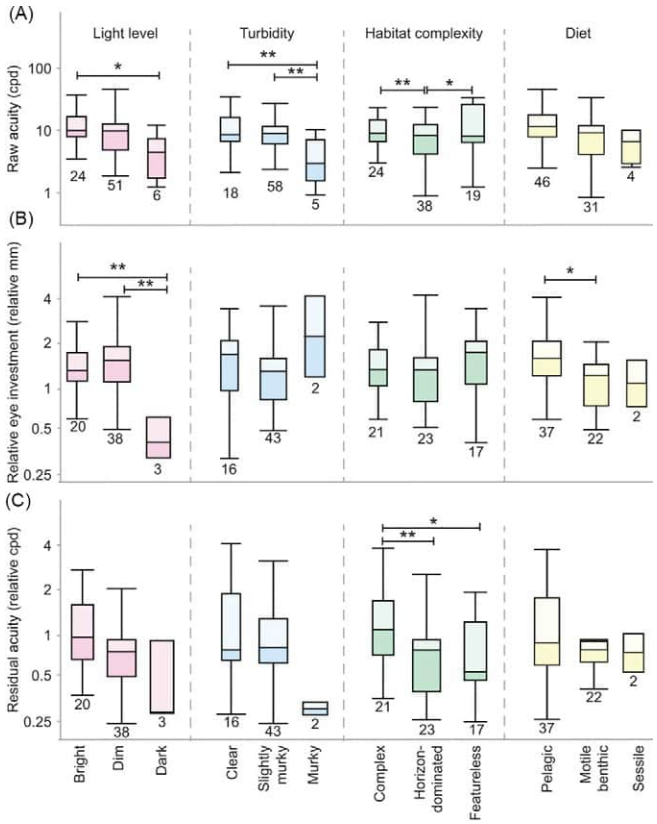

Fig. 8 Acuity and eye investment across ecological categories in ray-finned fishes. (A) Raw acuity (uncorrected for morphology or phylogeny), (B) relative eye investment, and (C) residual acuity across light level (pink), turbidity (blue), habitat spatial complexity (green) and diet (yellow) categories. Sample sizes are presented below each box. Statistics are from pairwise Student's *t*-tests ($^{*}0.02 > P > .01$; $^{**}P < .01$). Only comparisons with $P \leq .02$ are shown, which is the Bonferroni-corrected significance level for three pairwise comparisons. In B and C, the y-axis has been translated from log space into either relative eye investment (mm) or relative acuity (cpd). This means that, for example, a residual acuity of two in C indicates a species that has acuity twice as high as the mean of species with the same relative eye investment. Species with positive relative eye investment have larger eyes relative to their body size than expected, and species with negative relative eye investment have smaller eyes relative to their body size than expected. Reproduced with permission from Caves EM, Sutton TT and Johnsen S (2017) Visual acuity in ray-finned fishes correlates with eye size and habitat. *Journal of Experimental Biology* 220: 1586–1596.

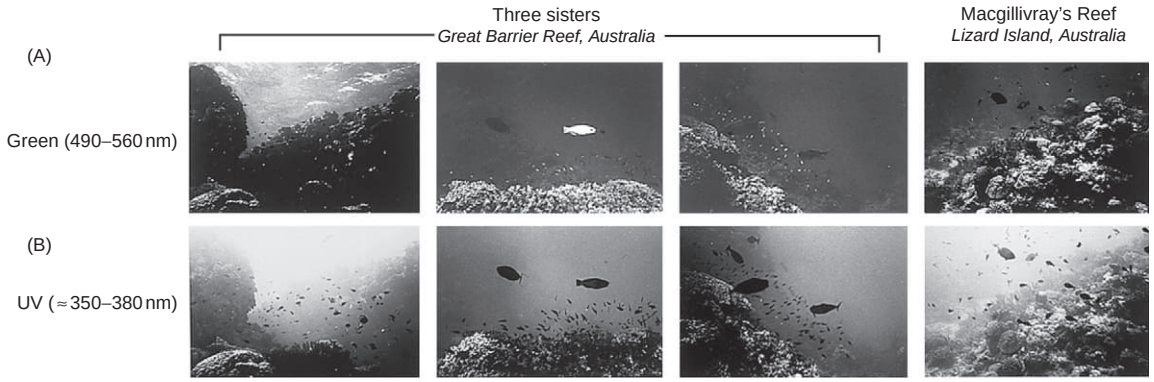

Fig. 9 Simultaneous images taken at (A) green (490–560 nm) and (B) ultraviolet (350–380 nm) wavelengths. Note the bright background in the UV image that silhouettes fish strongly, even against the reef. Also note that distant items in the UV images have lower contrast than in the visible images. Communication

Light also conveys important information about conspecifics with respect to schooling behavior, mate choice, and territory displays. Schooling animals are continually evaluating whether to join, stay, or a leave a group. While living in groups reduces predation risk, it does have certain costs, such as increased competition for food as well as susceptibility to disease. Selecting a group to join is therefore an important decision for an individual. In addition to the lateral line, light is believed to be essential for school behavior,

with fishes dispersing under dark conditions (Appenzeller and Leggett, 1992; Brodeur and Wilson, 1996). Three-spined sticklebacks (*G. aculeatus*) prefer to join schools seen under high UV conditions (Hiermes et al., 2015); however, wavelengths within the visible spectrum are also important (Pavlov and Kasumyan, 2000). Body coloration, including contrast stripes, spots, or other patterns, facilitates the recognition of conspecifics and aids in schooling coordination and orientation (Pavlov and Kasumyan, 2000), with the light environment critical to how these patterns are viewed and interpreted.

Colorful patterns are also important to mate choice and territorial displays, both playing an important role in sexual selection. Again, UV radiation may play an important role, such as in courtship behaviors of three-spined stickleback (Boulcott et al., 2005), the northern swordtail *Xiphophorus* (Cummings et al., 2003), and the guppy *Poecilia reticulata* (Smith et al., 2002; Sandkam et al., 2017). In the case of the latter, guppies mate primarily at dawn and dusk when short-wavelength violet and blue light dominate over middle and longer wavelength green to red light. In species inhabiting murkier waters, longer-wavelength red light is more vital to conspecific recognition, such as Amazonian cichlids (Escobar-Camacho et al., 2017).

Navigation

For anadromous fishes, which migrate between inland waters and the ocean throughout their life history, light provides both temporal and spatial information. In some species of salmonids (i.e., *Oncorhynchus nerka*, *O. tshawytscha*, and *O. keta*), UV photoreceptors are arranged in the retina such that animals can detect the polarization pattern of skylight (Kamermans and Hawryshyn, 2011). This is believed to assist salmonids in navigating to their natal streams for spawning. UV photoreceptors are expressed in larvae and early juveniles but disappear from the retina during a metamorphosis that prepares fish for deeper, marine waters. Subsequently, UV photoreceptors reappear 5–6 years later, with the onset of sexual maturation and the initiation of their return migration. Experiments have shown that polarized light is only detected in the UV range in these fish, with remarkable discrimination between small differences in the angle of the e-vector of skylight (Kamermans and Hawryshyn, 2011). As adult salmonids move from the ocean into riverine habitats, their vision shifts to longer wavelengths by switching the chromophore from A1 to A2 (Beatty, 1966; Temple et al., 2006). Enright et al. (2015) recently demonstrated an enzyme encoded by the gene *Cyp27c1* is critical to the switch as fish with mutated versions of the gene cannot make the transformation.

Non-visual functions

Circadian rhythms

Sunlight is a primary factor in setting and regulating biological clocks and circadian rhythms (~24 h) in all living organisms (Beale et al., 2016). Varying with latitude and season, day and night cycles have been a predictable environmental cue throughout the evolutionary history of life on Earth (Beale et al., 2016). Changes in photoperiod are correlated with changes in temperature, oxygen availability, threat of predation, availability of prey, and reproductive activity. In mammals, light perception through eyes is necessary to set circadian rhythms (Yerushalmi and Green, 2009). However, in fishes and other aquatic organisms, non-ocular photoreceptors are also important (Whitmore et al., 2000; Fernandes et al., 2013). Light perception regulates positive and negative feedback loops for the transcription of genes involved in the controls of physiological and behavioral processes. For example, the production of melatonin, the "time-keeper hormone," is linked to photoreception in bacteria, unicellular eukaryotes, macroalgae, fungi, plants, and animals (Vivien-Roels and Pévet, 1993; Zhao et al., 2019). Melatonin not only plays a role in sleep-wake cycles, it can also affect an individual's metabolism, immune responses, and behavior (Esteban et al., 2013; Zhao et al., 2019).

Physiological and behavioral functions in microbes

Both phototrophic and chemotrophic prokaryotes possess a diversity of photosensitive proteins, including bacteriorhodopsins, phytochromes, xanthopsins, cryptochromes/photolyases, phototropins, and flavoproteins that span the visible to near infrared spectrum (380–750 nm; Ernst et al., 2014). These photosensitive proteins are responsible for a number of non-visual functions. For example, bacteriorhodopsin helps move protons into the cells of bacteria and archaea, supplying energy for ATP synthesis (Ernst et al., 2014) while ion-pumping rhodopsins help to move chloride and sodium ions into and out of cells (Ernst et al., 2014). The freshwater bacterium *Caulobacter crescentus*, which primarily inhabits oligotrophic environments, uses flavoproteins sensitive to blue light to regulate its own attachment to suspended particles (Purcell et al., 2007). It is hypothesized that since nutrient concentrations in oligotrophic systems are lower in the surface waters compared to the benthic sediments, light may serve as a signal to surface-dwelling cells to quickly attach to a particle to aid in sinking (Purcell et al., 2007). Similarly, light has been shown to influence whether microbes remain in a motile single-cellular state or join a multicellular surface-attached community (i.e., biofilm) (Gomelsky and Hoff, 2011).

Potential fitness tradeoffs

While light perception is beneficial, it is not without fitness costs. Arguably, the greatest tradeoff is exposure to damaging ultraviolet radiation. In clear, high UV systems, particularly those in alpine regions, damaging levels of UV-A and UV-B radiation may travel deeply into the water column, affecting all life forms, from bacteria to higher vertebrates (Häder et al., 2015; Peng et al., 2017; Williamson et al., 2019). A recent meta-analysis determined that marine organisms in the northern hemisphere tend to be more

susceptible to UV damage compared to those in the southern hemisphere, due to higher levels of UV-absorbing stratospheric ozone in the former (Agustí et al., 2015). However, similar comparisons are not known for inland waters.

Reductions in growth, impaired development, changes in behavior, suppression of the immune system, reduction of disease resistance, DNA damage as well as metabolic and physiological stresses have been observed in a wide variety of aquatic species exposed to UV radiation (Häder et al., 2015; Peng et al., 2017; Williamson et al., 2019). Like humans, aquatic organisms can become sunburned with increased exposure to damaging sunlight (Häder et al., 2015). Similarly, fish eyes develop cataracts, corneal epithelium/stoma damage, thickening of the cornea, or "doughnut" opacities in the lens (Alves and Agustí, 2020), all of which reduce visual acuity. Early life history stages appear to be most vulnerable, but later stages are also susceptible to damaging affects (Häder et al., 2015; Peng et al., 2017; Williamson et al., 2019; Alves and Agustí, 2020).

To protect themselves, aquatic organisms have evolved several photoprotective strategies, including behavioral avoidance, production or dietary acquisition of photoprotective compounds (e.g., melanin, carotenoids, and mycosporine amino acids), and photorepair mechanisms for DNA and protein damage (Alves and Agustí, 2020; Häder et al., 2015; Peng et al., 2017; Williamson et al., 2019). Organisms may exhibit multiple photoprotective strategies, such as *Daphnia* spp. that possess melanin pigmentation, DNA photorepair, and behavioral avoidance. Animals are generally believed to acquire photoprotective compounds from their diets or symbionts; however, recent studies have shown that fishes and amphibians produce their own sunscreens (i.e., gadusol compounds) (Osborn et al., 2015). Undoubtedly, photoprotective adaptations come at a fitness cost to growth and reproduction, but little information is currently provided in the primary literature.

Alterations to underwater light and ecological consequences

Inland waters are modified by a complexity of human-induced environmental stressors, from local to global in scale (e.g., watershed development to global climate change). In terms of underwater light, variations in intensity and spectral characteristics are linked to changes in climate as well as land use/land cover, given their effects on nutrient and organic matter runoff. New sources of light have also been introduced during natural periods of darkness as shoreline development increases. Ultimately, these changes in light have complex ecological consequences, such as altered behavior and species interactions that subsequently affect biodiversity and ecosystem productivity.

Eutrophication and brownification

Eutrophication, or the "greening" of waters due to algal blooms fed by nutrient pollution, continues to be a global, systemic problem (Wurtsbaugh et al., 2019). More recently, many fresh waters in the northern hemisphere have also shown signs of "browning" due to increased runoff of chromophoric dissolved organic matter, and in some cases dissolved iron, from the terrestrial watershed (Solomon et al., 2015; Leech et al., 2018; Kritzberg et al., 2020). In both cases, light penetration is reduced, and the spectrum is shifted towards longer wavelength red light (Lythgoe, 1979; Kirk, 2010).

These changes to the photic environment influence aquatic systems from the organismal to ecosystem level. For example, cyanobacteria have a competitive advantage over green algae in red-dominated environments because of their suite of photopigments (i.e., phycobilisome-based versus chlorophyll-based pigments, respectively) (Luimstra et al., 2020). This may serve as a positive feedback loop for harmful algal bloom development in systems affected by eutrophication and brownification. As water transparency declines, visual predators (e.g., planktivorous fish) can be replaced with tactile predators (e.g., chironomids). Migration behaviors are often damped or halted in systems receiving increased nutrients and organic matter (Solomon et al., 2015), further altering species interactions and predator-prey overlap. Conspecifics may have increased difficulty finding mates, as is seen in African cichlids in eutrophic Lake Victoria (Seehausen et al., 1997). This led to increased interbreeding and an overall loss in diversity (Seehausen et al., 1997). Shifts towards longer wavelengths with eutrophication and brownification may particularly affect organisms using UV vision to find food and mates or avoid predators.

At the ecosystem level, alterations in species composition and food web dynamics may lead to decreases in productivity, particularly at higher trophic levels. Hyper-eutrophication and brownification can have negative effects on fisheries. For example, Craig et al. (2017) found that bluegill in lakes of increasing brown color were smaller in size and had lower fecundity compared to those living in lakes with less color. Taipale et al. (2018) noted that zooplankton and fish had poorer nutritional quality in browner systems because the phytoplankton on which they fed had lower concentrations of essential fatty acids, proteins, lipids, and carbohydrates. Consequently, changes in the underwater light environment may have cascading effects on fisheries, reducing recruitment strength, sustainable yields, and food web stability in systems affected by browning.

Artificial lighting and light pollution

In recent decades, artificial lighting (or light pollution) produced by urban, industrial, recreational, and roadway sources has dramatically altered the nighttime, underwater landscape. Electric lighting has the capacity to generate light intensities visible at night to satellites orbiting the Earth. Spectra produced by artificial lighting can be narrow- or broadband, as shown for low- and high-pressure sodium, light-emitting diode (LED), and metal halide lamps (Fig. 10). LEDs in particular produce broad spectrum white light that permits color vision at night (Zapata et al., 2019).

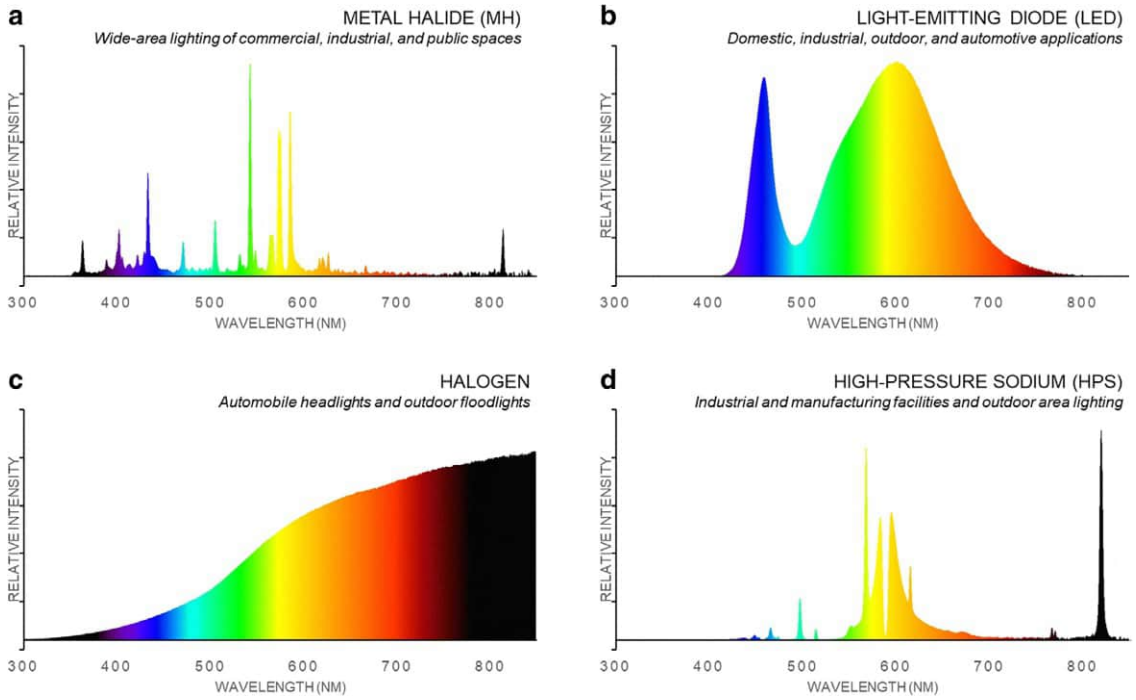

Fig. 10 Emission spectra of four artificial lighting types including metal halide, light-emitting diode, halogen, and high-pressure sodium lamps (spectra from Lamp Spectral Power Distribution Database 2017). From Zapata MJ, Sullivan SMP and Gray SM (2019) Artificial lighting at night in estuaries—Implications from individuals to ecosystems. *Estuaries and Coasts* 42: 309–330.

As a result of nighttime lighting, circadian rhythms can be disrupted. For example, even at fairly low levels of broad spectrum white light (~1 Lux: about the level of mid-nautical twilight), melatonin production was inhibited in Eurasian perch (*Perca fluviatilis*), resulting in increased nighttime activity (Brüning et al., 2015). Perch also displayed differences in the reproductive hormone gonadotropin, which the authors hypothesize may reduce fecundity and fitness (Brüning et al., 2015). Artificial lighting can also extend diurnal or crepuscular behaviors, such as vertical migration. In zooplankton, upward migrations into warmer, food rich surface waters at night can be inhibited by artificial lighting (Moore et al., 2000). Exposure to artificial lighting along estuarine migratory routes affects recruitment of salmonids to natal upstream habitats (Mueller and Simmons, 2008). At the community and ecosystem level, white LEDs have the potential to alter phytoplankton community composition, with varied effects on biomass (Grubisic, 2018). Aquatic insect biomass is often higher in artificially illuminated streams, potentially because the adult flying insects are drawn to the short wavelengths of LED lights and then deposit their eggs nearby (Manfrin et al., 2017). While beneficial to the immediate area, this attraction of insects has the potential to modify connections between terrestrial and aquatic ecosystems, reducing aquatic resources to consumers in terrestrial ecosystems (Manfrin et al., 2017).

Conclusions

Inland waters widely vary in their light environment, depending on the particulate and dissolved constituents within a system. Over time aquatic organisms have adapted to these varied conditions, both in terms of their light capturing abilities (e.g., eye structure, size) and spectral sensitivity (e.g., opsin gene selection). Light is an invaluable ecological resource used for numerous visual and non-visual tasks vital to an individual's fitness, such as foraging, mate choice, circadian rhythms, and cellular energy transport. Yet, executing these tasks may become increasingly more difficult as inland waters are degraded by climate change, land use alterations, and urbanization. Questions remain as to whether populations can evolve at a rate sufficient to keep up with human-induced environmental change. If not, similar to other environmental stressors, alterations in the underwater light environment may lead to reductions in biodiversity and ecosystem function.

Knowledge gaps

Studies linking every level of biological inquiry (i.e., genetic, biochemical, cellular, neurobiological, ecological, behavioral and evolutionary aspects) are needed: While great strides have been made in the fields of bio-optics and visual ecology, particularly with advances in

molecular biology, few studies explicitly link processes at the molecular and cellular level to behavior, ecology, and evolution. While hypothesized, questions remain regarding the quantitative effect of spectral tuning on fitness as well as cascading effects on species interactions and ecosystem productivity.

Studies examining other sensory mechanisms are needed: While light is an important ecological resource, it is not the only source of information in an individual's environment. As visual creatures, humans are often biased towards the importance of light and vision. Yet, to other species, particularly those in aquatic habitats, auditory, olfactory, electrical, or mechanical cues could be equally or more important. In comparison to vision, these senses are dramatically understudied (Cummings and Endler, 2018). Consequently, a greater understanding of alternate sensory drives is needed, particularly given declines in water transparency with continued eutrophication and brownification.

Glossary

Arrhenius relationship A form of relationship that uses a curvilinear formula to describe the influence of temperature on biological processes. These relationships are typically described by the amount of change in a given process for a 10 °C change in temperature. This parameter is referred to as the Q_{10} value.

Benthic An adjective describing organisms or habitats associated with the bottom of aquatic systems. The group of organisms associated with aquatic bottom areas is referred to as the benthos.

Evapotranspiration The process in which plants release water vapor through transpiration. This process is driven by evaporation of water from the surface of leaves, and is affected strongly by temperature and wind speed.

Latent heat The amount of heat energy released or absorbed by a substance during a change of phase; for instance, from liquid water to water vapor (latent heat of evaporation) or from water vapor to liquid water (latent heat of condensation).

Metabolism The sum of biological processes in an aquatic ecosystem that transform energy and materials. Such processes include photosynthetic, chemosynthetic, and respiratory reactions that affect the concentrations of oxygen and carbon dioxide in lakes.

Mixis The time period when vertical mixing of water in a lake occurs. Also referred to as the period of turnover in a lake. The number of mixing periods in a lake is often used to categorize lake dynamics.

Planktonic An adjective used to describe organisms or habitats found in the open water region of lakes and rivers. The plankton is the group of organisms that live suspended in the open water and that cannot move appreciably against water currents.

Poikilotherm An organism whose body temperature conforms to the temperature of the environment. These organisms are often called 'cold blooded' but their body temperature can be quite warm if the surrounding water is warm. Many poikilothermic animals can control their body temperature by selecting habitats with different temperatures. This process, called behavioral thermoregulation, is common for fish in lakes and rivers.

Productivity The construction of new biological material by organisms in an ecosystem. This is typically defined as the amount of material produced per unit time. Productivity can be determined for each separate component of an ecosystem or can be assessed as the sum of the separate rates.

Sensible heat The amount of heat energy released or absorbed by a substance that is accompanied by a change in its temperature, but not by a change of phase. In the case of lakes, when the lake water temperature is warmer than the atmospheric temperature, sensible heat will be transferred to the air. When air temperature increases above water temperature, heat energy will be transferred from the air to the water.
Stratification The situation where water with lower density is "floating" on a layer of water with higher density. During summer thermal stratification of lakes, warmer water occurs above colder water. In the winter, under ice cover, inverse stratification occurs where water between 0 °C and 4 °C is found above water that is warmer than 4 °C because it is less dense than the warmer water.
Thermal guild A grouping of organisms according to their preference for habitats with distinct temperatures. In lakes, the thermal guild concept has been used to distinguish between cold water, cool water, and warm water thermal guilds of fish.

Introduction

The distribution of heat is one of the most influential drivers of physical habitats and biological processes in freshwater ecosystems (Wetzel, 2001). Temperature is the main factor determining water density, and consequently establishes heterogeneity in the physical environments of lakes, rivers, and wetlands (Imberger and Patterson, 1990). Temperature also directly controls the rates of chemical reactions, and is therefore the major determinant of metabolic processes in inland aquatic ecosystems (Stumm and Morgan, 1995). Essentially all aquatic organisms in freshwater systems are poikilotherms (aside from a few types of birds and mammals), meaning that temperature has a direct effect on the rate of key processes such as photosynthesis, nitrogen fixation, growth, development, respiration, and excretion.

Temperature and heat

Heat balance in lakes

The heat balance of a water body, and hence its mean temperature, is determined by five main processes (Fig. 1): (1) the absorption of infrared radiation emitted by the atmosphere; (2) the emission of infrared radiation by the water body to the atmosphere; (3) the absorption of direct and diffuse short-wave solar radiation; (4) the exchange of latent heat of evaporation and condensation between the water body and the atmosphere; and (5) the exchange of sensible heat between the water body and the atmosphere by convection in the atmosphere immediately above the water surface (Imberger and Patterson, 1990).

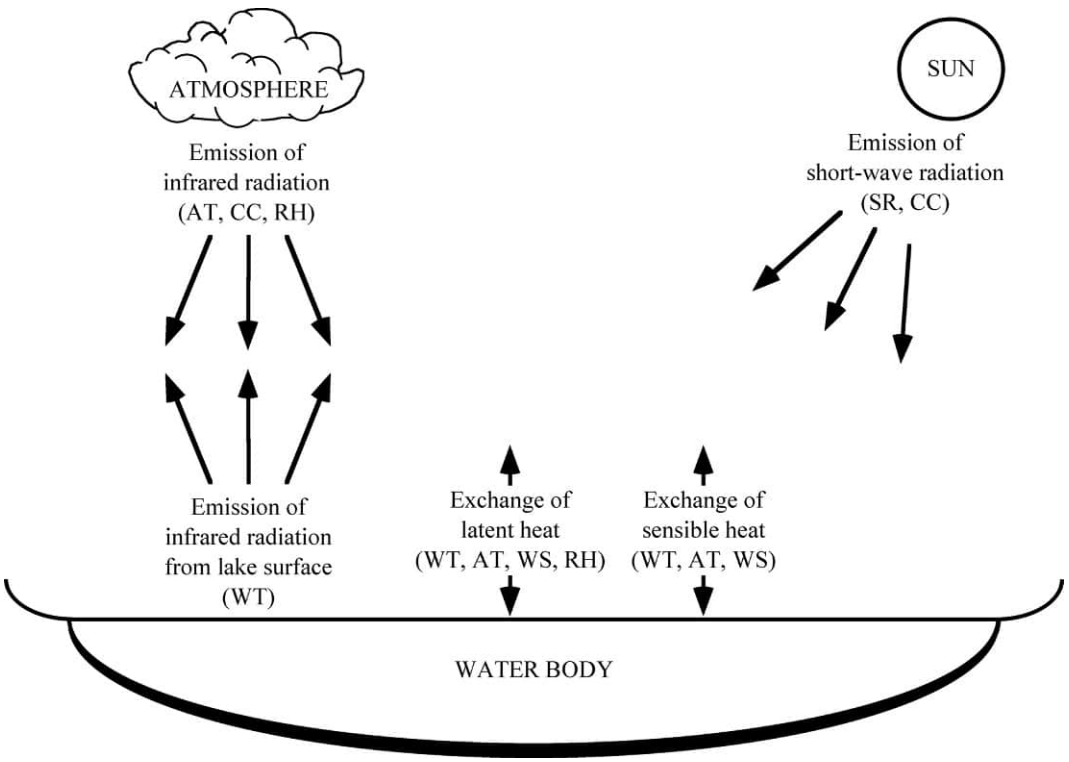

Fig. 1 The five major heat-exchange processes governing the heat balance of a water body. These processes involve the surface temperature of the water body (WT), ambient air temperature (AT), clear-sky solar radiation (SR), cloud cover (CC), wind speed (WS), and relative humidity (RH).

Temperature structure

In shallow bodies of water, such as wetlands and rivers, water temperatures are usually highly correlated with air temperature (Mohseni and Stefan, 1999). In deeper bodies of water such as lakes, mixing by wind energy at the surface in spring results in an isothermal surface layer that extends well into, or below, the photic zone (Fig. 2). As this surface layer continues to warm through spring and into summer, separate strata of isothermal water develop. A warm, well-mixed surface layer, or epilimnion, is separated from the colder, deeper water, or hypolimnion, by a vertical gradient in temperature (and hence in density) in the transition region, which is known as the metalimnion. The existence of the density gradient in the metalimnion results in extremely limited mixing between the epilimnion and hypolimnion in summer because of high relative thermal resistance to mixing. Because heat fluxes mainly occur at the surface, the epilimnion will continue to increase in temperature throughout the summer while the temperature of the hypolimnion is driven mainly by the water temperature in the spring when stratification is established. The hypolimnetic temperature generally remains cold throughout summer and early fall, except in some lakes that experience hypolimnetic heating during the summer by direct solar radiation (i.e., very clear lakes), turbulent transfer of energy across the metalimnion, or by seiche activity when the hypolimnion moves close to the surface during oscillations (Wetzel, 2001; Mortimer, 2003). As surface temperature decreases in the fall with decreased solar radiation and lower air temperatures, the thermal resistance to mixing also decreases. Fall mixis, or turnover, occurs when convection currents of cooled surface water and wind-driven circulation of the epilimnion exceed the resistance to mixing and the lake becomes homothermal at all depths. Lake waters continue to cool and circulate as air temperatures decline. If air temperatures decrease below the freezing point, and wind energy does not prevent ice cover, the lake will become capped with ice. Inverse stratification occurs when water just below the ice at the surface is colder than the temperature of maximum density (4 °C) and floats above deeper, slightly warmer water.

Patterns of stratification

Annual cycles of solar radiation, wind patterns, and atmospheric temperature changes primarily determine the stratification and mixing pattern observed in a given lake. Such mixing patterns have a large effect on biological processes, including metabolism, ecological interactions, and nutrient dynamics. Lakes have been classified into six basic groups according to annual mixing patterns

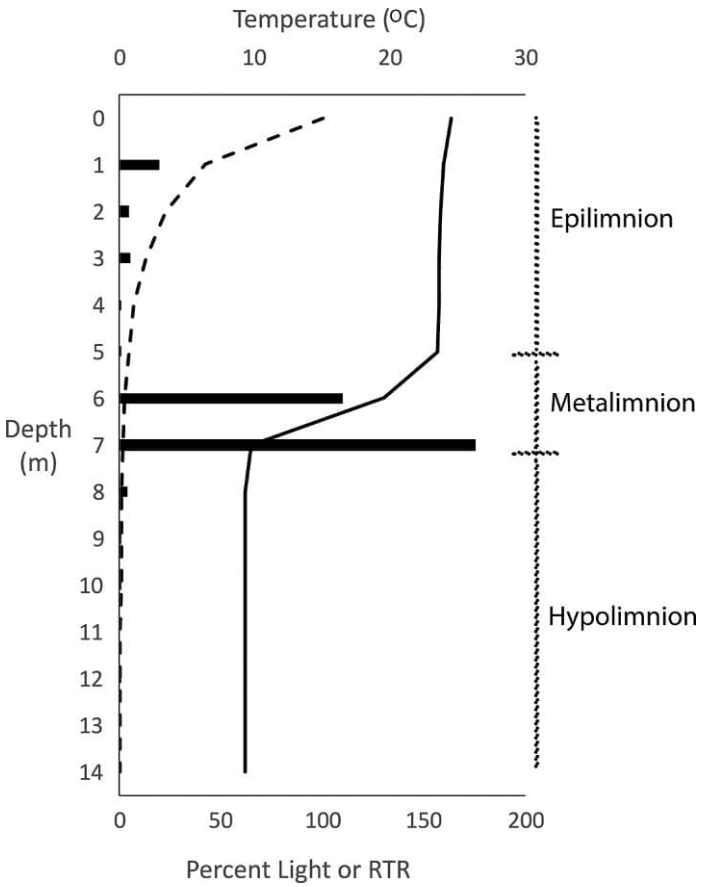

Fig. 2 Vertical depth profiles of light penetration (dashed line), temperature (solid line), and relative thermal resistance to mixing (solid bars) in Green Bay, WI, United States in August 2006. Depth region names based on thermal stratification are indicated (epilimnion, metalimnion, hypolimnion).

(Wetzel, 2001). Most lakes studied in the past have exhibited the annual cycle described above with two periods of mixing (spring and fall turnover), and are called dimictic lakes. Permanently frozen lakes never mix completely and are called amictic, while lakes that mix only once each year are called monomictic. Cold monomictic lakes mix in the summer during the ice-free period, while warm monomictic lakes mix from fall through spring and never freeze. Lakes that are stratified most of the year but which undergo cooling and circulation at irregular intervals are classified as oligomictic. Some lakes experience frequent or continuous mixing. These lakes are considered polymictic.

Temperature and biological processes

Metabolism and temperature

The overall metabolism of a lake ecosystem is largely driven by temperature, but many other factors can control overall metabolism depending on the group of organisms examined. In the most simplistic manner, ecosystem metabolism can be separated into carbon fixation processes (e.g., gross primary production via photosynthetic and chemosynthetic processes) and biological carbon oxidation processes typically termed as ecosystem respiration; (e.g., del Giorgio and le Williams, 2005; Staehr et al., 2010; Winslow et al., 2016). Phytoplankton productivity shows clear, direct temperature dependence, but also exhibits strong responses to other factors such as light intensity and nutrient concentration (Falkowski and Raven, 2013). In general, algal photosynthetic rate varies in a unimodal response pattern to temperature change, with taxa exhibiting various optima (Wetzel, 2001; Fig. 3). Because of the simultaneous changes in water temperature and light intensity in lakes at different times of the year, associations of algae tend to be dominated in some seasons by one or a few taxonomic categories. Diatoms tend to dominate in cold waters while cyanobacteria do well in warm waters in the late summer in many lakes. However, individual species within a given taxon can vary in their temperature optima over a wide range, a fact that is useful for recreating past environmental conditions using paleolimnological methods (Weckström and Korhola, 2001; Smol, 2019; Fig. 4). Diatom remains preserve well in sediments, and because many diatom species are good indicators of water temperature, examination of changes in diatom remains in various layers of sediments can provide evidence of past temperature changes in lakes.

Both chemosynthesis and respiration are also highly temperature dependent (Brown et al., 2004; Yvon-Durocher et al., 2012; Scharfenberger et al., 2019). In general, these processes have been described with the Arrhenius relationship and the van't Hoff rule, where change in the metabolic rate over a 10 degrees change in absolute temperature is expressed as a Q_{10} value. Respiration rates of planktonic and benthic organisms, measured over the range of 10–20 °C, typically have Q_{10} values in the range of 2.1–2.3 (Reynolds, 1984; Wetzel, 2001). The relative rate of change of respiration rates per degree Celsius is also temperature dependent, with higher relative rates of change at lower temperatures (Pace and Prairie, 2005; Fig. 5). This indicates that a given temperature change in the hypolimnion of a lake will result in a larger change in respiration rates than will a corresponding temperature change in the warmer epilimnion.

Growth rates

Growth rates of zooplankton and fish are heavily dependent on temperature due to the temperature dependence of feeding, respiration, and development rates. Zooplankton feeding rates exhibit optima over a wide range of temperatures from 5 °C to over 25 °C (Wetzel, 2001). Embryonic development time shortens as temperature increases for zooplankton such as rotifers and planktonic crustaceans (Bottrell et al., 1976), resulting in increased growth rates, faster development, and faster population generation time. Therefore, increasing temperatures increase the potential population growth rates of these groups. However, because growth rates of zooplankton are often strongly controlled by other factors such as food and nutrient limitation, direct relationships between temperature and zooplankton growth rates are rare. For fish, most metabolic processes increase with

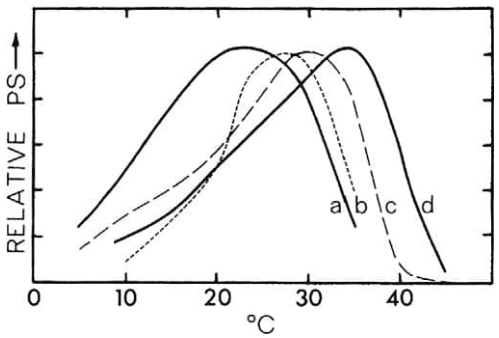

Fig. 3 Photosynthetic rate as a function of temperature for various algae: (A) *Synedra* (diatom), (B) *Anabaena* (cyanobacteria), (C) *Chlorella* (green algae), and (D) *Scenedesmus* (green algae). Fig. 5 Relation of relative change in respiration rate per degree Celsius and temperature for planktonic and benthic communities of organisms. Reproduced from Fig. 7.4 in Pace ML and Prairie YT (2005) Respiration in lakes. In: del Giorgio PA and le Williams PJB (eds.), *Respiration in Aquatic Ecosystems*, pp. 103–121. Oxford: Oxford University Press, with permission from Oxford University Press.

temperature up to a maximum rate, after which growth rates decline (Kitchell et al., 1977; Hanson et al., 1997; Essington et al., 2001; Fig. 6). This means that the specific growth rate of fish is directly determined by the water temperature experienced. The temperature at which the maximum growth rate occurs differs for different thermal guilds, as defined by F.E.J. Fry in the late 1940s (Fry, 1971). Fry defined the thermal niche of fish based on lethal, controlling, and directive temperature ranges. Fish in the warm water thermal guild have higher temperature optima for growth rates, and can generally tolerate a wider range of temperatures. Fish in each guild will also seek out water that is near the optimum temperature for growth (Magnuson et al., 1979), but in many lakes and rivers, water of the desired temperature is not always available, thereby limiting annual fish growth (Magnuson and De Stasio, 1996; Eaton and Scheller, 1996; Fig. 7).

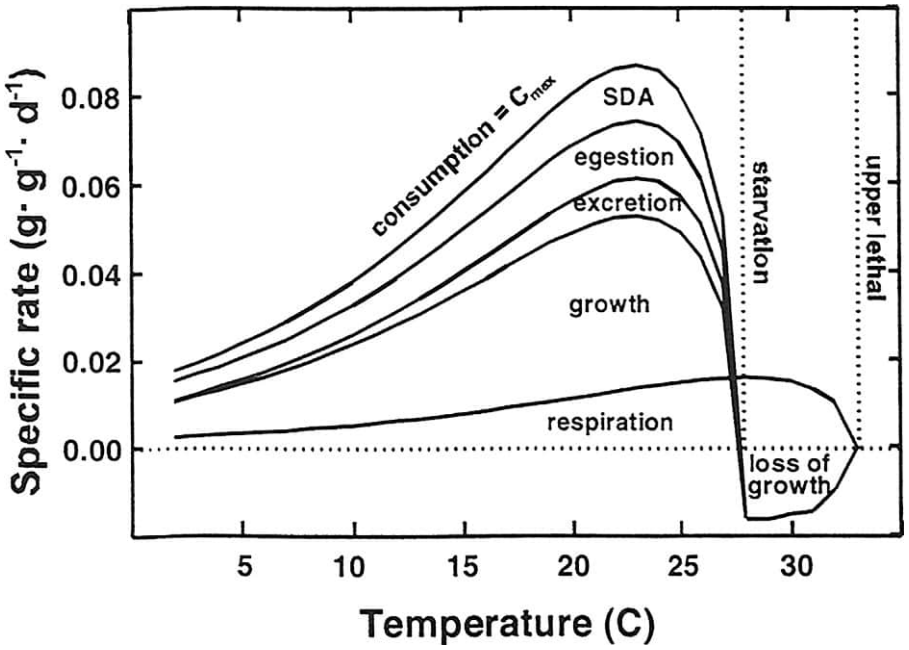

Fig. 6 Predicted specific physiological rates as a function of temperature for the yellow perch, *Perca flavescens*, using a fish bioenergetics model. Energy not used for specific dynamic action (SDA—cost of processing food), egestion, excretion and respiration can be used for growth. Cambridge: Cambridge University Press, with permission from Cambridge University Press.

Effects of climate change

Effects on lake physics and mixing

The current consensus of informed scientific opinion is that a long-term change in the global radiative heat balance, resulting primarily from human activities, is causing climate change on global and regional scales and will continue to do so into the foreseeable future (Intergovernmental Panel on Climate Change (IPCC), 2014). Climate change is already having an impact on temperatures not only in the atmosphere and oceans, but also in inland water bodies (Adrian et al., 2009; O'Reilly et al., 2015). Increasing concentrations of greenhouse gases in the atmosphere is increasing temperatures in rivers and surface waters of lakes and affecting mixing.

Air temperature effects on surface waters

All of the heat balance processes listed earlier are expected to be affected by climate change (Boucher et al., 2013). Most importantly, rising air temperatures result in an increased downward emission of infrared radiation from the atmosphere, and hence in an

increase in the amount of infrared radiation impinging on, and absorbed at, the water surface, leading directly to higher surface water temperatures. Rising air temperatures also affect the exchange of latent heat and sensible heat; however, the direction of the long-term change in heat flux that occurs because of these two processes depends on the long-term change in the temperature difference across the air-water interface and not on the long-term change in the ambient air temperature alone (Boucher et al., 2013). Thus, depending on whether the surface water temperature or surface air temperature rises faster, these two processes can either strengthen or weaken the increasing trend in water temperature.

Effects of clouds and aerosols on surface waters

Recent studies have linked the importance of climate change to changes in cloud cover dynamics and the phenomena of global dimming and global brightening. Clouds have powerful updrafts that contain aerosol particulate matter. These aerosol particles (both natural and anthropogenic) directly interact with cloud particles which lead to increased cloud cover causing global dimming (Boucher et al., 2013). Global dimming leads to a reflection of sunlight and a predominant decline in surface solar radiation and has a cooling effect on earth's surface temperature. Conversely, global brightening is the reversal of the trends seen in global dimming. There is an increase in total surface radiation and decreases in total Earth cloud cover due to fewer light-absorbing compounds (Wild, 2012). Noted instances of global dimming and brightening have been documented and used to understand the effects of these phenomena. Global dimming was documented during the 1950s–1980s whereas global brightening was observed during the 1980s–1990s. Data on global dimming/brightening trends after 2000 are mixed, showing both global dimming and brightening (Hatzianastassiou et al., 2020). These phenomena will affect the amounts of both atmospheric and solar radiation impinging on water bodies. Climate change and global dimming and brightening will also involve shifts in relative humidity and wind speed, but these shifts are likely to be geographically more heterogeneous than in the case of air temperature (Boucher et al., 2013). A shift in either of these variables would affect the exchange of latent heat across the air-water interface, and a shift in wind speed would additionally affect the exchange of sensible heat.

Effects on surface water temperature structure

In lakes, a long-term change in meteorological forcing is likely to lead not only to a change in the mean lake temperature, but also result in changes in the vertical temperature distribution and intensity and timing of vertical mixing (e.g., De Stasio et al., 1996, 2016; Livingstone, 2003; Fang and Stefan, 2009). This will alter the surface water temperature, thus indirectly affecting the heat flux associated with the emission of long-wave radiation from the lake surface, and the heat flux associated with the exchange of latent and sensible heat. Since climate change is not confined to air temperature, but involves several interdependent but geographically heterogeneous meteorological variables, the effect of climate change on lake temperature profiles in general is not easy to predict.

Lake modeling studies

Many modeling studies have been conducted to estimate the response of lake temperatures to future climatic change (e.g., De Stasio et al., 1996, 2016; Fang and Stefan, 2009; Peeters et al., 2002; Woolway and Merchant, 2019; Woolway et al., 2021). The studies consistently indicate increased lake surface temperatures. In addition, models indicate an increase in the intensity and duration of "heat waves" where surface temperatures exceed the 90th percentile of average historical baseline temperatures (Woolway et al., 2021). Most of these studies have been on strictly dimictic lakes, which freeze over each winter and in which lake temperatures are reset each spring to 4 °C, the temperature of maximum density. In such a lake, assuming winters do not become sufficiently warm to prevent ice cover, model studies predict that the mean lake temperature during the open-water period will undergo a long-term increase (Peeters et al., 2002). However, water temperatures are not predicted to increase at all depths. Within the epilimnion, a long-term increase in temperature is expected, but in the hypolimnion temperatures are predicted either to increase only slightly, or not at all, or even to decrease, implying an increase in the thermal stability of the water column (e.g., De Stasio et al., 1996, 2016; Peeters et al., 2002). This is because warm periods tend to be associated with stable water column stratification and little downward mixing of heat, whereas during cold periods such mixing tends to be enhanced.

Modeling studies on lakes that are not strictly dimictic—many of which do not freeze over in winter—are fewer. However, these studies reveal the necessity of including the heat carried over through winter in any predictive calculations for such lakes (e.g., De Stasio et al., 2016; Woolway and Merchant, 2019; Caramatti et al., 2020). If a lake does not freeze over during winter, it will generally not mix at the temperature of maximum density in spring. It will either mix at some higher temperature or will remain stratified to some extent during the entire year and will not turnover at all (Peeters et al., 2002). The meteorological conditions pertaining during the winter will then determine the amount of heat carried over from autumn to the following spring. In warm winters, more heat will be carried over than during cold winters, with the result that the effect of future warmer summers will be compounded by the effect of future warmer winters. In lakes in which heat is carried over from autumn to spring in this manner, deep-water temperatures can undergo long periods of gradual increase, owing to the continual downward mixing of heat from the lower metalimnion by turbulent diffusion. However, these periods of gradual increase are always brought to a sudden end when the deep-water temperature has risen far enough to allow deep, penetrative mixing to take place (Peeters et al., 2002). This usually occurs during a winter that is somewhat colder than normal, causing an extremely rapid fall in the deep-water temperature. If cold winters become rare, however, then these events may not occur. In the long term, the result of this process is a deep-water temperature time-series that exhibits an irregular sawtooth structure. The effect of climate change is thus not necessarily a continual, long-term increase in deep-water temperature, but rather an increase in the frequency of occurrence of longer-term sawtooth events.

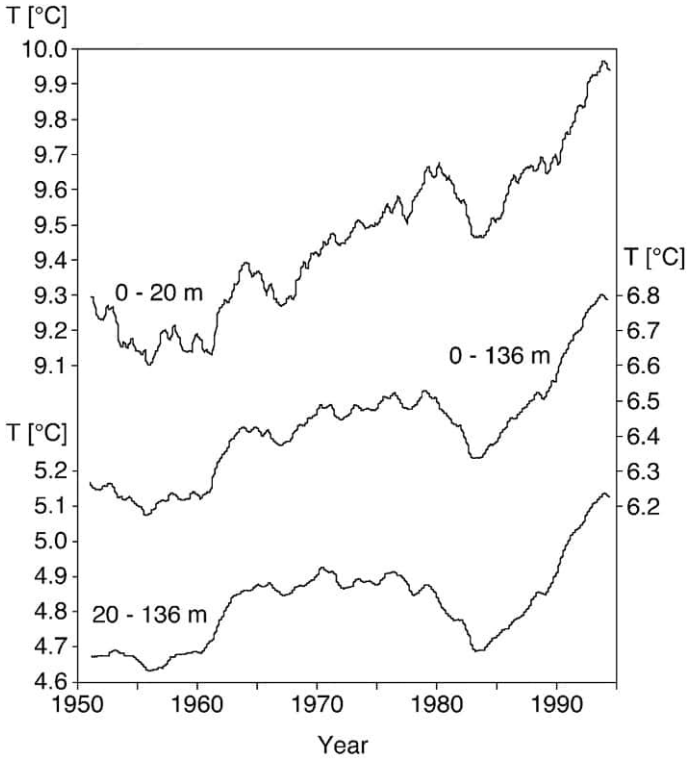

Fig. 8 Long-term increase in the water temperature of Zürichsee, Switzerland, in 0–20 m (epilimnion and metalimnion, left axis), 20–136 m (hypolimnion, left axis), and 0–136 m (the entire lake, right axis). Data (shown as centered decadal running means) from Wasserversorgung Zürich.

Averaged over several years, however, deep-water temperatures do exhibit a long-term increase (Fig. 8), since an increase in the frequency of sawtooth events implies a decrease in the frequency of complete turnover events.

Observed changes

Long-term monitoring data from lakes essentially confirm the results of the modeling studies. Summer surface water temperature data for a globally distributed lake dataset showed a mean temperature rise of 0.34 °C per decade from 1985 to 2009 (O'Reilly et al., 2015). These data indicated that seasonal ice-covered lakes (0.72 °C decade^{-1}) had greater temperature increases than ice-free lakes (0.53 °C decade^{-1}). Differences among lakes were related to both climatic and geomorphic factors, more than regional geographic aspects (O'Reilly et al., 2015). For shallower and smaller lakes, surface water temperatures are closely related to air temperature (Austin and Colman, 2007; Toffolon et al., 2014; O'Reilly et al., 2015). For larger and deeper lakes, a shorter ice cover duration and increasing air temperature resulted in earlier summer stratification leading to faster increases in surface water temperature than air temperature. Changes in stratification patterns have also been observed in other studies of globally distributed lakes, with generally deeper thermoclines and more stable stratification over the period 1970–2010 (Kraemer et al., 2015). In contrast to surface waters, effects of climate change on deeper water temperatures are more variable. In a study of 102 lakes distributed globally, summer surface water temperatures increased significantly but temperatures in the hypolimnion were more variable and did not change significantly (Pilla et al., 2020). There was higher variability in responses among lakes, with some exhibiting increased bottom temperatures but others decreasing over the period 1970–2009. In a separate study of 139 globally distributed lakes, 77% of the lakes showed increased mean temperatures from 1978 to 2013, and there were changes in thermal habitats zones (both increases and decreases) in almost 20% of lakes (Kraemer et al., 2021).

Decreases in temperature of hypolimnetic water typically occurred in lakes where conditions result in stratification being established when water temperatures are lower followed by stratification that persists longer, as indicated by modeling studies. Cooling trends for hypolimnetic water are therefore associated with smaller surface areas, location and higher dissolved organic carbon concentration (Pilla et al., 2020). In larger, deeper lakes with greater transparency, earlier thermal stratification and a prolongation of the summer stratification period reduces the period of homeothermy. For instance, the duration of the stratification period in Zürichsee increased by 2–3 weeks from the 1950s to the 1990s (Peeters et al., 2002; Fig. 8). During this stratification the effect of warmer summers on lakes will be stronger in the epilimnion than in the hypolimnion (O'Reilly et al., 2015; Pilla et al., 2020). The effect of warm winters on lake temperature profiles is significantly different from that of warm summers. As an example, in Zürichsee because the hypolimnion is shielded from meteorological forcing to a large degree during summer, its temperature

during summer is determined to a large extent by meteorological forcing during the previous winter, when large-scale vertical mixing can occur (Livingstone, 2003). Thus, the signature left in the water column by warm winters tends to persist throughout the following stratification period in the hypolimnion, but not in the epilimnion.

Due to changes in the winter and spring air temperatures over the past 150 years, dates of first ice formation on lakes and streams of the Northern Hemisphere are occurring later, with an average of more than 11 days later per 100 years (Magnuson et al., 2000; Sharma et al., 2019; Woolway et al., 2020; Fig. 9). At the same time, dates of ice breakup have been occurring earlier on average, leading to shorter durations of ice cover by 19 days per century (Woolway et al., 2020). These trends of decreased duration of ice cover on lakes and streams have contributed to changes in heat balance of lakes as indicated above through longer stratification periods and longer potential growing seasons for many organisms.

Effects on biological processes

While the effects of a warmer climate on temperature structure have now been observed clearly in a large number of lakes and rivers, the direct effects of climate change on metabolism and ecological interactions have been more difficult to document (e.g., Havens and Jeppesen, 2018). This is due in large part to the complex nature of the ecology of lakes, and the various time scales over which processes respond to climate forcing. As noted above, increased duration of the ice-free season has been observed in many lakes, resulting in longer growing seasons for phytoplankton, zooplankton, macrophytes, and fish.

Effects on primary production and algae

Increases in overall primary productivity have occurred in some ecosystems, but increases in total biomass of phytoplankton have not been observed in the same systems. Warmer conditions in spring have led to earlier increases in phytoplankton population

Fig. 9 Trends of (A) ice freeze and (B) breakup dates from lakes across the globe. Modified from Fig. 2 in Woolway RI, Kraemer BM, Lenters JD et al. (2020) Global lake responses to climate change. *Nature Reviews Earth & Environment* **1**: 388–403, by permission from Springer Nature.

abundance, especially for diatoms (Rühland et al., 2015). There have also been increases for groups with higher temperature optima, like cyanobacteria. Increased abundance and dominance of lake phytoplankton communities by cyanobacteria related to warming waters and longer duration of stratification has been observed repeatedly (e.g., Davis et al., 2009; Wagner and Adrian, 2009; Winder, 2012; Smol, 2019). However, warmer conditions do not always lead to an increase in phytoplankton populations. In fact, population abundance can vary under different circumstances, especially in shallow lakes where a more complex set of mechanisms (i.e., changes in wind speed, ice cover, stability of stratification, etc.) can result in shifts of phytoplankton species. In addition, a shift to larger sized benthic organisms and smaller sized planktonic diatoms has been documented during recent warming periods, in part because smaller species are favored by a more pronounced stratification regime (Przytulska et al., 2017). These clear trends related to temperature are even more striking considering the importance of other factors known to control populations of algae such as light intensity, nutrient availability, and losses due to grazing.

High-latitude arctic and sub-arctic lakes are often considered to be less susceptible to human influences because the ecosystems are relatively far away from the population centers; however, high-latitude regions are especially sensitive to environmental stressors (Smol, 2016). Changes in air temperatures have caused increased runoff of sediment and associated nutrients into arctic streams and lakes via a number of mechanisms (Hobbie et al., 1999; MacIntyre et al., 2009; Daniels et al., 2015). For instance, changes in permafrost characteristics have resulted in thawing of surface layers that causes slumping and increased sheer flow over underlying frozen layers (Mesquita et al., 2010). Moreover, terrestrial landscape changes resulting from permafrost thaw can influence carbon accumulation and mercury deposition in nearby shallow lake systems (Korosi et al., 2015). Consequently, increases in the sediment load to streams and receiving lakes have been observed. Similar eutrophication of rivers and lakes may also result from increased evapotranspiration relative to water supply rates, causing increases in concentrations of solutes like nutrients and trace metals (Smith et al., 2005). Such trends are especially prevalent in the abundant shallow lakes and ponds found throughout the higher latitudes of North America (Smol, 2016).

Effects on zooplankton

Similar to the patterns observed for algae, the seasonality of zooplankton populations has been observed to shift to earlier spring population increases, but zooplankton communities have not shown increases in overall abundance (Vadadi-Fülöp et al., 2012). Increases in *Daphnia* occur earlier in the spring of warmer years, but summer and fall dynamics do not appear to be driven strongly by climatic change (Adrian et al., 1999). Overall, abundance of zooplankton is likely to stay the same in warmer years, or perhaps even decrease. Studies show that zooplankton evolve to have different behavioral responses to temperature changes in their environment (Vadadi-Fülöp et al., 2012). Zooplankton can select habitats to offset changes in temperature and are able to migrate vertically to avoid predation and other harsh habitat conditions. Stratification and temperature changes in lakes can change abundance and spatial distribution of food for zooplankton (Wang et al., 2020). Large-bodied grazing zooplankton, like *Daphnia*, can respond to increases in phytoplankton abundance with improved and altered feeding mechanics, but are affected by antipredation adaptations like toxin production, growth in colonies or mucus capsule formation as occurs with cyanobacteria (e.g., Lampert, 1987; Trabeau et al., 2004). As indicated above, warmer water temperatures have a direct correlation with cyanobacterial blooms in lakes, potentially limiting *Daphnia* populations, but *Daphnia* are able to develop a cyanobacterial toxin resistance and select an alternate food source so that their population abundance does not always decrease in the presence of cyanobacteria blooms (Krzton and Kosiba, 2020). In addition, a shift to dominance by smaller-bodied species is expected under warmer conditions because zooplankton assemblages in warmer lakes have been observed to contain a higher percentage of smaller-bodied forms (Moore et al., 1996).

Effects on fish

The effects of climate warming are expected to differ for the different thermal guilds of fish (De Stasio et al., 1996; Magnuson and De Stasio, 1996; Stefan et al., 2001; Hansen et al., 2017). Because much of the water in large, northern lakes is colder than the temperature optima of most fish, warming of hypolimnetic waters may increase fish growth for cold-water fish, such as salmon, in the Laurentian Great Lakes (Magnuson et al., 1990). In smaller lakes, the data indicate that thermal guilds of warm and coolwater fish should experience increases in availability of preferred thermal habitats, and that growing seasons and overall growth rate potential will increase as well (De Stasio et al., 1996; Stefan et al., 2001). However, a few aspects may lead to decreases in fish populations. First, warming of shallow lakes that do not stratify may lead to temperatures beyond the lethal limits of some fish, especially cold-water species. Secondly, because earlier stratification can result in colder hypolimnetic temperatures and more stable stratification, overlap of fish with their prey may decrease if prey can find cold refugia in the hypolimnion (De Stasio et al., 1996; Pilla et al., 2020). Third, increased duration of stratification may lead to more severe depletion of hypolimnetic oxygen and restriction of suitable habitat for fish (Fang and Stefan, 2009). Finally, changes in biogeographic limits are likely to occur, essentially moving fish ranges northward and to higher elevations (Lynch et al., 2016; Hansen et al., 2017). Changes in elevation ranges may be especially troublesome for coldwater fish because habitat fragmentation may result as lower order streams begin to warm significantly and isolate cold and cool water fish in small headwaters of river systems (Rahel et al., 1996).

Conclusions

Direct effects of climate change on river, lake, and wetland ecosystems have clearly been documented over the past few decades. Based on numerous studies it is clear that mean lake temperatures have been increasing in response to warmer meteorological conditions and duration of the ice-free season has been increasing in both rivers and lakes. However, exact predictions of all lake temperature responses are difficult because of the complex interactions between aquatic environments and the atmosphere. Data indicate that in some cases there may have also been direct responses of ecosystem function to climate warming, including primary productivity, nutrient dynamics, seasonality of plankton, and habitat use and growth of fish. Challenges for the future include modeling such responses at the individual lake and population level to illuminate effects at the whole ecosystem scale.

Knowledge gaps

- Interactive effects of atmospheric and landscape changes on surface waters.
- Direct and indirect effects of temperature on whole ecosystem metabolism.
- Modeling lake-level responses within the context of ecosystem-scale changes.
- Understanding changes in lake temperature structure and effects on limnological and ecological dynamics.
- Relative effects of changes in trophic interactions vs. climate warming.

Glossary

Absolute rate A physiological rate expressed per unit time. For example, metabolic rate for a fish expressed as mg O_2 day^{-1}.
Allometry Relationships describing how biological processes scale with body size.
Assimilation efficiency The proportion of consumed food, nutrient or contaminant that is assimilated and retained by a consumer.
Ectotherm An organism whose regulation of body temperature is dependent on external sources such as water temperature or sunlight.
Egestion The process of voiding or discharging non-assimilated (undigested) food as feces.
Excretion In fish and other aquatic organisms, the process of eliminating assimilated energy as waste in the form of ammonia.
Gonadal growth Change in mass of reproductive organs that include testes in males and ovary in females.
Hypoxic Conditions characterized by water with low dissolved oxygen concentrations below 2 mg O_2 L^{-1} or less than 30% O_2 saturation.
Normoxic Conditions characterized by water with normal dissolved oxygen concentrations greater than 2 mg O_2 L^{-1} or between 30% and 100% O_2 saturation.
Somatic growth Change in mass of body tissue and organs, excluding gonads.
Specific dynamic action The amount of energy expenditure above resting metabolism due to the cost of processing food.
Specific rate A physiological rate expressed per unit weight per time. For example, metabolic rate for a fish expressed as mg O_2 g^{-1} day^{-1}.
Standard metabolism (poikilotherms) Minimum aerobic metabolic rate at a specific temperature.

Introduction

Development and application of bioenergetics modeling has increased in recent years owing to the complexity of issues being faced by aquatic scientists. Bioenergetics models provide a sound, theoretical approach for estimating energy allocation in animals by partitioning consumed energy into three basic components that include (1) metabolism, (2) wastes, and (3) growth. Because the models are based on an energy balance, they are often used to estimate growth or food consumption given information on other variables. Bioenergetics models are particularly attractive for estimating food consumption by free-ranging ectotherms given the

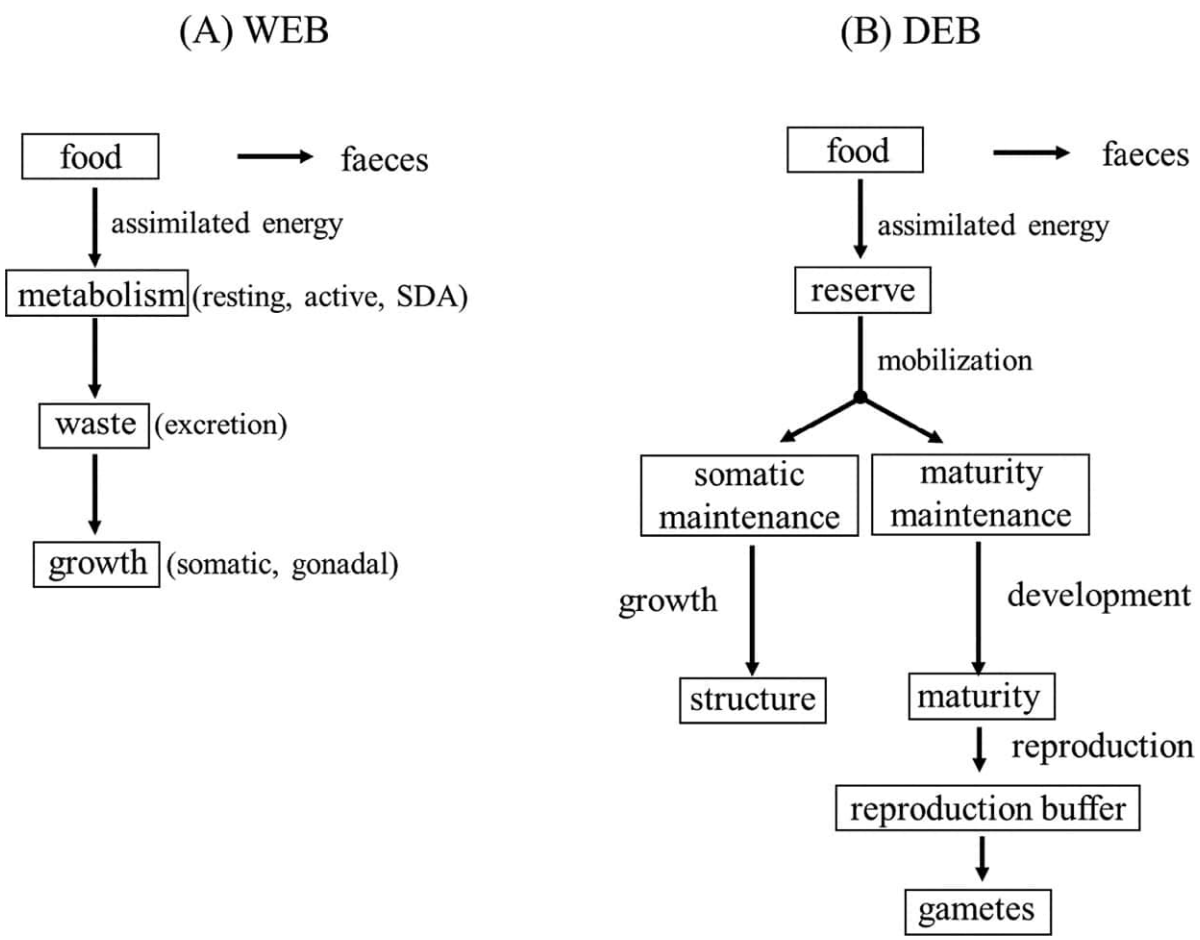

Fig. 1 Conceptual overview of (A) the Wisconsin Energy Budget (WEB) and (B) the Dynamic Energy Budget (DEB). The WEB approach is generally species-specific and is structured as a hierarchal model where food energy is first apportioned to metabolic costs, then waste loss, and finally to somatic and gonadal growth depending on maturity. The DEB approach can integrate intra- or interspecific information as well as life-stage specific data from a variety of studies during the parameterization process, thus providing a full-life-cycle approach to energy acquisition and allocation. DEB adapted from Kooijman SALM (2010) *Dynamic Energy Budget Theory for Metabolic Organization*, 3rd edn. Cambridge, UK: Cambridge University Press.

time and effort required of traditional approaches such as continuous feeding models or chronology-of-feeding methods (Adams and Breck, 1990). Today, bioenergetics models are widely used for a myriad of animals, ranging from zooplankton to whales, to address issues related to climate change, invasive species, sportfish management, and endangered species—just to mention a few.

Two modeling approaches are generally used in bioenergetics analyses. Traditional models based on the Wisconsin Energy Budget (WEB, Kitchell et al., 1977; Hanson et al., 1997) use a hierarchical approach to resolve energy allocation by an individual organism (Fig. 1). The wide-scale application of WEB modeling has benefited from the availability of user-friendly software first introduced in 1987 (Hewett and Johnson, 1987). The most recent version, *Fish Bioenergetics 4.0*, includes bioenergetics models for 73 species (Deslauriers et al., 2017). A more generalized, albeit abstract approach to bioenergetics modeling is based on the Dynamic Energy Budget (DEB) theory (Kooijman, 2010). Although conceptually similar to the data driven WEB approach, DEB modeling is a theory driven approach where an animal's biomass can be defined as the sum of three compartments: structure, reserve, and (adult) reproductive buffer (Nisbet et al., 2012; Fig. 1). DEB models can be parameterized to include full-life-cycle features, providing a robust platform for integrating available information from studies of specific life stages, habitats and processes (Nisbet et al., 2012).

Like other mathematical models, bioenergetics modeling approaches are simplifications of reality. How well they describe or predict actual conditions depends on appropriate measurement of model parameters and the input data used to drive them. Fortunately, as development and application of bioenergetics models have increased, so too have methods for parameterizing model input and evaluating model output, with the goal of reducing uncertainty in bioenergetics models (Chipps and Wahl, 2008). As our late colleague Dr. James Kitchell once noted, "The model cannot be wrong because it is based on a budget that must be right. It will improve in proportion to our ability to estimate the physiological parameters that regulate growth and the errors or bias of data employed as inputs."

Wisconsin energy budget: Core processes

Bioenergetics models are based on an energy budget that is driven by the second law of thermodynamics, where consumed energy is balanced by energy expenditures that ultimately lead to increased entropy. Conceptually, an energy budget can be expressed as,

$$\text{consumption} = \text{metabolism} + \text{wastes} + \text{growth}$$

where consumed energy is partitioned into three major processes that include metabolism, waste, and growth. We can refine each term on the right side of the equation to account for different aspects of consumed energy (C) as,

$$C = (R + A + SDA) + (U + F) + (SG + GG) \quad (1)$$

where metabolism includes standard metabolic rate (R), energy expended due to swimming activity (A), and specific dynamic action (SDA), the latter representing the energy required to digest and assimilate food. Similarly, consumed energy that is lost as waste is accounted for by excretion (U) and egestion (F) processes. Energy not partitioned to metabolism or waste is available for somatic (SG) and(or) gonadal growth (GG) depending on maturity. Relatedly, knowledge of any seven components above, allows us to estimate the eighth. Somatic growth, for example, can be derived by re-arranging the conceptual model above as,

$$SG = C - (R + A + SDA + F + U + GG) \quad (2)$$

The hierarchical partitioning of consumed energy in WEB models has been likened to an account balance, where the *living costs* paid to rent or mortgage are equated to metabolism. Similarly, *taxes*, which are proportional to income (i.e., consumed energy), are paid as waste losses (Hanson et al., 1997). Any *income* left over can be added to *savings* as individual growth (SG) or *invested* in the future in the form of gonads (GG). Generally speaking, the energy budget of a typical predatory fish, when represented simply as metabolism, waste, and growth, corresponds to about 44%, 27%, and 29% of consumed energy, respectively. Similarly, for herbivorous fishes, metabolism, waste, and growth correspond to about 37%, 43%, and 20% of consumed energy (Brett and Groves, 1979). Lower growth efficiency and greater waste loss among herbivorous fishes is likely due to eating foods with a greater proportion of indigestible material and lower energy content. Growth efficiency of fish is greater than that reported for mammals and birds, although the variation around estimates reported above can be high (±20% of the mean; Hanson et al., 1997).

Other processes that are commonly incorporated as sub-models in WEBs include nutrient regeneration and contaminant uptake. The excretion process in fish and aquatic invertebrates represents the primary loss of soluble nitrogen and phosphorus that is readily available for uptake by primary producers (e.g., algae). When information on P (or N) content of predators and their prey are known, phosphorus excretion (U_p) can be easily incorporated into bioenergetics models as,

$$U_p = (AE_p \cdot C_p) - G_p \quad (3)$$

where AE_p represents assimilation efficiency, or the proportion of P that is taken up by the predator (~0.7), C_p is the mass of P consumed by the predator, derived as prey consumed (g) multiplied by P concentration in the prey (g P/g wet weight), and G_p equals the mass of P (g) allocated to growth. In a similar fashion, contaminant uptake by target organisms can be evaluated using bioenergetics models when information on predator and prey contaminant levels are known.

Converting our conceptual bioenergetics model in equation 1 to a mathematical model requires that parameters be expressed in the same units; for the WEB, the standard unit of measure is the Joule (1 J = 0.239 cal). Physiological processes are typically measured in a laboratory setting under controlled conditions where precise measurements can be made. Body size and water temperature are the primary factors affecting physiological rates of ectotherms and must be accounted for in parameter estimation. Respiration rate (R), which is used as an estimate of standard metabolic rate, is an important component of the energy budget and is often expressed as a power function,

$$R\ (g\ O_2\ g^{-1}\ day^{-1}) = aW^{-b} \cdot f(T) \quad (4)$$

where W represents fish wet weight (in g), a and b are regression coefficients, and $f(T)$ is a temperature-dependent function. Oxygen consumption (g O_2 day^{-1}) and fish mass (g wet weight) are converted to J using an oxycaloric equivalent (13,560 J g^{-1} O_2) and information on fish energy density (J g^{-1} wet weight), respectively. Note that R can then be expressed as a specific rate relating to J of oxygen consumed per J of fish per day (J J^{-1} day^{-1}). In this context, energy allocation and scope for growth can be easily related to water temperature for a given size fish. As one might expect, the potential scope for growth of a fish is maximized when they feed in optimal water temperatures at their maximum feeding rate (Fig. 2).

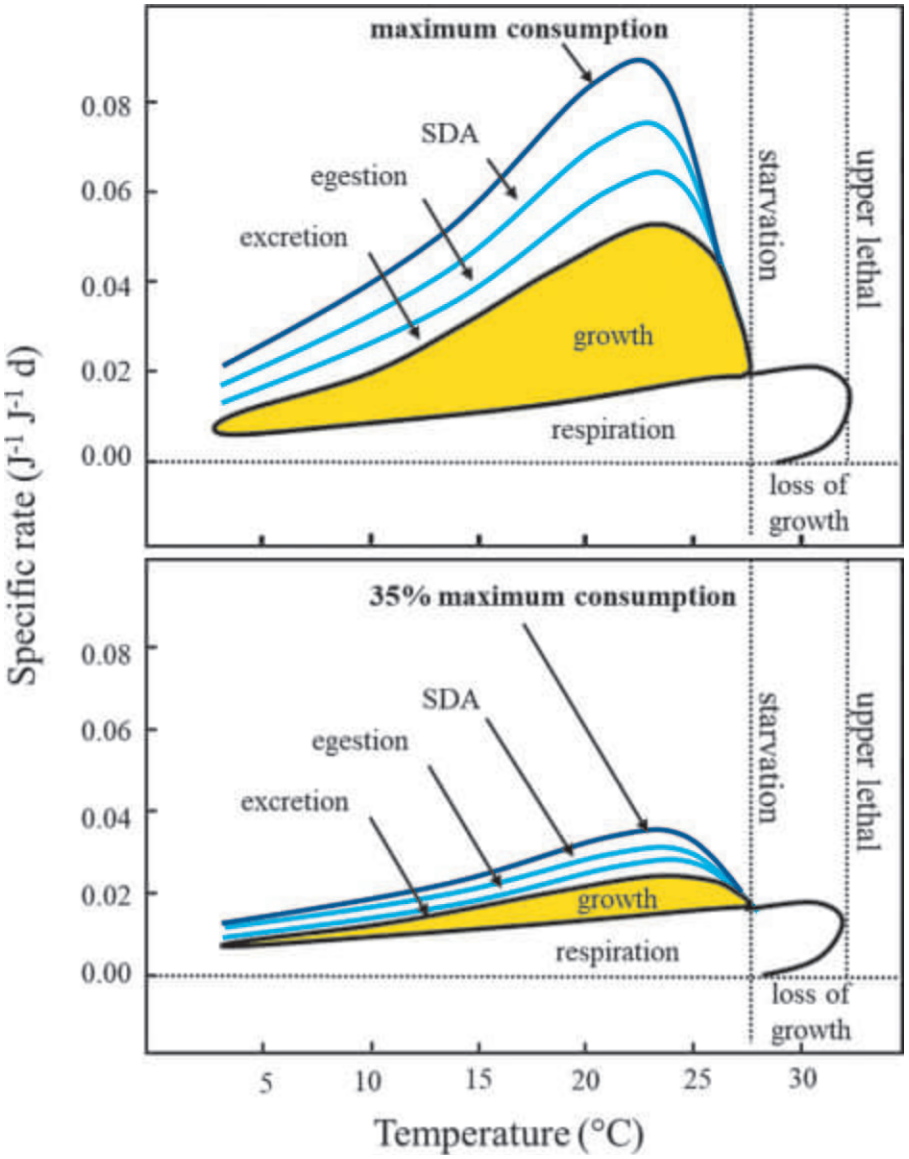

Fig. 2 Generalized Wisconsin energy budget (WEB) as a function of water temperature. The top panel depicts energy use and resultant growth for an ectotherm (e.g., fish) feeding at its maximum feeding rate (maximum consumption, $C_{max} = 100\%$). The bottom panel depicts similar energy allocation, but for a fish feeding at 35% of its maximum consumption rate. Adapted from Fig. 1 in Hanson PC, Johnson TB, Schindler DE, and Kitchell JF (1997) Fish Bioenergetics 3.0 Madison, WI: University of Wisconsin Sea Grant Program, with permission from University of Wisconsin Sea Grant Institute.

Specific rates also point out the importance of allometry on energy budget components that at first glance can appear contradictory. Consider R plotted as a function of fish weight at a fixed water temperature (Fig. 3). In this case, the absolute rate of standard metabolism (J day^{-1}) is positively related to fish size and thus greater for larger fish than for smaller fish—as would be expected. However, when expressed as a specific rate (J J^{-1} day^{-1}), standard metabolism is negatively related to fish size (i.e., –b coefficient) and is greater for smaller fish due to greater oxygen demand per unit of body mass. Similar allometric responses are observed in other physiological rates including feeding (C) and growth (SG) rate.

Once parameterized, bioenergetics models can be used to address a variety of applied or ecological questions. Because growth integrates how well a fish resolved its energy budget, it can relay important information about environmental conditions and(or) food availability that can be addressed by bioenergetics modeling. Moreover, bioenergetics models can be used to explore a variety of hypotheses related to food availability, habitat quality, species interactions, climate change, nutrient regeneration and contaminant uptake. Below, we highlight several areas where bioenergetics modeling has been used to address important questions in fisheries management and ecology.

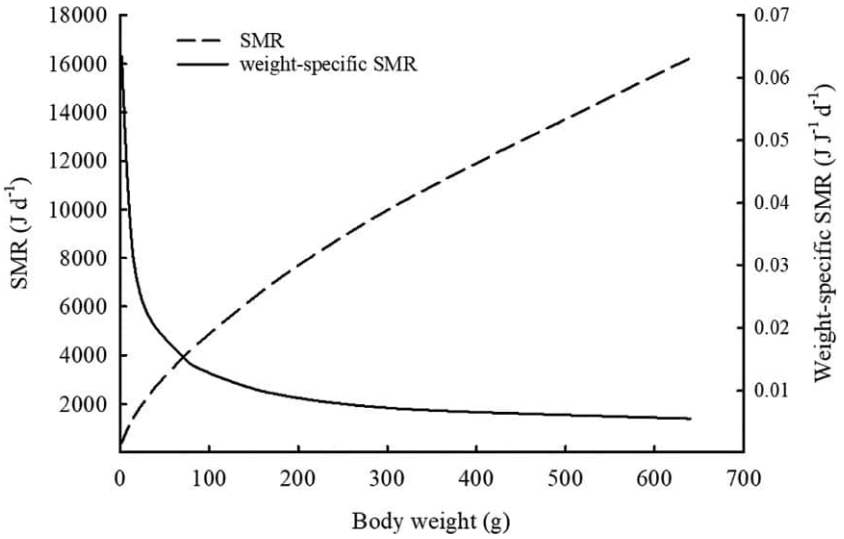

Fig. 3 Comparison of standard metabolic rate (SMR, dashed line) and weight-specific SMR (solid line) for 2–640 g largemouth bass (*Micropterus salmoides*) at 25 °C.

Modeling applications

Predator-prey dynamics

An often-cited example of a fish bioenergetics model application being used to guide fishery management decisions is the predator-prey modeling of the salmonine and alewife (*Alosa pseudoharengus*) populations in Lake Michigan (United States). Salmonines, including Chinook salmon (*Oncorhynchus tshawytscha*), lake trout (*Salvelinus namaycush*), rainbow trout (*O. mykiss*), coho salmon (*O. kisutch*), and brown trout (*Salmo trutta*), have fed primarily on alewives in Lake Michigan since the 1960s. Researchers at the University of Wisconsin Center for Limnology (CFL) applied bioenergetics models to salmonine populations in Lake Michigan during the 1970s and 1980s, and they determined that their estimates of annual consumption of alewives by salmonines were equal to 33% of the estimated annual biomass production of alewives in the lake in some years during the 1970s and early 1980s (Stewart et al., 1981). CFL researchers warned fishery managers that the high degree of predation exerted by salmonines would eventually result in a drastic decline in alewife abundance in Lake Michigan. During the 1980s, fishery managers in three of the four states bordering Lake Michigan heeded this warning by reducing the stocking rates of Chinook salmon into the lake. During the late 1990s and 2000s, researchers at Michigan State University developed a predator-prey model (PPM) for the salmonine and alewife populations in Lake Michigan by coupling salmonine bioenergetics models with age-based population models for the salmonines and alewives (Tsehaye et al., 2014). In their simulation model, annual consumption of alewives by salmonines was estimated, and the corresponding mortality on the alewife population is calculated and applied toward modeling alewife population size in the lake. For each year of the simulation, the PPM generates age-specific estimates of lakewide population sizes, population biomasses, and mortality rates for salmonines and alewives. Every year, fishery managers review the PPM output to make decisions on the stocking rates of salmonines, primarily Chinook salmon. Stocking rate of Chinook salmon into Lake Michigan has been reduced five times during 1990–2020. These decisions appear to have been effective, because the alewife population has not undergone a complete collapse and the Chinook salmon fishery has persisted since the 1960s. Clearly, bioenergetics modeling has been a keystone to effective management of the salmonine fisheries in Lake Michigan since the 1980s.

Endangered species

Bioenergetics models provide an important tool for understanding habitat-related energetic requirements of endangered species that can aid in conservation planning. However, empirical data can be limited for endangered species and they are often not readily available for experimentation due to their precarious status. Alternative approaches of developing bioenergetics models for endangered species are often needed to meet conservation objectives. A number of approaches exist to deal with this lack of information. A bioenergetics model for the humpback chub (*Gila cypha*), an endangered species of minnow inhabiting the Upper Colorado River Basin (United States), was developed using parameter bounds for other *Gila* spp. and fit to observed growth for humpback chub (Petersen and Paukert, 2005; Petersen et al., 2008). Similarly, field-based approaches that make use of mark-recapture and water temperature data have been used to estimate bioenergetics parameters for a number of endangered species including white sturgeon (*Acipenser transmontanus*) in the Upper Columbia River (Canada; van Poorten and McAdam, 2010). These models can then be used to predict growth rates and evaluate habitat quality.

The Dynamic Energy Budget (DEB; Nisbet et al., 2012) approach also offers the opportunity to estimate bioenergetics model parameters without directly having access to animals. This approach uses available laboratory and field data from the literature to estimate the parameters using a mathematical calibration technique. Such a model can then be used to recreate the life history of a species and evaluate the impacts of food limitation and elevated temperatures as has been done for early life stages of green sturgeon (*Acipenser medirostris*) in the Sacramento River, California (United States; Hamda et al., 2019), where this subpopulation of the species has been considered threatened since 2006.

Once a bioenergetics model has been developed using one of the approaches mentioned above it then becomes possible to apply it spatially to take advantage of often existing datasets describing water temperature and prey availability attributes that can be used as inputs in bioenergetics modeling. In systems that have been highly impacted by human activities, such as the Chesapeake Bay, a spatially-explicit bioenergetics approach can be used to identify areas for conservation and recovery efforts (Dalyander and Cerco, 2010) for species such as the Atlantic sturgeon (*Acipenser oxyrinchus*; Niklitschek and Secor, 2009) and Atlantic salmon (*Salmo salar*; Nislow et al., 2000). Bioenergetics modeling can also be used to evaluate the carrying capacity of a system (Eastern Oyster, *Crassostrea virginica*; Filgueira et al., 2014) to assess if conservation stocking practices might lead to a population collapse due to a high number of fish being stocked in a system where limited food resources exist to support growth as has been noted for endangered sturgeon species including the pallid sturgeon (*Scaphirhynchus albus*; Steffensen et al., 2019).

Extending bioenergetics modeling further, individual organisms within a population can be modeled independently allowing them to interact with their environment and generating population characteristics that provide unique insight about the system under study (Grimm et al., 2016). These models, termed Individual/Agent-Based Models (IBM/ABM) are becoming increasingly popular as a way to simulate ecological, biological, and physiological dynamics under a spatially-explicit framework. The main advantage of integrating an IBM/ABM framework within a virtual spatial environment is that individuals are allowed to move, thus recreating behaviors that will seek to optimize growth and survival. A few examples exist in the literature that have applied this approach in the context of endangered species conservation. In one study, experimental data on the physiology and behavior of pallid sturgeon were combined with empirical information on prey density, water temperature and velocity from the Missouri River (United States) to create a virtual environment in which the impact of habitat heterogeneity on the growth rates of larval fish could be assessed (Deslauriers et al., 2018). Results from this type of computer simulation can be used to identify favorable nursery areas for the pallid sturgeon, and then fishery and environmental managers can work together to protect these important areas of the river to better conserve the species. The use of an IBM/ABM approach allows for multiple sources of information to be combined and thus provides a valuable tool for the conservation and management of endangered species.

Trophic interactions

Trophic interactions involving the widely introduced opossum shrimp (*Mysis diluviana*), kokanee salmon (*O. nerka*), and lake trout have been well documented in North American lakes. Diel vertical migration exhibited by *Mysis* plays an important role in limiting their exposure to planktivorous fish predation, particularly among populations that were introduced into non-native environments. Following the establishment of introduced *Mysis* populations in large, western North American lakes, early research showed significant changes in zooplankton abundance and concomitant declines in kokanee salmon. As studies progressed, the application of bioenergetics modeling became an important tool in enabling researchers to evaluate trophic interactions among *Mysis*, kokanee and lake trout. Studies in Lake Pend Oreille, Idaho (United States) revealed that annual zooplankton consumption by *Mysis* was over four times greater than that by the kokanee population, accounting for 5–70% of the daily cladoceran zooplankton biomass (Chipps and Bennett, 2000). Bioenergetics modeling also revealed that annual phosphorus excretion by *Mysis* was over three times greater than that by the kokanee population, although much of the phosphorus recycling by *Mysis* was constrained to deeper strata where they spend a considerable portion of their day.

The establishment of non-native *Mysis* populations also influenced lake trout populations that in most cases, represented another introduced species in many lakes of northwestern North America. Because *Mysis* represent an important prey for young lake trout, many lake trout populations expanded following *Mysis* introductions. In Colorado reservoirs, bioenergetics modeling showed that the management of trophy lake trout fisheries led to an imbalance between lake trout consumption and their available prey base (i.e., kokanee), placing additional constraints on the kokanee population (Johnson and Martinez, 2000). It is now recognized that kokanee production is largely constrained by the degree of competition with *Mysis* that ultimately determines the magnitude of sustainable predation by lake trout (Corsi et al., 2019; Fig. 4).

Contaminant accumulation

Fish bioenergetics modeling has provided key insights into the processes regulating contaminant accumulation in fish. For example, during the 1960s and 1970s, direct uptake of polychlorinated biphenyls (PCBs) from the water into the fish's body via the gills was believed to be the predominant pathway of entry of these environmental contaminants into the bodies of free-ranging fish in lakes, rivers, and oceans. As discussed above, if the growth rates of free-ranging fish are known, then bioenergetics modeling can be used to estimate the amount of food consumption needed to attain the observed growth. In turn, the quantity of PCBs entering the fish's body via dietary uptake can be estimated. Computer simulation models, including a bioenergetics model subcomponent but also including a subcomponent for direct uptake of PCBs from the water via the gills, were developed and applied to populations of free-ranging fish during the late 1970s and 1980s. Results clearly revealed that the bulk (>95% in some cases) of PCBs accumulated

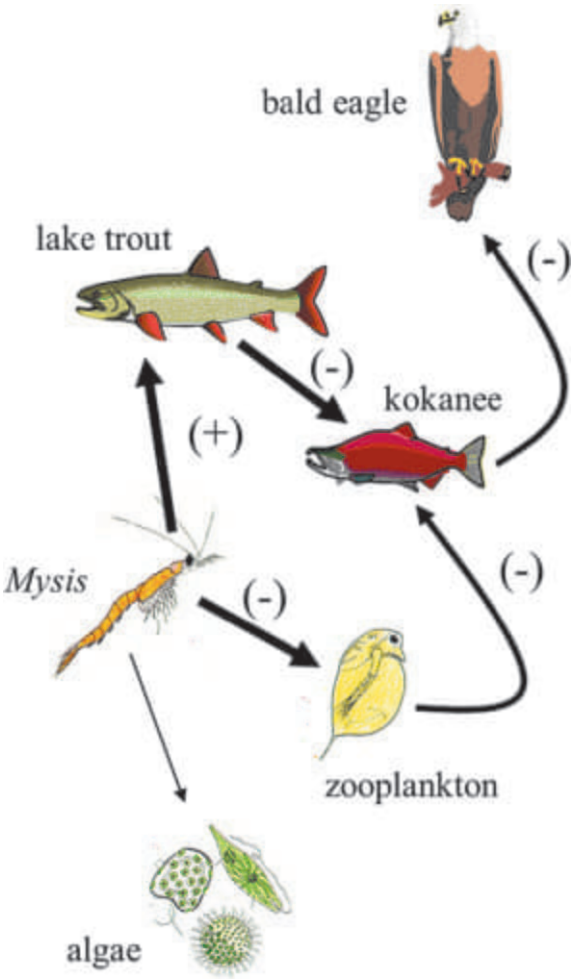

Fig. 4 Food web interactions in lakes containing non-native *Mysis diluviana* and lake trout. The width of the arrows corresponds to the relative strength of species interactions and the (+) or (–) signs indicate the direct or indirect effects of opossum shrimp and lake trout on kokanee salmon and bald eagles. Adapted from Fig. 13.1 in Chipps SR and Graeb BDS (2010) Ecology and management of lake food webs. in: Hubert W and Quist M, (eds.) *Inland Fisheries Management in North America*, (3rd edn.) Bethesda, Maryland: American Fisheries Society, pp. 395-424.

by fish entered via food consumption rather than direct uptake from water (Weininger, 1978). Bioenergetics modeling can also be used to quantify the growth dilution effect. The growth dilution effect refers to the phenomenon of lower contaminant concentrations in faster-growing fish compared with slower-growing fish, when all other factors are equivalent. Essentially, the contaminant concentration is "diluted" over the greater body mass of the faster-growing fish. Results from bioenergetics modeling have shown that the growth dilution effect can usually account for a modest (<20%) difference in contaminant concentrations between individual fish, but the growth dilution effect cannot explain relatively large (twofold or greater) differences in contaminant concentrations between individual fish (Madenjian et al., 2016). When incorporated into computer simulation models, bioenergetics modeling continues to be indispensable in predicting contaminant concentrations in fish under various scenarios of future environmental dynamics, such as climate change, changes in fishing mortality, and changes in the rates of discharge of contaminants into the environment.

Climate change

Bioenergetics models provide a powerful tool to address effects of climate change on feeding and growth dynamics of aquatic animals. Bioenergetics modeling is well suited to address organismal responses to changing climate conditions because it is grounded in a mass-balance model driven by physiological responses to water temperature. Metabolic rate represents an important component of the physiological response to climate change because it accounts for an appreciable part of the energy budget and has a non-linear response to increased water temperature. Consider, for example, a species at its southern and northern range where mean, summer water temperatures vary between populations. Because of the non-linear relationship between metabolism and

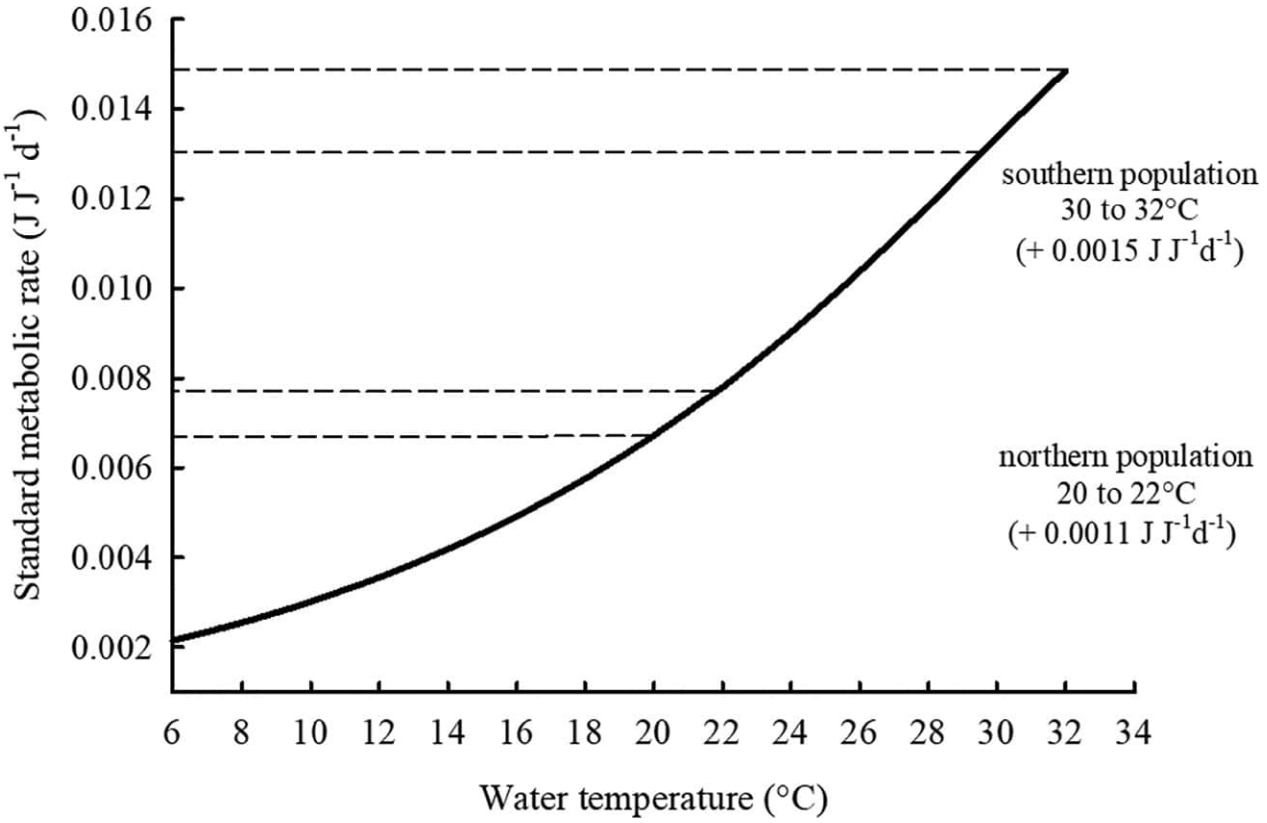

Fig. 5 Standard metabolic rate of an adult, 300 g bluegill sunfish (*Lepomis macrochirus*) at water temperatures ranging from 6 °C to 32 °C. Dashed lines correspond to a 2 °C increase in water temperature for simulated populations at the northern or southern edge of their range. Note that for the southern population, a 2 °C increase in water temperature (30–32 °C) results in a greater change in daily metabolic rate compared to the northern population (20–22 °C) due to the non-linear increase in metabolism.

water temperature, a 2 °C increase in water temperature results in greater metabolic cost to individuals from southern populations compared to those from cooler, northern climates (Fig. 5). And while much focus is directed to climate change in the mid- to high latitudes of the Northern Hemisphere where climate warming is occurring more rapidly, scientists have raised concerns that impacts of climate warming should be considered on a global scale that includes tropical regions (Dillon et al., 2010).

Climate change has become an important research focus in aquatic science. The degree to which global warming affects species distribution, aquatic food web interactions, fish production, and species extinction are topics receiving considerable attention. One example of how bioenergetics modeling is being applied to address climate change involves food web interactions in large reservoirs. Because many large reservoirs are managed for warm and coolwater sportfishes, questions arise as to the relative impacts of future warming trends on both groups of fishes. Lake Sharpe, a large, Missouri River reservoir in central South Dakota United States, contains both smallmouth bass (*Micropterus dolomieu*) and walleye (*Sander vitreus*). While walleye are native to the upper Missouri River, smallmouth bass were introduced to Missouri River reservoirs to provide increased angling opportunities. Bioenergetics modeling has shown that based on future climate predictions, warmer water temperatures could enhance growth potential for smallmouth bass that feed on gizzard shad (*Dorosoma cepedianum*)—a warmwater forage fish. At the same time, warmer water temperatures would reduce growth potential of walleye and threaten rainbow smelt (*Osmerus mordax*), an important coolwater forage fish for walleye (Wuellner et al., 2010).

Sex and life stage variation

Energy budgets have been developed for various species of fish, although they have not yet been developed for sexes within a fish species. For many bioenergetics model applications, including a level of detail such that differences between males and females are taken into account is not necessary to achieve the objectives of the modeling exercise. However, in some instances, sex-specific fish bioenergetics models may be useful. With continued research, sex-specific fish bioenergetics models will eventually become available.

A body of evidence has recently emerged that indicates that adult male fish expend energy at a higher rate than adult female fish (Madenjian et al., 2016). The higher energy expenditure rate in males stems from a higher standard metabolic rate and greater swimming activity by males. For a given size of fish, it has been estimated that energy expenditure rate of mature males may exceed that of mature females by up to 20% or more (Madenjian, 2020). Interestingly, the characteristics of higher resting metabolic rate and higher activity in males compared with females is shared by other vertebrates, including humans (Madenjian et al., 2016; Madenjian, 2020).

Extrapolation of the metabolic component of a fish bioenergetics model to the larval stage may result in inaccurate estimation of food consumption by fish larvae, because metabolism has an isometric relationship with weight when fish are larvae but an allometric relationship with weight in juvenile and adult fish (Post, 1990; Klumb et al., 2003). Typically, a bioenergetics model for a given fish species is based on respiration rate determinations for older juvenile and adult fish, but not on determinations for larval fish. Specific respiration rate is usually expressed in units of grams of oxygen consumed per gram of fish per day. Extrapolation of the respiration rate model based on respiration rate determinations for older juvenile and adult fish to fish larvae may lead to serious error in food consumption estimates for fish larvae (Post, 1990; Klumb et al., 2003). Of the fish species for which bioenergetics models are available, the models are appropriate for application to older juveniles and adults, but not to fish larvae in most cases. Because the physiological responses of larval fish are different from those of larger fish, bioenergetics models have been developed specifically for the larval stage and these models are available for several fish species.

Modeling limitations

All mathematical models of biological processes have some kind of limitation to their applicability, and bioenergetics models are not an exception to this general rule. As with any model, the reliability of output from bioenergetics modeling is strongly dependent on appropriate parameterization and the accuracy of the input data used to drive them. Because WEB-based models tend to be parameter-rich, corroboration of model output is an important step in the model development phase. Unfortunately, not all models are created equal as evidenced by field and(or) laboratory evaluations of bioenergetics models (Chipps and Wahl, 2008). In recent years, efforts to corroborate bioenergetics models have led to improvements to existing models and new insights affecting the accuracy of model output. Accounting for factors such as life-stage, sex, feeding rate and environmental adaptations in bioenergetics models can lead to refinement of species-specific models and improved understanding of fish physiology.

A case study of a muskellunge (*Esox masquinongy*) bioenergetics model demonstrates how field/laboratory evaluations led to improvements in the model and increased our understanding of muskellunge biology. Early studies showed poor agreement between field estimates of food consumption and those predicted by a bioenergetics model for juvenile muskellunge (Wahl and Stein, 1991). Field-derived estimates of food consumption were 39–53% lower than those predicted by the bioenergetics model. Subsequent studies using laboratory-derived estimates of food consumption revealed similar findings in that food consumption was 30–75% lower than that predicted by the model. Moreover, in winter months (<10 °C), the model overestimated food consumption by 113–328% (Chipps et al., 2000a). An evaluation of seasonal variation in juvenile muskellunge metabolism showed that respiration rate varied among seasons and was lower in winter months at temperatures of 5–25 °C (Fig. 6). After accounting for seasonal, metabolic compensation by juvenile muskellunge, the bioenergetics model generated food consumption estimates similar to those observed in independent feeding and growth trials.

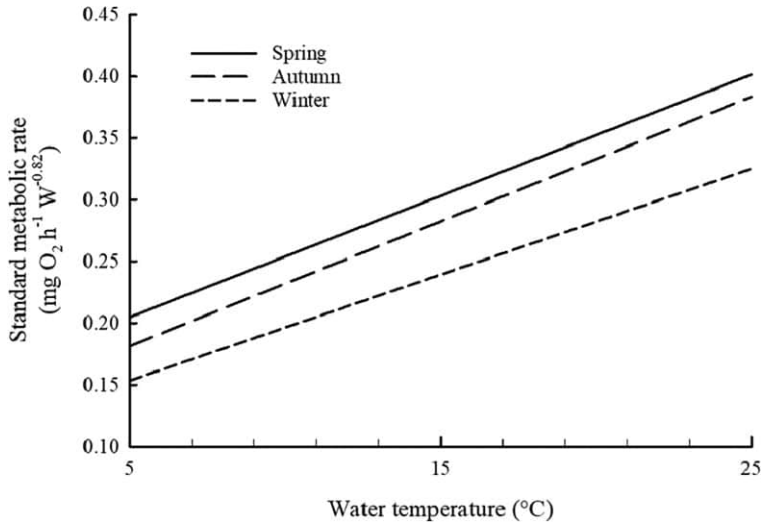

Fig. 6 Weight-adjusted, standard metabolism of age-0 muskellunge measured in spring, autumn, or winter at 5 °C, 15 °C, and 25 °C. Fish weight (W) is in grams. Adapted from Chipps SR, Clapp DF and Wahl DH (2000b) Variation in routine metabolism of juvenile muskellunge: evidence for seasonal metabolic compensation in fishes. *Journal of Fish Biology* 56:311-318.

Conclusions

Bioenergetics modeling offers a powerful tool to address contemporary issues in fisheries management and ecology. Increasingly, bioenergetics models are being used to address questions related to climate change, habitat quality, prey availability, and species interactions. In many cases, bioenergetics modeling provides insight into factors affecting fish growth and(or) food consumption. In other cases, quantitative predictions from bioenergetics modeling can be used to generate point estimates for setting harvest goals, stocking quotas, or balancing predator-prey demand, although such applications should be reserved for corroborated models. As we've seen with the example for Lake Michigan salmonines, the application of corroborated bioenergetics models can be a robust tool to successfully guide fisheries management in large ecosystems.

Future research/Knowledge gaps

- Efforts to integrate DEB theory with traditional WEB models should benefit both modeling approaches. Linking DEB theory with WEB modeling may reveal oversimplified assumptions for some applications but in other instances should prove useful in filling knowledge gaps in WEB models.
- Continued development of new, species-specific WEB models using traditional or new approaches will reduce "species borrowing" of parameters and expand the application of bioenergetics modeling.
- Field and laboratory evaluation of WEB models is an important aspect of the modeling process that can lead to refinement of WEB models for specific life-stages, sexes and(or) environments. The development of new methods to evaluate field performance of WEB models will be useful in advancing bioenergetics modeling.
- The application of new technologies (e.g., physiological telemetry) to better quantify swimming activity and associated energy expenditure of free-ranging fish will lead to more accurate modeling for both the DEB and WEB approaches.
- Otolith microchemistry, which can track trace elements and stable isotope fluctuations over the life cycle of fish, is an emerging technology being pursued in the development and application of bioenergetics models.

This is an update of L.De Meester, Diel Vertical Migration, in Encyclopedia of Inland Waters, edited by Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00151-4.
This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Lars Rudstam.

Introduction

Diel vertical migration (DVM) is a conspicuous and widespread behavior in planktonic organisms in both inland waters and marine environments. The first scientific studies on this behavior date from more than 100 years ago (Bandara et al., 2021), and DVM has been observed in a wide variety of habitats worldwide. DVM has attracted a lot of attention from researchers for several reasons: (1) it is a spectacular behavior, (2) its causes have remained enigmatic for a long time, and (3) the behavior has important ecological consequences.

DVM in its various forms

DVM is often associated with zooplankton, and zooplankton ecologists have indeed devoted great attention to the phenomenon. However, it should be mentioned that other organisms too have been shown to perform DVM, including fish, aquatic insects, and phytoplankton. Figs. 1–3 provide illustrations of DVM in zooplankton, chosen because they reveal several key aspects of the behavior and its variation. Fig. 1 (Hart, 1976) illustrates the migration pattern of a calanoid copepod in a subtropical lake. It shows the classical pattern of a "standard" migration: the animals reside higher in the water column during the night than during the day. During the day, they stay in deep water layers, whereas at night, they distribute themselves more evenly in the water column. The copepods move toward the surface water layers just after sunset, and they return to deeper waters before dawn. The migration is over a long distance relative to their body size. Indeed, the animals move 30–40 m twice every day, which is $>40 \times 10^3$ times their own body length (to human standards, this would translate into a traveling distance of >60 km a day). This illustrates why DVM is considered a spectacular behavior. Finally, the figure also illustrates another common feature: there is a clear tendency for more individuals to be caught during the night than during the day. This phenomenon is called the 'daytime deficit,' and is often observed in studies on zooplankton populations showing extensive DVM patterns. In the study system shown in Fig. 1, it was shown that a fraction of the copepod population actually moves into the sediments during the day. Although net avoidance by zooplankton during the light of day can contribute to this daytime deficit, in many more shallow lakes the daytime deficit is likely caused by the fact that the zooplankton is either residing so close to the sediments during the day that it cannot be sampled by traditional sampling gear or is even moving into the surface layers of the sediment. This is striking, as the sediment is a harsh environment for a zooplankton individual to reside in during part of the day. In many systems that show a strong oxycline, during the day the zooplankton resides at depths that are characterized by very low oxygen levels. Fig. 2 even shows a population of calanoid copepods that resides part of the day in the anaerobic monimolimnion of a meromictic lake (De Meester and Vyverman, 1997). In this coastal lake, there is no oxygen below 5 m depth. Fig. 2 also shows the pattern of changes in vertical distribution around sunset and illustrates that different life stages may differ in their daytime distribution and migration pattern. Indeed, it is clear from this

☆*Change History*: December 2021. L De Meester, T Mehner, and A Scofield were involved in the update. Updates involve smaller edits and the addition of recent references throughout the text, a paragraph on new methods and a new figure (Fig. 4) in the "DVM in its various forms section", and the addition of "DVM in fish" section.

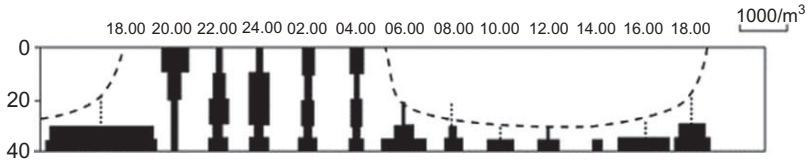

Fig. 1 Diel vertical migration of adult females of the calanoid copepod *Pseudodiaptomus hessei* in Lake Sibaya (March 1972). The broken line indicates a light intensity isocline (1 lux). X-axis: time of day; Y-axis: depth (m); thickness of bars indicates number of animals (see scale bar). Reproduced from Hart RC (1976). (B) Vertical distribution of different ontogenetic stages (small nauplii: N1–3; larger nauplii: N4–6; young copepodites: C1–3; larger copepodites: C4–6) of *Acartia tonsa* 1 h before sunset (17.00; small empty symbols), at sunset (18.00; larger empty symbols) and 1 h after sunset (19.00; filled symbols) at a mid-lake station, May 30, 1992. Reproduced from De Meester L and Vyverman W (1997). Diurnal residence of the larger stages of the calanoid copepod Acartia tonsa in the anoxic monimolimnion of a tropical meromictic lake in New Guinea. *Journal of Plankton Research* 19: 425–434, with permission from Oxford University Press.

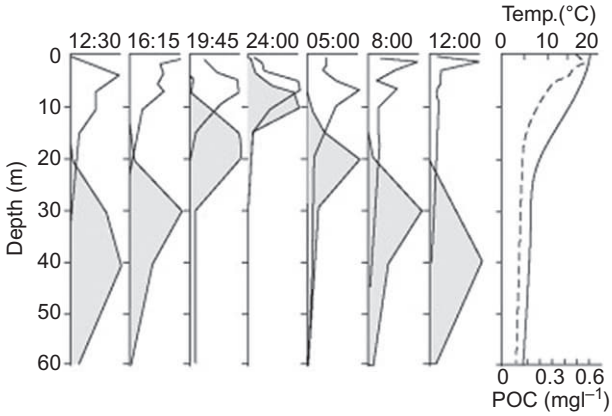

Fig. 3 Vertical migration patterns of *Daphnia galeata* (plain) and *D. hyalina* (shaded) during summer in Lake Constance. The right panel shows depth profiles of temperature (solid line) and particulate carbon (broken line) (particles <35 mm, i.e., potential food for *Daphnia*). Reproduced from Lampert W and Sommer U (2007) *Limnoecology: The Ecology of Lakes and Streams.* 2nd edn. Oxford: Oxford University Press, with permission.

figure that the youngest life stages tend to be distributed similarly to their food during the day, whereas most (sub)adult animals reside in the monimolimnion (depths that do not mix with the surface water) during the day and rapidly ascend to the mixolimnion (surface layer that mix vertically) after sunset. Fig. 3 illustrates strongly different DVM patterns among two congeneric species in the same habitat (Stich and Lampert, 1981). This same study also reported seasonal changes in DVM, with *Daphnia hyalina* migrating only vertically during the summer season. This pattern has been reported for many deep lakes in temperate regions (Ringelberg et al., 1991).

Our understanding of the diversity of forms DVM can take has also expanded with increased use of technological approaches to monitoring zooplankton distributions within the water column, such as hydro-acoustics methods and optical plankton counters (Stockwell et al., 2002; Finlay et al., 2007; Watkins et al., 2017; Scofield et al., 2020). These tools allow researchers to study in situ zooplankton distributions on much finer depth scales, as well as over much larger horizontal scales, than can be accomplished with traditional approaches like stratified net tows. For example, both stationary and towed acoustics transducers have been used to track DVM of *Mysis diluviana* in large deep lakes. This extremely light-sensitive omnivorous zooplankton species typically migrates from the hypolimnion to the metalimnion at night, remaining below the thermocline even at night (Euclide et al., 2017; Jensen et al., 2009). Laser optical plankton counter (LOCP) technology has shown that at times, zooplankton is concentrated in narrow thin layers of extremely high density within the metalimnion, especially during the day; zooplankton biomass within this layer may be an order of magnitude greater than the surrounding waters (Fig. 4; Vanderploeg et al., 2015; Scofield et al., 2020). Furthermore, extremely fine-scale differences in the distributions of different size groups of zooplankton can be observed using tools such as the LOCP, potentially shedding light on niche partitioning and/or predator-prey dynamics that may occur within the zooplankton.

Summarizing, DVM involves changes in depth distribution over a diel cycle, can take extreme forms, and shows tremendous variation through time as well as among life stages, species, and lakes. All four examples illustrated by the figures represent the most commonly observed pattern of migration, with the animals residing deeper in the water column during the day than during the night ("standard migration"). However, it should be mentioned that many natural zooplankton populations exhibit a clear-cut depth distribution that does not change over a diel cycle, and there are also observations of a range of non-standard migration behaviors, including partial migrations (Bayly, 1986; Ogonowski et al., 2013; Euclide et al., 2017) and "reverse migrations"—deeper during the night than during the day (Hairston, 1980; Ohman et al., 1983). The reverse pattern of DVM is less common, but it is nevertheless observed in several, often small-bodied species, such as rotifers (Dumont, 1968).

In the face of this overwhelming diversity in DVM patterns among species and populations, it is important to develop a broad perspective that allows structuring the observed variation. DVM can be considered a habitat selection behavior. More specifically, it is a depth selection behavior that consists of several elements that can vary among habitats, species, and populations: the depth at which the animals reside during the day, the depth at which they reside during the night, and the timing and speed of the migration from one depth to the other. This approach has proved productive in framing the observed variation in DVM patterns. For instance, it allows the viewing of the many observations of strong but constant depth preference during day and night as a DVM phenotype that may be selected for if the optimal depth is the same during the day and night, e.g., because it is only determined by the distribution of food. The ubiquity of standard migration would then reflect the fact that under a wide variety of circumstances it is adaptive to stay deeper in the water column during the day than during the night. It is revealing that DVM, viewed as a habitat selection behavior, is essentially very similar to twilight activity as reported for many small mammals, or the migration of aquatic macroinvertebrates in rivers to the underside of stones during the day. Furthermore, as a habitat selection behavior, DVM can also be considered an alternative to diel horizontal migration (DHM). DHM has been observed in many zooplankton species in shallow lakes with a well-developed littoral zone (Kvam and Kleiven, 1995; Burks et al., 2002). In a typical DHM migration, the zooplankton resides in the macrophyte vegetation in the littoral zone during the day and moves into the open water during the night. DHM shows many parallels to DVM: it exhibits similar diel dynamics, with the main movements being associated with dawn and dusk, and in both cases, the zooplankton moves to rather marginal habitats during the day.

Causes of DVM

What causes zooplankton to migrate vertically in a diel cycle? It is important to make a distinction between the proximate and ultimate factors leading to DVM in nature.

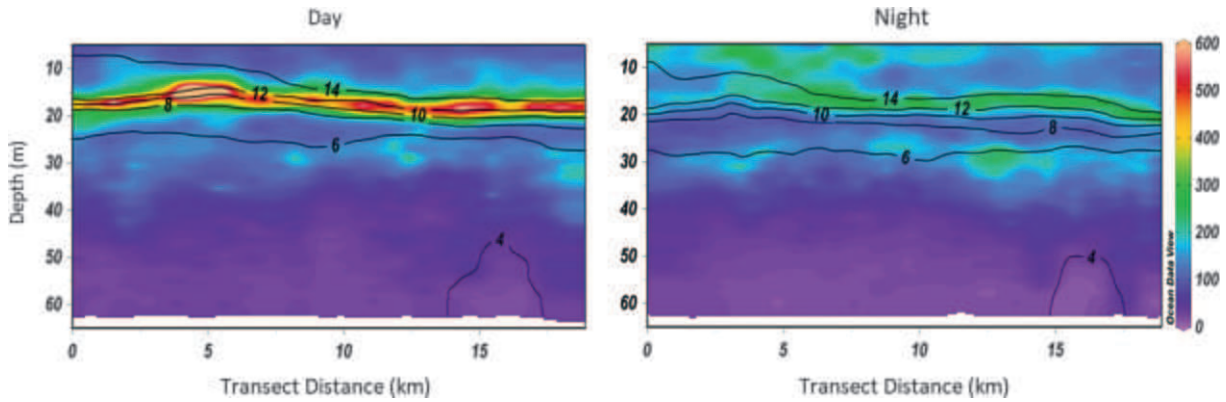

Fig. 4 Distribution of total zooplankton biomass at a transect in the open waters of Lake Michigan during the day (left) and night (right), based on laser optical plankton counter (LOPC). Data were collected offshore from Saugatuck, Michigan, U.S. on July 10–11, 2015. The transect distance is from east to west. The color scale indicates zooplankton biomass (μg dry weight/m^3), and the contour lines with labels show isotherms to visualize the thermocline. Redrawn from Scofield AE, Watkins JM and Rudstam LG (2020). Heterogeneity in zooplankton distributions and vertical migrations: Application of a laser optical plankton counter in offshore Lake Michigan. *Journal of Great Lakes Research* 46: 780–797.

Proximate causes

Proximate causes are the stimuli from the immediate environment of the individual organism that trigger the animal to move downwards or upwards. These stimuli–response processes relate to the physiology of the organism and translate environmental cues into the selection of a specific day- or nighttime depth as well as into a particular timing and speed of migration. It has been convincingly shown that zooplankton DVM is a response to relative changes in light intensity. Elegant laboratory experiments have revealed that a decrease in light intensity that surpasses a specific threshold elicits an upward movement, whereas an increase in light intensity above a specific threshold elicits a downward movement (Ringelberg, 1964, 1999). These responses have been called "secondary phototaxis"—in contrast to "primary phototaxis" that involves a response to a constant light intensity. Most detailed experiments have been carried out with the water-flea *Daphnia* and have shown that changes in light intensity result in eye rotations, which then translate in a change in body orientation and an upward or downward swimming behavior. These simple secondary phototaxis responses may allow for the prediction of day and night time depths as well as the timing and speed of migration. Moreover, several modifying factors affecting zooplankton migration behavior have been identified. For instance, the presence of fish kairomones (i.e., chemicals produced by fish that are recognized by zooplankton as indicating risk of predation) has been shown to increase the sensitivity to changes in light intensity, which translates into an increase in DVM amplitude in the presence of fish (De Meester et al., 1999). In contrast, both a strong temperature gradient and the absence of food may reduce the responsiveness of zooplankton to relative changes in light intensity, thus altering DVM behavior under different environmental conditions (Dini and Carpenter, 1992).

Ultimate factors

To the question why the zooplankton engages in DVM, one can also answer with reference to the ultimate factors causing DVM, i.e., its adaptive significance (Lampert, 1989). For a long time, the adaptive significance of DVM remained enigmatic, as researchers were puzzled by the fact that the zooplankton resided in deep, cold water layers that are characterized by low food concentrations during a large part of the diel cycle. Initially, many authors were convinced that DVM was a side-product of the visual system (Ringelberg, 1964). Others believed that there were metabolic advantages associated with residing part of the time at a lower temperature (Enright, 1977). These hypotheses were, however, at odds with empirical observations and are unsatisfactory with respect to the synchronized timing of DVM. The currently most widely accepted explanation for DVM in zooplankton is that it acts primarily as a predator-avoidance mechanism (Gliwicz, 1986a; Bollens et al., 1992; Stich and Lampert, 1981; Lampert, 1989; De Meester et al., 1999), driven by complex trade-offs between predation risk and optimal environmental conditions for feeding and growth (Lampert et al., 2003). The animals move into the deeper and darker water layers during the day to avoid predation by fish or visually-oriented predatory zooplankton (Bourdeau et al., 2011), returning to preferred habitat with warmer temperatures and higher food concentrations during the cover of night. When in oligotrophic lakes phytoplankton resources are concentrated in deep chlorophyll maxima, the cause of migration to the surface may be less apparent (Williamson et al., 1996; Winder et al., 2003).

There are many lines of evidence pointing to the importance of predator-avoidance in DVM, most of them being related to the observation that variation in DVM can often be explained by variation in predation risk:

- First, the hypothesis is logical: fish need light to detect their prey efficiently, and by hiding in the darker water layers, the zooplankton can reduce mortality by visually hunting fishes. During the night, the zooplankton moves to the upper water layers to feed on algae that remain in the epilimnion because they need sufficient light for photosynthesis. Thus, the hypothesis can explain both the day- and nighttime depth distributions, as well as the timing of the upward and downward migrations.
- Overall, there is a tendency for larger zooplankton species to migrate more or with more amplitude than smaller species. For instance, large *Daphnia* species migrate to deeper water layers than smaller crustacean zooplankton, whereas rotifers often do not migrate at all.
- Smaller life stages often migrate with less amplitude or do not migrate at all (e.g., Fig. 2).
- Individuals that are more conspicuous, such as egg-bearing females, often migrate with more amplitude (Vuorinen et al., 1983).
- It has been reported repeatedly that also within a population, there is a tendency for a correlation between body size and daytime residence depth within a given lake (De Meester and Vyverman, 1997) and in experimental settings (De Meester et al., 1995).
- Among-population variation in DVM amplitude can sometimes be related to differences in predation risk by fish (Fig. 5; Dini and Carpenter, 1991) This is illustrated by the absence of migration in many fishless lakes (e.g., Gliwicz, 1986a).
- Many populations show seasonal variation in DVM amplitude that can be explained by seasonal variation in predation risk by fish (highest in summer when the young-of-the-year are roaming through the pelagial; e.g., Fig. 6; Ringelberg et al., 1991; Bollens et al., 1992).
- Very direct evidence for the predator-avoidance hypothesis is provided by the many experimental studies that have shown that DVM behavior can be induced by the presence of predator-specific (fish and invertebrate predators) chemicals (kairomones; Fig. 7; Loose, 1993; De Meester et al., 1999).
- Several mathematical models have shown that DVM behavior can indeed be adaptive as a predator-avoidance strategy, i.e., that the benefits outweigh the costs of staying at low food and temperature during part of the diel cycle (Fiksen, 1997; Liu et al., 2003).

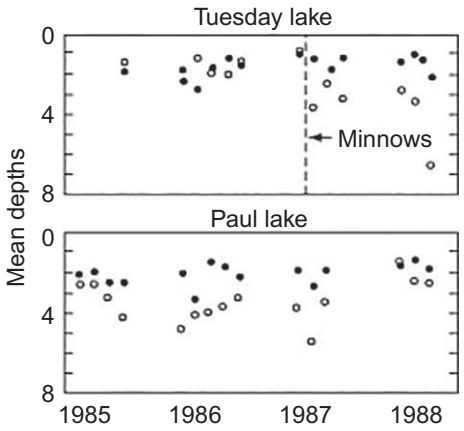

Fig. 5 Impact of fish on DVM: field data from Tuesday and Paul Lake, two kettle lakes at the University of Notre Dame Environmental Research Center. Shown are night (solid symbols) and day (empty symbols) average depth of the *Daphnia* assemblage in the two lakes as determined from vertical profiles taken during several sampling campaigns across four summers. In 1985 and 1986, Tuesday Lake was biomanipulated, resulting in a strong reduction in fish predation pressure; in 1987, fish were reintroduced to the lake, resulting in quite high minnow densities. DVM amplitude of the *Daphnia* assemblage is associated with the presence of planktivores. Paul Lake was not biomanipulated, and harbored planktivorous fish during the whole period. Reproduced from Dini ML and Carpenter SR (1991) The effect of whole-lake fish community manipulation on Daphnia migratory behavior. *Limnology and Oceanography* 36: 370–377, with permission from American Society of Limnology and Oceanography.

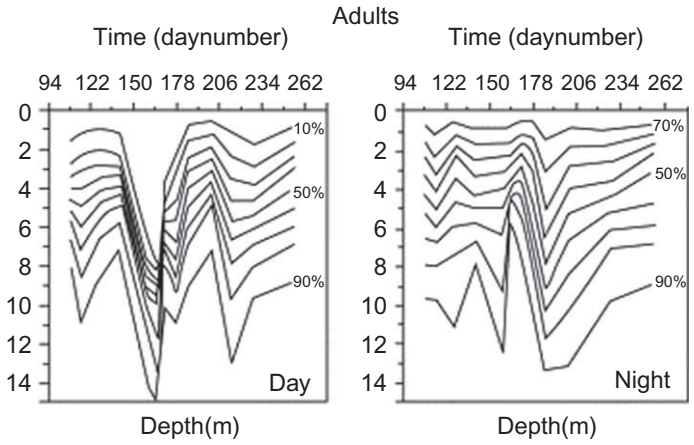

Fig. 6 The changes in day (left) and night (right) depth of adult *Daphnia hyalina x galeata* hybrids in Lake Maarsseveen during the course of the growing season (April 18—September 141,989). The dip in the bundle of lines indicates the period of strong DVM. This period corresponds with the massive appearance of juvenile perch in the pelagial of the lake. Reproduced from Ringelberg J, Flik BJG, Lindenaar D and Royackers K (1991). Diel vertical migration of Daphnia hyalina (sensu latiori) in Lake Maarsseveen: Part 1. Aspects of seasonal and daily timing. *Archiv für Hydrobiologie* 121: 129–145, with permission from E. Schweizerbart'sche Verlagsbuchhandlung.

- Evolution of DVM behavior linked to changes in predation pressure within a single lake (Cousyn et al., 2001; Stoks et al., 2016) or in experimental settings also provides strong evidence for predation being an important selection factor driving DVM.

The evidence for the predator-avoidance hypothesis is overwhelming. Yet, predator avoidance need not be the sole adaptive value of DVM. Indeed, some cases of day depth distribution or DVM cannot be satisfactorily explained by the predator avoidance hypothesis. Recently, evidence has accumulated that an important adaptive value of DVM may lie in the avoidance of damage caused by UV-radiation, or more generally, by high light intensity (Fischer et al., 2015; Urmy et al., 2016; Williamson et al., 2011). Especially in transparent high-altitude lakes, the presence of fish may not be the only or even the main reason for DVM behavior to develop. UV-avoidance can also explain the pattern and timing of typical normal DVM behavior. Moreover, there is an intrinsic interaction between UV- and predator-avoidance, as animals have two mechanisms to avoid photodamage: they may accumulate protective pigments, or they may migrate vertically. In the absence of predators, protective pigments may be the more beneficial option, but in the presence of predators, DVM may be the better alternative because pigmentation bears a high cost of increased predation risk (Hansson et al., 2007). It is often observed in alpine lakes that copepods are pigmented, whereas cladoceran zooplankton are not and migrate vertically (Hairston, 1980). What drives this difference is insufficiently understood, but it

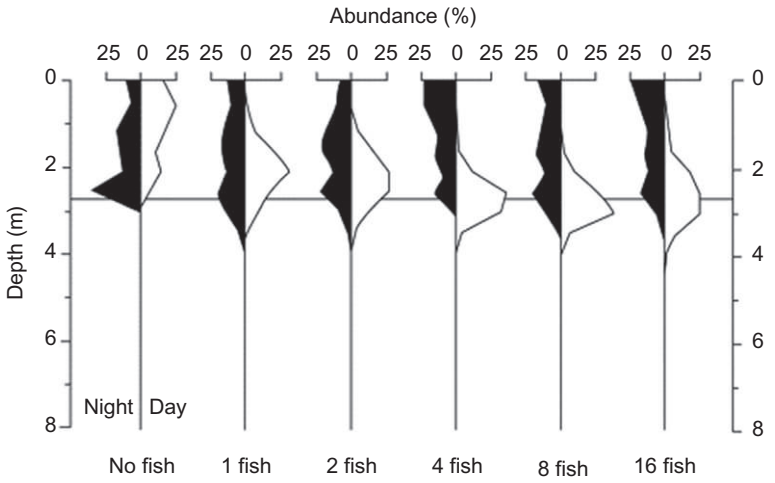

Fig. 7 Induction of DVM by fish kairomone in a clonal population of *Daphnia galeata x hyalina* hybrids in an experiment using the Plankton Towers at the Max Planck Institut for Limnology, Plön. The experiment was started without fish. Then, the upper 3 m of the tank received water that was conditioned by one fish (*Leucaspius delineatus*, 5 cm body length). After 4 days of adaptation, the vertical profile was recorded again at night and during the day. Subsequently, the number of fish was doubled, and the same procedure was continued three more times (cf. up to 16 fish). Reproduced from Loose CJ (1993) Daphnia diel vertical migration behavior: Response to vertebrate predator abundance. *Archiv fur Hydrobiologie-Beiheft Ergebnisse der Limnologie* 39: 29–36, with permission from E. Schweizerbart'sche Verlagsbuchhandlung.

might be related to the fact that most copepods are relatively small and better swimmers than water fleas. Alternatively, it may be that copepods have better capacity to accumulate photoprotective pigments from their food.

A third ultimate reason to exhibit a typical depth distribution or DVM may be avoidance of competition. This has been shown experimentally in rotifers (Dumont, 1968), and it is a likely reason for depth selection of small zooplankton, which may avoid depths at which larger bodied zooplankton accumulate. It should be noted, however, that this mechanism can only operate in a situation where the competitively superior species is restricted to its depth distribution by additional factors. If competitively dominant large bodied water fleas are forced to hide in the deeper water layers by predation risk or UV radiation, then this may open a window for coexistence of smaller species that occupy the upper water layers during the day. During the night, these smaller species may avoid the upper water layers to reduce interference competition with the large bodied species. The result is a reverse migration. A reverse migration may also be associated with the avoidance of invertebrate predation (Ohman et al., 1983; Gilbert and Hampton, 2001). Small bodied species are more vulnerable to invertebrate predators, and as these may be forced to hide in deeper waters during the day because of predation risk by fish or larger invertebrate predators such as notonectids, the small bodied species may increase their fitness by residing in the upper water layers during the day and then spread over the water column during the night, when the invertebrate predators move up into the open water to search for prey (Gilbert and Hampton, 2001).

Costs

Viewing DVM as a habitat selection behavior provides a flexible approach to the overwhelming variation in DVM patterns, as the observed day and night time depth distribution as well as timing and speed of migration can be considered to be selected because they provide a high benefit to cost ratio. The benefits of DVM are, as mentioned, often related to reduced mortality by predation, but also reduced damage from high light intensities, and in some cases, reduced competition. The costs are largely cast in terms of reduced food intake, reduced food quality, increased competition (when several competing taxa are migrating to the same refuge), and metabolic costs associated with residing at a lower temperature. In addition, there may be costs associated with residing in truly marginal habitats, such as near-anoxic conditions or being buried in sediments. Residing at or near the sediments can also increase the risk of infection by increasing the likelihood of taking up infective parasite spores, as has been shown in the water flea *Daphnia* (Decaestecker et al., 2002). The costs associated with the movement from one depth layer to the other has, however, been shown to be relatively low or even negligible (Vlymen, 1970; Dawidowicz and Loose, 1992). This is because the animals in general must actively swim to keep their position in the water column anyway, coupled with the observation that the descent is often passive. During the descent, the animals become less active, and they become more active during the ascending phase. In simple wording: if a water flea shows its typical hop–sink–hop–sink swimming behavior to keep its vertical position, descending is accomplished by hop–sink–sink–hop–sink–sink and ascending by hop–hop–hop–sink behavior. One can imagine that the energy lost during the ascending phase matches more or less the energy gained during the descending phase.

Linking proximate and ultimate factors in DVM

The previous paragraphs picture a situation in which the most advantageous DVM behavior may strongly differ from lake to lake. The question then arises as to how this is matched with the response to proximate stimuli. How do the physiological responses of the animals lead to the right vertical distribution during the day and night and the right timing and speed of the ascent and descent? There are two possible mechanisms that are not mutually exclusive, and both of which are supported by experimental evidence. On the one hand, part of the variation in DVM behavior can be accomplished by phenotypic plasticity, through a change in behavior at the level of the individual. It has, for instance, been shown that predator kairomones and hunger influence the sensitivity of zooplankton individuals to relative changes in light intensity, resulting in a modification of DVM behavior (Van Gool and Ringelberg, 1995; De Meester et al., 1999). Populations may thus adjust their DVM behavior by showing the appropriate phenotypic plasticity in response to changes in environmental conditions. At the same time, it has been shown that there is ample genetic variation for DVM behavior, among others through laboratory quantitative genetic analyzes of the variation in response to a light gradient (Fig. 8; De Meester et al., 1995) and, to a lesser extent, changes in light intensity. Moreover, it has been shown that there is also genetic variation in phenotypic plasticity for DVM, at least in the water flea *Daphnia* (De Meester, 1993). This sketches a picture of very high flexibility: populations can adjust their DVM behavior by phenotypic plasticity of the individuals as well as by changes in genetic composition with respect to DVM. It has indeed been shown that populations show local genetic adaptation for DVM in relation to predation risk (De Meester, 1996). Furthermore, reconstruction of microevolution in DVM behavior on laboratory populations hatched from dormant egg banks that were isolated from a dated sediment core has shown that local populations can genetically track changes in fish predation pressure over a period of less than a decade (Cousyn et al., 2001; Stoks et al., 2016).

The picture that emerges is that DVM is an important component of an antipredator strategy in many populations of zooplankton. It should be emphasized that DVM should not be seen in isolation from other antipredator traits (Stoks et al., 2016). It has, for instance, been shown that there is often a relationship between size at maturity and day-depth, with larger animals residing in deeper water layers than smaller ones (De Meester et al., 1995). Different genotypes and species may thus differ in the antipredator strategy they employ. This is nicely illustrated in the differences in migration pattern of *D. galeata* and *D. hyalina* in Lake Constance (Fig. 3; Stich and Lampert, 1981). The strategy of *D. galeata* involves a high predation risk associated with continuous residence at higher temperatures and under good food conditions. This results in high birth and death rates. The strategy of *D. hyalina* is to reduce mortality rates and bear the cost of having lower birth rates. The fact that both species can co-occur in the lake

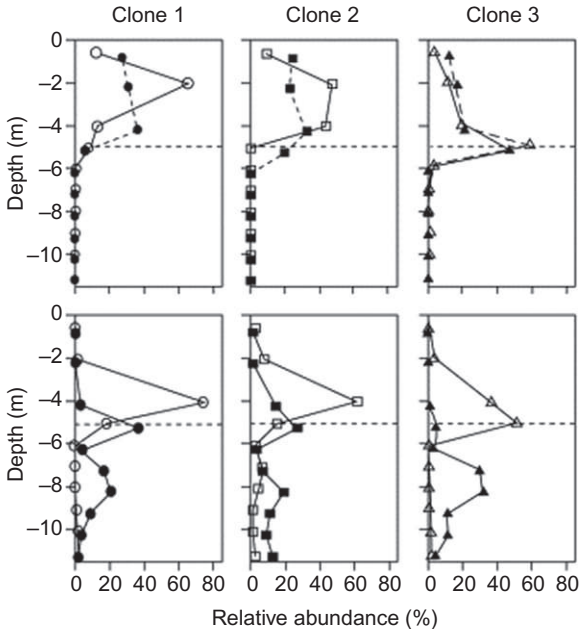

Fig. 8 Vertical distribution of three *Daphnia hyalina x galeata* hybrid clones isolated from the same population (Schöhsee, Germany) in the Plankton Towers of the Max Planck Institute for Limnology (Plön), showing genotypic differences in DVM behavior. Top: Average vertical distribution of adult females during the day (open symbols) and night (solid symbols) in the absence of fish chemicals or fish; bottom: daytime distribution in the presence of fish chemicals (open symbols) and fish (solid symbols). The dotted line indicates the thermocline. The experiment involved mixed populations of the three clones, and individuals were identified using allozyme markers. Clone 3 has a clearly different vertical distribution from clones 1 and 2. Reproduced from De Meester L, Weider LJ, and Tollrian R (1995) Alternative anti- predator defences and genetic polymorphism in a pelagic predator–prey system. *Nature* 378: 483–485, with permission from Nature Publishing.

illustrates that both strategies may have similar fitness. Part of this relationship is also observed at the genotypic level, with larger bodied genotypes showing a stronger response to light gradients (De Meester et al., 1995). Similarly, DVM behavior and pigmentation are both photoprotection strategies, of which the relative importance may be strongly influenced by predation risk. Both pigmentation and DVM have a cost, but the cost of pigmentation is strongly dependent on predation risk (Hansson et al., 2007).

Consequences of DVM

DVM has important consequences, as it strongly influences the top–down impact in lake food webs (Lampert and Taylor, 1985; Lampert and Sommer, 2007). DVM reduces the direct impact of fish predation on zooplankton. A more subtle consequence of DVM is that populations of large bodied zooplankton may survive longer in the lake, which thus extends the time during which this food resource remains available for the fish to feed on. In this sense, DVM can be expected to strongly buffer predator–prey interactions between fish and zooplankton. With respect to the zooplankton–algae interaction, DVM has been shown to strongly affect the grazing impact of zooplankton on algae (Lampert and Taylor, 1985; Reichwaldt and Stibor, 2005; Haupt et al., 2009). Here again, however, this has two aspects to it. On the one hand, grazing impact would be higher in the absence of fish-induced DVM, because DVM reduces the time during which zooplankton resides in the epilimnion to feed on algae. On the other hand, DVM may allow large bodied zooplankton to survive in lakes that harbor fish. Given that large bodied zooplankton are more efficient phytoplankton grazers than small bodied zooplankton (Gianuca et al., 2016), DVM may thus indirectly promote the grazing impact of zooplankton on algae, as it allows large-bodied zooplankton to graze on phytoplankton during at least part of the day. In lakes in which the zooplankton exhibits a strong DVM, the algae are indeed fed on by large and efficiently grazing zooplankton during the night. The impacts of DVM on population dynamics of zooplankton and algae and on predator–prey interactions are thus very pervasive. A nice illustration of the impact of DVM on population dynamics is given by the observation of a lunar cycle in zooplankton densities in Lake Kariba (Gliwicz, 1986b). The population densities of zooplankton species in this lake have been reported to show cyclic changes associated with increased predation success of fish on zooplankton during moonlit nights at full moon. In the tropics, sunset and moonrise occur quite fast, and at full moon, the zooplankton is trapped in the surficial water layers by the suddenly rising full moon, providing a feast for the fish.

An interesting avenue of thought in this context is the impact of predator-induced plasticity in DVM on predator–prey interactions and top–down control in lakes. As DVM has strong impacts on top–down control, it should be recognized that part of the impact of predators is actually mediated by induced avoidance behavior rather than by direct predation itself (Haupt et al., 2009).

Reverse migrations

We have focused on the DVM behavior of herbivorous zooplankton (mainly cladocerans, copepods, and rotifers). Omnivorous and predatory zooplankton may, however, also strongly engage in DVM. A good example is the fish-induced DVM behavior of phantom midge larvae (*Chaoborus*) (Dawidowicz et al., 1990). *Chaoborus* species that inhabit fishless habitats do not migrate vertically, but in fish lakes, the animals often migrate to the sediments during the day and appear in the water column at night (e.g., Oda and Hanazato, 2008). This is believed to be a strong structuring force on the zooplankton in lakes. During the day, large-bodied zooplankton, including *Chaoborus* larvae, hide in the deep water layers as a refuge from fish predation. By doing so, they provide enemy-free space to small-bodied zooplankton. The small-bodied zooplankton may, however, move out of the high food upper water layers during the night, as these layers are then invaded by efficiently grazing large-bodied zooplankton and gape-limited invertebrate predators that hunt for the small-bodied zooplankton. The resulting pattern is a strong standard migration for larger zooplankton and *Chaoborus* and a reverse migration for smaller zooplankton (Lagergren et al., 2008).

There is an interesting parallel in large, motile phytoplankton. Algae often perform a "reverse" DVM, residing deeper in the water column during the night than during the day. There is much less literature on DVM in algae, but here too, it is a useful approach to consider it a habitat selection behavior (Cullen, 1985; Heaney and Eppley, 1981; Ralston et al., 2007). There are two main reasons for DVM in algae. First, it may be a strategy to combine efficient photosynthesis during the day with a reduction of mortality by zooplankton grazing during the night. Alternatively, DVM of algae may also be a strategy to increase nutrient uptake. By migrating to deeper and nutrient-rich layers during the night, the phytoplankton may increase nutrient availability for photosynthesis during the day, thus reducing the impact of nutrient depletion in the epilimnion (Baek et al., 2009; Heaney and Eppley, 1981).

DVM in fish

Fish have also been reported to migrate vertically. They may do so for two reasons—to follow their prey, and to avoid their predators. Even though it is much less efficient to hunt in deeper water layers, it may still be more profitable for fish to follow their food in suboptimal conditions, rather than remaining in a habitat that is devoid of any food. It has been shown that fish may even venture for short dives into the near-anoxic conditions to hunt for zooplankton that use these inhospitable layers as a refuge (Rahel

and Nutzman, 1994). This may explain why zooplankton often migrate deeper than the border zone of the refuge. In turn, fish might migrate to avoid their own predators. By avoiding the surface waters during the day, they may reduce their mortality from both fish-eating birds and fish. Many fish populations have been reported to either change their vertical or horizontal distribution. In the latter case, they hide in the littoral zone during the day and migrate to the pelagial during the night (Bohl, 1980). Given that studies often show that both fish and zooplankton avoid the surficial layers of the pelagial zone during the day, one may wonder why the zooplankton does not simply reinvade the food-rich upper water layers. There are several explanations for this. First, it should be acknowledged that in zooplankton populations that show a very strong DVM behavior, intensive sampling of the superficial water layers often reveals some individuals residing there at very low densities. Secondly, it is easy to imagine that, if densities in the superficial layers would become higher, the fish would also rapidly start exploring this food source. Given that hunting at high light intensities is so efficient, even short excursions of the fish to these water layers would decimate the zooplankton. So, one expects densities of larger bodied zooplankton to be very low in the epilimnion in such lakes, which is the pattern that is observed.

It is intriguing that the vast majority of fish DVM is performed by species that can be classified as belonging to the cold-water thermal guilds. These species have thermal optima and preferences for water temperatures that are typical for the hypolimnion of stratified lakes (~4–12 °C). Accordingly, the standard DVM is characterized by a switch between deep and very cold hypolimnetic layers during daytime and shallower and warmer layers close to the thermocline during night-time. DVM patterns by which fish migrate from the hypolimnion through the thermocline up to the surface during the lake stratification phases have been rarely observed, while fish more often migrate into very shallow layers during the mixing phases when lakes are isothermal. Fishes of the warm-water guild seem to migrate dominantly horizontally between littoral (daytime) and pelagic (night-time) habitats within the epilimnion (Bohl, 1980), similar to the DHM of zooplankton.

The main proximate cue of fish DVM is the diurnal change in illumination strength, inducing migrations upwards in the water column during dusk and downwards during dawn for the standard DVM (Appenzeller and Leggett, 1995, Scheuerell and Schindler, 2003). There are several empirical observations that DVM stops when the vertical light gradient is strongly weakened, for example during the polar summer or if lakes are covered by thick ice and snow layers (Gjelland et al., 2009, Jurvelius and Marjomäki, 2008). However, the triggering of migrations by light intensity is superimposed by a small-scale orientation along vertical temperature gradients, which causes seasonal changes in night-time depths and hence migration amplitudes (Levy, 1990). If vertical depth and extension of the thermocline change over the months, fish likewise change their night-time depths to always being located in layers with their metabolically optimum temperatures (Mehner et al., 2010).

Ultimate explanations for fish DVM include feeding opportunities and predator avoidance, similar to the reasoning for the DVM of zooplankton. This creates the fascinating situation that zooplankton in stratified lakes are squeezed between warm-water planktivorous predators enforcing a standard DVM in zooplankton, and cold-water planktivores against which a reversed zooplankton DVM would be the best strategy. Under these conditions, amplitudes of standard zooplankton DVM are often small and spatially confined to the epilimnion and the upper part of the thermocline. Evidence that either feeding efficiency or predator avoidance alone explains fish DVM is rarely found. For example, planktivorous fish do not follow zooplankton DVM to maximize feeding efficiency. And fish DVM is often found also in systems where the predator density is very low, such that predator avoidance is unlikely to be the sole ultimate explanation. A third ultimate explanation for fish DVM is referred to as bioenergetics efficiency, for example by a "hunt warm—rest cool" strategy. Here, it is assumed that the temperature optimum for hunting and feeding differs from that optimal for digestion. Empirical evidence for fish DVM solely be explained by bioenergetics efficiency is likewise equivocal, at best (Neverman and Wurtsbaugh, 1994; Mehner et al., 2011).

Accordingly, a multi-factor ultimate explanation may be more suitable to understand fish DVM. One example is the "anti-predation window," based on the observation that the visual ranges of fish predators and their fish prey differ substantially (Scheuerell and Schindler, 2003). Planktivorous fish (the prey) can feed at lower light intensity than their predators (piscivorous fish) and hence may find a refuge under darker conditions. Therefore, prey fish actively seek layers characterized by this low illumination and continue feeding during the day but because of high light at the surface, these layers are relatively low in the water column. The layer with the optimal illumination moves upwards at dusk and downwards at dawn. Prey fish can move within this anti-predation window and therefore feed along the zooplankton gradient while ascending and descending. In this way, prey fish minimize the ratio between predation risk and feeding gain or growth (Scheuerell and Schindler, 2003). This concept can be expanded by also including bioenergetics efficiency. Predator avoidance causes the fish to stay in deep layers by day. Feeding opportunities drive the migration within the anti-predation window. Bioenergetics efficiency is enhanced when fish seek layers of optimum temperature at night. Therefore, DVM often reflects a three-way compromise between the three ultimate hypotheses on fish DVM—feeding efficiency, predator avoidance, and bioenergetics efficiency (Mehner, 2012).

Multi-factor ultimate explanations also reflect that DVM is an ecological trade-off for fitness optimization. Prey density, temperature, and light level affect feeding and hence growth rates, whereas predator density and illumination strength affect predation risk. It is expected that the costs of DVM incurred by residing in water layers that are suboptimal with respect to feeding are balanced by the benefits to minimize predation risk. An additional and almost unexplored cost in fish DVM is the energy needed for the movement itself. Most of the fish species possess a swim bladder, and hence the vertical movements during crepuscular phases induce changes in the compression of the swim bladder at the differing depths. It is likely that pressure compensation is not fast enough to keep neutral buoyancy of fish at all depths during the migration, hence indicating that fish must swim actively against the negative or positive lift resulting from non-optimal swimbladder volumes, at least for some time during vertical migrations (Fleischer and TeWinkel, 1998; TeWinkel and Fleischer, 1998; Clemens and Stevens, 2007). Fish without swimbladders and

most invertebrates do not have this problem. The contribution of migration costs to the cost-benefit ratio of fish DVM is currently unresolved.

Most of the empirical studies of fish DVM have focused on population behaviors. However, it has to be considered that the adaptive value of behaviors is related to individuals. Deciphering ultimate causes and proximate causes for a population is, therefore, only correct if all individuals of a population would be equal in the traits relevant for the cost-benefit ratio. However, individuals of a population always differ, for example with respect to size or life-history stages. The growth of fish during their ontogeny is substantial, and hence most fish populations are strongly size-structured. Size is decisive with respect to prey selectivity, feeding efficiency and predation risk because the intensity of predator-prey interactions in aquatic systems depends on the size ratios between predators and prey. Furthermore, differing phases of the life history, for example the switch from the immature individual to one that is reproducing, may modify the relative importance of having fast growth versus being safe from predation because fast growth in length has less priority when fish start reproducing. The typically recorded fish DVM at the population level is the average of individual DVMs. Few studies have focused on individuality of DVM patterns. However, the documentation of partial DVM by which fish populations split into migrants and residents supports the predictions that the cost-benefit ratio of a DVM strategy differs between individuals. The recent technological development of acoustic devices, for example scientific echosounders or acoustic telemetry arrays (Guzzo et al., 2018), has facilitated more in-depth studies on the individuality of DVM patterns and potential biotic and abiotic correlates (Gutowsky et al., 2013).

Models of Animal Distributions in Inland Waters

Milan Říha and Marie Prchalová, Biology Centre CAS, Institute of Hydrobiology, Ceske Budejovice, Czech Republic

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Lars Rudstam.

Glossary

Biotelemetry The method uses different type of tags (active and passive) to track movement of animals or gathering information about animal environment (e.g., temperature, depth).
Diel vertical migration Very common phenomenon in both marine and freshwater ecosystems when different taxa (most typical fish and zooplankton) perform regular day night depth changes. More common for migrating organisms to be deeper during the day and shallower at night but the opposite does occur as well.
Ecology of fear Concept studying the total impact of predators on prey populations and communities. Beside direct effect of predator (prey is killed) there is strong indirect cost of predation for prey. Cost of avoiding predation ("fear") may induce prey source avoidance and thus reduce prey fitness. This indirect predation effect can have higher impact on populations than the direct effect of predation mortality.
Evolutionary stable strategies Behavioral strategy (or set of strategies) that, if adopted by all individuals in a population, cannot be replaced or invaded by any alternative strategy.
Give-up-density The quantity of food remaining in a patch when an animal leaves that patch. It is often used to measure the effect of predation on optimal patch use (predation risk cause a substantial increase in give-up-density).
Handling time The time taken to move toward and consume a food item.
Lentic and lotic environment Lotic is related to running fresh waters, lentic to stagnant, still waters.
Predation-prey cycles Predator and prey populations cycle through time. Numerous predators decrease numbers of prey and lack of prey in turn decrease predator abundance which allows prey to increase again, thereby repeating the cycle.
Reaction distances The distance in which a predator can detect a prey, usually determined as the distance an animal would travel in a straight line directly toward a food item.
Remote sensing Is the process of detecting and monitoring the physical or biological characteristics (e.g., chlorophyll concentration) of an area by measurements from satellites or aircrafts.
Trophic cascades Cascades are defined as reciprocal predator–prey effects that alter the abundance, biomass or productivity of a population, community or trophic level across more than one link in a food web.

Background and significance of distribution modeling

Who is where, when, how and why? These are the fundamental questions of ecological modeling of distribution. Where are animals? When and how do they change their distribution? Why are they at specific sites? Why do they move somewhere else? The answers to these simple questions allow us to understand interactions between animals and their environment and gain insight into

 https://doi.org/10.1016/B978-0-12-819166-8.00065-7

how spatial distributions can affect ecosystem structure and function. Distribution models also contribute to theory development and inform applied issues associated with conserving and managing natural resources.

Distribution models (DM) are tools for describing and predicting distribution of animals under variable conditions. These models use several statistical approaches to predict the location of an animal in space and time. Hence, DM require an understanding of a species basic habitat requirements, such as physical structure, depth, or temperature. The field also developed numerous frameworks and mechanistic models for understanding drivers of habitat selections. By providing mathematical descriptions of the influence of factors such as food source, quality, predation, and competition on spatial distributions, the field of DM has enabled the development of testable hypotheses that can inform ecological theory. Models based on mechanistic understanding can be used for prediction and simulation of individual, population, or ecosystem behavior under altered conditions.

In this article, the focus is given to DM based on distribution of an individual animal rather than whole species. Modeling distribution of whole species derived from habitat or niche environmental parameters represents entire field of models covering approaches such as habitat suitability and species distribution models (environmental/ecological niche modeling). Here, we briefly summarize important parameters, influential concepts and tools used in modeling distribution of animals within inland aquatic environments.

Habitat and fitness definition

Animals are not distributed randomly. Their distribution is a result of their responses to biotic, abiotic and internal factors. A habitat is defined as a location with distinct abiotic and biotic factors where animals stay, and which provide food, shelter or mates (e.g., open water, bottom sediment or littoral structured habitats; Begon and Townsend, 2006). DM are often descriptions of an animal's habitat selection or habitat selection rules.

Animals usually change habitats during their lifetime. This change may occur within a lake, between marine and freshwater environments, or between aquatic and terrestrial ecosystems. Even sessile animals may have a highly mobile dispersal stage, such as gametes, seeds, or eggs. These movements depend on external or internal factors and can be of various spatial (e.g., a few centimeters or thousands of kilometers) and temporal (lifetime, year, seasons, diel cycle, etc.) scales. These changes should increase an animal's fitness as defined by its contribution to the gene pool of the next generation (Begon and Townsend, 2006). However, fitness is affected by a combination of variables (prey, predators, mates, abiotic factors) and the importance of these variables will change through the lifespan of an animal. Given the complexity of factors driving fitness, a key challenge for DM is selecting a measurable indicator (or proxy) for fitness. In DM, maximization of fitness or one of its components (feeding rate, growth, fecundity, predation risk, mortality) is usually used for finding the best strategy for habitat selection or movement among habitats (Giske et al., 1998).

Time scale and animal unit

Animals may change their distribution on hourly, daily, seasonal or even longer time scales depending on the species. DM need to operate on a time scale relevant to the animals and movements in question. Therefore, models are constructed to operate at different time scales, from hours (e.g., models of patch selection according to food resource quality), to diel cycle (e.g., diel habitat switch such as vertical migrations in lakes), to seasons (long-distance migrations), and to years (whole life cycle migrations).

DM also need to specify the animal units to be modeled, again given the questions the model intends to answer. Even within a species, spatial distribution may differ between individuals, certain personality types, ecospecies (e.g., individual sex, larvae, adults, cohorts, etc.), and different populations. Selection of an animal unit influences model complexity. The more complex the animal unit, the greater is the uncertainty in the model structure and parameters. Individual models can reflect specific individual behavior and variation, while ecosystem models often omit individual interactions and work instead with functional groups or whole species.

Abiotic factors

The key abiotic factors considered by spatial models in aquatic environments are temperature, depth, oxygen, light and current (Fig. 1, Giske et al., 1998). Temperature drives the rate of metabolic processes for nearly all freshwater animals (except water birds and mammals) and limits the occurrence of animals to the temperature ranges to which the animals are adapted (e.g., Hofmann and Fischer, 2002; Riha et al., 2017). In lakes and reservoirs (lentic systems), temperature is tightly correlated with depth and both are typically considered when modeling depth distributions. In temperate stratified waters, available temperatures can range from 4 °C at the bottom or even almost 0 °C close to ice to over 30 °C at the surface during the summer. Thus, depth preference is driven by species-specific temperature requirements and by metabolic advantages of being in cold or warm temperatures (Wurtsbaugh and Neverman, 1988; Lampert, 2005; Mehner, 2012).

Similarly, oxygen is a key element for most animals. Oxygen concentrations have to be included in DM when oxygen can be depleted, as is the case of hypolimnion of many eutrophic stratified lakes in the summer (Hanke et al., 2014).

Another important factor is light. Light availability largely determines how predator and prey can detect each other as well as the distribution of primary producers. Light is used in calculating reaction distances, an important part of predator-prey models and

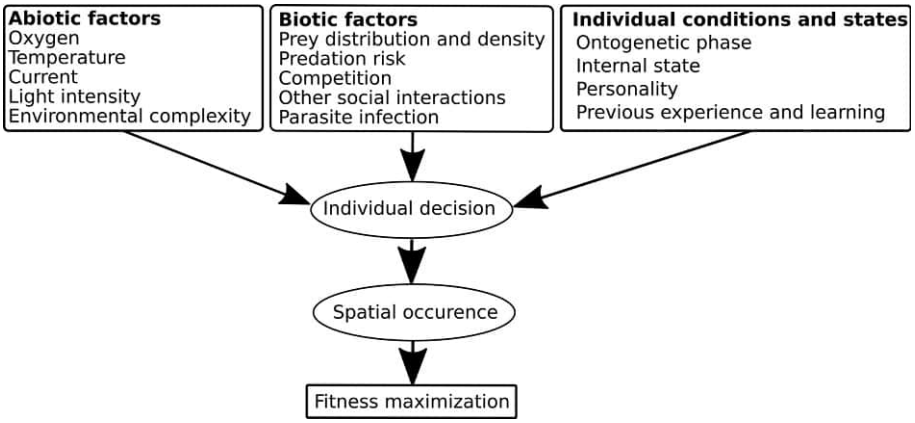

Fig. 1 Schematic overview of external and internal drivers influencing individual decision for spatiotemporal presence.

defined as the visual range in which the animal can detect prey (Vogel and Beauchamp, 1999). Light is also a factor in describing an animal perception of predation risk (Boscarino et al., 2010) and is used to understand the distribution of primary producers that are food sources for animals (Scofield et al., 2020).

In rivers and streams (lotic systems), water flow causes drag that requires additional energy for the animal to hold position or move upstream. How water flow affects habitat selection or migration pathway is often considered in river habitat selection models and in models predicting movement pathways through river or river obstacles such as weirs or fish passes (McElroy et al., 2012).

Biotic factors

The most important biotic factors considered in DM are food source (quality and distribution) and effect of inter- and intra-species interactions, especially predation and competition (Fig. 1). The effects of food source, predation and competition have been intensively studied over the last 30 years, yielding several important concepts for understanding distribution dynamics (see below). Other biotic interactions, such as parasitism (Barber et al., 2000; Poulin, 2013), diseases (Lefcort and Blaustein, 1995), and positive interactions such as cooperation, mutualism, symbiosis, and commensalism (Silknetter et al., 2020) can also influence spatial distributions. However, effects of these other interactions on spatial distribution in inland waters have received comparatively little attention to date (Silknetter et al., 2020).

Intrinsic individual conditions and states, such as neurobiological, developmental, or reproductive stage, can also be considered as biological drivers and some DM consider how habitat selection depends on these intrinsic factors. Juveniles and adult can differ in their need for food resources and in the risk of predation (Werner and Hall, 1974), hungry individuals likely tolerate higher predation risk (Moran et al., 2020), and learning may affect spatial distributions (Krebs and Inman, 1992). Recent research is also considering the effect of personality on the spatial distribution of animals with some individual being more risk prone and others more risk averse (Sih et al., 2015).

Model concepts and application

Next, we introduce several approaches and concepts widely used in modeling of animal distributions. These concepts are described approximately in the order they were introduced to the academic audience, as some were derived from previously developed concepts while others are more independent.

Optimal foraging theory

Optimal foraging theory (OFT) focuses on the effects of habitat quality and diet choice on the spatial distribution and movement of animals. This theory addresses the question of how long a forager should spend exploiting one food source before switching to another (Emlen, 1966; MacArthur and Pianka, 1966). A central assumption of OFT is that an animal will increase its fitness by minimizing the time and energy required to acquire the maximum amount of energy from food (Ritvo, 2018). Optimal forager should consider the quality of the food source and invest handling time for a food item only if, on average, it cannot maximize its food intake rate by passing up this food item to continue foraging and find a more valuable food item (Pyke and Stephens, 2019).

The original theory was developed in the 1970s and received considerable attention in the scientific community. Early empirical studies of this theory supported its prediction on patch and diet choice. The time spent by an animal in a food patch increased with increasing travel time between patches and decreased with increasing average patch quality (Stephens and Krebs, 1986). Werner and

Hall (1974) showed a good match of selection in size of consumed *Daphnia* (a common water flea) by bluegill (*Lepomis macrochirus*) in laboratory conditions. Ringler (1979) found that the size preference of prey for brown trout (*Salmo trutta)* in small streams was predicted by OFT. Milinski and Heller (1978) were able to predict optimal feeding strategies of stickleback (*Gasterosteus aculeatus)* while under risk of predation by kingfishers. Further examples of classical OFT studies on fish are given in Townsend and Winfield (1985).

However, quantitative comparisons between observed and expected residence times per patch have often found significant discrepancies, with foragers typically spending more time in patches than predicted by the model (Nonacs, 2001; Pyke and Stephens, 2019). The early OFT studies were found to be too simplistic and ignoring other important factors such as predation risk, competition, individual state, need for other nutrients than just calories, temporal environment dynamics, and incomplete food-source information (Gould and Lewontin, 1979; Pierce and Ollason, 1987). Therefore, the OFT framework was expanded to include these other factors. The influence of competitors on distribution was developed within ideal free distribution theory (Fretwell and Lucas, 1970), the effects of predation risk and cost of movement among source patches were developed in concepts of ecology of fear (Stephens et al., 2007) and landscape of energy (Wilson et al., 2012) and the importance of additional food resources in optimal diet theory (Sih and Christensen, 2001).

Foraging theory

Foraging theory (FT) is a result of merging OFT and Life history theory (LHT). Developed in parallel to OFT, Life history theory (LHT) is also based on optimization of various individual adaptations to maximize fitness. However, LHT considers the optimum strategies to maximize life-time fitness, whereas OFT makes the assumption that optimization of the immediate energy intake per unit time is proportional to individual fitness. Using life-time fitness maximization as a target function, it has been possible to analyze optimal lifetime reproductive patterns, energy allocation rules, phenology, and willingness to take risk (Giske et al., 1998). LHT has traditionally been concerned with questions such as the age at which an animal should first reproduce and whether it should breed once or repeatedly (MacNamara and Houston, 1996; Giske et al., 1998).

An approach that can be considered as a combination of OFT and LHT was proposed by Gilliam (1982) and Werner and Gilliam (1984). Because an animal should minimize predation risk ($\boldsymbol{\mu}$) and maximize foraging gain (growth, g), their suggestion was to use the ratio of $\boldsymbol{\mu}$/g as a measure of habitat profitability related to ontogenetic habitat shifts for pre-reproductive animals (or $\boldsymbol{\mu}$/f if we consider growth to be proportional to feeding rate, f). Studies of Mittelbach (1981) and Werner et al. (1983) showed that the presence of a piscivore (largemouth bass *Micropterus salmoides*) induced habitat segregation by size in their prey (bluegill). Such segregation resulted in increased individual growth rates for large (less vulnerable) individuals who selected open areas, and decreased growth rates for smaller (more vulnerable) individuals staying in safer, yet energetically poorer, vegetated areas. Other authors developed this approach by showing that this ratio can change with the timing of reproduction (the ratio differs when reproduction is timed to occur with seasonal events, such as increased water temperature and food production; Aksnes and Giske, 1990) or the state of the individual (Ludwig and Rowe, 1990). Further development of this approach includes attention to the physiological state of the animal as well at its condition and personality (Clark, 1994; Moran et al., 2020; Sih et al., 2015).

As the field developed, LHT and OFT were merged in Foraging Theory, which considered the effects of both short-term decisions and long-term strategies on fitness (Mangel and Clark, 1986; Giske et al., 1998). In turn, FT has spurred a large number of studies comparing predation risk, habitat use, and growth in many different aquatic taxa (Leibold and Tessier, 1997; Grossman, 2014). Persson and Greenberg (1990) studied perch (*Perca fluviatilis*) as they shifted from pelagic to benthic habitats. Brönmark et al. (2008) looked at the migration of cyprinids from a lake to winter refuge. Mehner (2012) studied the diurnal vertical migration phenomenon of fish in general.

Ideal free distribution

Ideal free distribution (IFD) theory builds on the OFT framework and offers an important baseline for predicting how foragers are distributed across resource patches and select habitat (Matsumura et al., 2010). Fretwell and Lucas (1970) put forth a continuous-input model which has become classic in the field of IFD theory. This model assumes that food items arrive randomly at different rates in different patches and that foragers consume food items immediately, with each getting an equal share of resources on the patch (Parker and Sutherland, 1986). If these assumptions are met, the distribution of foragers reaches an equilibrium when no forager can improve its intake rate by switching habitats. If two patches differ in quality, foragers move toward the point of ideal foraging density, which occurs when the density is proportional to the prey input rate in all patches (called input matching). Milinski (1979) provided a simple example of IFD distribution by conducting a tank experiment where a different number of prey (*Daphnia magna*) were offered at different rates in two sides of an aquaria containing sticklebacks. The number of sticklebacks feeding on each side reflected the ratio of patch profitability—more prey more sticklebacks; less prey, fewer sticklebacks. The distribution of sticklebacks balanced resource gains and resulted in the same amount of resources for all competitors. IFD has also been proposed as an explanation for habitat use of northern pike *Esox lucius* (Haugen et al., 2006) and vertical distribution of zooplankton (Lampert, 2005).

Early experimental studies in laboratory conditions found relatively good support for the predictions of the IFD in aquatic animals (Kennedy and Gray, 1993). However, not all studies found a distributional pattern following the model. These discrepancies between the expected and observed patterns suggest that some of the model assumptions were violated. Hence, subsequent

IFD studies attempted to include factors that might explain discrepancies, such as the effect of unequal competitors (Parker and Sutherland, 1986; Grand and Dill, 1997), predation risk (Grand and Dill, 1999), interferences (interference IFD, Parker and Sutherland, 1986), defense of territory (ideal despotic distribution, Brown, 1969; Pulliam and Danielson, 1991), and cost of travel time (Abrahams and Labelle, 2020). Ideal despotic distribution explained the distribution of salmonids during spawning (Purchase and Hutchings, 2008).

Game theory

In previous concepts (OFT, LHT, IFD), the effects of predation or competition are considered to be fixed. However, predators and competitors in the real world are often mobile and can react in real time to distribution of their prey or other competitors.

Imagine a situation where resources, foragers and their predators are distributed in patches. Foragers should consider patch quality and number of competitors, and then distribute themselves among patches according to IFD principles. When the use of some patches becomes risky (presence of a predator), foragers should redistribute according to the $\boldsymbol{\mu}/\mathbf{g}$ ratio. However, static models, such as OFT and IFD, use predation risk as a constant parameter and do not account for predators directly affecting the distribution of prey (Hugie and Dill, 1994). In the real world, mobile predators, are expected to go where prey are denser, and prey are expected to simultaneously avoid areas where there are more predators (Lima, 2002).

The framework used to explain these interactions is called game theory (GT). GT studies situations where there is a conflict of interest between two or more players (Owen, 2001). The goal of the theory is to find an equilibrium distribution where neither player, in our case animals, improves their fitness by shifting to another patch (evolutionary stable strategies EES; Hammond et al., 2007). In the predator-prey case, both predator and prey have options that can potentially thwart the other, but the consequences of these options are not intuitively obvious (Lima, 2002). For example, a predator-prey distribution model based on GT developed by Hugie and Dill (1994) predicts that prey would prefer safer habitats and that the predator, but not the prey, would be distributed according to IFD. However, a predator's IFD is not related to the density of its main prey, but to the feeding rates (production) of the prey. Such a situation is called a three trophic level IFD model, as the predator redistributes according to the abundance of the food of their prey. This model also suggests that the prey distribution may not respond to an experimental manipulation of its food resources when the predator is present. Several studies have provided empirical examples from aquatic environments supporting these GT predictions (Heithaus and Dill, 2002; Hammond et al., 2007; Luttbeg et al., 2009; Vijayan et al., 2018) and the model was further extended by Sih (1998). Beside predator-prey interactions, GT has been used to explain diel vertical migration (e.g., Iwasa, 1982; Thygesen and Patterson, 2019) and IFD (Křivan et al., 2008).

The GT approach, however, is still not fully utilized in DM of predator-prey interactions within the aquatic environment due to a lack of information about key components, such as predator behavior and spatial interactions with prey, and anti-predator behavior in a multi-predator environment (Lima, 2002).

Landscape of energy and fear

Landscape of energy (LE) and Landscape of fear (LF) are two novel approaches that attempt to model predation risk and cost of movement. Their development is mostly driven by our increased ability to precisely measure both movement of animals and quality of the environment and merging them together (Gallagher et al., 2017). These approaches are derived from OFT, but, unlike OFT, consider the importance of energy loss or exposure to predation risk during movement in real heterogeneous landscapes, riverscapes or lakescapes (Laundré et al., 2001; Wilson et al., 2012). These real-life conditions include not only profitability of habitat, but also physical barriers, structural complexity, shelters, or the presence of predators.

LE calculates required energy for transport in real conditions. It predicts that animals will move to optimize their access to resource patches and will spend as little energy as possible to move (Wilson et al., 2012). In a simple OFT model, cost of transport is usually considered as energy required to linearly move from point A to point B under constant speed. However, such an assumption is a simplification of reality. Many physical obstructions determine movement cost in aquatic ecosystems, such as currents, debris, depth, temperature, or oxygen availability. Calculating the cost of transport in each location of the real landscape creates a landscape of energy, with peaks of high cost and valleys of low cost. Projections of real trajectories of moving animals (usually obtained from tracking devices) show the energy cost to move across the landscape and whether the movement follows an optimal trajectory (where the sum costs of moving along the chosen trajectory across the different energy landscapes are minimized). These projections can also show that the optimal trajectory of getting from point A to point B can be far from linear in real-life conditions (Gallagher et al., 2017).

In freshwater environments, this concept was used mostly to find optimal pathways during fish migration through river or fish passages. For example, McElroy et al. (2012) found that Pallid sturgeon (*Scaphirhynchus albus*) selected a pathway to minimize energy expenditure during the river upstream migration. Lindberg et al. (2016) tested usage of the optimal pathway for Atlantic salmons (*Salmo salar*) within fish passages and, ultimately, informed fish passage design. Hanke et al. (2014) modeled optimal pathways to determine if silver perch (*Bairdiella chrysoura*) could escape hypoxic lake spaces.

The concept of the landscape of fear (LF) was introduced in 2001 (Laundré et al., 2001) and belongs to a broader concept called ecology of fear (Stephens et al., 2007). LF describes spatial variation of predation risk, risk perception, and prey response in a real landscape. The LF theory is based on the assumption that predators elicit a fear of being killed in their prey (so called predator-induced resource avoidance). This predator-prey interaction dynamic affect how both groups navigate through their landscapes (Power, 1984; Gaynor et al., 2019).

The visual presentation of LF is similar to LE, where the peaks represent high risk regions and valleys represent low risk regions. Thus far, LF has been largely used for visualization of predator-mediated space use. However, LF concepts are rapidly developing, and researchers have suggested ways to calculate predator-mediated energy loss for prey (e.g., effect to give-up-density or optimal movement trajectory) and further consequences for an ecosystem (Gaynor et al., 2019). The LF concept has been applied more in the terrestrial ecology, but several studies using the LF concept were recently published for coral reef fishes in marine environments (e.g., Mitchell and Harborne, 2020). Further, several recent LF studies have been done in freshwater environments (Detmer and Wahl, 2020; Manenti and Barzaghi, 2020).

Foraging arena theory

Foraging arena theory (FAT) is not an approach to predict habitat selection. Rather, this theory is a quantitative model for calculating predator-prey consumption. Unlike traditional models used to predict consumption (such as functional response models), FAT models incorporate spatiotemporal dynamics in overlap between predator and prey (Ahrens et al., 2012). FAT is based on research of behavioral interactions between predator and prey (Werner et al., 1983; Walters and Juanes, 1993; Walters et al., 1997). The basic assumption of FAT is that spatial and temporal restrictions in predator and prey activities result in the division of prey into vulnerable vs. invulnerable animals. Invulnerable prey are hidden perhaps in a refuge (close to structures, in dark or anoxic water, or burrowed in bottom sediments), and not available for predators. Only vulnerable prey share space with predators within the foraging arena and can be consumed. Predation rates are then limited by exchange rates between vulnerable and invulnerable individuals within the prey population. The foraging arena could be defined by time when a large portion of the prey are available, for example during crepuscular migration to surface or the periodic drift of benthic animals in small streams (Ahrens et al., 2012).

The FAT framework helps to explain some common features of predator-prey interactions, such as the lower-consumption rates of predators in the field compared to predictions based on laboratory experiments, the stability of predation-prey cycles, the common occurrence of trophic cascades, and the common observations that multiple predators share one prey (predators utilizing prey in different forage arenas; Ahrens et al., 2012). FAT is part of the Ecosim and Ecopath modeling software and used as the background theory for predicting the impacts of changing trophic interactions in multispecies fisheries and whole aquatic food webs.

Individual based models

Recent decades have seen increased used of Individual or Agent Based Models (IBM) as scientist need to account for individual variation when predicting at the population, community, and ecosystem levels (DeAngelis and Mooij, 2005). Spatially explicit IBM are used to investigate how local interactions and movements of animals manifest themselves in population-level consequences, in other words, investigate the collective behavior emerging from the behavior of individuals obeying simple rules. Individuals (also called agents) can vary by trophic position (predator & prey), state (juvenile & adult) or personality (shy & bold; DeAngelis and Mooij, 2005). It is also possible to incorporate learning or adaptation by individuals through time (Railsback, 2001). In spatially explicit IBM, individuals apply assigned response rules to conditions at their locations, their internal state, and their performance in previous steps (adaptive component) to achieve the best performance (fitness, growth, or other currency that should be maximized).

The most common IBM approach used in ecology is Pattern-Oriented Modeling (POM). Researchers using POM build models of an observed pattern found in a real system, pose hypotheses explaining this pattern, and derive testable predictions from these hypotheses. These models are structurally realistic and can be verified and validated (Grimm and Railsback, 2006). DeAngelis and Grimm (2014) divided IBM according to their application as either paradigmatic or pragmatic models. Paradigmatic models help to gain a better understanding of the underlying causes of ecological phenomena, while pragmatic models construct simulations for specific situations (ecosystem or communities) usually with a management goal.

Railsback and Harvey (2002) present a POM-IBM designed to test whether they could reproduce six patterns of habitat selection by three trout species (*Oncorhynchus clarki*, *Salmo trutta*, *Oncorhynchus mykiss*) by contrasting three alternative habitat-selection objectives: maximizing actual growth rate, current survival probability, or expected maturity. They compared model predictions with field observation to deduce the habitat selection mechanisms operating in these trout species. Their POM-IBM appeared successful especially when expected maturity is used as it provides reasonable trade-offs between growth and mortality risks. Similarly, DiNuzzo and Griffen (2020) tested the effect of animal personality on IFD distribution and suggested that a prevalence of inactive personality types lead to lower predictability of the IFD. An example of a pragmatic use of IBM is a model developed by Phang et al. (2016) predicting the growth and distribution of juvenile Atlantic salmon and brown trout in response to changes in summer flow in rivers.

Currently, spatial ecology is going through a transformation by elevating the importance of the role of individuals in driving ecological processes. IBM is a very fitting tool for addressing these challenges.

Applications of spatial models

Knowledge of where, when and why a particular animal is present is not only important for mechanistic understanding of behavioral rules, but also for the management of inland waters. Distribution models are used for understanding the effect of

fishing on harvested population densities and life traits (e.g., Jørgensen et al., 2008; Claireaux et al., 2018). The foraging arena theory that is an implicit distribution model is an important assumption in the widely used Ecopath with Ecosim models of whole ecosystem dynamics and explorations of management applications (Christensen and Walters, 2004). Spatially explicit individual-based models are used for simulating targeted species responses to environmental and biological changes. For example, Railsback and Harvey's trout IBM (Railsback and Harvey, 2002) was used to further develop inStream software used for simulation of trout population responses to environmental changes. These models can also contribute to the design of appropriate sampling schemes for reliable estimates of species densities and communities (Oberdorff et al., 2001). Finally, spatial models are important for the design of protected areas, thus far, mostly in marine environments (Botsford et al., 2003). There are many more examples and examples in this article represent only a small sample of the modeling approaches currently in use.

Conclusions and future directions

Models of animal distribution have brought both empirical knowledge and theoretical concepts to our understanding of how and why animals are distributed across geographic space (Fig. 2). Classical concepts (such as OTF, LHT and IFD) consider how animals optimize their foraging strategies based on all relevant environmental factors (such as the amount of prey, predation risk, and number of conspecifics) and their internal physiological states to choose the behavior that maximizes the animal's individual fitness and future reproduction (Giske et al., 1998). But individuals never have complete knowledge of their environment, have imperfect ability to analyze information and foresee consequences of alternative behavioral options, and process this information in relation to their internal state and personality (Andersen et al., 2016). This realization has led to the incorporation of individual abilities in distribution models. More attention is paid to the role of how individual decisions are made and how these decisions regulate behavior (Nathan et al., 2008; Andersen et al., 2016). Mechanistic models of behavior and distribution of animals now include a broader range of individual traits, such as the genome, physiology, hormonal system, perception, emotions, motivation, and cognition (Budaev et al., 2019).

The field has also moved toward a deeper understanding of the proximate causes of animal distribution, a development which has been enabled by the rapid development of automatic high resolution sampling tools, such as biotelemetry (Baktoft et al., 2015), fast zooplankton samplers (Watkins et al., 2017; Bochinski et al., 2019) and remote sensing (Shuchman et al., 2013). These technological advancements are contributing significantly to the development of spatial data which allow us to describe animal distribution in new and better ways. Further, technological development is tightly linked with the rapid increase of computational power and with the development of artificial intelligence capable of complex pattern recognition (Christin et al., 2019). We believe this process will stimulate a rapid development of current and novel frameworks and models for predicting spatial distributions.

Distribution models have and will continue to greatly contribute to our understanding of the distribution and movement of animals in inland waters. They help us to unravel the rules behind animal movement dynamics, which will enhance our ability to predict distributions, even under novel conditions. However, all models, even extremely sophisticated and complex ones, are a simplification of nature and as such the results have to be interpreted consciously.

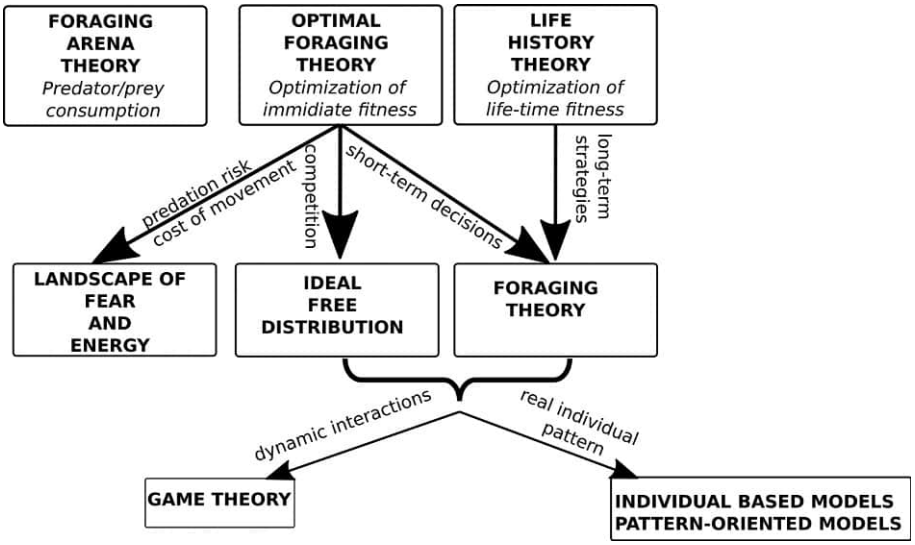

Fig. 2 Schematic overview of links between spatial modeling frameworks.

Further reading

Further reading about forage theory in Stephens et al. (2007) and Pyke and Stephens (2019). Ahrens et al. (2012) provide a review with detail description of forage arena theory. More details on the concept of landscapes of fear are in Gaynor et al. (2019). DeAngelis and Grimm (2014) provide a summary of progress in individual based models during last decades.

Glossary

Adaptive evolution A genetic change in a species' trait in response to its environment that results in an increased fitness in that environment.

Common garden experiment An experiment in which trait values of individuals from different populations are quantified in a single (i.e., 'common') environment. Common garden experiments often involve multiple generations of culture in a similar environment, and are typically used in quantitative genetics to determine the degree to which differences in trait values among populations have a genetic basis.

Common gardening experiment An experiment in which one places individuals or populations that differ in trait values in the same environment ('common garden') to then quantify how they differentially influence the garden. Common gardening experiments are a well-established approach to quantify the impact of evolutionary trait change on ecological processes.

Eco-evolutionary dynamics Simultaneous occurrence of reciprocal interactions between ecological and evolutionary processes, each influencing the outcome of the other.

Evolution Any change in gene frequencies in a population of a species.

Evolving metacommunity A framework that integrates evolutionary processes in metacommunity ecology and thus considers how evolution and community assembly interact in space. Environmental gradients, dispersal and stochasticity are key processes structuring both landscape genetics and metacommunity structure, which leads both to parallel processes and opportunities for eco-evolutionary dynamics.

Metacommunity A set of spatially distinct local communities linked by dispersal of multiple interacting species

Transplant experiment An experiment in which individuals from populations originating from different experimental or natural environmental conditions are (reciprocally) transplanted between these conditions or natural sites, and their trait values measured after one or more generations.

Introduction

Eco-evolutionary dynamics refers to the simultaneous occurrence of reciprocal interactions between ecological and evolutionary processes, each influencing the outcome of the other. Ecological processes encompass any aspect of an organism's interaction with its environment, while evolution is defined as any change in gene frequencies in a population of a species. Evolution can be adaptive if it involves a genetic change in a species' traits in response to its environment that results in an increased fitness in that environment. The classic view of ecological and evolutionary dynamics has been that they are largely independent, occurring on different time scales. There are, however, two pathways that connect both. The first, long recognized in biology, is an eco-to-evo pathway in which the environment imposes pressures on populations, which may influence evolutionary trajectories through evolution by natural selection. The second, an evo-to-eco pathway, only became fully appreciated during the 1990s and 2000s (Pianka, 2000), and depends on the changing trait distributions that result from contemporary evolution immediately altering ecological interactions. Recognition of the importance of the evo-to-eco pathway has been mainly inspired by accumulating studies demonstrating that evolution can be rapid, occurring within a few generations. As a result, evolution can occur on similar time scales as the ecological processes it affects, resulting in a continuous feedback between ecological changes altering evolutionary trajectories (Fig. 1). This dynamical view of rapid evolution influencing ecological interactions, makes eco-evolutionary dynamics different from the more traditional field of 'evolutionary ecology' (Orians, 1962; Pianka, 2000), which has been more focused on whether the expression of organism traits can be understood as adaptations to particular environments (e.g., optimal foraging, body size, life history, etc.), and how trait expression in nature can influence ecological interactions.

It is the combination of rapid evolution (often in response to a changing environment) combined with the effects of the evolving traits on the strength of ecological interactions that is central to eco-evolutionary dynamics. For example, when a predator population increases in abundance, a prey species may evolve to increase its defenses against predation (Fig. 1). That is a case of contemporary evolution or evolution that occurs in the same time frame as ecological processes. If that trait evolution in prey defense results in a decline of the predator population, those combined events reflect eco-evolutionary dynamics. The importance of these dynamics is that many interactions that were hitherto considered to be ecological might reflect the combined action of both ecological and evolutionary processes.

In freshwater systems, evidence of rapid evolution started to accumulate in the early 1980s. An important milestone is the work of John A. Endler on male coloration in wild guppy populations from different predation environments (Endler, 1980). Using a transplant experiment, he showed rapid evolution to brighter male coloration. Brightly colored males are highly attractive to females but are also easily seen by predators. When predators are present, male colors are less bright. When predators are absent, female preferences dominate, and males tend to be more brightly colored. This work was followed by David N. Reznick's study showing rapid evolution of the life history traits of the guppies transferred from high-predation to predator-free sites (Reznick and Endler, 1982).

Another example involves the demonstration of rapid evolution of diapause in the copepod *Onychodiaptomus sanguineus* by Nelson G. Hairston Jr. and William E. Walton (1986). During a severe drought event, the shallower of two natural forest ponds

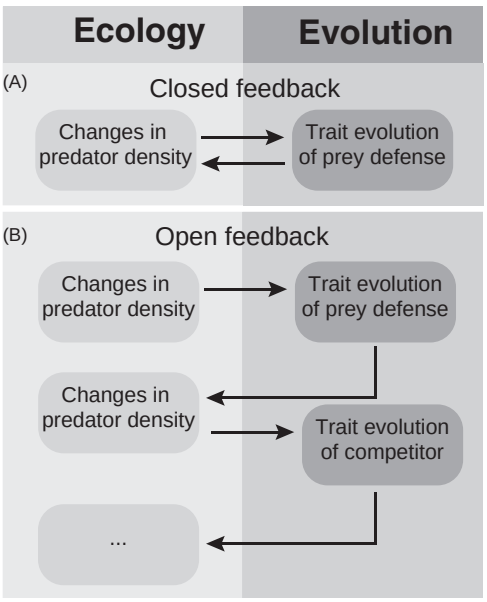

Fig. 1 Example of a (A) closed and (B) open eco-evolutionary feedback loop, in which ecological and evolutionary processes recurrently influence one another. Figure inspired from Fig. 4 from De Meester L, Brans KI, Govaert L, Souffreau C, Mukherjee S, Vanvelk H, Korzeniowski K, Kilsdonk L, Decaestecker E, Stoks R, and Urban MC (2019) Analysing eco-evolutionary dynamics—The challenging complexity of the real world. *Functional Ecology* 33: 43–59.

containing fish dried out completely killing all the fish, while the deeper pond did not dry and had no fish kill. Before the drought, the copepod populations in both ponds entered diapause on nearly the same date in spring as an adaptation to avoid summer-time intense fish predation. Hairston and Walton (1986) found that 2 years after the drought the copepods in the pond that lost its fish had evolved an onset of diapause nearly a month later in the year, demonstrating rapid evolution. This study and Reznick's in 1982 were among the first to demonstrate, for freshwater organisms in nature, that traits closely related to fitness can harbor large genetic variation upon which selection can act.

The accruing evidence of rapid phenotypic evolution in natural systems showcases that strong selection and heritable variation in adaptive traits are more common in nature than previously recognized. This contrasts with the 'standard model' in the field of population genetics, which has assumed random genetic drift as the dominant force in genetic change, with nearly all evolution being stabilizing, i.e., removing deleterious mutations, but with rare exceptions of selective sweeps (Messer et al., 2016). In this model, genetic variation is primarily maintained by selection-mutation balance and is mostly non-adaptive. Examples of eco-evolutionary dynamics, in contrast, often involve fluctuating selection tracked by rapid trait evolution frequently reversing direction in response to environmental change, and with the result that adaptive genetic variation is maintained. Under such circumstances, the net effect of evolution might be small or even negligible over longer time periods, but evolutionary rates can be fast on short time scales, and the resulting trait changes can have important implications for ecological dynamics. Given that evolution occurs on the same time scale as ecological processes, it is the fast genetic tracking of environmental change that is important in eco-evolutionary dynamics.

For eco-evolutionary interactions and feedbacks to occur, one needs (1) sufficiently strong natural selection, (2) genetic variation for the trait under selection, leading to (3) a genetic change in trait value, and (4) a feedback of that evolutionary trait change on one or more ecological processes (e.g., population dynamics, species interactions, ecosystem fluxes). This feedback loop can be 'closed' if the changed ecological interaction then alters the strength and/or direction of natural selection on the original trait which then affects the original ecological interaction, and so on. Alternatively, the loop may be 'open' if the evolving trait change alters some different ecological process, which in turn alters evolution of some different trait (Fig. 1). Eco-evolutionary feedbacks result in a fundamental change in the dynamics of ecological entities, because of the iterative interplay between ecological and evolutionary responses.

Experimental approaches for detecting eco-evolutionary dynamics

Eco-evolutionary dynamics have been shown in a diversity of freshwater systems, and involve population evolution affecting feedback loops at different levels of ecological organization (population, community, ecosystem) (Palkovacs and Hendry 2010) (Fig. 2). Because phenotypic traits often determine the strength and quality of ecological interactions, from population processes (birth and death rates) to community and ecosystem properties, eco-evolutionary dynamics are governed by the traits of organisms. This makes phenotypic traits the 'common currency' between ecology and evolution (De Meester et al., 2019). Phenotypic traits consist of a genetic and an environmental component (Lynch and Walsh, 1998). The latter component, often referred to as phenotypic plasticity, is the ability of a single genotype to produce multiple phenotypes under different environmental conditions. Eco-evolutionary dynamics requires evolutionary change, and thus one needs to separate evolutionary trait change from phenotypic plasticity, with the recognition that there can also be evolution of plasticity (Pigliucci, 2001).

Approaches to studying eco-evolutionary dynamics have varied from measuring ecological and evolutionary changes over time and inferring how changes in ecology have influenced evolution, and vice versa, to comparing dynamics of systems that have the

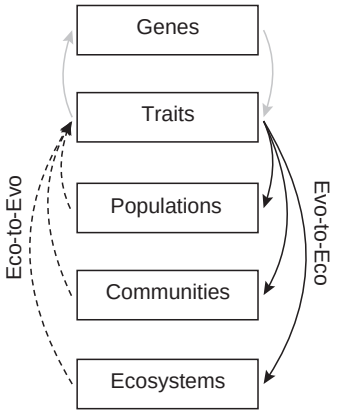

Fig. 2 Conceptual scheme illustrating eco-evolutionary dynamics, in which changes in population, communities and ecosystem dynamics influence phenotypic traits and their underlying genes (eco-to-evo pathway; dashed black arrows), and evolutionary trait changes in turn feedback to influence populations, communities and ecosystem dynamics (evo-to-eco; solid black arrows). Figure is modified from Fig. 1 from Palkovacs EP and Hendry AP (2010) Eco-evolutionary dynamics: Intertwining ecological and evolutionary processes in contemporary time. *F1000 Biology Reports* 2.

potential for eco-evolutionary feedbacks with those that do not (De Meester et al., 2019). In both cases, experiments are quite complex, because one needs to show both that evolution (i.e., genetic differentiation) has occurred, and that this influences an ecological process. Experiments on eco-evolutionary dynamics can often be distinguished in two sets, aligned with the eco-to-evo and the evo-to-eco pathways outlined above.

Demonstrating (past) evolution: Common garden and transplant experiments

In the first pathway—the eco-to-evo pathway—evolutionary response to an ecological condition is assessed. One way to quantify evolution is to introduce a set of individuals with the same distribution of genotypes into experimental units with different ecological conditions, and determine whether these different ecological conditions results in different evolutionary responses. At the end of the experiment, to distinguish evolved genetic differences between the populations from phenotypic plasticity, 'common garden' experiments are often used in which trait values of individuals from different populations are quantified in a single (i.e., 'common') environment. In such experiments, it is important to reduce interference from common environmental effects, including (grand)maternal effects (Lynch and Walsh, 1998). If trait values of individuals from different populations continue to differ in a common garden experiment, this then indicates that genetic differences have evolved as a result of exposure to the different environments. If in addition, trait expression is assessed in two or more distinct environments (two or more 'common gardens'), then phenotypic plasticity, as well as genetic differences in the extent of that plasticity among the populations, can be measured.

Such common garden experiments can also be used with individuals directly collected from natural populations, either at different time points to investigate a population responding to changing environmental conditions or from locations that differ in ecological conditions. Evaluating the traits of those individuals originating from settings exposed to different environmental conditions in a common environment, allows an assessment of genetic differences and quantification of adaptation to their respective environments. For example, a study by Cousyn et al. (2001) demonstrated adaptation to fish predation for the trait phototactic behavior (i.e., vertical migration of zooplankton; see Further Reading) in a population of the zooplankton species *Daphnia magna*. The study used a common garden experiment involving individuals hatched from dormant eggs collected from three different layers of a sediment core corresponding to distinct time periods in the pond where they lived that varied in fish predation intensity. In the laboratory, *Daphnia* from these different sediment ages were exposed to two treatments, with and without fish kairomones (i.e., a chemical cue detectable by *Daphnia*), and exhibited distinct levels of predator avoidance behavior by different levels of vertical migration through the water column. The study thus showed that the population was able to rapidly evolve a reduction in phototactic behavior in response to an increase in fish predation demonstrating the eco-to-evo pathway (see Further Reading).

As an alternative to common garden experiments, one can also use transplant experiments, in which individuals from populations originating from different experimental or natural environmental conditions are (reciprocally) transplanted between these conditions or natural sites, and their trait values measured after one or more generations. For example, Reznick and Endler (1982) studying natural populations of guppies used a transplant approach to detect whether predation influenced life-history traits of these fish (Fig. 3). They transplanted guppies from high-predation sites to low-predation sites, and vice versa, and found that the shift in predation regime affected both guppy densities (an ecological response) and life history traits (an adaptive evolutionary response). Specifically, guppies transferred from high-predation to low-predation sites evolved a later age at maturity, larger size at maturity, and produce larger and fewer offspring compared with guppies that stayed in the high-predation communities (Fig. 3B–D; Reznick et al., 1997). This study, and an increasing number of others, thus quantify how ecological differences impact evolutionary trajectories and rates, and in this way demonstrate the eco-to-evo pathway.

Demonstrating the evo-to-eco feedback: Common gardening experiments and partitioning metrics

In the second pathway—the evo-to-eco pathway—one tests whether evolved trait changes have implications for ecological dynamics. This is often done via 'common gardening' experiments, an experimental design rooted in community genetics (Crutsinger et al., 2006). In a common gardening experiment, one introduces different genotypes, or genetically-differentiated populations, into experimental units with identical ecological conditions. One then assesses whether the genetic differences among individuals or populations result in the development of different ecological properties and dynamics in the experimental units, i.e., one checks whether the different genotypes differentially influence the 'garden'. In one example, Pantel et al. (2015) quantified the impact of evolution on community assembly in zooplankton. A genetically variable *Daphnia magna* population was allowed to adapt genetically (evolve) to different ecological conditions (i.e., a full-factorial design of presence and absence of fish and macrophytes). Then in a second experiment, the investigators quantified whether the evolved populations impacted zooplankton community assembly differently from the original, non-evolved *D. magna* population. They found that the effect of *D. magna*'s adaptation to the different environmental conditions was equally large in driving zooplankton community structure as the differences in environmental conditions (i.e., presence of fish and macrophytes). There is an increasing number of studies that show that eco-evolutionary feedbacks indeed often have an important impact on ecological processes (Hendry, 2017).

Many studies only quantify either the eco-to-evo or evo-to-eco pathway, but in a complete investigation of eco-evolutionary dynamics ideally both pathways are integrated into a single study (as in, e.g., Pantel et al., 2015). As an alternative to using genetically differentiated populations in the common gardening approach, one can also manipulate the potential for evolution by using non-evolving versus evolving systems. This can be done by using a mono-clonal population or one with low genetic variation

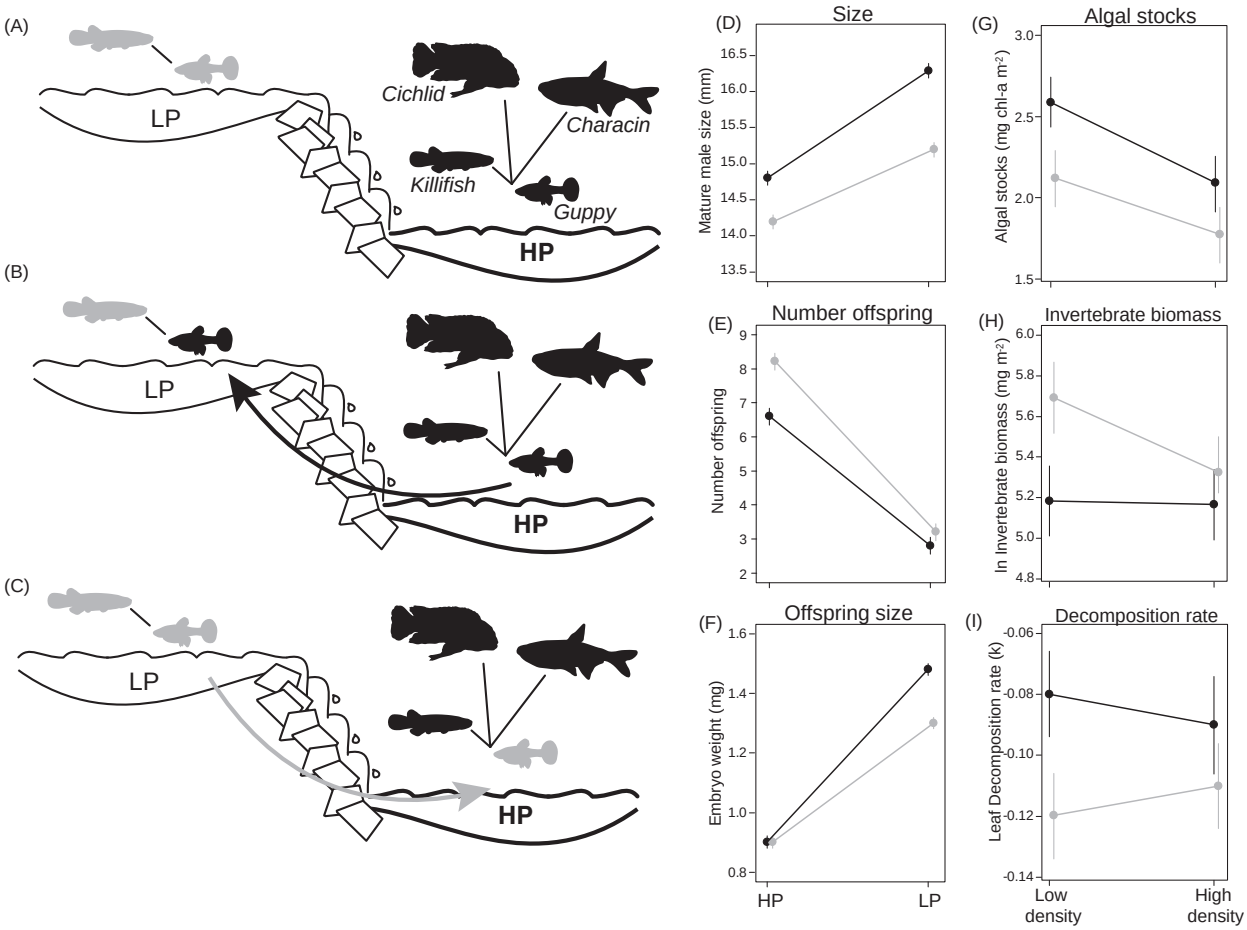

Fig. 3 (A) Representation of food web composition in the High-Predation (HP; below waterfall; depicted in black) and Low-Predation (LP; above waterfall; depicted in grey) environment inhabited by Trinidadian guppies. (B and C) Representation of the transplant experiment in which guppies from (B) a HP environment are transplanted to a LP environment (depicted by the black filled guppy in LP), and from (C) a LP environment are transplanted to a HP environment (depicted by the grey filled guppy in HP). Trait values of (D) mature male size, (E) number of offspring per female and (F) embryo weight (i.e., dry weight of developing offspring) from the HP and LP population in the High-Predation (HP) and Low-Predation (LP) sites. Experimental measures of (G) algal standing stocks, (H) invertebrate biomass, and (I) leaf decomposition rate from common gardening experiment when using LP guppies (black circles), and HP guppies (grey circles) in low and high guppy density. Data in (B–D) are obtained from Fig. 3 in Reznick DN, Ghalambor CK, and Crooks K (2008) Experimental studies of evolution in guppies: A model for understanding the evolutionary consequences of predator removal in natural communities. *Molecular Ecology* 17: 97–107. Data in (G–I) are obtained from Fig. 1 in Bassar RD, Marshall MC, López-Sepulcre A, Zandonà E, Auer SK, Travis J, et al. (2010) Local adaptation in Trinidadian guppies alters ecosystem processes. *Proceedings of the National Academy of Sciences* 107: 3616–3621.

for the non-evolving system (in the absence of genetic variation, there can be no evolution even if there is strong selection) and a multi-clonal or genetically diverse population for the evolving system (see e.g., Yoshida et al., 2003).

The data obtained from experiments or field studies can be used to parametrize mathematical eco-evolutionary models. In these models, one can then manipulate evolutionary potential, strength of selection, and ecological context (e.g., community context). Modeling different scenarios can provide further insight into how ecological and evolutionary dynamics interact, and influence each other (Jones et al., 2009; Cortez, 2016).

The data of common gardening experiments and models can be used to quantify the impact of evolution on ecological dynamics. Eco-evolutionary partitioning metrics have been developed (Hairston et al., 2005; Ellner et al., 2011; Govaert et al., 2016) that enable quantification of the relative importance of evolution (i.e., of traits important to interactions with other species) and ecology (e.g., environmental variation, differences in population densities) on population dynamics, community assembly and ecosystem properties. This allows comparative analyses across systems, species and at particular time points in natural and experimental systems. Such studies have shown that the effect of evolution on ecological properties of the system (e.g., community composition, species diversity) can be similar in magnitude to the effect of ecological drivers (e.g., temperature, predation). However, in most of these studies, the effect of evolution on the population, community or ecosystem features was in the opposite direction from the effect of ecology. As a result, evolutionary changes reduce the impact of ecology rather than augmenting it.

Freshwater environments as model systems for eco-evolutionary dynamics

Freshwater systems, especially ponds and lakes, are ideal for studying eco-evolutionary dynamics as these systems often have distinct boundaries (i.e., the water's edge) so that interactions among organisms, and between organisms and their physical and chemical environment, are naturally confined, and often intense. They provide excellent model systems to explore patterns across spatial and temporal scales, including seasonality and spatial patterns in the landscape in response to a geographic mosaic of stressors. Ponds and lakes represent patches in the landscapes that are each inhabited by local communities that are composed of species that may show evolutionary dynamics and that can be linked to one another via dispersal of species (i.e., movement of individuals from one place to another) and gene flow (i.e., exchange of genetic material from one population to another, changing the genetic composition of the receiving population). The set of communities inhabiting such patches and connected via dispersal is also referred to as a metacommunity (Leibold et al., 2004). The concept of 'evolving metacommunities', also considers evolutionary dynamics in addition to integrating spatial and community dynamics, and thus provides a strong conceptual framework to study how eco-evolutionary dynamics play out in a multiple species context and in space (Urban and Skelly, 2006; Urban et al., 2008). Eco-evolutionary dynamics can play a role at both local and regional scales in shaping community patterns and dynamics.

Eco-evolutionary dynamics are likely to affect aquatic trophic webs through multiple routes. In many freshwater systems, organisms at the lower trophic levels are often characterized by very short generation times, providing the opportunity for rapid evolution to be detected within the duration of a typical study, and providing a high potential for observing eco-evolutionary dynamics. At the same time, rapid evolution has also repeatedly been reported in fish. Given that aquatic systems are often characterized by important top-down cascading effects, evolutionary trait change in fish has the potential to have strong impacts on the dynamics of lower trophic levels.

Key freshwater examples of eco-evolutionary dynamics

Eco-evolutionary dynamics have been demonstrated using (a) laboratory experiments where the environment and interacting organisms can be highly controlled, (b) field experiments where tight control is more difficult, but which can come much closer to including natural environmental variation, and (c) in unconfined nature where the processes of interest play out against the full background of natural complexity. Below, we develop five well-documented examples of eco-evolutionary dynamics in freshwater environments. Three of the five examples include studies using *Daphnia* (water fleas), small crustaceans of the order Cladocera, as a model system. *Daphnia* is frequently used as model organism to address ecological and evolutionary questions due to its short generation time, its reproduction mode and its ease of maintenance in the laboratory. In section '*Daphnia* as model system for eco-evolutionary dynamics', we explicitly focus on the breadth of interactions for which questions at the interface of ecology and evolution have been addressed using *Daphnia* as a model organism.

Rotifer-algal predator-prey cycling: Eco-evolutionary dynamics in highly controlled laboratory microcosms

A clear example of eco-evolutionary dynamics involves rapid prey evolution in response to oscillating predator density, which has been both mathematically modelled and demonstrated in highly controlled experimental laboratory microcosms (called chemostats) using the freshwater alga, *Chlorella vulgaris*, and its planktonic consumer, the rotifer *Brachionus calyciflorus*. Both taxa are common in many lakes. Fussmann et al. (2000), investigating joint predator-prey dynamics in populations of these two species, found unexpectedly that instead of exhibiting the quarter-period phase lag between *Chlorella* and *Brachionus* peak densities predicted by consumer-resource theory (Bulmer, 1976), the dynamics displayed anti-phase cycles with peak rotifer density occurring at the minimum in algal density and the minimum in rotifer density occurring at peak algal density. An exploration of alternative possible explanations using mathematical modeling found that the most compatible model incorporated algal evolution in response to predator density (Shertzer et al., 2002). This hypothesis was then experimentally tested by Yoshida et al. (2003) who manipulated genetic variability in the algal prey population. They found that rotifer-algal dynamics exhibited typical quarter-period phase lags when single-clone algal populations lacking genetic variability were used, i.e., in the absence of prey evolution (Fig. 4A), but anti-phase cycles occurred when the algal population was comprised of multiple clones, and so could evolve (Fig. 4B). The anti-phase cycles could be explained as the shift in relative abundances of defended versus undefended clonal genotypes in response to changing predator density. This shift in clonal frequencies was governed by a trade-off between defended and undefended algal clones. Defended clones survive passage through rotifer guts (Meyer et al., 2006) and so provide no sustenance to the consumers, but are poor competitors for limiting nutrients when predators are scarce. The undefended clones, which do not survive gut passage, instead are good food for rotifers. However, undefended clones are also superior competitors for limiting nutrients. Thus, when rotifer densities are high, defended algal clones have an advantage compared with undefended ones, and increase in abundance. This dominance by defended clones causes rotifer densities to decline. Low densities of the predator give undefended but superior competitor algal clones an advantage over defended clones, which results in an increase in the frequency of undefended clones, which allows rotifer densities to increase once more, starting the cycle all over again. The resulting anti-phase predator-prey cycles are thus an example of eco-evolutionary dynamics in which rapid evolution radically alters classic ecological predator-prey dynamics, as previously shown theoretically by Abrams and Matsuda (1997).

Daphnia evolution structures zooplankton community structure: Evolution and its feedback in outdoor mesocosms

In a study by Pantel et al. (2015), outdoor mesocosms were used to evaluate the evolutionary response of *Daphnia magna* to two key ecological gradients structuring lake and pond zooplankton communities—the presence/absence of fish and the presence/absence of macrophytes (Fig. 5A–C). In a full-factorial design, the authors started from a random sample of the genetic variation present in the dormant egg bank of a natural population of *D. magna* inhabiting a shallow pond (Fig. 5A), and allowed the resulting genetically diverse populations to evolve and adapt to the four environmental conditions during a selection experiment (Fig. 5B). This resulted in sets of populations that differed in their selection background. At the end of a two-month selection experiment, 20 clonal lineages were isolated from each of the experimental units. These isolates were then used in a subsequent community assembly experiment (Fig. 5C). Specifically, the authors re-created the four environmental conditions in mesocosms (i.e., full factorial design of presence/absence of fish and presence/absence of macrophytes), and inoculated each of these environments with the same number of *D. magna* individuals, but obtained from populations that were allowed to adapt to that environmental condition (obtained from the selection experiment) or with individuals from the original, non-adapted population. After 1 week, a standardized and species diverse cladoceran non-*D. magna* community inoculum was added to all mesocosms. This community sample was obtained by collecting zooplankton from multiple ponds chosen such that no *D. magna* was present. One month later, the resulting zooplankton community was sampled.

From the community assembly experiment, it was found that the two-months of evolution in response to the divergent environmental conditions had far-reaching effects. First, the *D. magna* densities were on average higher when using the adapted versus non-adapted genetic lineages (Fig. 5D), showing that 2 months of adaptation resulted in significantly higher performance in the respective habitats. Second, adaptation of *D. magna* had a significant effect on the composition of the cladoceran community. Strikingly, even though the presence of fish and macrophytes are known to be key environmental gradients driving zooplankton community structure, Pantel et al. (2015) found that the effect size of *D. magna* evolution, in response to the presence of fish and macrophytes, on zooplankton community structure was similar to the effect size of the presence of fish and macrophytes themselves (Fig. 5E). However, *D. magna* evolution resulted in a shift in community structure in the opposite direction of the shifts in community structure resulting from exposure to fish and macrophytes (Fig. 5E). The direction of the effect of evolution was thus opposite to the direction of the effects of the environmental gradients. Finally, the evolution of *D. magna* had distinct effects on different cladoceran taxa. For instance, whereas chydorids generally were suppressed in the presence of adapted-compared with non-adapted-*D. magna*, the effect of evolution of *D. magna* on the densities of *Simocephalus* depended on whether or not fish were present. This study thus demonstrates rapid evolution of *D. magna* in response to key ecological factors feeding back to altering the zooplankton community structure.

Alewives, sticklebacks and zooplankton: Eco-evolutionary dynamics in field mesocosms

Beginning with the classic study by Brooks and Dodson (1965) it has been well accepted that size-selective predators can change the zooplankton community of lakes. A study by Palkovacs and Post (2009) demonstrated that predation by two genetically distinct

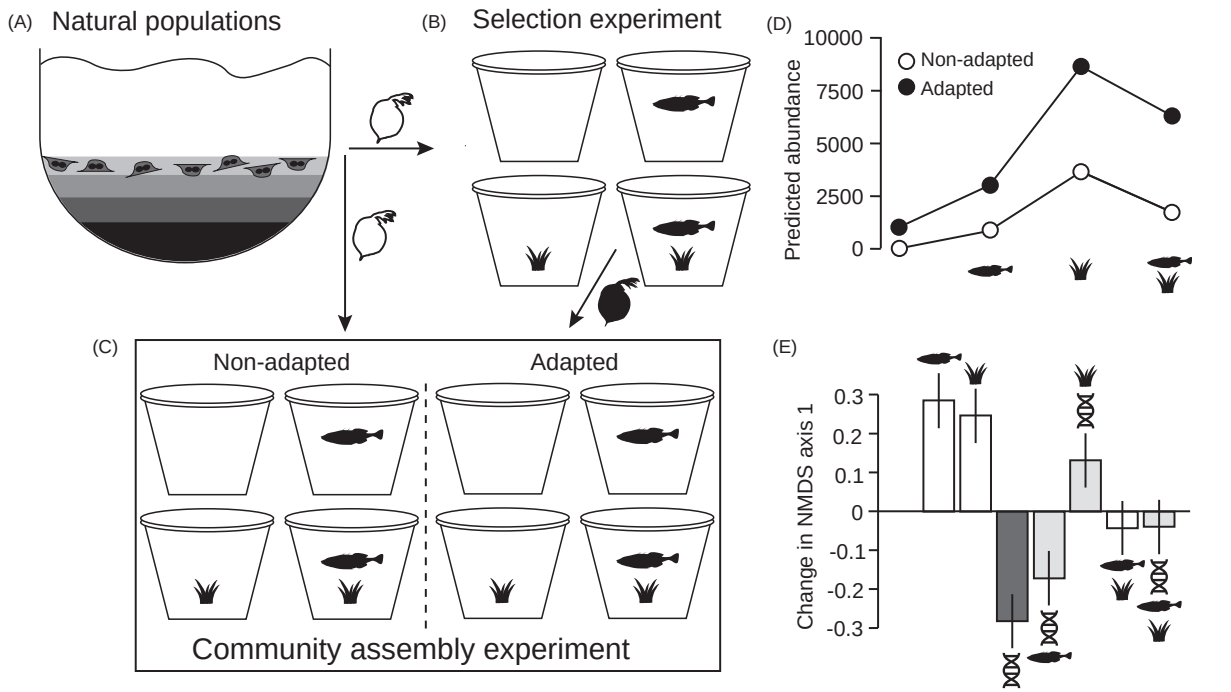

Fig. 5 Representation of the experimental design in which Pantel et al. (2015) started with (A) a random sample of *D. magna* clonal lineages obtained from dormant eggs in (B) a selection experiment consisting of a full-factorial design combining presence/absence of fish with presence/absence of macrophytes followed by (C) a community assembly experiment in which adapted and non-adapted clonal lineages were exposed to the full-factorial design of presence/absence of fish and the presence/absence of macrophytes. (D) Predicted *D. magna* abundances of non-adapted *D. magna* (empty circles) and adapted *D. magna* (filled circles). (E) Effect sizes of ecological factors (fish and macrophytes depicted with respective symbols) and *D. magna* local adaptation (depicted with helix) and their two- and three-way interactions on community structure (as quantified by the main axis of variation in a multidimensional plot, i.e., score for NMDS axis 1). Pure ecological effects are indicated with white bars, pure evolutionary effects are indicated with dark grey bars, and eco-evolutionary interactions are indicated with light grey bars. Data in (D) and (E) is obtained from Fig. 2 and Fig. 5A in Pantel JH, Duvivier C, and De Meester L (2015) Rapid local adaptation mediates zooplankton community assembly in experimental mesocosms. *Ecology Letters* 18: 992–1000, respectively.

types of alewives (zooplanktivorous fish) structures lake zooplankton prey communities differentially. Anadromous fish (seasonally migrating from the ocean to lakes) and non-migrating 'land-locked' alewives differ morphologically (Fig. 6A). In addition to a large difference in adult body size, anadromous populations have larger mouth gapes and wider spacing between their gill rakers (i.e., a kind of internal sieve that retains ingested prey) compared with land-locked populations (Fig. 6B–C). As a result, anadromous alewives tend to feed selectively on larger bodied zooplankton than do land-locked alewives. Genetic data show that these phenotypic differences among alewife populations have evolved repeatedly in independent land-locked lake populations. Further, as land-locked alewives are continuously present in their lake ecosystems, while anadromous alewives are only present part of the year, this difference in presence, in addition to differences in feeding morphology, also determines the predation intensity on zooplankton communities resulting in lower zooplankton biomass and dominance of smaller zooplankton species in lakes with anadromous alewives.

Palkovacs and Post (2009) explicitly tested the hypothesis that evolved phenotypic divergence of alewife morphology caused a difference in zooplankton community structure using experimental mesocosms suspended in a lake, with treatments of no alewives, 15 land-locked alewives, or 15 anadromous alewives. Treatments with anadromous fish showed a steeper reduction in zooplankton biomass, a greater decline in average zooplankton body size, and lower zooplankton species diversity (Fig. 6D–F). Predation by size-selective anadromous alewives eliminated large-bodied zooplankton species, and reduced the biomass of medium-bodied species, while predation by land-locked alewives did not eliminate large-bodied zooplankton species. The evolution of trait differences between these fish populations thus resulted in a different prey zooplankton community, and a common gardening experiment in which genetic differences in a key species were manipulated produced an ecological pattern consistent with the zooplankton community differences observed in the field.

Eco-evolutionary dynamics in this example reach further than evolution of fish impacting zooplankton communities. First, in a follow-up study, Walsh et al. (2012) used a common gardening experiment to show that *Daphnia ambigua* clones originating from lakes containing either land-locked, anadromous or no alewives had distinct effects on algal biomass. Algal densities declined faster in mesocosms with *Daphnia* from lakes with anadromous alewives than they did with *Daphnia* from lakes with land-locked or no alewives. This result stems from the fact that *Daphnia* populations had evolved different adult body sizes in these different lake

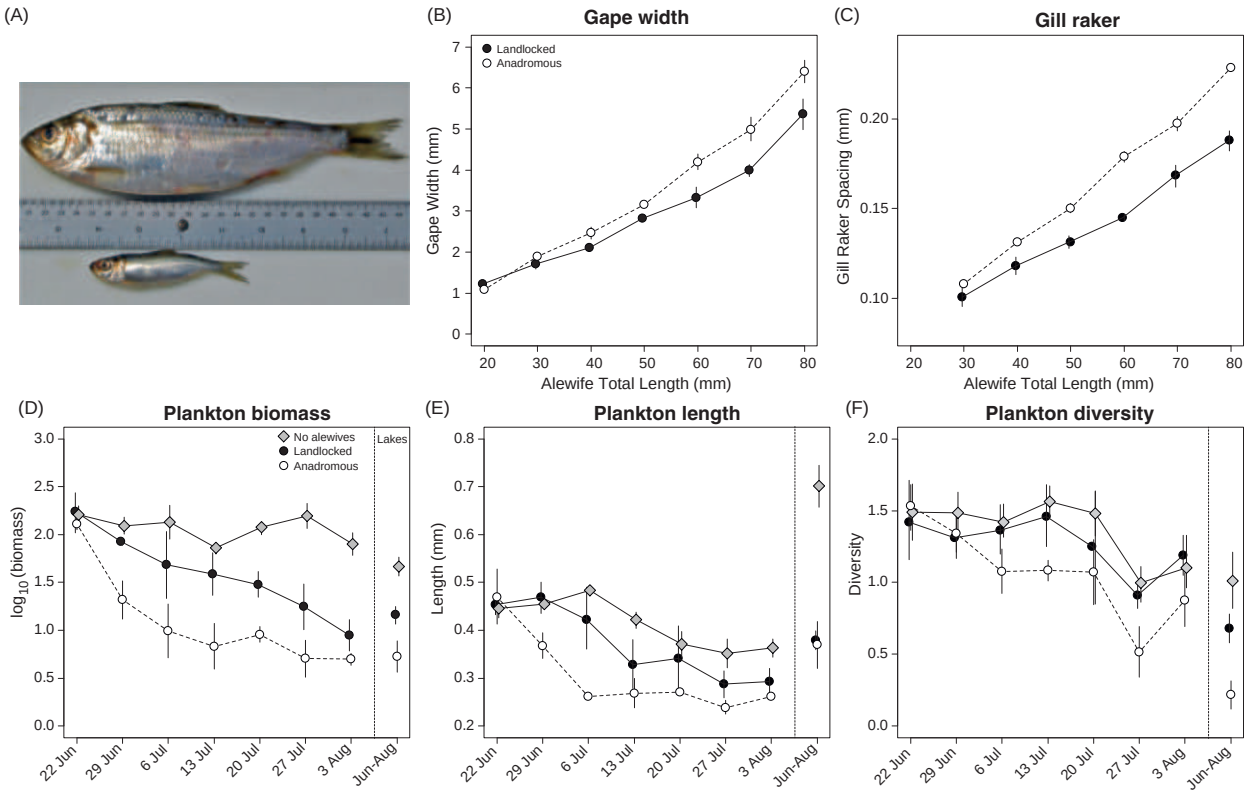

Fig. 6 (A) Anadromous (top) and land-locked (bottom) alewife (photo by D. M. Post). (B) Mean gape width and (C) gill raker spacing for wild anadromous (empty symbols) and land-locked (filled symbols) alewife populations calculated across a range of size classes. Weekly experimental measures of (D) log-transformed biomass, (E) body length and (F) species diversity calculated as Shannon's diversity of crustacean zooplankton assessed in three treatments: no alewives (grey diamonds), land-locked alewives (filled circles), and anadromous alewives (empty circles). Values right of the dashed line represent mean trait values obtained from lake samples (detailed in Palkovacs and Post, 2009). Error bars represent standard errors around the mean. Data in (B and C) are obtained from Fig. 2 in Palkovacs EP, and Post DM (2008) Eco-evolutionary interactions between predators and prey: Can predator-induced changes to prey communities feed back to shape predator foraging traits? *Evolutionary Ecology Research* 10: 699–720. Data in (D–F) are obtained from Fig. 2 in Palkovacs EP, and Post DM (2009). Experimental evidence that phenotypic divergence in predators drives community divergence in prey. *Ecology* 90: 300–305.

types, and body size is important in determining feeding rate. In this system, the combination of studies thus suggests that evolution of fish, along with differences in fish densities, induced evolution in *Daphnia*, and that this evolution in turn impacts top-down control of algae. Moreover, Palkovacs and Post (2008) also showed that the observed difference between zooplankton communities intensified the selection on the feeding morphology of the alewives, resulting in subsequent further evolution of fish feeding traits. This creates a direct closed eco-evolutionary feedback from evolved fish morphology to prey community structure and back to selection and evolution of fish morphology.

Evolutionary divergence in predatory fish morphology and its effects on prey communities has also been shown for sticklebacks (Matthews et al., 2016), where recent adaptive divergence of lake and stream populations of these fish resulted in lower zooplankton biomass and richness in the presence of stream compared to lake populations.

Guppies in Trinidad: A field transplant experiment followed by a field mesocosm study

In Trinidad, guppy populations live in streams often interrupted by waterfalls due to the steep-sided ravines. These waterfalls result in a barrier for the upstream dispersal of some fish species, such as the predatory cichlids and characins. Thus, upstream and downstream fish communities are often very different, even when these habitats are immediately adjacent to each other and connected by water flow. As these types of communities can be found in multiple drainages, they represent natural replicates. Guppies are present both down- and up-stream. However, the presence of multiple predators downstream of the waterfalls exerts strong predation pressures on the guppies found in these downstream communities (further referred to as 'high-predation'). In the upstream habitats, guppies co-occur with only an omnivorous species of killifish (further referred to as 'low-predation'). The presence of predators has a strong ecological effect on the guppy population density: in the high-predation communities, guppy population density is four to five times lower compared with low-predation communities. Using transplants followed by a common-garden experiment, Reznick et al. (1997) found that guppies transferred from high-predation to low-predation

communities evolved towards a later age at maturity and larger size at maturity, and produced larger and fewer offspring compared with guppies that stayed in the high-predation communities (Fig. 3D–F) (see also Reznick et al., 1990; Reznick et al., 2008; Reznick et al., 2012).

This classic study of rapid evolution in response to an ecological change (i.e., showing the eco-to-evo link) was followed up by a large field mesocosm common gardening experiment (in this study artificial rivers established in the natural habitat of guppies were used) in which it was shown that guppies from low-predation and high-predation environments differentially influence ecosystem functioning (Bassar et al., 2010; Palkovacs et al., 2009). Guppies from the high-predation environment increased algal biomass, and displayed greater food selectivity by consuming more invertebrates and less algae and detritus compared with guppies from the low-predation environment. Moreover, mesocosms with guppies from the high-predation environment had lower primary productivity and leaf decomposition rates (Fig. 3G–I). The study also tested for and revealed important interactions between the ecological effect (different densities) and the evolutionary effect (different guppy types) of guppies in these two contrasting but neighboring habitats. The effect sizes of differential evolution of guppies were large. This study therefore shows a strong evo-to-eco link, where the phenotypic differences between guppies locally adapted to different predation environments has strong impacts on the structure and the functioning of the whole stream ecosystem.

Daphnia-algal consumer-resource dynamics: Eco-evolutionary dynamics in unconfined nature

Daphnia plays a major role in the top-down control of algal biomass and species composition, influencing seasonal phytoplankton dynamics. In many lakes, there is a seasonal shift from dominance by edible algae in spring (diatoms, chlorophytes, cryptophytes) to relatively inedible phytoplankton (especially cyanobacteria) in summer (Fig. 7A). Schaffner et al. (2019) showed that in a large shallow lake *Daphnia mendotae* evolved increasing tolerance to dietary cyanobacteria as spring 'good food' progressed to summer 'bad food' (an eco-to-evo pathway). In spring the *Daphnia* population was dominated by clones not resistant to dietary cyanobacteria (Fig. 7B): in laboratory feeding trials they exhibited a steep decline in the growth rate of juveniles when fed a diet containing 50% cyanobacteria and 50% edible chlorophyte algae (Fig. 7C). By late summer, clones resistant to cyanobacteria became dominant in the population (Fig. 7D). These were the clones that showed little or no depression in juvenile growth rate on the diet with 50% cyanobacteria (Fig. 7C). The rapid evolution of increased tolerance to dietary cyanobacteria led to an evo-to-eco pathway, influencing the per capita population growth rate of *Daphnia* in the lake (Fig. 7E).

Daphnia as model system for eco-evolutionary dynamics

Three of the examples developed previously (sections '*Daphnia* evolution structures zooplankton community structure: Evolution and its feedback in outdoor mesocosms', 'Alewives, sticklebacks and zooplankton: Eco-evolutionary dynamics in field mesocosms', and '*Daphnia*-algal consumer-resource dynamics: Eco-evolutionary dynamics in unconfined nature') involved studies using the water flea *Daphnia* as a model system to study eco-evolutionary dynamics. Because *Daphnia* is a well-known model organism in ecology and evolution, it is no surprise that it also serves as a good model for exploring dynamics at the interface of ecology and evolution. In this section, we highlight the advantages of *Daphnia* as a model system and showcase the ubiquity of eco-evolutionary dynamics in which *Daphnia* might be involved. The latter is intended to illustrate that it is worthwhile to investigate eco-evolutionary dynamics in a wide variety of contexts and interactions.

Daphnia are small crustaceans in the order Cladocera that reproduce by cyclical parthenogenesis: during their growing season they reproduce asexually, while at the end of the growing season they reproduce sexually. During asexual (i.e., clonal) reproduction, female *Daphnia* produce offspring genetically identical to themselves, which makes them especially useful in studies of traits that may be either genetically determined, phenotypically plastic, or both. In addition, clonal reproduction implies that *Daphnia* can be easily kept in a laboratory environment as pure genetic lineages for many years.

Daphnia is an example of a 'strong interactor' as it is a highly efficient grazer on phytoplankton, a major recycler of nutrients and a preferred prey item for planktivorous fish and other predators (Fig. 8) (e.g., Miner et al., 2012). Its strong ecological interactions depend in part on its plastic and variable morphological, physiological and behavioral traits. Those traits may evolve in response to environmental changes, including changes in the interactions with other organisms. For example, large-bodied *Daphnia* graze phytoplankton more efficiently compared with smaller-bodied zooplankton taxa including other cladocerans, copepods and rotifers. In addition, due to their higher filtration rates and broader food size spectrum, large *Daphnia* excrete nutrients at a higher rate than smaller *Daphnia*. Furthermore, because of their high growth and reproduction rates, large *Daphnia* require and retain from their diet larger amounts of phosphorus compared with other nutrients, resulting in lower excretion rates of phosphorus, altering the availability of nutrients for phytoplankton (Sterner and Elser, 2002). *Daphnia* with large body size are also more visible to predatory fish than are smaller *Daphnia*. Thus, evolution in *Daphnia* body size (e.g., in response to urbanization, as in Brans and De Meester, 2018) will have both top-down consequences for phytoplankton communities as well as bottom-up consequences for its predators. Changes in ecological properties of *Daphnia*'s environment can thus, through changes in selection patterns or changes in drift and gene flow, alter its evolution (eco-to-evo pathway), and this evolution in *Daphnia* can feed back onto one or more

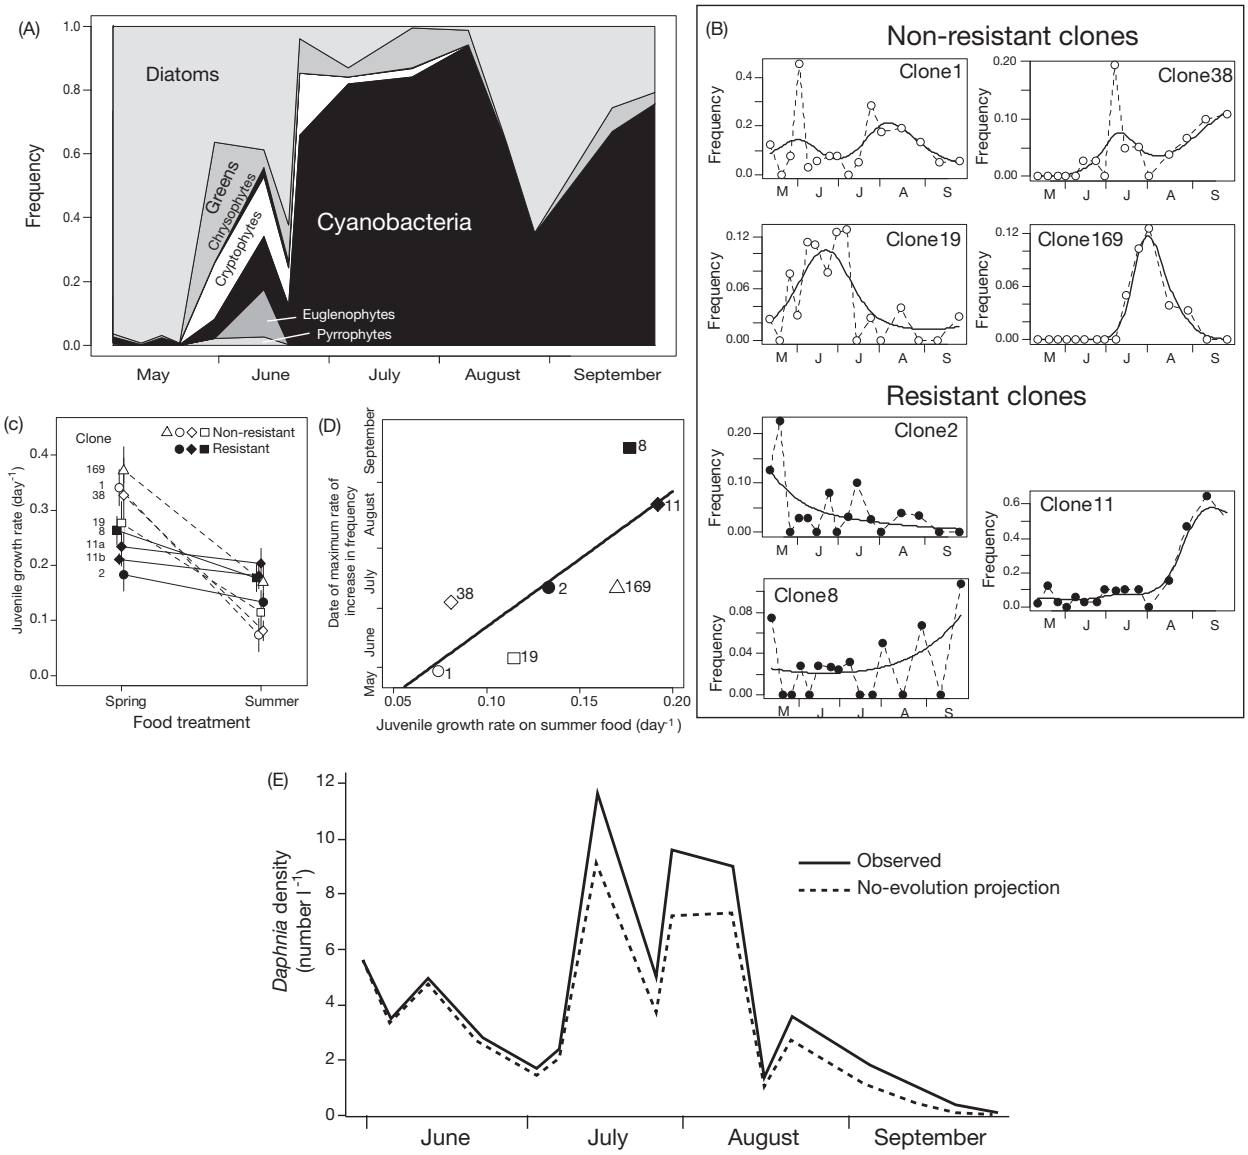

Fig. 7 (A) Frequency of phytoplankton phyla over the course of the season showing a succession from a spring bloom dominated by edible algae to a summer bloom of inedible cyanobacteria. (B) Frequencies of the seven *Daphnia mendotae* clones used in the laboratory common garden experiment during the season. (C) Reaction norms of juvenile growth rate of the seven clones measured in a spring and summer food treatment. Unfilled (resp. filled) symbols reflect non-resistant (resp. resistant) clones. Clone 11 was represented by two independent clonal isolates. (D) Regression of the time point at which each clone had its maximum rate of frequency increase and its juvenile growth rate on cyanobacteria-rich summer food. (D) The observed and projected density of *Daphnia* population. Projected densities were calculated based on no change in clonal frequencies across the season. Data are obtained from Fig. 1C, 2, 3, and 5A in Schaffner LR, Govaert L, De Meester L, Ellner SP, Fairchild E, Miner BE, Rudstam LG, Spaak P, and Hairston NG (2019) Consumer-resource dynamics is an eco-evolutionary process in a natural plankton community. *Nature Ecology & Evolution* 3: 1351–1358.

ecological properties (evo-to-eco pathway). The central role of *Daphnia* in the aquatic food web (Fig. 8), its ability to evolve rapidly in response to changing ecological conditions, and its long-standing role as a model system in ecology and evolution makes it an ideal model system to study eco-evolutionary dynamics. We next highlight with some examples ways in which evolution of *Daphnia* can affect its interactions with other organisms, influencing food web structure and the structure and functioning of aquatic ecosystems. We cannot be exhaustive in our examples; rather the following paragraphs are intended to show the breadth of potential eco-evolutionary dynamics, and stimulate readers to explore them.

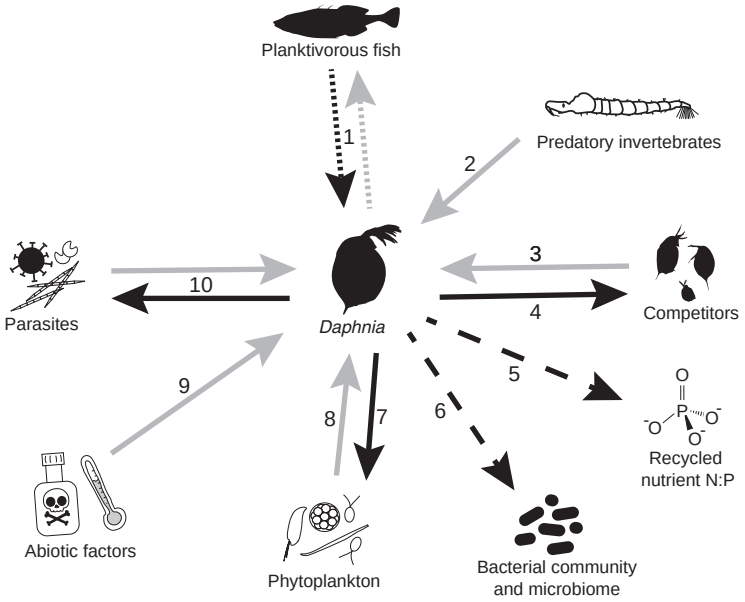

Fig. 8 Illustration of evolutionary and ecological interactions of *Daphnia* in freshwater ecosystems. The arrows refer to interactions reported in the literature (indicated by number); likely other interactions exist, but these have not yet been studied. Solid black arrows indicate evolution of *Daphnia* influencing ecological dynamics. Dashed black arrows indicate the potential of *Daphnia* evolution to influence these ecological properties. Dotted black arrow indicates evolution of fish influencing ecological *Daphnia* dynamics. Solid grey arrows indicate changes in ecological conditions inducing evolutionary change in *Daphnia*. Dotted grey arrow indicates ecological changes in *Daphnia* enforcing evolutionary changes in fish. Settings in which both arrows are present offer opportunities for direct eco-evolutionary feedbacks. Numbers refer to the following studies: 1—Palkovacs and Post (2008), 2—De Block et al. (2013), 3—Steiner et al. (2007), 4—Pantel et al. (2015), 5—Sterner and Elser (2002), 6—Degans et al. (2002) and Callens et al. (2020); 7—Chislock et al. (2013), 8—Schaffner et al. (2019), 9—Brans et al. (2017) and Ward and Robinson (2005), 10—Decaestecker et al. (2007). Figure modified from Miner BE, De Meester L, Phrender ME, Lampert W, and Hairston NG Jr. (2012) Linking genes to communities and ecosystems: Daphnia as an ecogenomic model. *Proceedings of the Royal Society B* 279: 1873–1882.

Eco-evolutionary dynamics in *Daphnia* and its predators

Fish generally exert a strong top-down effect on zooplankton, and impose strong selection pressures on zooplankton populations (Stoks et al., 2016). Evolution of predation-defense traits in zooplankton such as smaller body size and more safe habitat selection in the water column (cf. diel and horizontal migration), will then likely affect feeding rates of fish and can thus alter predator-prey interaction strengths, although we know of no studies that explicitly quantified this. Similarly, *Daphnia* also shows among-population genetic variation in predator-induced defenses against *Chaoborus* predation, involving changes in body size and the development of neck spines (Spitze, 1991). Reger et al. (2018) similarly showed genetic variation in predator-induced defenses among *Daphnia* populations isolated from habitats that vary in the type of predators present. Several studies have shown that predator-induced defenses in *Daphnia* are effective in reducing predation rates by *Chaoborus* (Tollrian, 1995; Laforsch and Tollrian, 2004), but we know of no study showing a clear effect of local adaptation on predation rates.

De Block et al. (2013), in a space-for-time approach on adaptation to warming lake temperatures, showed that *Daphnia* survival when predated upon by damselfly larvae depended upon the interplay of temperature and the latitude of the predator, consistent with a scenario of local thermal adaptation. Specifically, a common garden experiment was performed exposing *Daphnia* clones from southern, central and northern latitude European populations to predation by damselfly larvae from these same latitudes, at both 20 and 24 °C. Relative survival of *Daphnia* was higher at 24 °C than at 20 °C in southern *Daphnia*, while the reverse was found for northern *Daphnia*. However, this thermal advantage disappeared when *Daphnia* were predated by damselfly larvae of the same latitude. This study thus shows that both evolution of *Daphnia* and of its damselfly predator can impact interactions strengths, and differentially so at different temperatures.

Eco-evolutionary dynamics in *Daphnia* and its prey

The study by Schaffner et al. (2019) demonstrated an eco-evolutionary feedback, where *Daphnia* evolution of tolerance to nutritionally poor food affects *Daphnia* population growth during the growing season. It is likely that this might also impact the changes in phytoplankton abundance and composition during the season, but this was not quantified by Schaffner et al. (2019). Chislock et al. (2013), however, did show that different genotypes of *Daphnia pulicaria* can differ strongly in the strength of top-down control of phytoplankton. Different *Daphnia* clones varying in genotype-specific differences in tolerance to toxic phytoplankton had distinct effects on phytoplankton biomass. Tolerant *Daphnia* genotypes had a larger effect on phytoplankton biomass compared with toxic-sensitive genotypes. There is thus a clear potential for strong feedbacks.

In addition to food-induced evolution impacting top-down control of phytoplankton, there are several studies demonstrating that evolution in response to other selection factors can impact top-down control of phytoplankton. As mentioned previously, Walsh et al. (2012) showed that alewife-induced evolution in *Daphnia* results in a faster suppression of algal growth in *Daphnia* isolated from lakes with anadromous alewives compared to *Daphnia* isolated from lakes with land-locked alewives. Similarly, Goitom et al. (2018) showed, in a mesocosm experiment using *Daphnia* subpopulations that are differentially adapted to fish predation pressure, that these differ in their capacity to control phytoplankton. They inoculated mesocosms with *Daphnia* subpopulations derived from hatching dormant eggs from different times in the past that had evolved in response to changes in fish predation pressure (Stoks et al., 2016) and then quantified changes in both *Daphnia* densities and phytoplankton biomass. In this study, similar to that of Walsh et al. (2012), the differential suppression of algal growth was linked to the influence of trait evolution on *Daphnia* population development. In a selection experiment in outdoor mesocosms combined with common garden experiments, Vanhamel et al. (n.d.) show that eutrophication and warming can directly lead to evolution of differential grazing pressure in *D. magna*. In a follow-up transplant experiment, they then show that this differential evolution also impacts phytoplankton biomass development in outdoor settings.

These studies demonstrate the breadth of eco-evolutionary pathways, in which evolutionary changes in *Daphnia* induced by different ecological factors such as changes in food quality (Schaffner et al., 2019), changes in predation (Walsh et al., 2012; Goitom et al., 2018) and via global change (Vanhamel et al., n.d.) can all impact top-down control of phytoplankton.

Eco-evolutionary dynamics in *Daphnia* and its competitors

Steiner et al. (2007) showed evidence of evolution of competitive ability in *Daphnia ambigua*. They hatched clones of *D. ambigua* from long-lived dormant eggs deposited in lake sediments at different times in the past and used them to test for heritable changes in population traits over an interval when the environment changed—a research discipline called 'resurrection ecology' (see Further Reading). They used clones from two time periods: one before *Daphnia dentifera*, a competitor of *D. ambigua*, had been introduced to the lake, and the other after *D. dentifera* became present. Steiner and colleagues then tested the outcome of competition between the two species and found that *D. ambigua* clones present before the introduction of *D. dentifera* performed poorly in competition, whereas clones from after the introduction were able to persist in the competition trials. Because this study focused on an interaction trait through quantifying competitive ability, it also illustrates an eco-to-evo link.

For competition, one may also expect eco-evolutionary impacts of selection by abiotic stressors: if a focal species succeed to adapt to a given stressor (e.g., pesticides, warming) then it may increase their competitive performance towards other species that fail to do so. This, however, will also depend on trade-offs, given that adaptation to a stressor might come at a cost of reduced competitive strength. The earlier highlighted study by Pantel et al. (2015) in which adaptation by the *D. magna* to the combined absence or presence of fish predation and submerged vegetation altered zooplankton community composition is an example of a study in which the capacity of a key interactor to adapt to specific stressors impacts it competitive interactions, resulting in an eco-evolutionary feedback.

Eco-evolutionary dynamics in *Daphnia* and its parasites

Host-parasite interactions can exhibit closed loops of eco-evolutionary dynamics. When there is genetic variation in both *Daphnia* resistance to parasites and parasite virulence, the two antagonists can co-evolve and in this way impact performance and population densities of each other (Thompson, 2005). As a result, many studies on host-parasite co-evolution and its consequences provide evidence for eco-evolutionary feedbacks (Duffy and Hall, 2008). In one example, Decaestecker et al. (2007) hatched *Daphnia magna* clones from dormant eggs obtained from different sediment layers, together with populations of its parasite, the bacterium *Pasteuria ramosa*. In a laboratory experiment, *Daphnia* clones from the different sediment layers were exposed to parasites obtained from the immediately previous time period, as well as from the same and subsequent time periods, thus exposing the *Daphnia* host to parasites from 'the past', 'the present', and 'the future'. They found that infectivity was higher when *Daphnia* were exposed to parasites of the present, than to parasites from the past or future. This study shows that parasites rapidly evolved to track the evolving defenses of common host clones, but also that the host population rapidly evolved in response to the parasites. Because this study quantified infectivity as the proportion of hosts that were infected, it also measured the effect of this co-evolution on prevalence of the parasite in the host population.

Eco-evolutionary dynamics in *Daphnia* and its microbiome

Recently, there has been an upsurge in host-microbiome research using *Daphnia* as a model system. Here too, we may expect strong eco-evolutionary feedbacks, given that the results of several studies point to the fact that *Daphnia* genotype may significantly affect microbiome composition (Callens et al., 2020), and that microbiome composition may be a key component in some ecological interactions and responses to the environment, including the degree to which *Daphnia* genotypes are resistant to toxic cyanobacteria (Macke et al., 2017). In future research, it will be important to disentangle trait changes mediated by evolution, by changes in the microbiome, or by the interaction of genotype and microbiome when quantifying the consequences of trait change on ecological responses and ecosystem functioning.

Overall, while eco-evolutionary dynamics have been reported for an ever-widening scope of ecological dynamics, we are only at the start of quantifying the impact of evolutionary trait change on ecological processes in natural settings. The previous examples address how ecological changes at different trophic levels can influence evolution in *Daphnia*, and how this evolution in turn can influence ecological interactions at various trophic levels. Other ways in which evolution of *Daphnia* can impact ecosystem functioning are likely through the impact *Daphnia* can have on the bacterial community (Degans et al., 2002; Macke et al., 2020) as well as on the availability of nutrients for phytoplankton (Sterner and Elser, 2002).

Conclusion

Anthropogenic processes are rapidly changing the Earth's environments altering the strengths and kinds of ecological interactions. There are many examples of rapid adaptive evolutionary responses of organisms to these changes. If this rapid evolution occurs in traits that determine the nature or strength of interactions among organisms or between organisms and their environment or ecosystem, there is the potential to alter ecological processes with further consequences for evolution, resulting in eco-evolutionary dynamics and feedbacks. Although we have discussed here the ubiquity of such rapid evolution and its eco-evolutionary dynamics in inland waters, examples also exist across a variety of other taxa and model systems (see Hendry, 2017). Understanding when and how such dynamics and feedbacks occur in natural systems is important as they change the predicted outcome of evolution, ecology and their interplay. The demonstration of such feedbacks in these and other natural systems raises the question of how prevalent eco-evolutionary dynamics are in nature, and how they affect responses of populations, communities and ecosystems to human-induced global change.

Glossary

Bet-hedging strategy An evolved life history that maximizes long-term fitness in variable environments. Bet-hedging organisms may have a lower than maximum possible fitness under good environmental conditions but also never have zero fitness under poor conditions.

Bioturbation The mixing of sediments by organisms, living in or on the lake bottom, due to their burrowing, filtering, ingestion, or defecation.

Eco-evolutionary dynamics The feedback between evolutionary changes and ecological processes. Rapid evolutionary changes impact the strength and direction of ecological interactions, which alters natural selection, which in turn causes further evolutionary change.

Dormant egg, embryo, cyst, propagule and spore Life-history stages of animals, algae, bacteria and other organisms that facilitate dispersal in space or time through prolonged dormancy. They are typically resistant to environmental conditions that would kill an active individual, and are often encased (encysted) in a protective coating.

Life history strategy The pattern of timing of life stage events determined by the allocation of resources to growth, maintenance, reproduction and survival so as to maximize fitness.

Paleolimnology The study of the history of lake organisms and ecosystems using physical, biological, and chemical properties of lake sediments deposited in historical order, often used to reconstruct past climate or environmental changes.

Prolonged dormancy Dormancy that persists longer than to the next annual growing season.

Red Queen dynamics The proposition that a population must constantly evolve in order to survive and reproduce successfully in the presence of natural enemy species (competitors, predators or parasites) that are themselves continuously evolving to overcome their competitors, prey or hosts.

Sediment focusing The tendency for sediments to accumulate in the deepest part of a lake basin because sediment resuspension processes are greatest near shore resulting in net sediment movement from shallow to deep.

Introduction

"Egg bank" is both a specific term describing the accumulation of diapausing eggs of zooplankton within the sediments at the bottom of a lake or pond, and a more general term describing the sediment accumulation of a diversity of dormant life-history

☆*Change History*: September 2020. NG Hairston Jr. and JA Fox (1) modified title to include "Resurrection Ecology" as desired by editor Lars Rudstam, (2) updated text, (3) added more section subheadings, (4) replaced Fig. 6, (5) added literature citations within the text and updated referenced.

stages made by a variety of aquatic organisms. These stages, known collectively as "dormant propagules," include embryos of invertebrates (Fig. 1), encysted gametes of protists and algae, and spores of bacteria and cyanobacteria. Many of these stages have the ability to remain dormant for long periods of years, decades, and in some cases more than a century while retaining the capacity to emerge from dormancy to become metabolically and ecologically active in lake ecosystems (Hairston Jr., 1996). This "prolonged dormancy" (i.e., dormancy that lasts longer than from one growing season to the next) leads to the formation of an egg bank as on average more dormant propagules are deposited each year on the lake bottom than the number that emerge. As will be explained below, the adaptation of prolonged dormancy that leads to the formation of egg banks (life-history bet-hedging) has important implications for the maintenance of biological diversity in lakes and ponds, while the existence of egg banks provides a resource for the study of evolution in response to changing environments (resurrection ecology).

Dormant propagules typically possess traits that permit them to survive harsh conditions that would be lethal to individuals in the active stage; these harsh conditions include, but are not limited to, temperatures that are too warm or too cold, freezing, low dissolved oxygen, desiccation, low food availability, and high predator or pathogen densities. Prolonged dormancy permits otherwise short-lived organisms to persist in environments that vary in how hospitable they are from one growing season to the next (i.e., occasional occurrence of a harsh season). In a temporally unreliable environment, a parent organism that produces multiple dormant propagules, some of which emerge the following growing season and some of which remain in dormancy for longer periods, increases the chance that its descendants will persist in the long term. A single season that is so harsh that individuals not in dormancy fail either to reproduce or to survive would quickly cause population extinction if it were not for the fact that some individuals survive through the harsh season as dormant propagules. A life history in which some of the offspring of an individual emerge to try out one growing season while others wait to try out other growing seasons is called a "temporal bet-hedging strategy" (Seger and Brockmann, 1987).

Because dormant propagules are resistant to harsh conditions, they can also provide a means for individuals to disperse from one lake to another. Dormant eggs, cysts, or spores may become attached to the fur, feathers or integument of vertebrates or insects that visit first one lake or pond and then another. Propagules disperse spatially if they attach to the visitors in one lake and then fall off in another (Simonis and Ellis, 2014). Some dormant propagules, consumed by a predator, can survive gut passage and can disperse between lakes if they are ingested in one lake and defecated in another (Mellors, 1975). Other dormant propagules may be dispersed by wind when floating eggs or spores accumulate against the shore from which they can be lifted by a breeze (Pinceel et al., 2016; Sirianni, 2017). Still other dormant propagules may be transported by water flows from one water body to another (Pellow-Wagstaff and Simonis, 2014). The dispersal of dormant propagules to numerous lakes, each with a different environmental condition can result in spatial bet-hedging, which is similar conceptually to the temporal bet-hedging already described.

Egg banks are important in lake ecosystems in three ways.

(1) They are a means by which populations survive through periods of stressful or uninhabitable conditions in a lake, whether those harsh conditions are natural in origin or are caused by human activity. Species or genotypes produced in the past, but absent from the water column in the present, can emerge from dormancy and reinvade rapidly in response to a change in the environment. Reinvasion by hatching from an egg bank provides a mechanism for the long-term maintenance of biological diversity in a lake.

(2) Species or genotypes that establish large water-column populations after a period of absence by reinvading from an egg bank can affect how the lake ecosystem functions and how lakes respond to environmental change. For example, when a keystone taxon, such as the dominant phytoplankton grazer, *Daphnia*, appears from the egg bank after some years of absence, the abundance and composition of phytoplankton and other suspended particles can be dramatically altered by their feeding

(Effler et al., 2015). If distinct assemblages of *Daphnia* genotypes emerge from diapause in different years, those genetic differences may likewise affect consumer-resource dynamics (Hairston Jr. et al., 2001; Schaffner et al., 2019).

(3) The sediments of lakes typically accumulate year by year, with the most recent sediments at the surface and older sediments occurring progressively at greater depths. Buried eggs, cysts, and spores provide a historical record of the species, genotypes, and phenotypes that existed in the past. Hatching or germinating these propagules from different sediment depths (*i.e.*, times in the past) provides a means to study how populations have evolved qualitatively and quantitatively in response to changing environments. This relatively new field is called "resurrection ecology."

Prolonged dormancy as an adaptive life history strategy

Dormancy and diapause defined

Dormancy is any state of reduced metabolic activity; either a temporary loss of the ability of cells to divide (in single-celled organisms such as bacteria, algae, and protists), or the suppression of growth, development, and reproduction (in complex organisms such as rotifers and crustaceans). Many dormant life-history stages also possess a resistant covering that aids survival in harsh conditions. Nondiapause dormancy is seasonal quiescence—a reversible state of suppressed metabolism directly imposed by exposure to harsh conditions (e.g., low temperature, low dissolved oxygen). Diapause-dormancy is induced by environmental factors that do not directly reduce metabolic rate but which act as a signal to the organism that conditions will soon deteriorate (e.g., day-length, temperature, food concentration, population density, and presence of predators or pathogens) (Tauber et al., 1986). Life history stages in "prolonged dormancy" do not all emerge at the first return of favorable conditions in the lake; it is these long-lived dormant stages that accumulate in sediments to produce an egg bank (De Stasio, 1989).

Egg and cyst viability

Dormant propagules can remain viable for amazingly long time periods. Eggs of cladocerans and copepods have been found to remain viable in lake sediments for as long as several centuries (Fig. 2) (Hairston Jr. et al., 1995; Frisch et al., 2014). Egg and cyst viability of several decades is common (Hairston Jr. and Cáceres, 1996). At least some eggs and cysts reduce their metabolic rate in dormancy to undetectable levels. The physiological mechanisms maintaining prolonged embryonic diapause and hence egg banks include accumulation of sugars, carotenoid pigments, and heat-shock proteins that inhibit physical–chemical damage during dormancy (Clegg, 2001).

Very short time scales (2–3 years) seem to have little effect on the ability of diapausing eggs to hatch. Over longer time periods, from a few years to several decades, viability generally decreases with age. Reduced viability is evidenced by decreased hatching rates, and by both the increased time to hatch of older eggs and the decreased health of the individuals that do hatch (Fig. 3; Fox, 2007).

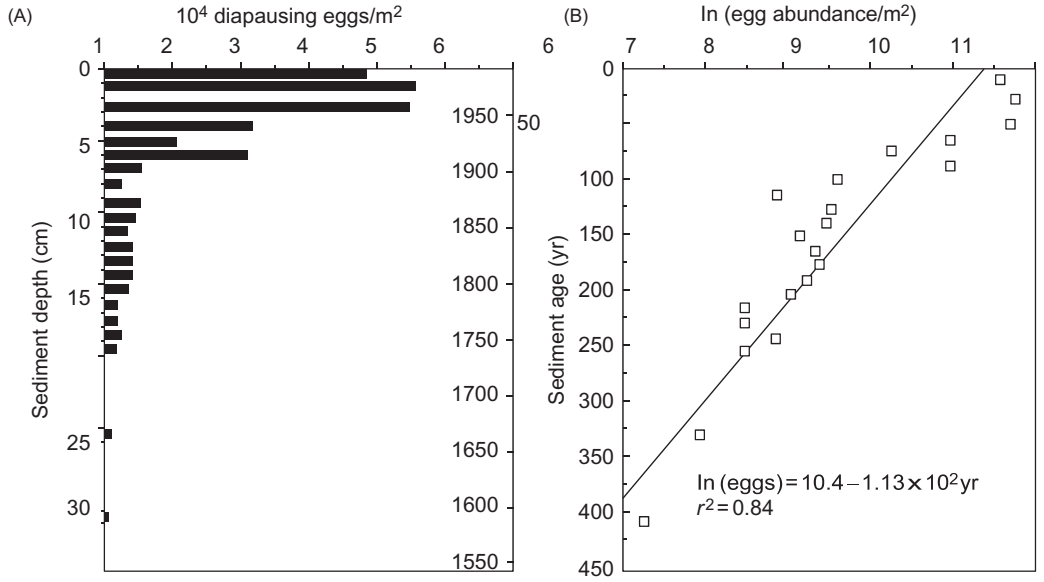

Fig. 2 (A) The density of diapausing eggs of the copepod *Onychodiaptomus sanguineus* in the sediments of Bullhead Pond, RI, as a function of sediment depth and sediment age; (B) The slope of the relationship between the natural logarithm of viable-egg density and sediment age is the mortality rate of the eggs, which in this case is 1.13% per year. From Hairston NG Jr., Van Brunt RA, Kearns CM and Engstrom DR (1995) Age and survivorship of diapausing eggs in a sediment egg bank. *Ecology* 76: 1706–1711.

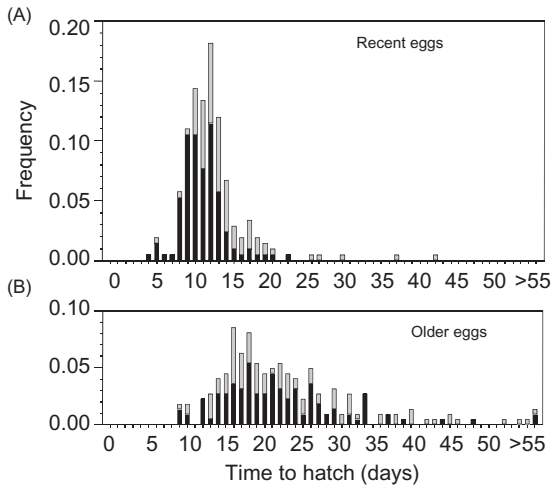

Fig. 3 The time to hatch and incidence of inviable hatchlings. (gray portion of bars) for diapausing eggs of *Daphnia mendotae* taken from sediments less than 5 years old (A) and 15–20 years old (B) in Onondaga Lake, NY. Hatchlings were considered inviable if they had obvious physical deformities or survived less than 7 days in culture. Adapted from Fox JA (2007) Hatching timing of *Daphnia mendotae* diapausing eggs of different ages. *Fundamental and Applied Limnology* 168: 19–26.

Temporal migration, temporal dispersal, and temporal bet-hedging

Many environments vary seasonally. In the temperate zone and higher latitudes, winter conditions are harsh for organisms. In tropical regions and elsewhere, the dry season can be stressful in naturally shallow ponds. Mobile organisms avoid these physiologically challenging periods by migrating to a region where conditions are more benign. Organisms of limited mobility, including the plankton of lakes, lack the ability for long-distance directional movement from one favorable habitat to another. For them dormancy and diapause provide a capacity for "temporal migration" when spatial migration is not possible (Brendonck and De Meester, 2003). For example, cladoceran crustaceans in a pond that dries every summer can produce diapausing eggs that are able to survive in the pond sediments in the absence of standing water. When the pond refills the following spring the eggs hatch, transiting the organisms from one favorable period to another.

One way for organisms to survive in an unpredictable and spatially patchy environment is to disperse their eggs (or their offspring) randomly (similar to spatial seed dispersal in plants). Some individuals will land on unfavorable habitat patches but others will land on good sites and can grow and reproduce to disperse again. The dormant propagules of lake organisms may be dispersed to other lakes by more mobile organisms or by wind or overflows, as described earlier. Long-lived dormant propagules, however, also possess the capacity for "temporal dispersal" in which the propagules stay in one place, but emerge from dormancy in different years. For example, a copepod crustacean may produce a clutch of 20 diapausing eggs in a temporary pond. In some years when the pond refills, predator densities may be so great that any individual hatching has little or no chance of survival. In other years, however, predator density may be low and individuals hatching can mature and produce diapausing eggs of their own. Temporal dispersal occurs when the hatching of diapausing eggs from a single clutch hatch is spread out over multiple years, some of which are favorable and some of which are not.

In a temporally varying environment, years differ in their suitability for the survival and reproduction of an organism. The fraction of propagules that should theoretically emerge from the egg bank in any given year depends upon the likelihood of a year being either good or bad and the ability of the diapausing propagule to survive to subsequent years. The greater the probability of any year being good, the greater the optimal hatching fraction. This optimal emergence (or hatching) fraction is called a "bet-hedging strategy" and can be calculated based upon the probability of a good year occurring. It is probable, however, that year suitability will not simply be either good or bad; mediocre years can also occur in which survival and reproduction is not zero but is less than in good years. Again, an optimal hatching fraction can be calculated depending upon the probability of the occurrence of particular year types. Finally, environments may or may not become uninhabitable (e.g., a pond may or may not dry depending upon the amount of rainfall in a given year). Organisms may make some eggs that hatch immediately and some that enter diapause, and again, an optimal allocation of reproduction to diapausing and nondiapausing eggs can be calculated as a bet-hedging strategy.

Structure of egg banks

Egg bank formation and dynamics

An egg bank represents the summation of the allocation to prolonged dormancy by the organisms living in a particular lake or pond. Dormant propagules accumulate in lake sediments both because long-lived propagules settle to the lake bottom when they are released and because sediment processes cause them to become buried (Fig. 4) (Cáceres and Hairston, 1998). Only those

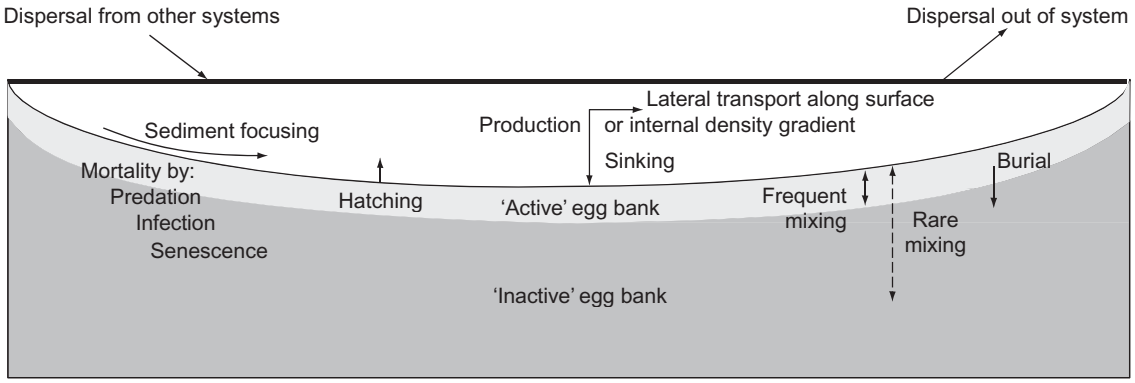

Fig. 4 Side-view schematic diagram of a lake and its sediments depicting the distribution of dormant propagules within the egg bank. Because deeply buried propagules are viable but unlikely to hatch, the egg bank consists of "active" and "inactive" compartments. The active fraction receives the new propagules from the water column and is defined as the depth to which propagules can receive the cue to exit from dormancy and emerge successfully, most likely less than 1 cm into the sediment. Although propagules in the inactive compartment may remain viable for many years, they cannot emerge from dormancy unless some localized disturbance returns them to the active compartment. Adapted from Cáceres CE and Hairston NG Jr. (1998) Benthic-pelagic coupling in freshwater zooplankton: The role of the benthos. *Archiv für Hydrobiologie – Advances in Limnology* 52: 163–174.

propagules within the top few millimeters of the sediment surface can successfully emerge (Hairston Jr. and Kearns, 2002). Propagules that become buried below this depth may remain viable for decades or more, but they cannot emerge unless brought to the surface by a dramatic event such as burrowing by a vertebrate or sediment disturbance by a boat anchor.

Sediment deposition buries propagules at rates varying between less than a millimeter to greater than a centimeter per year, depending on lake and watershed conditions. Sedimentation rates also vary spatially within a lake. Sediment focusing—the tendency for sediments to accumulate in the deepest portion of a lake basin—makes it likely that eggs deposited in the deepest portion will be buried more quickly, and so will be less likely to hatch, than those near shore. Sediment mixing by insects and worms living in the mud at the bottom of lakes (called "bioturbation"), transports propagules near the sediment surface deeper into the mud, while propagules at depth may be transported to the surface from which they can emerge (Kearns et al., 1996). Bioturbation typically mixes only the top few centimeters of lake sediments. Physical disturbance (e.g., wave action, currents, fluctuations in water depth) is typically greater for shallow near-shore sediments. Macrophytes also influence egg movement by stabilizing sediments and channeling movement of benthic invertebrates (Hairston Jr. and Kearns, 2002).

Lake size influences the relative importance of biological and physical disturbance of sediments. In larger lakes physical mixing, particularly in shallow, near-shore areas where wind action is greatest and near inlets where currents are strongest, may play an important role in mixing sediments. Smaller bodies of water are often more protected from wind action and have a greater proportion of shallow, near-shore regions where bioturbation may be more important. Egg density is typically greatest in deep-water sediments and lowest in near-shore areas (Table 1); however, the probability of receiving a hatching cue is greatest in shallow-water sediments. Thus, different regions of the same lake play different roles in the egg bank dynamics. Hatching from near-shore sediments may act as an important contribution to ongoing population processes while long-term storage in deeper sediments serves as an archive of population history in a lake.

Number versus depth

The density of dormant propagules or eggs in sediments varies widely by lake and species, with densities of 10^3 to 10^6 m^{-2} typical for algae, rotifers, copepods, and cladocerans (Table 1). The vertical distribution of eggs within the sediments is not uniform. The abundance of eggs at a given depth below the sediment surface is a function of the history of the rates of production, mortality, and emergence, as well as sedimentation rate and disturbance (Brendonck and De Meester, 2003). The number of eggs typically decreases with depth in the sediments, often with a peak in abundance just below the actively mixed sediment layer near the sediment–water interface (Fig. 2). The distribution of eggs in the sediments may show gaps or breaks, corresponding to periods of time when the species was absent from the water column or present in smaller numbers (Fig. 5).

Evidence of lake recolonization from the egg bank

Resistant diapausing eggs play an important role in facilitating colonization of new environments and recolonization of temporarily unsuitable water bodies. An egg bank allows species to persist years after no adults survived to reproduce. Several experiments monitoring emergence of hatchlings from sediments have shown that copepods and cladocerans hatched from the egg bank years after no adults were present in the water column. Two studies of lakes, in which newly stocked fish eliminated water-column populations of zooplankton, showed that after the fish were removed, both copepods and *Daphnia* returned to the water column of

Table 1 The densities of zooplankton diapausing eggs in central deep sediments compared with shallow near-shore sediments in lakes and the ratio of densities in deep compared with shallow sediments.

Taxon	Lake	Egg densities (no. m^{-2}) and depth (m)			Source
		Deep	Shallow	D/S	
Cladocera					
Holopedium[a]	Windgfällweiher	2.5×10^6 (4.7)	$<1.0 \times 10^5$ (0–2)	25	1

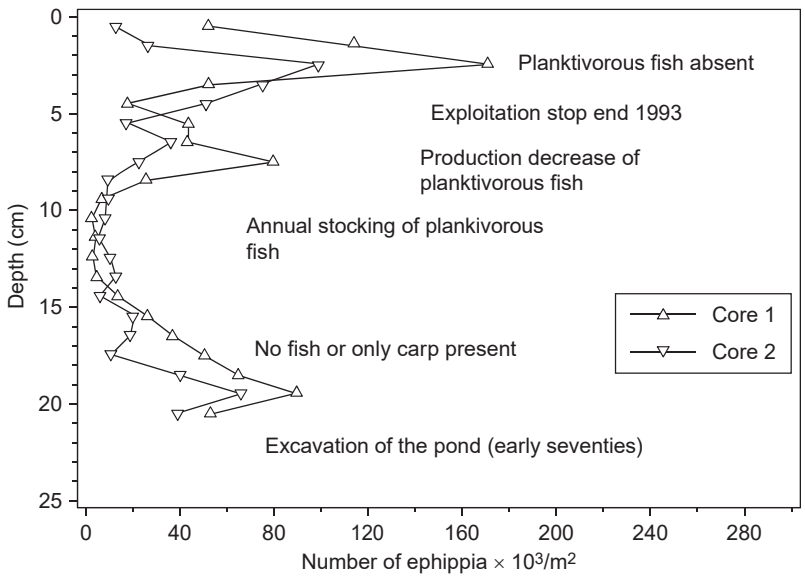

Fig. 5 The depth distribution of dormant egg cases (ephippia) of *Daphnia magna* in two sediment cores taken from an artificial pond created in Belgium in the 1970s. Noted on the figure are periods of high and low abundance of fish that consume *Daphnia*. Adapted from Cousyn C and De Meester L (1998) The vertical profile of resting egg banks in natural populations of the pond-dwelling cladoceran Daphnia magna Straus. *Archiv für Hydrobiologie – Special Issues Advances in Limnology* 52: 127–139.

lakes that had a large sediment egg bank, but did not return in a lake that had no egg bank because the eggs had been consumed by a large population of predatory benthic invertebrates (Parker et al., 1996; Knapp and Sarnelle, 2008).

Studies of the genetic structure of populations provide indirect evidence of recolonization from the resting egg bank. For example, using population genetic analyses of diapausing eggs obtained from different sediment ages, a population of *Daphnia* in a Kenyan lake was shown to recolonize that water body after a 50-year period absence (Mergeay et al., 2007). A bryozoan population

showed the same genetic composition before and after a significant demographic bottleneck, suggesting recolonization from the dormant propagule bank rather than from neighboring populations that are genetically distinct (Freeland et al., 2001).

In most species examined, hatchlings from the egg bank exhibit tremendous genetic diversity, which is often greater than the diversity of the planktonic population at the end of the season (Freeland et al., 2001; Schaffner et al., 2019).

The role of egg banks and the storage effect in the maintenance of lake biodiversity

Temporal bet-hedging by long-lived dormant propagules present in egg banks can play an important role in maintaining species diversity in lakes. This occurs when the environment in a lake varies from year to year and species differ in the environmental conditions under which they do best. Without an egg bank, two species with similar ecological requirements may not be able to coexist due to competition. Even when the environment varies and species differ in the environmental condition that is favorable to them, on average one species will be better at using the available resources and over time will eliminate the other. If, however, individuals emerge each year from an egg bank into a varying environment, newly emerging individuals will have high reproductive success in years that are favorable and low success in unfavorable years. In favorable years, the individuals can build up a large population, produce a large number of new dormant propagules, and restock the egg bank before the end of the season. If each species is successful in survival, reproduction, and ultimately restocking its egg bank under environmental conditions when the other does poorly, then conditions exist for the two species to coexist over the long term. This mechanism, by which biological diversity is maintained, is called the "storage effect" and makes it possible for many species to coexist (Chesson, 2000). In one study (Cáceres, 1997), *Daphnia pulicaria* and *Daphnia mendotae* were shown to coexist for several decades even though the former species was the superior competitor in most years. The latter had a more substantial egg bank that it was able to restock in years when high fish predation (to which it is less vulnerable) gave it a fitness advantage.

The egg banks and the storage effect also serve to maintain genetic diversity within a species if genotypes differ in the environmental conditions under which they do best (Ellner and Hairston, 1994). In a population of the copepod *Onychodiaptomus sanguineus*, genetic variation for a trait that influences their ability to survive predation by fish is apparently maintained *via* the storage effect in the presence of year-to-year variation in predation intensity (Ellner et al., 1999).

Egg banks as historical archives and resurrection ecology

Dormant propagules buried in lake sediments provide a paleolimnological record of the changes in a population over years, decades, or centuries. Several different approaches are used, often together, to reconstruct the history of populations using egg banks: (1) determining the distribution and relative abundance of species and genotypes within species through time, (2) performing genetic analyses on the dormant propagules, and (3) hatching individuals from eggs of different ages to compare phenotypes. These methods provide insights into the evolutionary history of the species being examined as well as community and ecosystem processes.

The abundance of dormant eggs in the sediments is correlated with population size at the end of the season in which the eggs were produced. Therefore, in the absence of significant disturbance of the sediments, changes in egg density throughout the sediments can be used to estimate the size of past populations. Egg banks have been used extensively to document the impact of human-induced changes on zooplankton community structure. Changes in cladoceran community structure over two centuries in Lake Naivasha, Kenya (Mergeay et al., 2004) showed that the introduction of exotic fish played a key role in determining which species were most abundant, with large-bodied species being absent during periods of intense fish predation. In addition, increased erosion from agricultural lands caused increased turbidity and decreased the abundance of submerged aquatic plants, which in turn led to a decline of smaller species that are found in macrophyte beds. Conversely, changes in the abundance of macrophyte-associated species in an egg bank may indicate past vegetation or other ecosystem changes. The effects of heavy metal pollution on zooplankton populations in lakes in Europe and North America have been recorded in the egg banks of these lakes. For example, analysis of the zooplankton egg bank in a Canadian lake recovering from acidification reveals a species shift associated with changes in the lakes' acidity levels interacting with the effects of drought (Arnot and Yan, 2002) and the *Daphnia* egg bank and *Bosmina* microfossils show declines in abundance during periods of peak industrial activity in a small lake near Lake Superior (Kerfoot et al., 1999).

Studies of egg banks have led to greater understanding of the processes of colonization and the relative importance of population re-establishment from the egg bank and from external sources. For example, the historical species record in the egg bank revealed that the establishment of a particular *Daphnia* species in lakes recovering from acidification must be from external sources, despite the existence of a large bank of viable eggs of other *Daphnia* species.

Egg banks also register unusual past events, such as the invasion of exotic species. In Onondaga Lake, NY, the presence of two salt-tolerant exotic *Daphnia* species during periods of high industrial pollutant salt-loading into the lake were documented by the presence of large numbers of diapausing eggs in the sediments (Hairston et al., 2005). These species had been undetected or misidentified in samples taken during those years, and were later identified through a combination of morphological, hatching, and genetic analyses of ephippia and eggs stored in the sediments. Genetic analyses revealed that the population of one of these species was established by the introduction of only one or two individuals into the lake, a reminder of the tremendous dispersal and establishment capabilities of these dormant stages.

Evolution can also be studied using molecular genetic techniques applied to dormant propagules from lake sediments. The approach has enabled genetic analyses directly on diapausing eggs, without introducing the potential bias of examining only those individuals capable of hatching. DNA has been successfully extracted, amplified and genotyped from diapausing eggs hundreds to over a thousand years old (Ellegaard et al., 2020). Genotyping, though not able to provide insight into functional trait evolution, nevertheless has been used to document changes in clonal, species and hybrid composition. This approach has been used to demonstrate changes in genetic structure corresponding to alterations of the environment for a variety of taxa including rotifer response to changing water level (Epp et al., 2010) and *Daphnia* response to lake eutrophication (Brede et al., 2009; Frisch et al., 2014). Methods for whole genome sequencing of single diapausing eggs have been reported (Lack et al., 2018), providing potential for analysis of evolution in even greater detail once sequences are assigned to functional traits.

Resurrection ecology

Dormant propagules produced at different times in the past can be hatched or germinated and then grown in the laboratory to investigate how population physiological, morphological and behavioral phenotypes have changed in response to environmental change. This research approach, named "resurrection ecology" by Kerfoot et al. (1999), is an extension of classic paleolimnology that provides a powerful method for investigating the trajectories and rates of evolution.

A study of the 17-year history of changes in size-selective predation by fish on *Daphnia magna* was recorded by observing changes in the size and density of the cladoceran ephippia in the sediments of a fish pond (Fig. 5) (Cousyn et al., 2001). Then, studies of the predator avoidance behavior of clonal genotypes hatched from different time periods demonstrated that the species evolved rapidly in response to changes in fish predation pressures (Fig. 6).

Eutrophication of Lake Constance caused an increase of cyanobacteria in the water column, a phytoplankton group known to be of poor food quality to *Daphnia*. Experiments on *Daphnia* hatched from sediments corresponding to times after a decade of eutrophication show that they are more resistant to toxic cyanobacteria than are *Daphnia* hatched from sediments deposited before eutrophication, when cyanobacteria levels were much lower. This rapid evolution of phenotypes is associated with a change in molecular genetic frequencies over the same time period (Hairston Jr. et al., 2001).

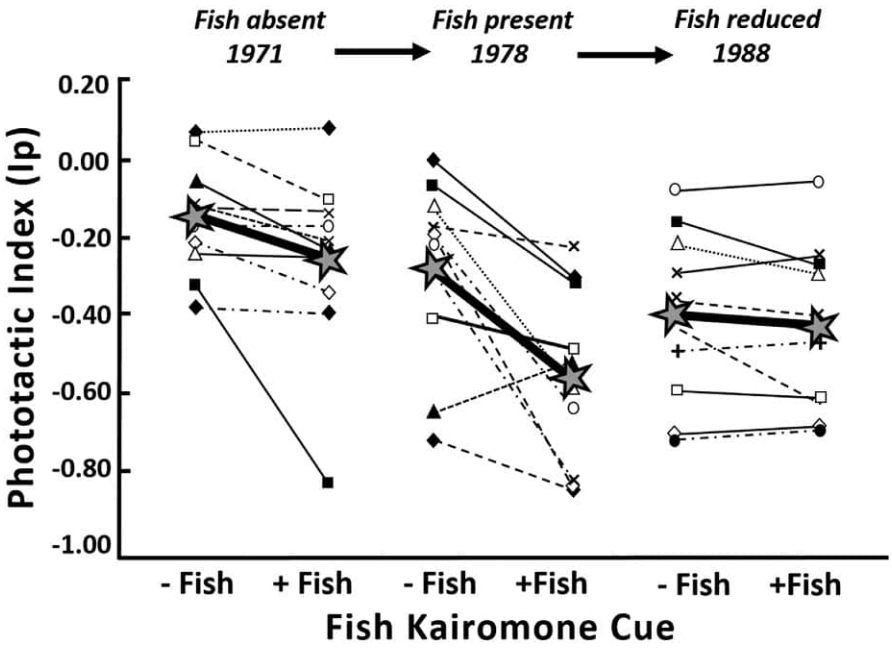

Fig. 6 Evolution of *Daphnia magna* predatory-fish avoidance behavior when fish were present in a Belgian fish pond, and loss of that avoidance behavior when fish were absent or rare. The predator-avoidance behavior was determined for *Daphnia* hatched from diapausing eggs collected from three different sediment depths. The 1988 and 1971 sediments are from time periods when *Daphnia*-eating fish were either rare or absent; the 1978 sediments are from a time when these fish were abundant (see Fig. 5). For each time period, the vertical distribution of *Daphnia* was determined in an illuminated cylinder of water ("phototactic index") for each of 10 different *Daphnia* clones (each clone descended from a single diapausing egg) in water without (– Fish) or with (+ Fish) fish kairomone cue. *Daphnia* sensitive to fish have a low phototactic index (lp) because they swim away from illuminated water (in a pond that would be to a depth where fish cannot see them). The sloping lines show the lp for each clone in the absence or presence of the fish kairomone cue. Sensitive clones have a strong response to the kairomone and so a steep slope; insensitive clones have lines with little or no slope. The average sensitivity, shown with stars connected by a thick solid line, is greatest during the period when fish were present. Original data from Cousyn CL, De Meester L, Colbourne JK, Brendonck L, Verschuren D and Vlockaert F (2001) Rapid, local adaptation of zooplankton behavior to changes in predation pressure in the absence of neutral genetic changes. *Proceedings of the National Academy of Sciences USA* 98: 5256–6260; figure redrawn from Hairston NG Jr. and De Meester L (2008) Daphnia paleogenetics and environmental change: Deconstructing the evolution of plasticity. *International Review of Hydrobiology* 93: 578–592.

Decaestecker et al. (2007) used a resurrection ecology approach to show the co-evolutionary interplay between host sensitivity to its pathogens and pathogen virulence over the course of three decades. Both *Daphnia* diapausing eggs and spores of *Daphnia*'s bacterial pathogen, *Pasteuria*, were hatched or germinated from a series of sediment ages and the susceptibility of the host was assayed for pathogens present before, during and after each time period from which the *Daphnia* were obtained. The study showed that, evolutionarily, pathogen infectivity rapidly tracked host resistance: a clear example of so called "Red Queen" dynamics.

It is furthermore possible from these resurrection ecology studies to delve deeper into the evolutionary process by exploring the rates of evolution and the evolution of plasticity (Hairston Jr. and Meester, 2008), comparing the rates of molecular and phenotypic evolution (Cousyn et al., 2001; Frisch et al., 2014), defining the constraints placed by trait covariance on evolutionary response (Ellner, 2013), and quantifying the reciprocal effects of ecological change on the evolution of traits and influence the strength of ecological interactions, which then in turn affect further evolution (Ellner et al., 2011), in a process called eco-evolutionary dynamics (Hendry, 2017).

Conclusions

Egg banks collect dormant propagules of many aquatic organisms in lake sediments. These propagules allow populations to move in time in the sense that their genetic descendants can emerge many years after the propagules were deposited on the lake bottom. Long-term dormancy allows species to "bet hedge" and survive in temporally-varying environments, escape competitive exclusion, minimize the negative effects of predators and pathogens, and recolonize after periods of environmental change. Lake size and shape influences both where dormant propagules accumulate and the likelihood that they will receive hatching cues, and can therefore influence the dynamics of populations that rely on egg banks for persistence.

Egg banks can be used to better understand evolutionary and ecological processes. The history of a lake or pond population can be reconstructed by examining its egg bank. Past population sizes and genetic diversity, as well as community composition can be explored using egg banks. We can also directly assess rates of evolution and or responses to environmental change in past populations by hatching individuals from different time periods to measure their phenotypes.

Trophic Dynamics and Food Webs in Aquatic Ecosystems☆

U Gaedke, University of Potsdam, Potsdam, Germany

This is an update of U. Gaedke, Trophic Dynamics in Aquatic Ecosystems, In Encyclopedia of Inland Waters, Edited by: Gene E. Likens, Academic Press, 2009, https://doi.org/10.1016/B978-012370626-3.00208-8

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor, Lars Rudstam.

Glossary

Detrital food chain Food-web components that begin with particulate organic matter (detritus) or dissolved organic matter, and pass through bacteria to other consumers.
Ecological stoichiometry Study of element ratios within biomass in relation to element ratios within food or in the surrounding environment.
Food web A diagram or model that shows the feeding connections between all major groups of organisms in an ecosystem.
Grazer food chain Components of a food web that begin with photoautotrophs (in pelagic systems: cyanobacteria, algae, aquatic vascular plants) and pass through herbivores to carnivores.
Trophic guild A group of organisms that share common food sources and common predators.
Trophic level A group of organisms that obtain their food from sources of equal distance from the original source. Autotrophs equal level 1, herbivores equal level 2, primary carnivores equal level 3, and secondary carnivores equal level 4. Species feeding from more than one level may be assigned a fractional trophic level called trophic position based on their diet composition.
Trophic transfer efficiency The fraction of total production at a given trophic level that is converted to production at the next trophic level.

Introduction

An understanding of the role of individual species within an ecosystem and the functioning of ecosystems in their entirety is only possible by considering the multitude of simultaneous interactions among all species present. Feeding relationships have proven to be an essential part to bridge the gap between populations and ecosystems. Early studies of this type involved pyramidal diagrams of feeding levels (trophic levels) in an ecosystem (Fig. 1). Such a diagram begins with photoautotrophs (level 1) such as phytoplankton and higher plants, which live by using inorganic substances and solar energy to synthesize biomass. Photoautotrophs are consumed by herbivores, which are the first level of consumers. Herbivores in turn are consumed by carnivores of the first level, which are consumed by carnivores of the second level. When the organisms are arranged by trophic level, they can be shown as a vertical stack of boxes that comprises a feeding pyramid (or trophic pyramid), or they can be shown in more detail as a diagram with separated compartments connected by lines indicating the feeding pathways (Fig. 2).

Because there are numerous kinds of organisms at any given trophic level, a feeding diagram takes the form of a web, which gives rise to the term "food web". A diagrammatic analysis of a food web may be relatively simple if it aggregates all species into only a few compartments. However, it is typically more realistic to differentiate more precisely between the different properties of the component organisms and explicitly include the subdominant members as well, yielding a higher number of compartments.

A purely qualitative diagram is informative in respect to who eats whom, but a quantification of the amount of energy or materials passing through the food web produces considerably more insight into ecosystem functioning as the quantitative importance of the fluxes varies by orders of magnitude (Fig. 2). Quantitative studies of feeding relationships at the ecosystem level may be referred to as "food-web analysis" or "trophic dynamics."

☆*Change History:* December 2020. U. Gaedke updated entire text and added Fig. 4 for extra explanation.

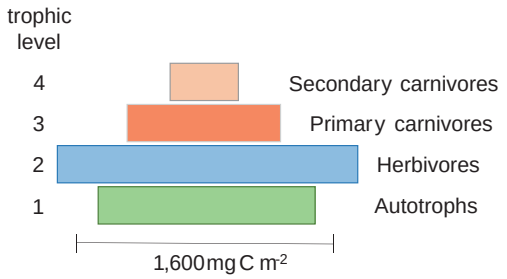

Fig. 1 A pyramid of the annual biomass of organisms arranged by trophic level from the pelagic zone (open water) of Lake Constance, adjacent to Germany, Switzerland, and Austria (grazing chain only). The biomass at the third and at the fourth trophic level, in particular, are reduced by severe fishing pressure (Gaedke et al., 2002).

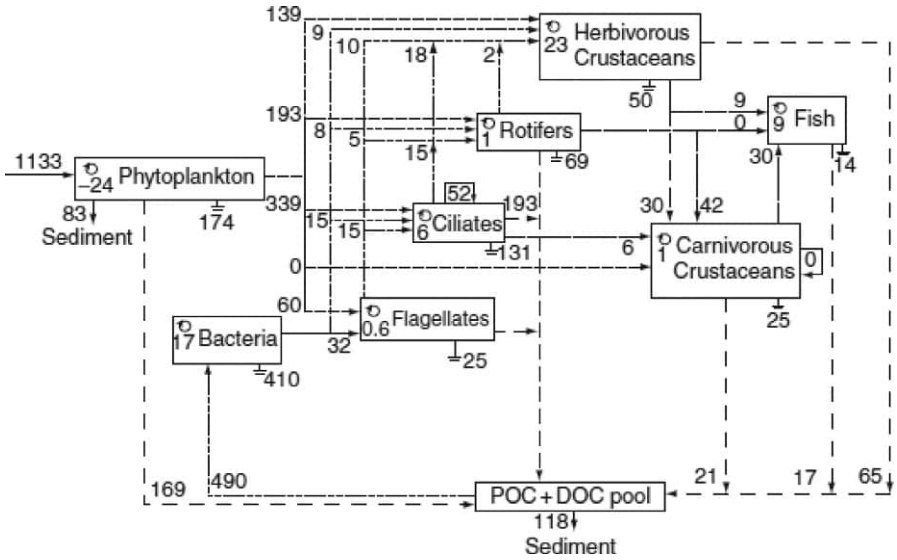

Fig. 2 A modern food-web diagram for the pelagic zone (open water) of Lake Constance. Fluxes are given as mg C m^{-2} d^{-1}. Circles within the compartments symbolize biomass changes during the investigation period and the symbol with two horizontal bars the losses by respiration. Gaedke U, Hochstädter S, and Straile D (2002) Interplay between energy limitation and nutritional deficiency: Empirical data and food web models. *Ecological Monographs* 72: 251–270.

Feeding relationships as portrayed in a food web may be quantified by any of several commodities, according to their relevance to understand the food web dynamics. For example, the amount of biomass passing from the prey to the predators may be quantified in units of fresh weight, dry weight or carbon. The energy equivalent per unit mass is fairly constant among most organism if the biomass is measured in units of carbon (or ash-free dry weight which can typically be converted to carbon by multiplying by 0.5 approximately). Hence, it provides also a quantification of energy flows, which can be connected to the metabolism of the groups of organisms.

It is also possible to study food webs quantitatively in terms of the passage of an element or even a class of compounds through the food web. In addition to carbon, representing a surrogate for food quantity and energy, fluxes are often quantified additionally in units of phosphorus, nitrogen and/or silicate, representing potentially limiting inorganic nutrients for autotrophic and for herbivore growth. Using nutrient fluxes enables studies of the importance of nutrient recycling within food webs. To further account for food quality it is also possible to include the flow of other essential organic substances such as polyunsaturated fatty acids or cholesterol through food webs. Thus, food webs can be quantified in various ways to answer a large variety of questions.

Trophic levels and trophic positions

Modern food-web analysis grew from the concept of the trophic pyramid (Fig. 1), which was used by the British ecologist Charles Elton (1900–91) and other founders of modern ecology to summarize information on the roles of organisms in ecosystems. When based on biomass, such a diagram takes a pyramidal shape for terrestrial environments whereas it resembles more a column for pelagic ecosystems at least for the lower trophic levels. That is, the laws of nature do not require the pyramidal shape, and a higher trophic level may have the same or even more biomass than a lower trophic level adjacent to it (for details see below).

The concept of the trophic pyramid was advanced significantly toward modern food-web analysis by Raymond Lindeman (1915–42) who, working with Evelyn Hutchinson (1903–91), introduced the concept of trophic dynamics. The linkages between trophic levels, when portrayed as energy flows, provide a view of the ecosystem that is linked to the solar energy source and to the metabolism of individual organisms. Furthermore, an analysis of trophic relationships based on energy leads to the calculation of the efficiency to transfer energy from lower to higher trophic levels.

The early concept of trophic levels contained several important flaws, the solution of which has produced a number of innovations. The first and most obvious flaw is that individual organisms often cannot be assigned to a single trophic level. For example, an omnivorous organism, such as a crayfish, is able to derive nourishment from both plant and animal matter, and therefore cannot be assigned either to the level of herbivores or to the level of carnivores. It is especially common for high-level carnivores to feed at multiple lower levels, including herbivores and lesser carnivores, at the same time. But also photoautotrophs, such as pitcher plants and numerous phytoplankter, may supplement their gain of energy and inorganic nutrients by consuming heterotrophic organisms such as insects or bacteria. In the case of phytoplankton, they are called mixotrophs as they combine an autotrophic and heterotrophic life style.

Hence, the modern view is that species must be assigned to fractional trophic levels, called trophic positions that reflect their diet. For example, an omnivore (e.g., a bear or a crayfish) feeding 50% on level 1 (e.g., autotrophs) and 50% on level 2 (e.g., herbivores) would be assigned a trophic position of $2^{*}0.5 + 3^{*}0.5 = 2.5$. Thus, models can take into account proportionate differences in the diet composition.

A second problem arises from organisms that use particulate organic matter (POM, detritus, also designated as particulate organic carbon POC) or dissolved organic matter (DOM; also designated dissolved organic carbon, DOC) as food. Modern food-web analysis views such feeding relationships as a "detrital food chain", which is an important complement to the more traditionally recognized "grazing food chain" that is based exclusively on photoautotrophs passing organic matter to herbivores and subsequently carnivores. The detrital food chain, like the grazer food chain, contains multiple levels (Fig. 3).

Inclusion of the detrital food chain leads to a more realistic view of bacteria in ecosystems. Heterotrophic bacteria are often the direct consumers of detritus (which they dissolve prior to consuming) and dissolved organic matter. Even though they create biomass at the base of the detrital food chain, they cannot do so through use of sunlight, as in the case of production of photoautotrophs, such as algae and vascular plants at the base of the grazing food chain. The realities of the detrital food chain must be incorporated into quantitative models because detritus and dissolved organic matter are abundant in all ecosystems. Detritivores such as bacteria are now commonly assigned to the first trophic level.

The increasingly realistic view of food webs leads away from the traditional pyramid or four-step energy diagram (Fig. 1) and more toward diagrams that show various groups of organisms occupying non-integer positions in the grazing food chain, and connected to the detrital food chain, which incorporates bacteria as first-level producers of biomass (Fig. 2) (Gaedke et al., 2002).

Use of trophic guilds to analyze the trophic structure of food webs

A trophic guild consists of all organisms within a food web that have similar food sources and predators (e.g., the compartments shown in Fig. 2). In most cases, trophic guilds defined in this way would consist of multiple species, all of which would occupy similar positions in the trophic diagram or food-web model. Thus, application of the concept of guilds simplifies analysis and modeling of food webs.

The use of trophic guilds also enables us to handle the complication that species may change their feeding habits during their ontogenetic development. For example, piscivorous fish typically feed on zooplankton when they are small but feed on other fish

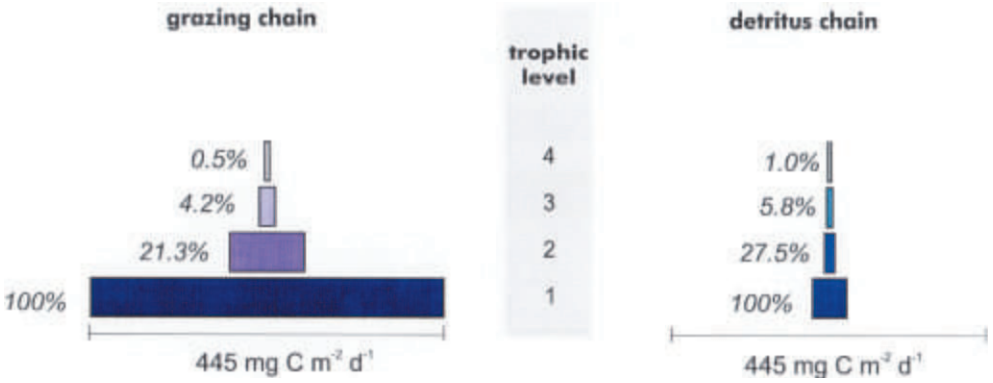

Fig. 3 Trophic pyramids for the grazing chain and the detritus chain of Lake Constance, shown is the daily production averaged across years. That is, values are higher in spring and lower in winter. Gaedke U, Hochstädter S, and Straile D (2002) Interplay between energy limitation and nutritional deficiency: Empirical data and food web models. *Ecological Monographs* 72: 251–270.

when they are large. In such cases, the younger stages of a certain species are assigned to a different guild than the older individuals of the same species.

Fig. 2 shows the structure of a food-web model of the open waters of Lake Constance, which adjoins Germany, Switzerland, and Austria. The model is based on compartments corresponding to guilds of organisms as well as a pool of DOM and POM. Carbon comes into the food web through this DOM and POM pool or through a photosynthetic guild (in this case, phytoplankton) and leaves the food web either as sedimentation of POM to the bottom of the lake or release of CO_2 gas to the water as a by-product of respiration. Circles within each of the compartments indicate biomass changes (in this case expressed as mg C m^{-2} d^{-1}). Arrows passing from one compartment toward another indicate consumption, and arrows passing out of each compartment going to the POC + DOC pool indicate fecal output. Further losses of C and energy occur via respiration. The numbers indicate fluxes (biomass per unit time for a given unit area of the lake, here mg C m^{-2} d^{-1}). Establishing such mass-balanced quantitative food web models demands appropriate computer programs, which assure that the energy entering each compartment via, for example, ingestion equals the sum of all loss factors (e.g., excretion, respiration, predation and changes in biomass).

A quantitative model such as the one shown in Fig. 2 is either an average for a considerable period of time or snapshot of a short period of time (Gaedke et al., 2002). The flow of mass from one compartment to another can be expected to change substantially from season to season and even week to week in a lake. Thus, modeling that encompasses changes occurring over any substantial period of time (e.g., a year) can require a great deal of information. It results in a web that likely never exists at any distinct moment in time. Nevertheless, it is informative by revealing average conditions of the main fluxes that account for ecosystem metabolism and the efficiency of transfer of mass or energy through the food web.

Trophic transfer efficiency

The trophic structure of a food web is affected greatly by loss of energy that occurs when transferring energy from one trophic level to the next. It amounts to at least 70% but is often higher (90% or more, see below) (Fig. 3) (Gaedke and Straile, 1994). The second law of thermodynamics, when applied to trophic transfers, requires that dissipation of energy as heat will be a substantial loss even for the most efficient transfers. For example, the growth efficiency of individual cells seldom exceeds 40%, even when non-metabolic losses are disregarded (Straile, 1997). Ecological factors introduce additional non-metabolic inefficiencies related to non-grazing mortality, export of organic matter from the system (outflow or sedimentation), and excretion/egestion (urine and fecal output, hereafter referred to as excretion). That is, biomass produced at a distinct trophic level is either not consumed but dies prior to consumption and is thus channeled to the detritus chain, or ingested by the next higher trophic level (Fig. 4). The ingested food is either excreted because it cannot be digested, or it is assimilated. The assimilated substances are either used to cover the respiratory needs or converted into new consumer biomass (including somatic growth and reproduction).

Losses by excretion are typically high for organisms feeding on organic sources that are difficult to digest. This is particularly the case for herbivores consuming vascular plant tissue, which is rich in chemically complex substances that are difficult to digest such as lignin.

All organisms must respire in order to live. Respiration involves the release of chemical energy from organic matter. The energy gain is used either for synthesis of new biomass (including somatic growth and reproduction), or to maintain the integrity of basic metabolic functions that sustain life. This basal respiration is relatively low for unicellulars and invertebrates, increases for ectothermal vertebrates such as fish, amphibians and reptiles, and is very high for endotherms like birds and mammals.

A further loss factor is non-grazing mortality, which can occur when organisms are exposed to lethal physical or chemical conditions, physiological death related to age, or inadequate nutrition. It diverts biomass and energy from the transfer process that

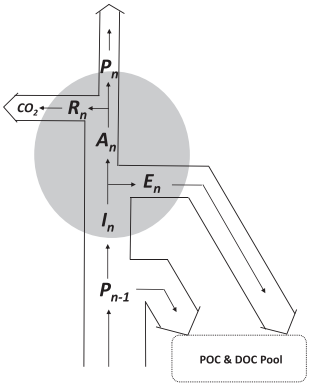

Fig. 4 Bioass produced at the trophic level n–1, P_{n-1}, either dies prior to consumption and fuels the pool of dead particulate or dissolved organic carbon (POC and DOC), or it is ingested by the next trophic level, I_n, i.e., it is taken up by a consumer, here symbolized by the shaded circle. The ingested food is either excreted, E_n and channeled to the POC + DOC pool, or assimilated, A_n. An often substantial fraction of A_n is respired, R_n, and the remaining part can be used for new production, P_n.

connects one trophic level to the next. Both, non-grazing mortality and excretion pass energy and mass to the POC + DOC pool and thus the detrital food chain (Fig. 4).

The various modes by which energy and mass can be lost are the basis for quantifying several kinds of ecological efficiencies that are used in food-web analysis. The ratio of biomass production to biomass ingested, P_n/I_n, as food is symbolized by $K1$, the gross growth efficiency (which corresponds to the trophic transfer efficiency discussed earlier if all prey production is consumed). $K1$ rarely exceeds 0.30 under natural conditions, and often is considerably lower. The net growth efficiency of an organism ($K2$) is defined as the ratio of new biomass produced to the amount of biomass that is assimilated (i.e., passing through the gut wall into the body of the organism), P_n/A_n. This efficiency has a maximum value of ca. 50% for small organisms but is much lower for large organisms (e.g., fish or mammals) (Straile, 1997). Finally, the consumption efficiency represents the ratio between the amount of matter and energy ingested by the upper trophic level divided by the total production at the next lower level, I_n/P_{n-1}. Thus, it accounts for the non-grazing mortality. This efficiency is low if the material produced is hard to ingest or digest (e.g., wood) or if there are few consumers which can exploit the prey production at that time and location. This may be because the consumer level is itself strongly depressed by its predators, or because the prey grows much faster than the consumers and can build up high biomasses before predator abundances increase. This happens for example during the phytoplankton spring bloom.

Finally, the trophic transfer efficiency is the ratio of biomass production at one trophic level to the biomass production of the next lower level, P_n/P_{n-1}. Thus, it is the product of the consumption efficiency and the gross growth efficiency. In plankton food webs, trophic transfer efficiencies may be high (0.15–0.30) (Fig. 3) when compared with webs dominated by a transfer from vascular plants to herbivores or strongly involving birds or mammals. Temporal variability of the trophic transfer efficiency is high, even within a given ecosystem, because of the instability of the numerous factors that can affect it. For example, the trophic transfer efficiency is strongly reduced when inedible algae (such as cyanobacteria) dominate or when animals with high respiratory needs (such as vertebrates and especially birds and mammals) prevail.

Food quality and quantity

Heterotrophs (consumers, including bacteria) live by consumption of biomass or nonliving organic matter. Due to the chemical composition of biomass (disregarding skeletal material or support structures) across all heterotrophs falls within a relatively narrow range, carnivores that feed on other heterotrophs are assimilating approximately the same mixture of elements that they will need in order to synthesize their own biomass (skeletal material and support structure typically pass through the gut unassimilated). Hence, their food quality is high. Detritivores also benefit from this carryover of elemental mixtures from one kind of organism to another, although detritus is more likely to show some selective loss of elements such as nutrients that would alter the balance typical of living biomass.

Unlike heterotrophs, photoautotrophs assimilate elements separately from water or, if they are rooted vascular plants, from sediments. For example, carbon is derived from H_2CO_3 and related inorganic carbon forms dissolved in water, and phosphorus is taken up separately as phosphoric acid that is dissolved in water. Large imbalances may develop when some essential components are much more abundant than others because the inorganic substances required to synthesize biomass are taken up separately. For example, phytoplankton has a high carbon:nutrient ratio under nutrient-depleted conditions. Thus, autotrophs face greater challenges than carnivores in assembling the necessary ratios of elements to synthesize biomass, but also herbivores (and bacteria) can experience imbalances of elements.

The approximate ratios of elements that are characteristic of autotrophic biomass have been extensively studied. Characteristic ratios of carbon to nitrogen and phosphorus are often the greatest focus of analysis. Because carbon is the feedstock for photosynthesis and phosphorus and nitrogen are the two additional elements that are often in short supply for conversion of photosynthetic products (carbohydrates) to other molecule types that are needed for the synthesis of protoplasm (e.g., amino acids which are rich in N, or RNA which is rich in P). The importance of C:N:P ratios in aquatic organisms was first brought out by Alfred Redfield (1890–1983), who discovered that healthy oceanic phytoplankton show a characteristic molar C:N:P ratio of about 106:16:1. Thus, the nutrient status of a phytoplankton community can be judged to some degree from the elemental ratios. For example, a phytoplankton community suffering phosphorus deficiency may show a C:P ratio of 500:1 rather than 106:1, as predicted by the Redfield Ratio for well-nourished phytoplankton. The analysis of elemental ratios for diagnosis of elemental imbalances is termed “ecological stoichiometry” (Sterner and Elser, 2002).

Imbalances in elemental ratios in one trophic level can create imbalances in the diet and thus an inefficient transfer of energy to the next trophic level. This is particularly true between primary producers and herbivores. For example, plants suffering phosphorus scarcity may pass biomass with a high C:P ratio to their grazers. The grazers must then consume extra food in order to obtain the correct balance for the synthesis of their own biomass because of an imbalance of elements in the food. Similarly, an especially low C:P ratio (e.g., 50:1) will provide an oversupply of phosphorus (e.g., when bacteria are consumed), a large part of which is released to the environment without generating any biomass.

Another strategy that herbivores may employ in improving the elemental balance of food intake is to consume heterotrophs in addition to autotrophs (omnivory, which is feeding at multiple trophic levels) as animals and bacteria are generally more nutrient rich than autotrophs. Thus, combining the consumption of a phosphorus-rich food (high quality) with a carbon-rich food (often available in high quantity, e.g., grass), enables a more efficient use of ingested mass than a single food type.

Trophic structure of food webs in open water, near shore and wetlands

In the open water of a lake or the ocean at some distance from the shore (i.e., in the pelagic zone), the dominant autotrophs are phytoplankton, which live as individual cells or colonies of small cells suspended in the water. Some groups of phytoplankton (e.g., filamentous cyanobacteria) are rejected by most grazers because they are difficult to ingest or digest due to their toxicity. Algae of low palatability may become quite abundant when grazing pressure is high under highly eutrophic conditions. Overall, however, phytoplankton often is composed of a high proportion of edible and digestible species. Thus, a large proportion enters the grazing chain. Rooted vascular plants, which can only grow in shallow waters, offer a less useful food supply because the digestible component of their biomass is embedded in complex carbohydrates that maintain the shape of the plant. This is particularly valid for emergent growth forms like reed. For this reason, much of their biomass that develops during a growing season dies and decomposes rather than being eaten while alive. The detrital food chain benefits from the biomass that was left uneaten by the grazer food chain. This pattern strongly resembles terrestrial ecosystems.

Macrophytes may account for most of the autotroph biomass in a littoral zone, but attached algae colonize macrophytes and all other surfaces that are illuminated. Given their high food quality, edibility and growth rate, these attached autotrophs (periphyton) are an important food for herbivores in the littoral zone despite their low biomass compared to the macrophytes.

The trophic structure in the pelagic zone often is dominated by four significant trophic levels (or even more in the ocean) (Andersen et al., 2016). The top predator guild, which may consist of multiple fish species, is not exposed to substantial predation pressure because of its size and mobility. It therefore builds up biomass until it is limited by scarcity of appropriate food. This type of limitation is called a "bottom up" limitation because the trophic level below is restricting the increase in biomass of the trophic level above. The prey of the top predator, in turn, is controlled from the top down. "Top down" control in this situation involves suppression of the biomass of the trophic level that serves as food for a bottom-up controlled level which heavily exploits its food sources. Thus, top-down and bottom-up control alternate along a food chain.

In a four-level food web, the third level consists of first level carnivores. When top predators are abundant, these intermediate predators (e.g., fish that eat herbivorous zooplankton) are suppressed, which relieves predation pressure on herbivores. Therefore, herbivores may become abundant and increase in biomass. This, in turn, will impose a strong grazing pressure on autotrophs like phytoplankton, which can cause a decline in their biomass, yielding a higher water transparency. Thus, water clarity may be enhanced by stocking large predatory fish. This technique is called biomanipulation. However, its success is often limited due to the usually web-like structure of pelagic food webs.

Physical factors may affect the structure of food webs as well. For example, the absence of any solid attachment points in the pelagic zone requires that all autotrophs are small. This is partly because large cells have a lower surface-to-volume ratio making them less competitive than small cells in taking up nutrients from the water. In addition, large cells may sink faster out of the illuminated surface layer. Thus, the pelagic food web must be based on herbivores capable of harvesting large numbers of small autotrophs. The grazers that can do this work have to be small, which implies that generally only small carnivores can efficiently exploit the (small) herbivores (unless they are, for example, very efficient filter feeders that can rely on spatial subsidy effects like some whales). This leaves the opportunity for a top carnivore level that feeds on the small carnivores but cannot use the herbivores efficiently as they are too small compared to its own body size. Thus, the food chain cannot be shortened by having the top predator feeding directly on the more abundant herbivores. Hence, we find a distinct relationship between trophic position and body size in pelagic ecosystems (Gaedke and Kamjunke, 2006; Andersen et al., 2016). This stands in contrast to terrestrial systems where autotrophs, herbivores and carnivores of almost every size occur and the food chains often comprise only three significant trophic levels as the top predator can hunt large herbivores. This shortens the food chain.

Food webs of the littoral zone in lakes are more similar to those of terrestrial environments or wetlands than to those of pelagic food webs if their production is dominated by vascular plants. Under these conditions often tall plants can attain more light and are thus more competitive. Grazers (herbivores) may then have a larger body size because larger plants are available. Thus, top carnivores may feed directly on herbivores rather than on intermediate carnivores and body size and trophic level are not as strongly correlated as in pelagic food webs. In this case, the herbivores come under top-down control, and the efficiency of energy transfer from plants to herbivores is reduced because there are not enough herbivores to consume the total plant production. Thus, the length of the food chain influences the amount of biomass present at each trophic level (Oksanen et al., 1981), often referred to as the trophic cascade (Carpenter et al., 1985).

The fact that in pelagic ecosystems all autotrophs are small and that the following trophic levels are increasingly larger in body size explains why we find a biomass column rather than a biomass pyramid in pelagic systems (cf. Fig. 1 and Gaedke, 1992). The weight-specific metabolic activity declines with increasing size, e.g., a kilogram of mice is metabolically more active than a kilogram of elephants. This so-called allometric relationship holds for all organisms and implies that small organisms consume and produce more per unit biomass than larger ones.

Hence, even with similar biomasses at each trophic level the autotroph production exceeds that of the herbivores which, in turn, is higher than that of the carnivores. Obviously, a lower production implies that also the food demands are lower at higher trophic levels. In other words, a certain biomass of autotrophs (herbivores) can sustain a similar biomass of herbivores (carnivores) because the losses occurring at each trophic transfer may be compensated by the higher weight-specific production of lower trophic levels comprising smaller organisms (Gaedke, 1992). This holds in particular if the non-grazing mortality is low and unicellular organisms or invertebrates dominate, having a high growth efficiency due to relatively low respiratory needs. Both conditions are typically fulfilled in unpolluted pelagic systems but not in terrestrial ones where often a large proportion of the primary production

is not consumed by herbivores. In contrast to pelagic systems, these herbivores may be birds or mammals which build up relative little biomass compared to their food intake given their high respiratory needs. However, in every ecosystem there is always a pyramid for the production as a substantial amount of energy is lost during each trophic transfer due to losses by non-grazing mortality, excretion and respiration (Fig. 3).

Transfer efficiency along the size gradient in pelagic food webs

In pelagic food webs, all autotrophs are small and predators exceed the size of their prey. Thus, matter and energy flow from small to progressively larger organisms. The entire food web's transfer efficiency along the size gradient of organisms reflects each of the trophic linkages and the number of trophic levels in the web (Gaedke et al., 1996). For example, the efficiency of fish production in oligotrophic lakes is lower than in eutrophic lakes when expressed as a proportion of the total amount of photosynthesis.

In oligotrophic lakes, food is more strongly dispersed, and has to be gathered by consumers that search for their prey and handle it individually. Consumers that locate their prey by searching usually are closer in size to their prey than filter-feeding consumers that can take up a large number of particles simultaneously. This feeding mode is successful under eutrophic conditions where prey densities are higher. When consumers are very close in size to their food source, the transfer of energy and materials along the size gradient up to large fish is less efficient because it requires more trophic transfers to reach a given size. Thus, there is a theoretical explanation for the lower transfer efficiency along the size gradient in oligotrophic lakes. This is an example of the use of food-web analysis to explain observations about productivity and efficiency in pelagic ecosystems.

Conclusion

Quantitative studies of food webs greatly magnify the value of information on individual populations. Analysis of linkages in the food web provide explanations for the efficiency of energy or mass transfer to various points in the food web and the controlling influences that either enhance or suppress production at a given trophic level. Thus, quantitative food-web studies support the understanding of mechanisms that govern the functioning of ecosystems.

Glossary

Biogeochemistry Scientific study of the mass flux of any element, compound, or group of compounds within or across the boundaries of an ecosystem or any other spatial component of the environment. Mass flux within an ecosystem is often designated as nutrient cycling or element cycling.
Cycling A biogeochemical term referring to the movement of elements or compounds within an ecosystem or any other bounded environmental system.
Ecosystem Any portion of the earth's surface that shows strong and constant interaction among its resident organisms and between those organisms and the abiotic environment.
Lake trophic state Fertility of a lake, as measured either by its concentrations of key plant nutrients (especially phosphorus and nitrogen) or the annual production of plant biomass (aquatic vascular plants and algae). Trophic-state categories include oligotrophic (weakly nourished), mesotrophic (nutrition of intermediate status), and eutrophic (richly nourished).
Mass flux Movement of mass per unit time, often in ecosystem studies expressed as mass per area per time.
Stable isotope Any isotope of an element that does not decay spontaneously.
Trophic dynamics Fluxes of energy or mass caused by feeding relationships, including rates of grazing by herbivores on plant matter, rates of predation by carnivores on other animals, or rates of decomposition of organic matter by microbes.

Introduction of the ecosystem concept

Scientific studies of lakes began as early as the seventeenth century, but at first were descriptive rather than analytical. Toward the end of the nineteenth century, measurements and observations on lakes became more directed. For example, the thermal layering of lakes was attributed to specific physical causes, and such phenomena as the movement of plankton in the water column were the subject of hypotheses that were tested with specific kinds of data (Kalff, 2002).

Comprehensive studies of lakes began with the work of Alphonse Forel (1841–1912) on Lac Léman (Lake Geneva), Switzerland, as well as other Swiss lakes. In a three-volume monograph (*Le Léman*: 1892, 1895, 1904), Forel presented data on a wide variety of subjects including sediments and bottom-dwelling organisms, fishes and fisheries, bacteria, water movement, transparency and color, temperature, and others. Thus Forel, who introduced the term 'limnology' (originally the study of lakes, but later expanded to include other inland waters), demonstrated the holistic approach for understanding a lake as an environmental entity, but without application of an explicit ecosystem concept (Vincent and Bertola, 2012).

The conceptual basis for studying lakes as ecosystems was first clearly given by Stephen Forbes (1844–1930; Fig. 1) through a short essay, *The Lake as a Microcosm* (1887). Forbes was professor of biology at the University of Illinois in Champaign, IL, USA, and director of the Illinois Natural History Laboratory (subsequently the Illinois Natural History Survey), which was charged with describing and analyzing the flora and fauna of Illinois. Forbes realized that it was not possible to achieve a full understanding of a lake or, by implication, of any other environmental system such as a stream or forest, simply from knowledge of the resident species. Forbes proposed that the species in a particular environment, when interacting with each other and with the nonliving components of the environment, show collective (system) properties. The microcosm that Forbes described today would be called an ecosystem,

☆*Change History:* July 2021. WM Lewis updated synopsis for clarity, added new paragraph and Table 1 in Introduction, edited Metabolism in Lakes section for clarity, edited Community Organization section for clarity, and added a new reference.

although this term did not come into use until 48 years later through the work of the British botanist A. G. Tansley. By current usage, an ecosystem is any portion of the Earth's surface that shows strong and constant interactions among its resident organisms and between these organisms and the abiotic environment (Golley, 1993).

Forbes not only described accurately the modern ecosystem concept, but also identified ways in which critical properties of ecosystems could be measured and analyzed (Table 1). In contrast to his fellow natural historians and ecologists, he was numerically oriented in that he emphasized the quantitative measurement of abundance and comparative abundance for species in an ecosystem or across ecosystems. He also recognized that ecosystem science best reveals the interface between human actions and the natural function of ecosystems; he characterized adverse human effects on ecosystems as comparable to the effects of disease on humans. He was probably the first ecologist to make specific use of statistics in testing ideas about relationships between different kinds of organisms. Overall, Forbes brought extraordinary intellectual vitality to the new science of ecology.

Although the essay by Forbes now is considered a classic in limnology and in ecology generally, it caused no immediate change in the practices of limnologists or ecologists. Like many important discoveries in science, it was a seed that required considerable time to germinate.

In studies of Cedar Bog Lake, Minnesota, for his Ph.D. at the University of Minnesota, Raymond Lindeman (1915–1942; Fig. 2) gave limnologists the clearest early modern example of the study of lakes as ecosystems. Rather than focusing on a particular type of organism or group of organisms, which would have been quite typical for his era, Lindeman decided that he would attempt to analyze all of the feeding relationships ('trophic' relationships) among organisms in Cedar Bog Lake. Thus, his Ph.D. work extended from algae and aquatic vascular plants to herbivorous invertebrates, and then to carnivores, and conceptually even to bacteria,

Table 1 Examples of innovative concepts that Forbes brought to ecology and limnology.

Concept	*Implication or outcome*
A key unit of nature is the ecosystem	Ecology requires the study of ecosystems
Ecosystems are integrated and self-regulated	Ecosystems show the balance of nature
Humans damage ecosystem functions	Ecosystem science has applications
Quantitative study of nature is essential	Descriptive or lab studies are insufficient
Statistics can be used in studying interactions	Ecosystem science needs quantitative tools
Competition takes several forms	Interactions require careful analysis
River ecology is important	Established first river lab (Illinois River)

Fig. 2 R. L. Lindeman and his famous study site, Cedar Bog Lake, MN. Reproduced from People of Cedar Creek website, with permission from Cedar Creek Natural History Area.

although there were no methods for quantifying bacterial abundance accurately at that time. Lindeman's descriptions of feeding relationships were voluminous but straightforward to write up and publish, but he sought some more general conclusions for which he needed a new concept.

Lindeman took a postdoctoral position with G. Evelyn Hutchinson at Yale University in 1942. Hutchinson had become a limnologist of note through his quantitatively oriented studies of plankton and biogeochemical processes in the small kettle lakes near New Haven. He would in subsequent decades become the world's most influential limnologist, and part of his reputation grew out of his contributions to the field of biogeochemistry, an important tool of ecosystem science (Sterner, 2012).

Hutchinson encouraged Lindeman's work on a groundbreaking paper, *The Trophic Dynamic Aspect of Ecology* (1942, published in the journal *Ecology*), which now is recognized as a landmark in limnology and in ecology generally. Lindeman proposed a way of converting the tremendous mass of highly specific information for Cedar Bog Lake into a format that would allow comparisons with any other lake or even with other kinds of ecosystems. Building on the work of the German limnologist August Thienemann and the British ecologist Charles Elton, Lindeman organized the feeding relationships as a feeding hierarchy within which each kind of organism was assigned to a specific feeding level (trophic level). He then proposed that the feeding relationship represented by any given link in the food web be quantified as an energy flow. Thus, the total energy flow from level 1 (plants) to level 2 (herbivores) could be quantified as the summation of energy flows between all pairs of plants and herbivores; a similar estimate could be made for all other adjacent pairs of trophic levels. In this way, the flow of energy across the levels of the food web could be expressed in quantitative terms.

The first important conclusion from Lindeman's energy-based approach was that each transfer of energy between trophic levels is governed by the second law of thermodynamics, which requires that significant energy loss must occur each time energy is transferred. Thus, Lindeman demonstrated why food webs have relatively few trophic levels: progressive dissipation of energy as it passes through the food web from the bottom (plants) to the upper levels (upper-level carnivores) ultimately provides insufficient energy for expansion of the food web to further levels. Also, analysis of a food web in this way sets the stage for calculating efficiencies of energy transfer, comparison of efficiencies across different ecosystem types, and the identification and analysis of bottlenecks restricting the flow of energy within the food web.

The contributions of G. Evelyn Hutchinson in the 1940s on the biogeochemistry of carbon in lakes also must be counted as landmarks in the development of ecosystem science. Even so, ecosystem science was scarcely represented in the research agenda of ecologists or in the academic curriculum as late as 1950. Penetration of ecosystem thinking into research, teaching, and public awareness occurred first through the publication of a textbook, *Fundamentals of Ecology* (1953), written by Eugene P. Odum, and especially through the second edition of the same book (1959), written by E. P. Odum and Howard T. Odum. The Odums visualized ecology as best viewed from the top down, with ecosystems as a point of departure and studies of ecosystem components as infrastructure for the understanding of ecosystems.

The ecosystem perspective has not displaced the more specialized branches of ecology that deal with particular kinds of organisms or specific kinds of physical phenomena, such as studies of water movement, optics, or heat exchange. Rather, ecosystem science has had a unifying effect on studies of ecosystem components (Fig. 3). Study of a specific ecosystem component produces not only a better understanding of that component, but also a better understanding of the ecosystem, which is a final objective for the science of an ecosystem type, such as lakes.

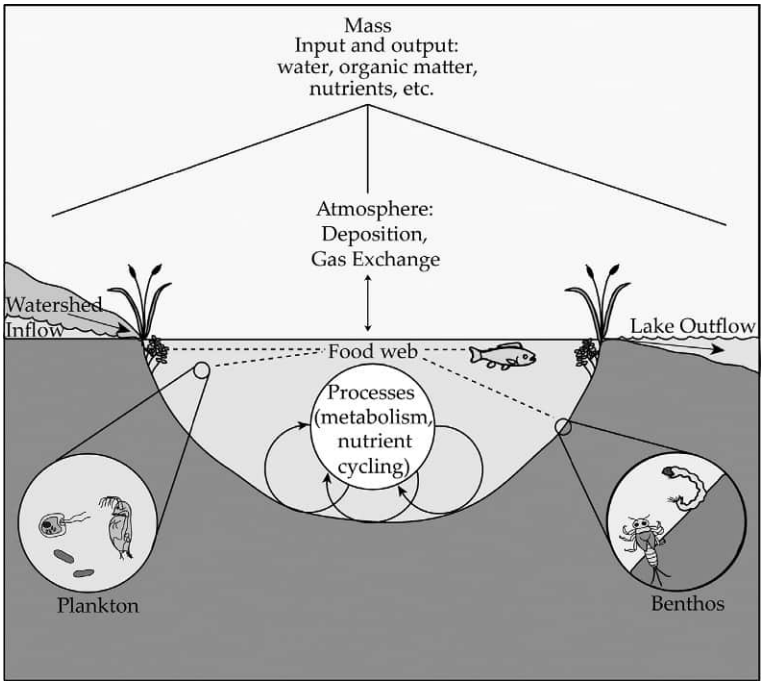

Fig. 3 Ecosystem diagram of a lake.

Metabolism in lakes

The dominant anabolic component of metabolism in lakes is photosynthesis based on carbon dioxide and water plus solar irradiance as an energy source. The dominant catabolic component is aerobic respiration based on the oxidation of organic matter with oxygen as an electron acceptor. Conversion of solar energy to stored chemical energy in the form of biomass seldom reaches 1% efficiency in lakes because of losses inherent in the wavelengths that can be intercepted by photosynthetic pigments, inefficiency in the interception process, and thermodynamic losses in the conversions leading to the production of biomass. Respiration also involves thermodynamic losses. Therefore, the solar energy source greatly exceeds photosynthetic output, and cellular capture of the energy released from organic matter by respiration greatly exceeds the energy stored in the organic matter. Aerobic photosynthesis is characteristic of the aquatic vascular plants, attached algae, and phytoplankton of lakes and occurs wherever light and oxygen are present. Aerobic respiration is characteristic of aerobic autotrophs as well as invertebrate and vertebrate consumers and bacteria; it occurs wherever oxygen is present (Table 2). Other categories of metabolism occur under either of two more restrictive conditions: (1) where light penetrates into an anaerobic zone, and (2) where there is an interface or mixing between oxidizing and reducing conditions, as is common near a sediment–water interface or between water layers of differing oxidation states.

A study of whole-ecosystem metabolism would require consideration of all of the metabolic categories listed in Table 2. The dominance of aerobic photosynthesis and aerobic respiration, however, often allows ecosystem studies to focus on these two metabolic components. In open water, photosynthesis and respiration are often measured with a vertical series of paired transparent and darkened incubation bottles filled with lake water; rate of decline of oxygen in the dark bottles indicates respiration rate, and rate increase of oxygen in the transparent bottles indicates net photosynthesis. In unproductive lakes, uptake of ^{14}C-labeled CO_2 can be used as an even more sensitive indicator of photosynthesis. Where macrophytes or attached algae are important, as is often the

Table 2 Summary of metabolic processes in lake ecosystems (note that aerobic respiration extends to animal consumer respiration in addition).

Metabolic process	*Energy source*	*Capabilities*			*Occurrence conditions in lakes*
		Eukaryotic plants	*Cyanobacteria*	*Other bacteria*	
Aerobic photosynthesis	Solar	Yes	Yes	No	Universal, photic, oxic
Anaerobic photosynthesis	Solar	No	No	Specialists	Occasional, photic, anoxic
Aerobic chemosynthesis	Inorganic oxidation	No	No	Specialists	Common, oxic/anoxic interfaces
Aerobic respiration	Organic oxidation	Yes	Yes	Yes	Universal, oxic
Anaerobic respiration	Inorganic or organic reduction	No	No	Yes	Common, oxic/anoxic interfaces

case in small lakes, separate measurements must be made of their photosynthesis, typically by the use of enclosures. The metabolic rates of microbes in deepwater sediments can be inferred from the rate of oxygen loss from the hypolimnion of a stratified lake, or can be measured with enclosures.

Annual rate of photosynthesis and respiration per unit area (typically given as mg C m^{-2} $year^{-1}$) is the most commonly used metabolic statistic for lakes. A complete metabolic accounting would also include processing of organic matter entering a lake from the surrounding terrestrial environment, primarily through stream flow and groundwater inflow.

Total annual net production of autotrophs (production in excess of respiration) is a measure of the capacity for a lake to generate biomass at higher trophic levels (Fig. 4).

Also, the time-course of production, which shows seasonal and nonseasonal variation, is often a useful point of departure for the analysis of mechanisms that control biotic functions in a lake. Factors that may suppress production include deep mixing of the water column, exhaustion of key nutrients, grazing, and hydraulic removal of biomass. Photosynthesis and respiration often respond differently to a specific physical or chemical change.

Food-web analysis

Modern food-web analysis follows the example given by Lindeman. The sophistication of the analysis is much greater today than it was in 1942, however, and the methods of food-web analysis have diversified as well (Belgrano et al., 2006; Carpenter, 2003).

At the base of the food web is organic matter generated within a lake or coming to a lake from its watershed and atmosphere above (Fig. 5). All of these sources of organic matter can be quantified, as explained in the preceding section, but require the application of several methods and must take into account both spatial and temporal variability in the synthesis or transport of organic matter.

Quantification of linkages in the food web begins with feeding relationships between autotrophs (primary producers) and herbivores (primary consumers). Analysis of gut contents is one method for establishing the linkage between a specific kind of consumer and one or more plant foods. A linkage measured in this way has two disadvantages, however: (1) it is not quantitative because consumed food items often cannot be identified fully, and (2) it is subject to errors of interpretation caused by the ingestion of foods that are not assimilated or only partially assimilated through the gut wall of a consumer. The first problem can be overcome either by the use of feeding experiments or by the quantification of growth rate of the consumer, supported by empirically-based knowledge of growth efficiency of the consumer. The second problem can be resolved by experimental use of tissue labels (typically radioisotopes) or, more efficiently, by the use of stable isotopes as passive tracers (i.e., relying on the natural abundance of stable isotopes to infer food sources). For example, because primary producers of different categories may differ substantially in their

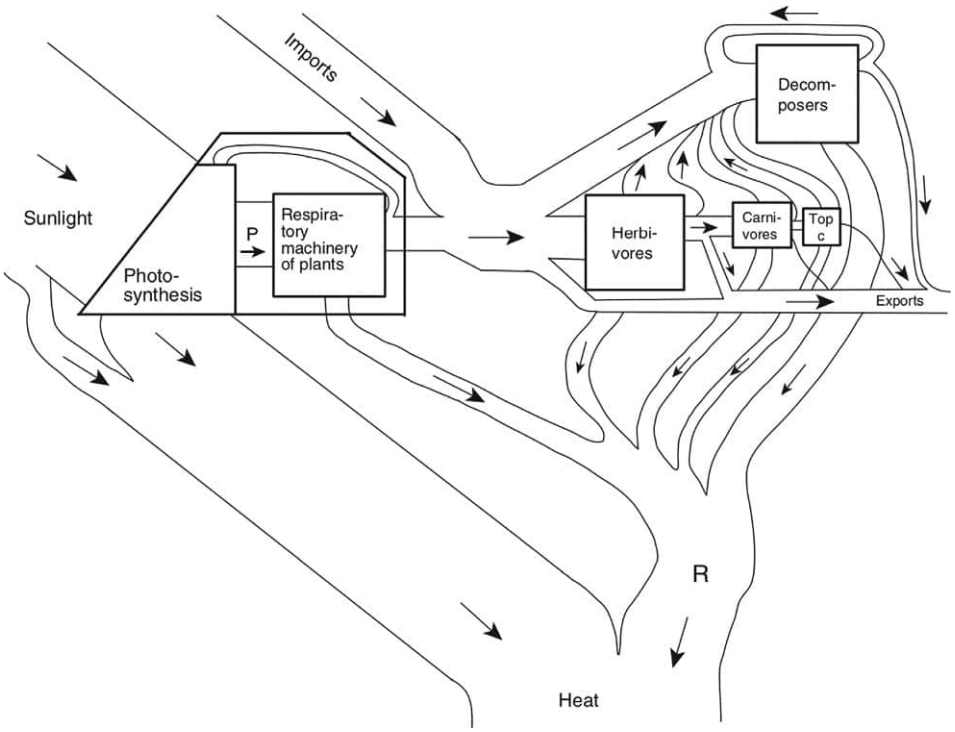

Fig. 4 Example of an early metabolic (energy-flow) diagram for an aquatic ecosystem. Reproduced from Odum HT (1956) *Limnology and Oceanography* 1: 102–118, with permission from the Association for the Sciences of Limnology and Oceanography (ASLO).

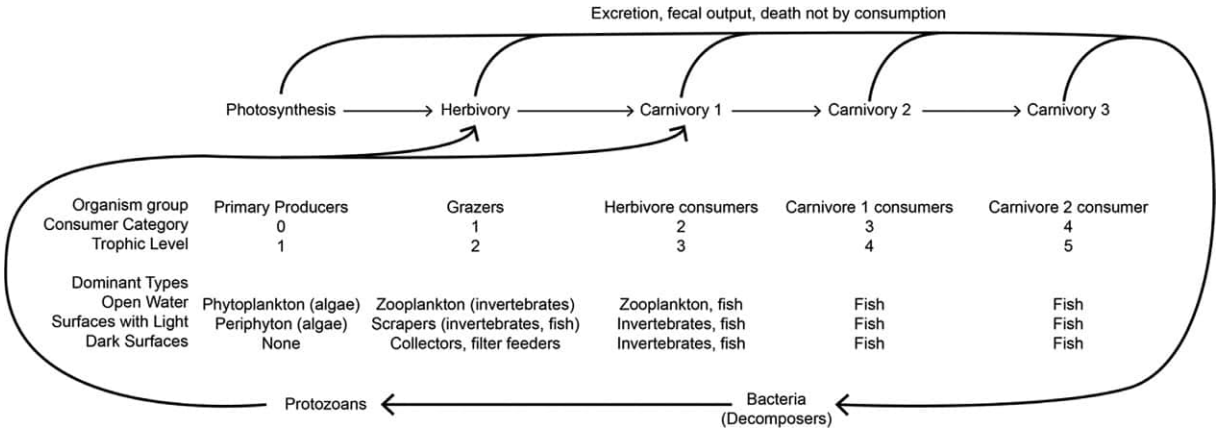

Fig. 5 Ecosystem foodweb components shown as flow of energy or biomass. Bacteria and protozoans, shown at the bottom of the figure, are abundant in all ecosystem components (open water, surfaces with light, dark surfaces, anaerobic synthesis omitted). concentration of the stable carbon isotope ^{13}C, analysis of ^{13}C content of protoplasm from a consumer may allow a quantitative estimation of the relative importance of several possible foods contributing to the synthesis of biomass by the consumer.

Above the level of primary consumers (herbivores) are carnivores that consume herbivores or other carnivores (third and fourth level consumers). Measurements of growth rate, along with gut-content analysis and use of passive or active tracers, can be applied to carnivores just as they are to herbivores. Within the carnivore trophic levels, however, the assignment of consumers to a specific trophic level may be difficult because carnivores often consume foods belonging to more than one trophic level. The stable nitrogen isotope ^{15}N is useful in assigning a species to a fractional position on the food web because ^{15}N shows increasing tissue enrichment from one trophic level to the next.

When completed, a food-web analysis shows the efficiency of energy transfer from one level to the next. Because of the thermodynamic limits on efficiency and inefficiency in capture and assimilation of food, a food-web analysis based on energy shows whether particular linkages are unusually weak or strong. Such observations in turn lead to hypotheses about mechanisms of control for energy transfer within the food web. For example, modern ecosystem theory includes the concept of 'trophic cascades' involving 'top-down' and 'bottom-up' effects on trophic dynamics, which is easily applicable to lakes. Change in one trophic level may be visible in other trophic levels, in the form of a cascade (Fig. 6). Top-down effects pass from any trophic level to the next trophic level below. For example, an unusual abundance of algal biomass in a lake could be traced to unusually efficient removal of herbivores through predation at such a rate as to leave algae mostly uneaten (a top-down effect).

Similarly, bottom-up control passes from any trophic level to the next level above. For example, the inability of an oligotrophic (nutrient-poor) lake to grow substantial amounts of algal biomass (phytoplankton) exerts a bottom-up effect on all higher trophic levels by restricting the amount of energy that is available at the base of the food chain.

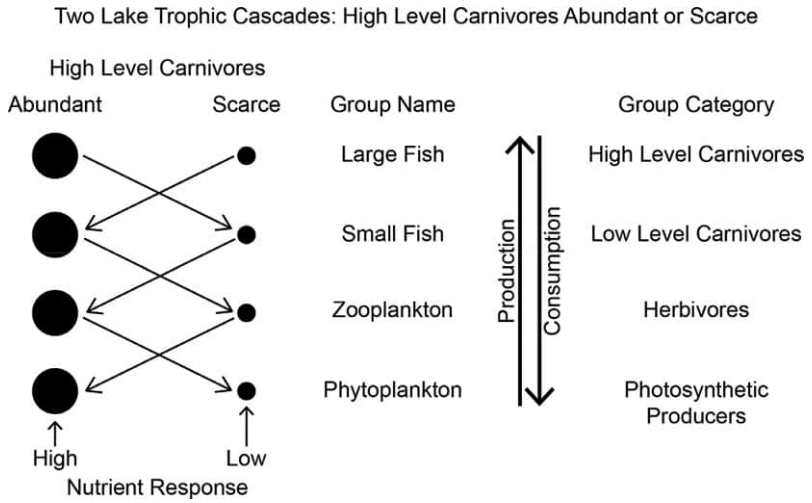

Fig. 6 Lakes with abundant large fish suppress (eat) populations of small fish, which then fail to remove zooplankton herbivores effectively; the abundant herbivores then suppress phytoplankton, even if stimulating nutrients are added; this is a trophic cascade. Where large fish are scarce, the cascade is reversed. Source: WM Lewis and JL Roberson, with permission.

Trophic-dynamic analysis also leads to other fundamental questions involving the structure of biotic communities. For example, food webs might or might not be more productive or more efficient with a high diversity of herbivores than with strong dominance from a very successful, specific type of herbivore. Such questions bear not only on the analysis of natural ecosystems, but also on ecosystem management.

Biogeochemistry

Many of the functional attributes of lake ecosystems can be analyzed through biogeochemical studies. While metabolism and trophic dynamics are viewed in terms of energy flux, biogeochemistry typically is viewed in terms of mass flux. As with energy analysis, the foundation is basic physics: mass is neither created nor destroyed under conditions that are compatible with the presence of life. The conservation of mass leads to the mass-balance equation, which can be given as follows for an ecosystem: $O = I + \Delta S$ where I is input of mass of a particular type (carbon or phosphorus, for example), O is output of mass, and ΔS is change in storage of mass. Input and output pathways for lakes are either hydrologic (flow) or atmospheric (deposition or gas exchange).

Over the short term, change in storage may involve changes in concentration of mass in the water column, but over the long term, change in storage mostly reflects accumulation of mass in sediments. Any element can be a target for biogeochemical studies, but the most frequently studied biogeochemical processes in aquatic ecosystems involve carbon, phosphorus, and nitrogen.

The mass-balance equation applies not only to the entire ecosystem, but also to compartments within the ecosystem (Fig. 7).

For example, carbon in the water column could be partitioned into compartments, each of which would have its own mass-balance equation. Some of these compartments would have a high turnover rate, while others would not. The dynamics of compartments explain restrictions on specific biological processes such as photosynthesis, and account for differences in individual lakes or categories of lakes, such as those that differ greatly in nutrient supply.

Studies of the carbon cycle are ideal complements to studies of lake metabolism and food webs. CO_2, which is the feedstock for photosynthesis, enters aquatic autotrophs from either free CO_2 ($CO_2 + H_2CO_3$) or bicarbonate (HCO_3^-). CO_2 is converted to organic matter by the reduction process of photosynthesis. Either within an autotroph or through consumption of autotroph or other biomass by consumers or decomposers, reduced carbon is reconverted to its oxidized form as CO_2 through aerobic respiration.

Organic carbon resides not only within organisms, but also in water or sediments in dissolved or nonliving particulate form. Dissolved organic carbon derives from the watershed, atmosphere, or organisms within the lake. Watershed contributions to dissolved organic carbon in lakes are composed to a large extent of humic and fulvic acids, which are the byproduct of the degradation of organic matter within soils. Humic and fulvic acids are refractory (resistant to breakdown), although they are slowly decomposed by microbes and can be broken down by ultraviolet light in a water column. Humic and fulvic acids are generally present in concentrations of 1–10 mg l^{-1} in lakes and, when present at concentrations above 5 mg l^{-1}, generally impart a brown or orange color to the water.

Organic compounds that are released to the water column of lakes by the resident organisms vary greatly in composition. All soluble organic compounds present in organisms can be found in the water column at measurable concentrations. Thus, a careful analysis of lake water would show a wide variety of amino acids, carbohydrates of varying complexity, and other metabolites of organisms. These compounds enter the water column through leakage (excretion), death, or the production of fecal matter. As might be expected, the turnover rate for metabolites is generally high because most of these compounds are labile (easily used by bacteria), in contrast to humic and fulvic acids.

	Inorganic	Organic
Dissolved	CO_2, H_2CO_3, HCO_3^-	Humic and fulvic acids from soils Protein, carbohydrate, and nucleic acid breakdown products from organisms
Particulate	$CaCO_3$	Nonliving debris, organisms

Fig. 7 Compartment matrix for analysis of carbon cycling in the water column of a lake.

Particulate organic matter present in a water column may be either living or nonliving. Frequently, these two compartments are physically joined, as all nonliving particulate organic matter in water is colonized by bacteria and, under some conditions, fungi. Most of the carbon attributable to living organisms is accounted for by phytoplankton and zooplankton; fish and bacteria make smaller contributions in the sense of mass but have important ecosystem effects. Carbon is continually stored in sediments, which accumulate at rates often about 1 mm per year, much of which is organic. As sediments become buried by additional sediments, their decomposition slows because of the lack of oxygen and chemically hostile conditions for active metabolism of bacteria. Thus, while some of the organic matter in sediments is remobilized into the water column, other organic matter in the sediments becomes long-term storage.

A study of mass flux and storage, when viewed in terms of ecosystem compartments and subcompartments, tells a story about the mechanisms by which a lake functions. For example, lakes may differ greatly in the terrestrial contribution to carbon processing and carbon storage, and also may differ greatly in speed of carbon turnover in specific living and nonliving compartments.

The cycling of phosphorus in lakes has been studied intensively, because phosphorus is one of the two elements (nitrogen is the other) most likely to be critically depleted by aquatic autotrophs. Thus, phosphorus at the ecosystem level is commonly viewed as an ecosystem regulator; lakes in which it is abundant (eutrophic lakes) have potential to produce high amounts of plant biomass (phytoplankton, attached algae, or aquatic vascular plants) and have water-quality characteristics that are often viewed as undesirable (low transparency, green color, potential for odor production, and severe loss of oxygen in deep water). In contrast, lakes having low supplies of phosphorus (oligotrophic lakes) may show constant suppression of plant growth through phosphorus scarcity. Such lakes have much lower amounts of carbon in the water, higher transparency, often appear blue, and retain oxygen in deep water consistent with the requirements of fish and other eukaryotes.

Because the phosphorus requirement of plants is only approximately 1% of dry biomass, scarcity of phosphorus can be offset by relatively modest increases in the phosphorus additions to a lake. Addition of 1 kg of phosphorus per unit volume or area, e.g., could easily generate 100 kg of dry mass or 500 kg of wet mass of autotrophs. Thus, mobilization of phosphorus by humans has the potential to change lakes and has done so throughout the world wherever human populations liberate phosphorus through waste disposal, agriculture, and disturbance of soil. For this reason, the study of trophic state (nutrient status) has received more attention than any other ecosystem feature of lakes. The practical application of modeling or analysis of trophic status in lakes arises through the desire to prevent changes in trophic state or to reverse changes in trophic state that have already occurred, which requires ecosystem-level understanding of the lake and particularly of its nutrient budgets.

Lakes may also be limited by low concentrations of the forms of inorganic nitrogen that are readily available to aquatic autotrophs (ammonium, nitrate). In this case, nitrogen limitation rather than phosphorus limitation may control plant growth. In fact, the two types of nutrient limitation may occur sequentially across seasons or across years in a single lake.

Nitrogen cycling in lakes is much more complicated than is phosphorus cycling because nitrogen has a gaseous atmospheric component that phosphorus lacks, and because nitrogen exists in seven stable oxidation states within a lake, which sets the stage for the use of nitrogen as a substrate for oxidation reduction reactions supporting microbial metabolism (Table 2). Like phosphorus, nitrogen enters lakes through the watershed and, in small amounts, with precipitation. Unlike phosphorus, nitrogen also enters lakes as a gas by diffusion at the air–water interface in the form of N2. N2 is so inert chemically that it cannot be used as a nitrogen source by most organisms. Certain prokaryotes have the ability to use N2 by converting it to ammonium, which then can be used in organic synthesis, provided that a substantial energy supply is available. This process is called nitrogen fixation, in that it converts the gaseous nitrogen to a solid that is soluble in water (ammonium). The dominant nitrogen fixers in lakes are the cyanobacteria. Not all cyanobacteria fix nitrogen, but certain taxa that have a specialized nitrogen-fixing cell (heterocyst) grow commonly in lakes that show nitrogen depletion.

Nitrogen fixers escape the limitation of growth associated with nitrogen depletion, thereby gaining an advantage over other autotrophs. Thus, lakes that are enriched with phosphorus but showing nitrogen depletion often have nuisance growths of nitrogen-fixing cyanobacteria, which produce all of the expected symptoms of nutrient enrichment, and sometimes also produce toxins. There is currently much interest in predicting and preventing the development of circumstances that lead to large and persistent blooms of nitrogen-fixing cyanobacteria.

Nitrogen is a multiplier element, just as phosphorus is. It constitutes approximately 5% of dry mass in plants. Therefore, when it is added to lakes, provided that phosphorus is added at the same time, it supports a 20-fold multiplication of dry plant biomass. A detailed documentation of the carbon, nitrogen, and phosphorus cycles for a lake produces an understanding of factors that regulate the metabolic rates of lakes and the accumulation of biomass of various kinds in lakes. These ecosystem phenomena have numerous practical applications, ranging from interest in biomass production (e.g., fish) to interest in constraining water quality within boundaries that are either natural or that favor human purposes.

Community organization

Ecosystems have a strong degree of spatial organization involving the arrangement of organisms according to abiotic constraints based on factors such as amount of irradiance, concentration of dissolved oxygen, or substrate characteristics. The requirement for irradiance is especially important because it dictates the distribution and growth potential for aquatic autotrophs. Phytoplankton grow strongly only within the euphotic zone, which corresponds approximately to water receiving at least 1% of the solar irradiance available at the water surface. Thus, vigorously growing phytoplanktons often are confined to the upper part of the water column

(epilimnion and sometimes metaliminon). The same principle applies to periphyton and rooted aquatic plants, which can occupy substrates only over portions of the sediment that are exposed to at least 1% surface irradiance. The gradient of irradiance is controlled by transparency of the water.

Spatial organization of animal communities and microbial communities is dictated partly by physical conditions and partly by the distribution of autotrophs. Crustacean zooplankton, e.g., may migrate large distances vertically in the water, hiding in deep water during the daytime but rising to feed within surface waters at night. The zooplankton of the littoral zone differs from that of open water, in that the littoral zone offers food types (periphyton especially) that are not available in open water. Distribution of fishes may be dictated in part by the presence of structure associated with littoral zone. The effect of structure may even be related to life history in that immature or small fish may seek the structure of the littoral zone for shelter from predation.

Because organisms conduct the business of an ecosystem, an understanding of their habitat requirements, reflected as spatial organization, leads to explanations of the total abundances of certain categories of organisms, the failure of certain organisms to fare well in one lake but not in another, and the consequences of habitat disturbances of natural or human origin.

Synthetic analysis of ecosystems

Synthetic analysis of ecosystems often involves the statistical study of empirical information, particularly if the objective is to test a particular hypothesis. A quantitative overview of multiple ecosystem functions or of the intricate detail for an ecosystem component typically involves modeling as a supplement to other types of quantitative analysis. When computers first became available, it was anticipated that ecosystem science would ultimately be driven almost entirely by mechanistic models that would predict ecosystem responses to natural or anthropogenic conditions. These expectations were not realized. Ecosystems, like other complex systems such as climate or economics, are moderately predictable from modeling that combines a modest number of well-quantified variables addressed to a specific question, but typically are unpredictable on the basis of large number of variables addressing more general questions. Even so, modeling of numerous variables in an ecosystem context can be useful in setting limits on expected outcomes or showing possible outcomes of multiple interactions that cannot be easily discerned from the study of individual variables. Therefore, modeling is useful in promoting the understanding of ecosystems.

Conclusion

Lakes first inspired the ecosystem concept, and have been a constant source of ideas about ecosystem structure and function. Ecosystem science, as applied to lakes, is supported by and is consistent with other kinds of ecological studies that are directed toward specific organisms, groups of organisms, or specific categories of abiotic phenomena in lakes. The strength of ecosystem science lies in its relevance to the understanding of all subordinate components in ecosystems, and to its often direct connection to human concerns in understanding and managing lakes.

Glossary

Denitrification A microbially facilitated process where nitrate is reduced ($NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$) and ultimately produces molecular nitrogen (N_2); denitrification occurs in low oxygen environments and organic C is consumed in the process; incomplete denitrification can result in the emission of N_2O.
Emergent property An emergent property of an ecological unit is one that arises through interactions among smaller parts that alone do not exhibit such properties; properties or behaviors which only emerge when the parts interact with the wider whole.
Lake metabolism The collective term for the turnover of biomass and energy in a lake ecosystem through carbon fixation (gross primary production) and biological carbon oxidation (ecosystem respiration).
Nitrification A microbially facilitated processes where ammonia is oxidized to nitrite followed by the oxidation of the nitrite to nitrate.
Retention Fraction of the reactant input load that is held within the lake (1-output/input).
Source limitation When inputs of dissolved organic matter and nutrients are limited by the abundance, location, or production of the elements on the landscape, particularly in regions that are already subjected to high annual precipitation; an increase in discharge decreases the concentration of elemental inputs.
Transport limitation When inputs of dissolved organic matter and nutrients are limited by the amount or connectivity of inflowing water; an increase in discharge increases the concentration of elemental inputs.

Inland waters play an important role in global biogeochemical cycles. They collect, transform, store, and export to the atmosphere or to the oceans the organic and inorganic nutrients that wash in from terrestrial ecosystems. Carbon, and to some extent nitrogen, can also be taken up from the atmosphere to fuel aquatic primary production, which is then transformed and either stored or exported. The movement of water to and through aquatic ecosystems plays a major role in controlling rates and extents of biogeochemical transformations in those ecosystems via two mechanisms (Fig. 1). First, hydrologic loads deliver the carbon and nutrients that fuel microbial communities and geochemical processes. Second, hydrologic loads flush carbon, nutrients, and microbial communities downstream.

In this chapter, we start by discussing the complexity and heterogeneity of lake hydrology with a concept we term 'hydrologic setting.' We emphasize the role of hydrologic setting in influencing water and chemical residence time, a property of aquatic systems that ultimately controls many biogeochemical cycling rates. Next, we discuss the utility of models in helping us understand this complexity, and its implications for the biogeochemistry of lake ecosystems. We highlight what has been learned from empirical studies about the role of hydrology and residence time in the biogeochemical cycling of carbon (C), nitrogen (N), and phosphorus (P). Finally, we conclude by identifying knowledge gaps and highlight emerging research needs.

Hydrologic setting and its influences

Hydrologic setting is defined by a lake's size, shape, geographic location, geologic context, and climate which combine to dictate hydrologic flows to and from the lake (Fig. 2). Physical factors of hydrologic setting include lake and landscape morphology such as lake volume, watershed size, connectivity to surface and groundwater, and watershed land cover. These features ultimately set a template that interacts with climate to dictate supply of material to the lake and pace of processing of matter in the lake. Variation in

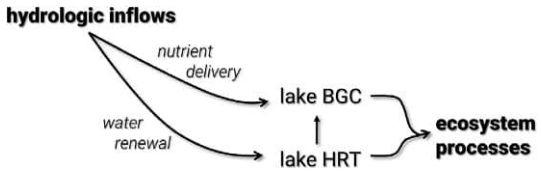

Fig. 1 Competing hydrologic drivers of aquatic biogeochemistry. As hydrologic inflows to a lake from its catchment increase, the amount of nutrients and carbon delivered increases, but the hydrologic residence time (HRT) decreases as a result of increased water renewal. As HRT decreases the fluvial export of solutes increases and time for lake biogeochemistry (BGC) decreases. The interaction between these two effects of hydrologic inflow have strong implications for carbon, nitrogen, and phosphorus fate in lake ecosystems.

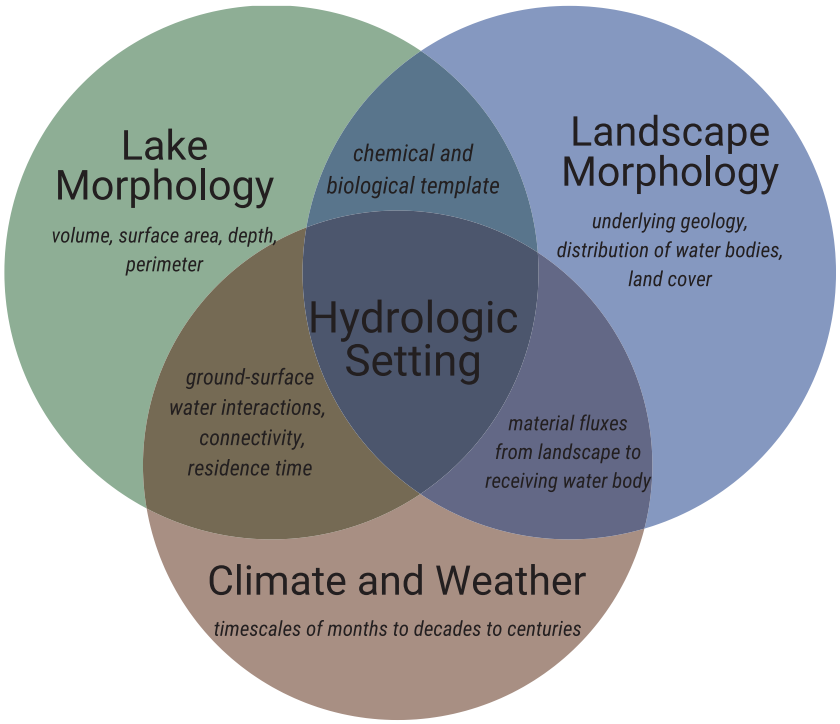

Fig. 2 A Venn diagram depicting how variation in lake morphology, landscape morphology, and climate describe the hydrologic setting of a waterbody. Points of intersection show emergent properties of hydrologic setting, which arise from interactions between two drivers. For example, variation in precipitation and lake volume result in variability in residence time. Climate and landscape characteristics interact to influence loads of material from the landscape. Together, lake morphometry and landcover interact to form the basic biogeochemical constraints within which lake ecosystem processes operate.

climate and weather exert temporal controls on lake morphology and hydrology (volume, hydrologic residence time) and landscape features at various timescales. For example, catchment land cover may change at short (e.g., seasonal succession) or long timescales (e.g., decadal drought cycles, land use change). Climate and weather will also influence the water sources to lakes and the overall hydrologic load (runoff, groundwater, direct precipitation) and interact with lake morphology (volume, surface area, depth) to determine input rates of organic and inorganic compounds for a given land use or land cover of the catchment. Hence, climate and lake and landscape morphology are inextricably linked in the concept of hydrologic setting.

The relative importance of different components of water budgets, and the concentrations of elements in those flowpaths, varies substantially but in some fairly systematic ways. Sources of hydrologic load include surface runoff and inflow streams, groundwater, and direct precipitation. The importance of surface water inputs is dependent on catchment area and slope. Hydrologic inputs to a lake with a large catchment are likely dominated by surface inflows, whereas hydrologic inputs to lakes with relatively small catchments will often rely on direct precipitation. Groundwater inputs and outputs will depend on landscape position and regional hydrogeology. Although sometimes overlooked, evaporation is an important hydrologic loss, especially in small lakes with small catchments and no outlets.

Surface inflows, groundwater inputs, and direct precipitation often differ in their relative contributions of water to a lake, but these flow paths also differ in concentrations of carbon, nitrogen, and phosphorus. Surface waters generally are much more concentrated in particulate and dissolved forms of carbon, nitrogen, and phosphorus when compared to groundwater or precipitation. Groundwater can be a meaningful source of dissolved constituents, but these flow paths do not contribute particulate

material to lakes. Finally, precipitation is dilute in its dissolved carbon, nitrogen, and phosphorus concentrations, but can be a meaningful source of particulate carbon. Notably, in some instances, direct precipitation can account for a substantial proportion of nutrient budget (e.g., sparsely vegetated mountainous areas subjected to elevated N deposition; Baron and Campbell, 1997). These are generalities, and the influence of hydrology on nutrient biogeochemistry will ultimately also depend on geographic location and catchment land cover and land use.

Distinct types of hydrologic setting arise from interrelationships among these landscape features but substantial variation also exists in space and time (Fig. 3). For example, steep, mountainous landscapes typically have little wetland cover and hydrologic flow paths dominated by surface runoff, direct precipitation, and relatively little groundwater influence. High-elevation and high latitude lakes are typically dominated by seasonal snowmelt. In contrast, flat and hydro-geomorphologically complex landscapes in boreal and north temperate regions may have high wetland cover and both surface and subsurface connectivity. In these types of landscapes, evaporation may play a particularly important role for lakes lacking surface water connections or for lakes perched above the regional groundwater table.

An important component of hydrologic setting is hydrologic residence time (HRT). The geographic context of a lake provides predictive power for HRT because the ratio of catchment area to lake area (the drainage ratio) is a useful predictor of HRT. However, lake volume or mean depth are important modifier of this relationship (Jones et al., 2018). The importance of evaporation as a hydrologic loss is influenced by drainage ratio and mean depth. Specifically, in shallow lakes with small drainage ratios, evaporation can be the main pathway for water loss. Interestingly, neither catchment size nor lake size alone are good predictors of drainage ratio or HRT (Hill et al., 2018).

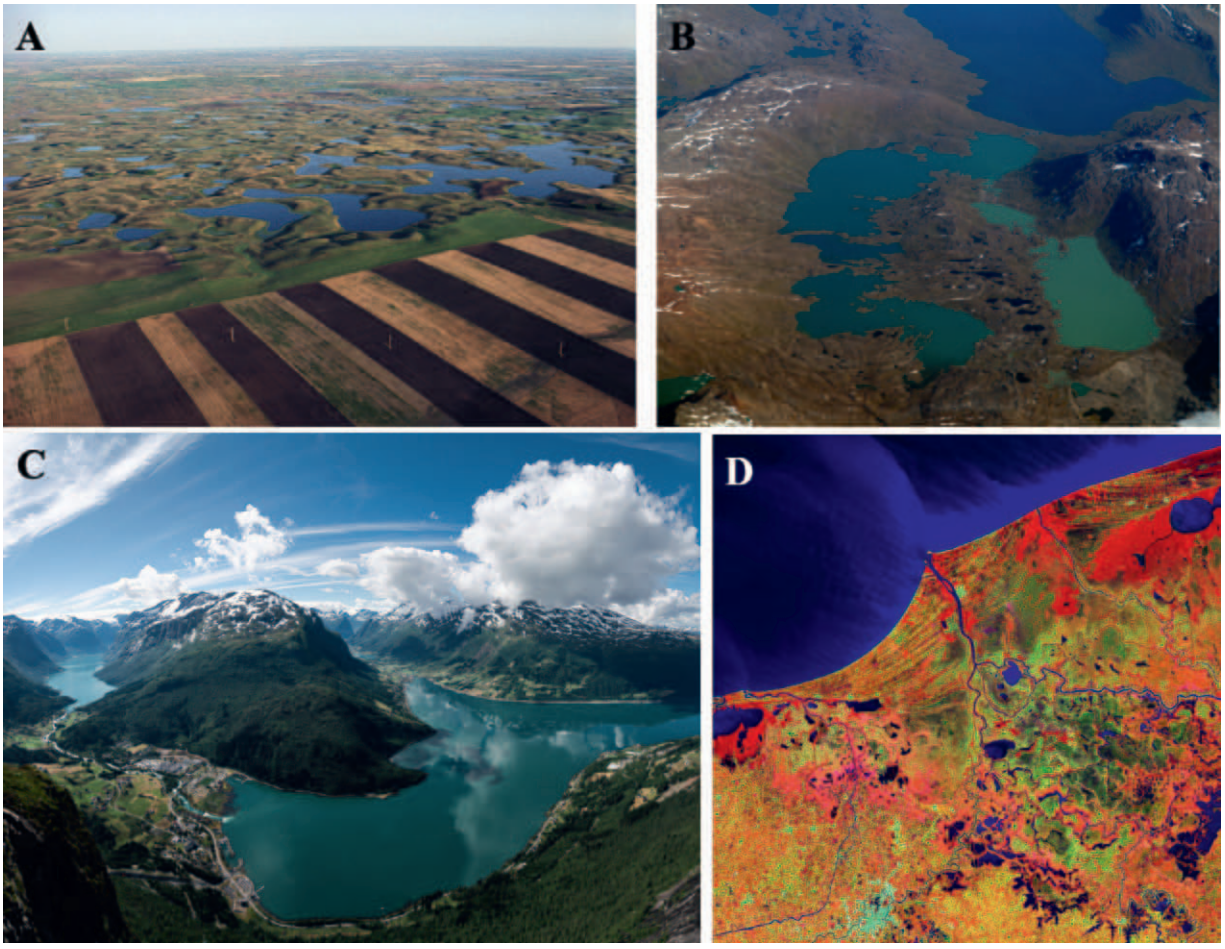

Fig. 3 Real world examples of various hydrologic setting archetypes. (A) Prairie pothole lakes in the upper midwestern United States and Canada have a high degree of groundwater connectivity, high wetland cover, long residence times, and high evaporative demand. Photo credit: Jim Brandenburg, Minden Pictures. (B) In northern Norway, slopes are steep, vegetation cover is low, and water clarity is determined by the influence of glacial till. A mosaic of lake sizes and surface water connections exist, and groundwater plays a relatively small role in hydrologic budgets. Photo credit Peter Prokosch, creative commons: (C) In the Alps mountain range of Europe, hydrology is dominated by seasonal snowmelt and surface water connectivity among valley lakes and streams is high. Photo credit: Lachlan Gowen creative commons. (D) Satellite imagery of Reserva de la Biosfera Pantanos de Centla, Frontera, Tabasco, Mexico illustrates the importance of scale in describing hydrologic settings. In reality, lakes exist in a landscape mosaic with continuous variation in landscape cover, surface water and groundwater connectivity. Photo credit: U.S. Geological Survey creative commons, where color represents different land cover types.

Regional hydrogeology is the primary determinant of the influence of groundwater on lake water budgets. In regions with the potential for groundwater-lake interactions, lake elevation or landscape position determine whether lakes exclusively lose water to the regional aquifer (seepage lakes) or gain appreciable amounts of groundwater (drainage lakes). Drainage lakes are also dominated by fluvial processes, thus large loads and short hydrologic residence times mean retention is low but instantaneous biogeochemical rates are high. In smaller seepage lakes, loads of water and matter are relatively low, which means instantaneous biogeochemical rates are low, but evaporation, which does not transport matter, becomes an important hydrologic loss (Brooks et al., 2014). As a result, chemical residence time is decoupled from hydrologic residence time in these systems and very high rates of retention are predicted and observed.

Research on nutrient dynamics and metabolism of aquatic ecosystems has demonstrated how considering water bodies along residence time gradients leads to insights into rates of key ecosystem processes and transformations of elements, especially carbon (Table 1). In the remainder of the chapter, we focus our discussion on lakes, but note that considering water bodies along residence time gradients allows scientists to make predictions in both lentic and lotic systems, which are usually studied separately (Hotchkiss et al., 2018). In the next section we outline general approaches to modeling lake hydrology and biogeochemistry and note how these models have evolved over time. We conclude the chapter by exploring the role of residence time in structuring spatiotemporal variability in carbon, nitrogen, and phosphorus cycling.

Modeling lake hydrology and biogeochemistry

Models help us gain an understanding of the mechanisms underpinning ecosystem processes. By necessity, models include assumptions and simplifications of systems, but in reality, we know that lakes are heterogeneous both within and across systems (Fig. 4). Simplified models negate many natural complexities of lakes by grouping or ignoring certain hydrologic flow paths and biogeochemical processes, assuming instantaneous and perfect mixing, and assuming static behavior and the existence of hydrologic and biogeochemical equilibria. For example, as a consequence of stratification, thermal and chemical gradients exist within many lakes that ultimately control rates of biogeochemical processes. Bathymetry, or the overall geometry of a lake, is also highly irregular and no two lakes are alike. That spatial complexity inherently structures the flow of water, energy, and materials into and out of lakes. As our understanding of lake ecosystem function grows, the mechanistic framework guiding predictions must include some gradients of heterogeneity. Even so, simplified models have guided and continue to improve our understanding of the role of hydrology in biogeochemical cycling in inland waters (Vollenweider, 1975 is a classic example).

We owe much of our current understanding of the interplay between lake hydrology and biogeochemistry to simple box models that rely on the mass balances of water and matter. Early versions of these models were likely derived from chemical and environmental engineering applications, including the completely mixed, flow reactor (CMFR) model. Interestingly, work in enzymology and microbiology gave rise to chemostat models that are also commonly used in aquatic ecology and have a very similar mathematical derivation (Fussmann et al., 2000). The strength of these models is their simplistic, but process-based representation of hydrologic inputs, biogeochemical rates, and their interaction (Box 1). Over the intervening decades, these models have been applied at lab to continental scales to consider a multitude of biogeochemical processes (primary production, decomposition, internal loading of phosphorus, and denitrification) and cycling of numerous elements (carbon, nitrogen, phosphorus, chloride, and more).

Although aquatic ecosystems are complex, chemostat and CMFR models capture many of the basic hydrologic and biogeochemical behaviors of lakes, which can be represented as naturally occurring reactors in the landscape (Fig. 4). From their earliest

Table 1 Gradients in metabolism from the extremes of small streams to large lakes and aquifers, and their respective roles in OC cycling over broad temporal and spatial scales, when viewed through the continuum lens of hydrologic residence time.

Low HRT (e.g., small streams)	← →	*High HRT (e.g., large lakes)*
Metabolic behavior dominated by loads		Metabolic behavior dominated by trophic state
Events are a dominant time-scale feature		Integration of longer time periods is the dominant time-scale feature
Allochthonous organic C (OC) pool is relatively young		Allochthonous OC pool is relatively old
Mineralization of allochthonous OC $\geq$ 0.1 days^{-1}		Mineralization of allochthonous OC $\sim$0.001 days^{-1}
Particulate OC can be a dominant constituent of the transformed OC pool, because of high energy		Particulate OC rarely a dominant constituent of the transformed OC pool, because of low energy
Large gradient in biologically reactive solute concentrations (e.g., carbon, nutrients) at landscape scale		Smaller gradient in biological reactive solute concentrations
Closely coupled with surrounding landscape		Loosely coupled with surrounding landscape
Allochthony is the dominant term in most metabolic budgets		Autochthony is the dominant term in metabolic budgets at decadal and longer timescales

Table originally appears in Hotchkiss ER, Sadro S, and Hanson PC (2018) Toward a more integrative perspective on carbon metabolism across lentic and lotic inland waters. *Limnology and Oceanography Letters* 3: 57–63.

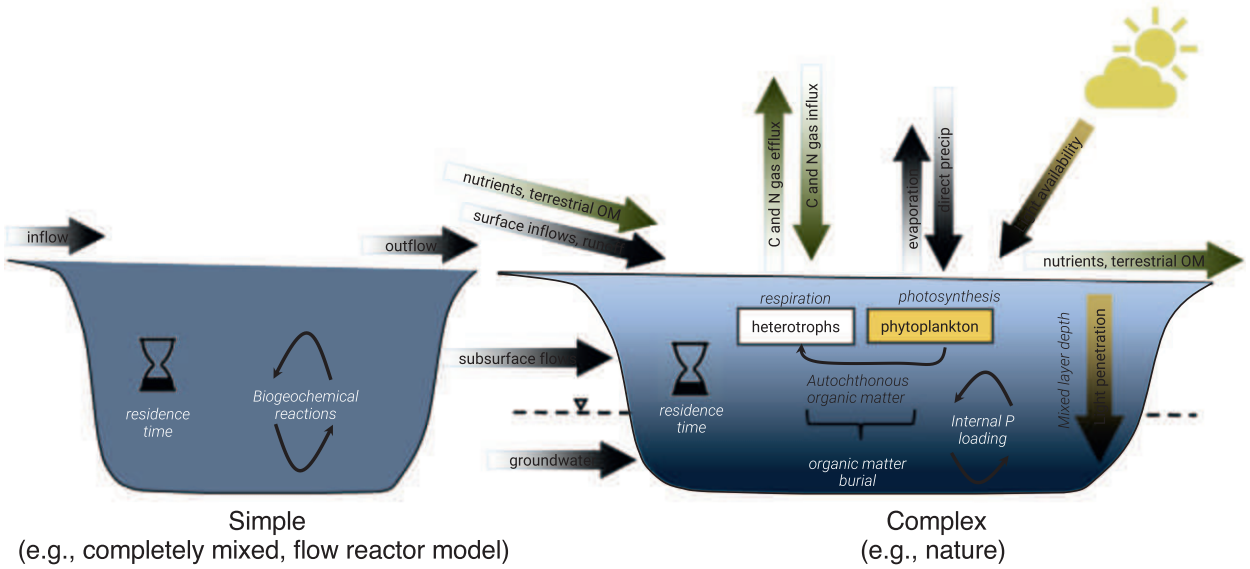

Fig. 4 Models versus reality. On the left, is a modeled lake that includes inflows and outflows of water and a chemical constituent and the resultant biogeochemical reactions within the system. On the right is a hypothetical "natural" lake with arrows depicting the myriad pathways for water and nutrient loss and gain within the system.

application, the limitations of these models have been recognized and refined. Early refinements of the Vollenweider model of phosphorus retention split the total phosphorus pool into dissolved and particulate forms and represented contrasting physical and biogeochemical environments of the epilimnion and hypolimnion of lakes. The physical complexity and treatment of internal lake hydrodynamics has been a major focus over the last decade or more (e.g., Dynamics Reservoir Simulation Model, Imberger et al., 1981; General Lake Model, Hipsey et al., 2019). Other work has sought to explore the importance of representing heterogeneity in the chemical availability of carbon, nitrogen, or phosphorus (reactivity continuum; internal loading of P). By adding multiple hydrologic flow paths into and out of a simple lake biogeochemistry model, our appreciation for the importance of hydrologic setting for lake biogeochemistry and retention of matter has expanded (Fig. 4).

Despite their simplicity, adoption of CMFR and chemostat models has generated adequate prediction for many systems and enabled transformative scientific inference. This work has been applied both within a single ecosystem and at broad spatial scales. Early application of these models provided important prediction and understanding of the process of eutrophication of lakes due to excess phosphorus supply (Vollenweider, 1975; see also "Further Reading"). Similar models have improved our understanding and prediction of the freshwater carbon cycle, including the fate of terrestrial carbon in freshwaters (Jones et al., 2018), ecosystem-scale aquatic primary production (Jäger and Diehl, 2014; Kelly et al., 2018), and the intricacies of predation and competition within the microbial loop (Thingstad and Lignell, 1997).

Residence time and biogeochemical cycling of C, N, P

In this section we discuss the relationships between hydrology and the import, processing, and export of C, N, and P in lakes. The cycles of these elements are important because of their implications for primary productivity and global climate, and they are relatively well-studied.

Import from land to lakes

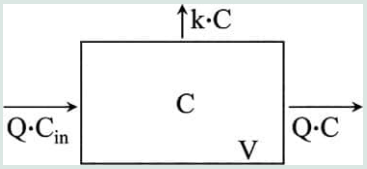
The total input of nutrients to a lake depends on the volume of water coming in via all flow paths, and on the concentrations of nutrients in those sources of water. The flow paths of water to the lake – including whether it has traveled over the surface, through shallow soils, or in deep groundwater – influence the concentration and composition of the dissolved and particulate C, N, and P that this water transports (Kaiser and Kalbitz, 2012). For instance, shallow subsurface flow paths often yield high concentrations of dissolved organic carbon, while surface flow paths have the highest concentrations of particulate organic carbon. The relative importance of different flow paths for the total hydrologic load to a lake depends on factors like topography, geology, and climate (Fig. 2).

Box 1 Mathematical representation of completely-mixed lake

Simple box models that rely on the mass balances of water and matter allow us to gain a process-based understanding of how hydrologic inputs and biogeochemical rates interact. Early versions of these models were derived from chemical and environmental engineering applications, including the completely mixed, flow reactor (CMFR) model for the concentration of a reactant, C (g L^{-1}).

The CMFR model assumes that the volume of the reactor, V (L), is constant. Consequently, inflows to the reactor at rate Q (L d^{-1}) are exactly balanced by outflows at the same rate. The concentration of reactant in the inflow is denoted by C_{in} (g L^{-1}). The model also assumes that the reactor is continuously and instantaneously mixed, which means that the output concentration is equal to the concentration in the reactor. The reactant decays in the reactor following a first-order reaction with rate k (d^{-1}).

This model can be represented with a box-and-arrow diagram:



Or, equivalently, with an equation that describes how the concentration of the reactant changes as a result of each of the inputs and outputs. Recall that flow multiplied by concentration gives mass, and dividing mass by volume gets back to concentration:

$$\frac{dC}{dt} = \frac{QC_{in}}{V} - \frac{QC}{V} - kC$$

Or further simplified:

$$\frac{dC}{dt} = \frac{Q}{V}(C_{in} - C) - kC$$

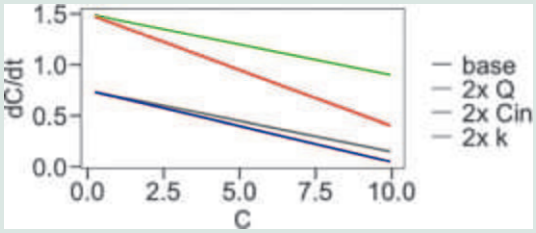
At steady state $\frac{dC}{dt} = 0$, therefore $kC = \frac{Q}{V}(C_{in} - C)$. Hydrologic residence time (θ) is defined as $\frac{V}{Q}$ in units of days. From there, we can define the reaction kC as:

$$kC = \frac{C_{in} - C}{\theta}$$

Ultimately, the equilibrium reactant concentration (C^*) is a function of input concentration, the reaction rate, and residence time:

$$C^* = \frac{C_{in}}{1 - k\theta}$$

Graphical exploration shows us that the rate of change in concentration in the chemostat (dC/dt) responds linearly to the concentration (C). Further, the slope and intercept of this linear response is influenced by any of the three parameters included in our model (Q, C_{in}, and k).



Where surface runoff is the dominant hydrologic input, variation in the amount of runoff into the lake is the primary driver of variation in element inputs. The volume and nutrient concentration of water tend to be positively correlated, because nutrient fluxes tend to be transport- rather than source-limited. For a given lake, discharge is the primary driver of variation in nutrient load, because it often varies over several orders of magnitude while concentration varies over a much narrower range. Localized loads of elements into a waterbody depend on landscape features such as land cover and the degree of hydrologic connectivity. Overall our best estimates of terrestrial loads to inland waters illustrate that loads of organic and inorganic C are several orders of magnitude higher than they are for N and P. Ultimately, these three elements are cycled and buried at different rates, resulting in shifts in C:P and C:N ratios along the freshwater continuum (Maranger et al., 2018).

Processing - production, consumption, and burial

The major biogeochemical elemental cycles (C, N, P) are tightly linked via key ecosystem functions such as primary production and ecosystem respiration. Within the lake, organic carbon is produced by photosynthesis and consumed by respiration. Nitrogen and phosphorus, though not directly involved in photosynthesis, play key roles in the structure of proteins and lipids synthesized by

primary producers, who compete directly with microbial heterotrophs for these same nutrients. In this section, we discuss how C, N, and P are produced, consumed, and buried in lake ecosystems, and how the rates of biogeochemical cycling are influenced by hydrologic residence time. While these elemental cycles are coupled, key distinctions in the transformations among these elements exist.

Rates of photosynthesis depend in large part on the availability of nutrients and light, both of which are dictated by hydrology. Hydrologic inputs bring inorganic nutrients and dissolved organic matter-bound N and P, which stimulate photosynthesis. They also bring dissolved organic matter and particulates, which can inhibit photosynthesis by reducing light penetration. The net effect of these opposing influences depends on the carbon-nutrient stoichiometry of the hydrologic inputs to the lake, how darkly colored the organic matter inputs are, and on other factors like lake size, which interacts with water color to determine mixed layer depth and thus the light climate experienced by phytoplankton.

Rates of ecosystem respiration are both directly and indirectly linked to hydrologic inputs. They depend directly on hydrologic inputs of organic carbon, which provide the predominant substrate for heterotrophic respiration in many lake ecosystems. When inputs of organic carbon are low, instantaneous rates of ecosystem respiration are also low, because the supply of relatively labile carbon compounds is only slowly renewed. At the same time, however, the proportion of the organic carbon input that is respired may be relatively high, because low hydrologic inputs mean a long residence time of water and solutes in the system. This is particularly true in lakes where evaporation is an important component of the water budget, lengthening the residence time of solutes like dissolved organic carbon relative to the residence time of the water itself, with potential for increased gaseous C emissions (see Section "Export"). Ecosystem respiration is also linked to rates of photosynthesis by the autotrophic respiration of phytoplankton and by heterotrophic respiration of organic carbon fixed by phytoplankton, and thus are indirectly linked to hydrologic inputs.

Hydrologic residence time (HRT) affects rates of flushing and sedimentation, ultimately influencing the retention of C, N, and P in lake ecosystems (Fig. 5). For example, instantaneous rates of P sedimentation may be higher in lakes with short HRT because these lakes often have greater inputs of particulate P bound to terrestrial organic matter. Despite faster rates of removal of P by sedimentation at short HRT, most lakes with short HRT retain less phosphorus than lakes with long HRT due to the competing influence of sedimentation and flushing on phosphorus retention. At long HRT, the sedimentation rate of P has a larger relative influence on phosphorus retention while flushing has a larger relative influence at short HRT. Similar patterns are observed for carbon, where rates of both dissolved organic carbon production and consumption can be predicted from hydrologic residence time. Extended residence times allow for greater mineralization of dissolved organic carbon, but also flocculation and settling of dissolved organic matter. In contrast, short residence time systems will not mineralize a large fraction of their dissolved organic carbon load, but are likely to receive higher loads of particulate organic carbon that is buried in lake sediments. Rapid rates of sediment accretion in man-made reservoirs are a good example of the importance of particulate load and burial in short residence time systems.

Denitrification, the primary biogeochemical process responsible for nitrogen removal, has three requirements to proceed: anoxic sediments, nitrate, and organic matter. Because of these three players, the rates and relative importance of denitrification are difficult to predict from HRT alone. Nitrogen loading impacts the magnitude of organic matter available for denitrification through its limitation of primary production. Depth impacts nitrate availability via the coupling of nitrification and denitrification processes

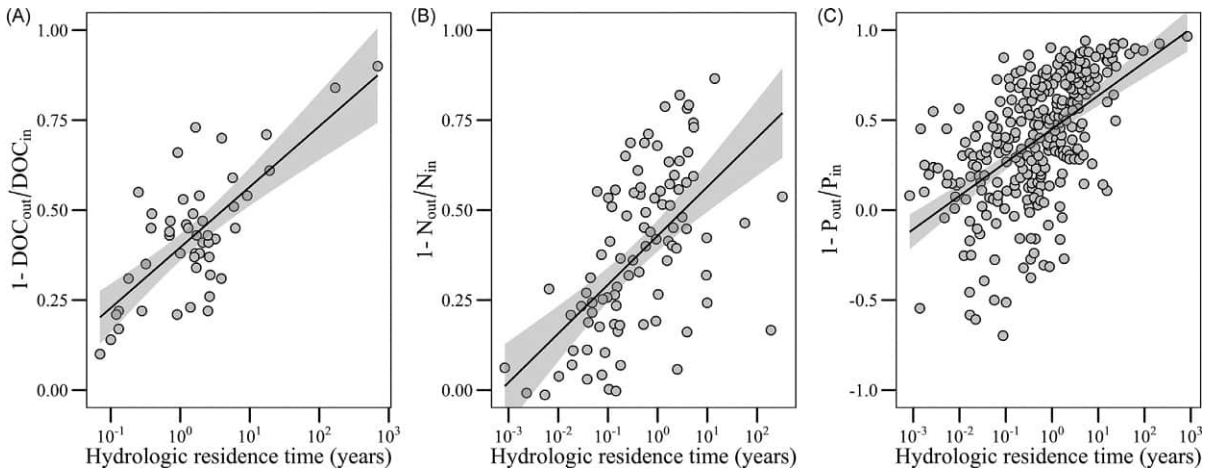


Fig. 5 Carbon (A), Nitrogen (B), and Phosphorus (C) removal efficiency as a function of hydrologic residence time. Note: in panel C, negative values on the y-axis indicate that lakes export more P than is received, possibly as a consequence of internal nutrient loading from sediment release. (A) Figure redrawn from Evans CD, Futter MN, Moldan F, Valinia S, Frogbrook Z, and Kothawala DN (2017) Variability in organic carbon reactivity across lake residence time and trophic gradients. *Nature Geoscience*, 10(11), 832–835., (B) Figure reprinted from Finlay JC, Small GE, and Sterner RW (2013) Human influences on nitrogen removal in lakes. *Science*, 342 (October): 247–250.); (C) Figure redrawn from Brett MT and Benjamin MM (2008) A review and reassessment of lake phosphorus retention and the nutrient loading concept. *Freshwater Biology*, 53(1): 194–211.

which is maximized at the sediment-water interface and dictates the probability that organic matter makes sediment contact via sedimentation. Finally, phosphorus availability may underly and limit nitrogen fate and processing rates because P often limits primary production. Despite these caveats, empirical work shows a similar relationship between retention and HRT for all three elements (C, N, and P; Fig. 5).

Export

Matter in lakes can be exported from the water column of a lake to one of three pools: the atmosphere, lake sediments, or downstream toward the ocean. Hydrologic residence time influences the instantaneous rates of export to each of these fates, and the importance of each fate relative to the others and to the inputs of organic matter from the watershed. Periods of high precipitation (at time scales ranging from individual storms to multi-year climate cycles or changes) can decrease the proportion of carbon exported to the atmosphere (as CO_2 or methane, CH_4) by increasing inputs and decreasing hydrologic residence time thereby increasing the relative importance of fluvial export.

When residence times are long, inputs of terrestrial organic matter are relatively small but they are exposed to degradation processes in the lake for a long time (see previous sections). This means that, proportionally, most of the incoming organic matter is exported to the atmosphere, but the instantaneous rate of export to the atmosphere is low. In oligotrophic systems with long residence times, only a small portion of the available organic carbon is exported downstream or buried in sediments. In more productive lakes, substantial *in-situ* production of organic carbon by photosynthesis may lead to larger downstream exports and burial.

One factor that sets the P cycle apart from C and N cycles is the lack of a gaseous loss. Elements or solutes that lack a gaseous phase can have decoupled residence times from water with implications for ecosystem function. Retention or permanent removal for such solutes is dependent on permanent burial in lake sediments or fluvial export from the system, respectively. Due to this dependence, lake hydrologic setting plays a key role in determining solute fate and a more nuanced understanding of hydrology, outside of hydrologic residence time, is crucial. For example, seepage lakes lack a fluvial outlet and water is primarily lost by evaporation. In this hydrologic setting, solutes without a gaseous phase are less likely to be exported from the system and may become more concentrated due to the decoupling between their residence time and water. Consequently, an increase in the elemental or solute residence time relative to hydrologic residence time introduces the potential for eutrophication particularly in systems with a strong anthropogenic presence. In contrast, drainage lakes, with comparatively shorter HRTs, have hydrologic budgets dominated by fluvial export rather than evaporation which increases the likelihood of fluvial solute export.

Knowledge gaps and opportunities for future research

Several ideas stand out as important topics for future work on the connections between hydrology and ecosystem processes. Questions remain in understanding how key aspects of hydrologic setting are related (e.g. correlations among topography, connection to network, flow path, residence time, etc.). What do these patterns mean for patterns of biogeochemical processing? In regard to modeling approaches, the coupling and interdependency of elemental cycles must be more fully embraced within the context of CMFR- and chemostat-style models (see Cheng and Basu, 2017). Many past and recent successful applications of these models focused on a single elemental cycle, but including a combination of hydrologic and stoichiometric constraints within these models will likely enhance what we can learn and predict.

While empirical studies have demonstrated that HRT influences N processing rates and retention (Finlay et al., 2013), the relationship is more context-dependent than for C and P due the mechanistic complexities of the N cycle. As with C and P, the fraction of N retained in a water body is positively correlated with HRT. This is likely due to more time for removal processes to occur such as primary production, sedimentation, and denitrification. Although fractional nitrogen retention is positively correlated with HRT, the rates and relative importance of the processes involved in nitrogen cycling do not demonstrate clear patterns. For example, studies have found both positive (Jansson et al., 1994) and negative correlations between denitrification rates and HRT (Harrison et al., 2009). This suggests that there are complex, non-linear interactions between HRT, lake depth, and N loading on the retention and transformation of N in aquatic ecosystems that deserve further investigation given the global perturbation of the N cycle.

Future work must consider the coupled roles of the three major elements that drive aquatic metabolism and incorporate hydrology in making predictions about ecosystem processes. As discussed above, the carbon, nitrogen, and phosphorus cycles are inherently linked to each other through aquatic ecosystem metabolism. Many unanswered questions remain such as: How do C, N, and P loads and HRT interact to impact the rate of primary production? How does the rate of primary production feed back into the rates and relative importance of sedimentation, flushing, and internal loading of phosphorus? How does temporal variability in weather or climate interact with lake hydrology to influence ecosystem processes? Addressing some of these questions may provide answers to some of the considerable scatter that is evident around the fit between C, N, and P retention and HRT of Fig. 5. Finally, our knowledge of coupled biogeochemical cycles are highly biased toward boreal and temperate waterbodies—future research is critically needed in humid tropics and other data-poor regions to deepen our understanding on the role of hydrology and residence time on aquatic ecosystem processes.

Conclusion

- Movement of water controls biogeochemical processes in aquatic ecosystems by delivering carbon and nutrients and by flushing those reactants and microbial communities downstream.
- Lake morphometry, climate, and the surrounding landscape define a "hydrologic setting" that determines how water and nutrients enter the lake, and in what quantities.
- Simple models have been useful for understanding the influences of hydrology on biogeochemical processes in lakes.
- Hydrologic residence time provides a simple description of the hydrologic cycle of a lake with considerable power for understanding how biogeochemical process rates vary in space and time.

Glossary

Allee effect Is a feature of small populations whereby low density limits population growth.
Alternative stable state Different (multiple) states (equilibria) of a system under the same environmental conditions. The state to which a system converges is path dependent (i.e., it depends on the initial conditions).
Basin of attraction Set of initial conditions that lead to a particular state (equilibrium).
Bifurcation A critical threshold in environmental conditions at which the qualitative behavior of a system changes.
Bistability The case where two alternative stable states exist.
Critical slowing down The phenomenon that the return time of a disturbance back to equilibrium increases close to a bifurcation.
Equilibrium The condition at which competing processes are balanced. At a stable equilibrium, a system returns to it upon a small perturbation. At an unstable equilibrium, a system moves away from it upon a small perturbation.
Hysteresis Is the dependence of state of a system on its history.
Positive and negative feedback A process through which a change has a respectively positive or negative effect on itself. Also referred to as self-enforcing and dampening feedback respectively.
Regime shift A sharp change from one regime (state) to a contrasting regime. A regime is a dynamic "state" of a system.
Threshold A point where the system is very sensitive to changing environmental conditions.
Tipping point A point where the system flips from its current state to another state.

Introduction

The terms regime shifts, ecological thresholds, and tipping points are often used in aquatic ecology to describe abrupt transitions ranging from population collapse to community reorganization, and even shifts at the whole ecosystem scale. A large range of examples of regime shifts have been described in the literature including the shift from healthy coral reefs to deteriorated corals (Hughes, 1994), shifts of tropical forests to savanna vegetation (Hirota et al., 2011) and historic and contemporary regime shifts in the Sahara and Sahel (Foley et al., 2003; Tierney et al., 2017), but perhaps one of the most illustrative examples is the rather sudden transition observed in shallow lakes going from clear water and dominated by submerged vegetation to turbid water and dominated by phytoplankton. This sudden transition can occur when a tipping point is surpassed. The two contrasting states—clear versus turbid water states—are often resilient to change, i.e., internal feedback mechanisms maintain the lake turbid and large changes are needed for the system to return back to the clear state. In this chapter we explain how this works. We explain (1) what regime shifts and tipping points are, (2) how they are manifested in inland waters, (3) how they are linked to ecosystem functioning and (4) if and how we can detect regime shifts in time to prevent an ecosystem from tipping.

Regime shifts and tipping points

An ecosystem can respond to changes in different ways. Some changes occur in a smooth, near-linear way (Fig. 1A). Imagine, for example, a fish pond from which benthic fish are harvested. The fish resuspend the sediment causing turbidity. Without an *Allee effect* and when internal feedback mechanisms are weak or absent (see below), a small—gradual—decrease in fish biomass may lead to a small—gradual—decrease in bioturbation which in turn reduces turbidity. Stronger shifts may occur when conditions change while the system is near a certain threshold (Fig. 1B). Imagine a vegetated stream receiving an increasing herbicide load. Initially, the herbicide concentration remains below the concentration at which effects occur. When the concentration increases to levels that surpass the tolerance of the stream vegetation, a massive death of the plants with an unvegetated stream as a result is expected.

The third type of system response is the focus of this chapter; it occurs when under the same conditions alternative states exist (Fig. 1C). Imagine a system where increased nutrient loading slowly increases periphyton and phytoplankton growth, resulting in decreased light availability for submerged plants. At low nutrient loading, the submerged plants still receive sufficient light to grow and plant coverage remains relatively stable. However, when a certain critical periphyton density or a critical turbidity level is surpassed the submerged plants do not receive enough light and the vegetation will wane. Although the external driver—here nutrient loading—changed gradually, the system reacts abruptly. The critical nutrient loading at which this shift from a clear water and vegetation dominated state to a phytoplankton dominated turbid state occurs is often referred to as an ecological threshold or tipping point. In mathematical theory, such tipping points are called catastrophic bifurcations, with the fold catastrophe (F1 and F2 in Fig. 1C) as the most prominent example. Close to a bifurcation point a small perturbation can flip the system into its alternative stable state, in other words "little things can make a big difference" (Gladwell, 2000). The reason for this is that a small perturbation leads to a self-propagating change that eventually causes the system to shift to a qualitatively new state. The self-propagated change caused by the existence of strong positive feedbacks determines the nature of an ecosystem response with hysteresis (see "Feedbacks and hysteresis" section). In practice, a transition across a threshold without alternative states (Fig. 1B) cannot be distinguished from a transition in a system with alternative states (Fig. 1C). In both cases, such transitions will appear as abrupt and persistent shifts over a gradient of environmental conditions. For this reason, they both can be characterized as regime shifts but it is only the latter (Fig. 1C) that is associated with the existence of a tipping point.

The concepts of tipping points and alternative stable states, also referred to as alternative regimes to underline that a system state is not fully static, can be explained using "stability landscapes" (Scheffer et al., 2015; Fig. 2). The ball in this "landscape" represents the state of an ecosystem and the valleys—or basins of attraction—the stable equilibria a system can be in. The hilltops represent the unstable equilibria. The stability landscape can have different shapes, depending on external conditions. Projecting the same example as above (Fig. 1C) on the stability landscape in Fig. 2, we can interpret the front most stability landscape as an oligotrophic shallow lake full of submerged plants. Nutrient loading is too low for algae to be able to outcompete the submerged plants. Hence there is only one valley, no alternative states exist and the lake belongs to the submerged plant dominated state. In the transition from oligotrophic to more eutrophic conditions (central 3 stability landscapes), a second valley appears, the ball can be in either one depending on the initial conditions. Going from oligotrophic to eutrophic conditions the ball will be in the valley on the left (in our example the submerged plant dominated state), while during the recovery from eutrophic conditions to oligotrophic conditions the ball will be in the valley on the right (the algal dominated state). When nutrient loading increases, the valley shrinks and the system becomes less resilient to external perturbations. This means that a small perturbation—e.g., removal of some of the vegetation—, can lead to a transition to the alternative algal dominated state. A catastrophic shift occurs when nutrient loading crosses the F2 threshold: higher than this point the valley on the left disappears, submerged plants cannot dominate the system, and a positive feedback causes a self-propagating increase in algal concentrations until the submerged plants disappear and the lake reaches the alternative turbid water state.

In short, the stability landscape visualizes that a system can tip in two different ways: either through change in conditions or through a large perturbation (van Nes et al., 2016). The first type of tipping is the result of the gradual decrease in stability of a stable

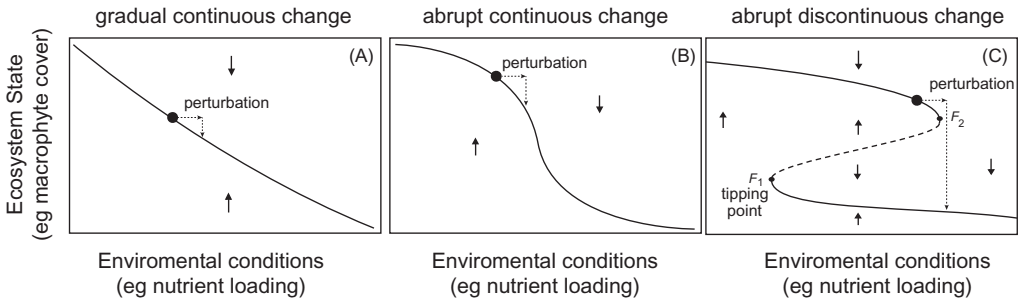

Fig. 1 Ecosystem response to changing conditions: near-linear response (A: small change in environmental conditions results in a small surprise); a non-linear response indicating a strong response around a certain threshold (B: a small change in conditions leads to a big but reversible surprise); a non-linear response indicating a strong response at a tipping point (F2, catastrophic (fold) bifurcation) (C: a small change in conditions leads to a big and hard-to-reverse surprise). In (C) F1 is the tipping point in the system where the system shifts back to the previous state. The range of conditions between the two tipping points (F1 and F2) marks the range of bistability in the system.

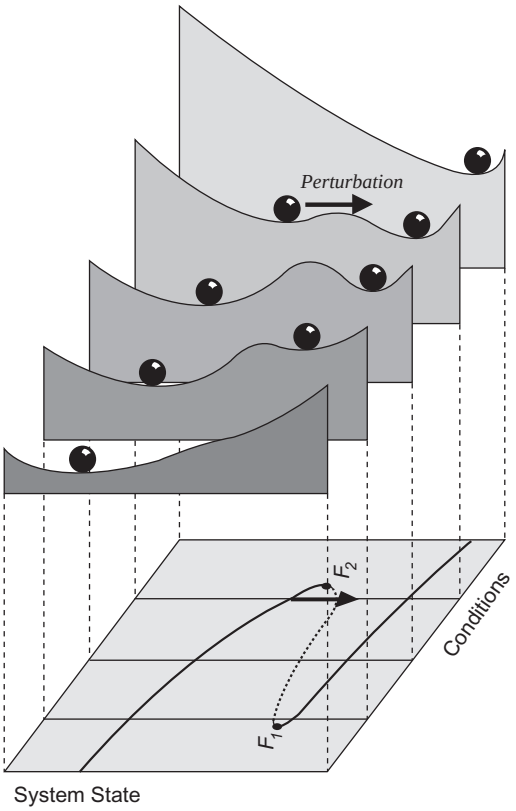

Fig. 2 Stability landscape illustrating the existence of alternative stable states, resilience and transitions. Bistability occurs in the three central landscapes. Scheffer M, Carpenter SR, Dakos V and van Nes EH (2015) Generic indicators of ecological resilience: Inferring the chance of a critical transition. *Annual Review of Ecology, Evolution, and Systematics* 46: 145–167.

state and can be anticipated using resilience indicators (see "Foreseeing regime shifts" section). The ability to remain in a stable state is defined as the systems "resilience." However, note that between scientific disciplines, there are numerous different concepts of resilience. In ecology, the most commonly used definition is the one postulated by Holling (1973);

"Resilience (. . .) is a measure of the ability of systems to absorb changes of state variables, driving variables, and parameters, and still persist (. . .). Stability, on the other hand, is the ability of a system to return to an equilibrium state after a temporary disturbance. The more rapidly it returns, and with the least fluctuation, the more stable it is."

Besides ecological (or Holling's) resilience, the *rate of recovery* after a disturbance is another measure of resilience, also referred to as *engineering resilience* (contrasting Holling's *ecological resilience*). Changes in recovery rate have been also used as a way of detecting regime shifts (see "Foreseeing regime shifts" section).

Another common regime shift in inland water is the shift between dominance of floating plants such as duckweed, water hyacinth or water lettuce, to alternative regimes consisting of either a submerged-plant dominated state (Strange et al., 2018), or a phytoplankton-dominated state (de Tezanos Pinto and O'Farrell, 2014). Besides shifts in the macro-ecological aspects of inland waters, regime shifts and hysteresis also occur in microbe-driven biogeochemical functioning. For instance, in deep, seasonally stratified lakes, shifts can occur between an oxic, cyanobacteria-dominated state and an anoxic state dominated by sulfate-reducing bacteria and phototrophic sulfur bacteria (Bush et al., 2017). Likely, this is a ubiquitous feature in stratified ecosystems, in which microbial feedback loops cause a rapid decline in oxygen levels which are not easily reversed (Bush et al., 2017).

Feedbacks and hysteresis

The stability of alternative ecosystem states as well as the accelerating change during a regime shift derive from internal feedbacks. Such feedbacks have been defined as "processes where changes in the state feed back to the input" (DeAngelis et al., 2012). Feedbacks can be either negative (stabilizing or dampening change), or positive (self-enforcing or magnifying change). Returning to the classic shallow lake example: submerged plants suppress algal growth—and thereby turbidity—by decreasing nutrient concentrations, as well as by secreting algal-repressing substances (Scheffer and Jeppesen, 1998; Fig. 3A and B). At the same time, low turbidity facilitates the establishment and growth of submerged plants, leading to a stabilizing positive feedback loop (Fig. 3D). However, if part of the submerged plants would be removed—leading to a change in system state-, or if nutrient loads would pass a

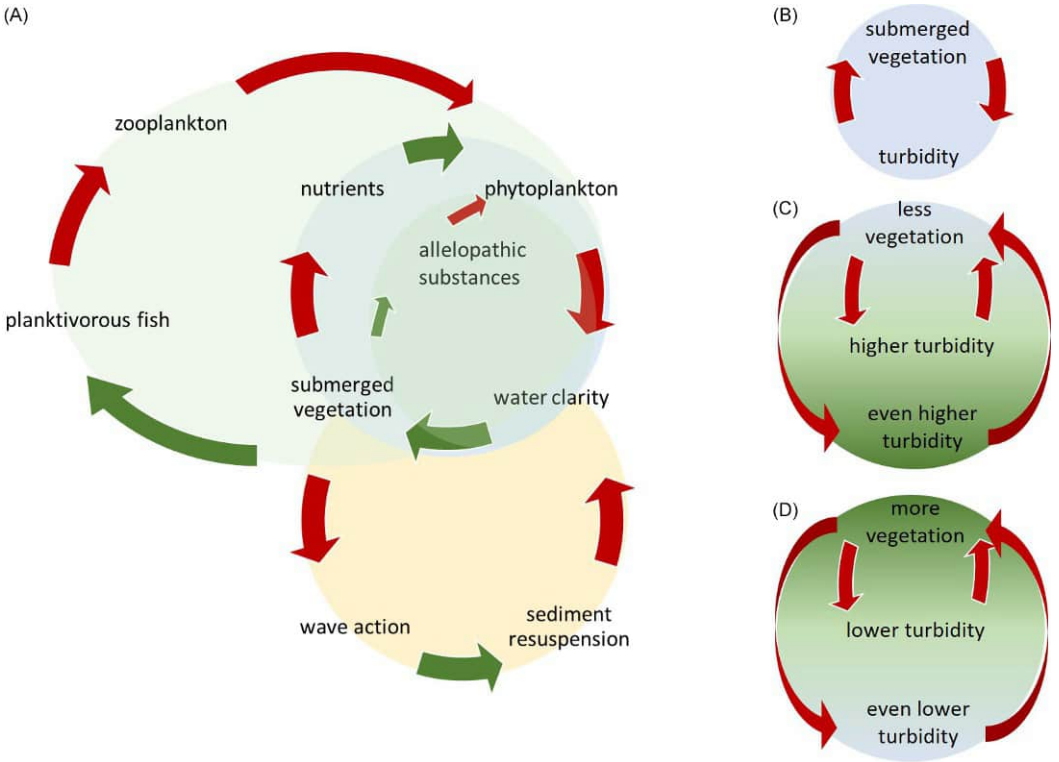

Fig. 3 Different self-enforcing feedback loops in a shallow lake, arising from positive (green arrows) and negative (red arrows) interactions in the network (A). Vegetation has a negative effect on turbidity (B and D), while turbidity has a negative effect on vegetation (C). Modified from Scheffer M and Jeppesen E (1998). Alternative stable states. In Jeppesen E, Søndergaard M, Søndergaard M and Kristoffersen K (eds.), *Structuring Role of Submerged Macrophytes in Lakes* vol. 131 ed., pp. 397–406. New York: Springer-Verlag and van Nes EH, Arani BM, Staal A, van der Bolt B, Flores BM, Bathiany S and Scheffer M (2016) What do you mean, 'tipping point'? *Trends in Ecology & Evolution* 31(12): 902–904.

critical threshold—leading to a change in external conditions-, stabilizing feedbacks are weakened and the system can be propelled into the turbid state, through self-enforced deterioration (Fig. 3C; van Nes et al. (2016)). Less submerged plants lead to less-efficient nutrient uptake, leading to algal growth, causing shading which further suppresses submerged plant growth. Once arrived in the new—turbid-state, a new stabilizing feedback is in place, where turbidity enhances turbidity.

To return to the clear water state, one cannot simply restore nutrient loads, but one must reduce these to a much lower level (represented by critical threshold F1 in Fig. 2). This is a defining property of systems in which alternative stable states exist. Here, due to stabilizing feedback loops, the road to recovery is much more difficult than tipping into a deteriorated state, a principle referred to as *hysteresis*. The first unambiguous proof of biological hysteresis was found in a phytoplankton population consisting of the cyanobacterium *Aphanizomenon flos-aqueae*, which was exposed to increasing light irradiance (Faassen et al., 2015, Fig. 4A). These cyanobacteria need light for growth, but too much light damages their cells. Even at low light levels, cells already profit from mutual shading, resulting in density-dependent growth due to an *Allee effect*. When light irradiance passes a critical threshold, too many cells are damaged, leading to loss of cells and thereby loss of the mutual shading underlying the *Allee effect*. The system is now propelled into extinction. To return to a high-biomass state, the light level has to be reduced to a much lower intensity than where the population went extinct, before a fresh inoculum will regrow to its original density.

Hysteresis in inland waters

Hysteretic effects have also been observed in inland waters. For example, Lake Veluwe, the Netherlands, went through several regime shifts over a period of 30 years (Meijer, 2000; Scheffer et al., 2001; Fig. 4B). Three alternative stable states occur in this lake: (1) a clear, submerged plant dominated state; (2) an intermediate state in which clear and turbid lake areas coexist, and turbidity is caused by sediment resuspension rather than phytoplankton blooms; (3) a turbid, phytoplankton dominated state arising from excess phosphorus (P) loads. In this lake, the road to recovery was considerably more difficult than the road to deterioration. Submerged plants disappeared at total phosphorus (TP) concentrations above 0.20 mg L^{-1}, whereas they only returned when TP was decreased to below 0.10 mg L^{-1} (Ibelings et al., 2007). After reducing P-loads, an intermediate state occurred where shallow areas of the lake were clear and recolonized by *Chara* spp., whereas deeper areas of the lake remained turbid through sediment

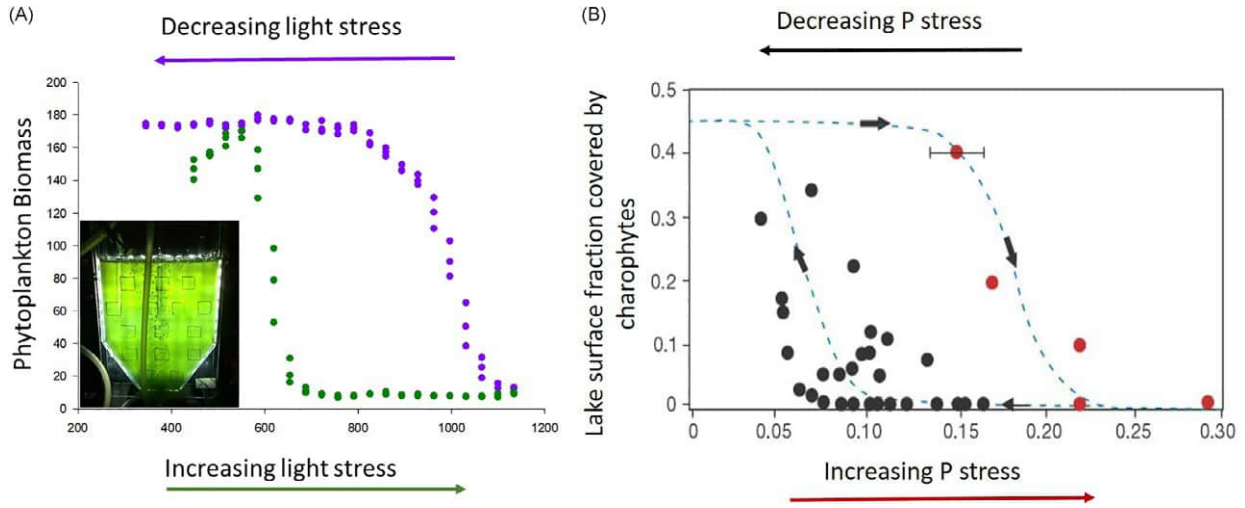

Fig. 4 (A) Hysteresis in an experimental phytoplankton population exposed to increasing and decreasing light stress (x-axis in μmol photons m^{-2} s^{-1}), the inset shows the experimental system. (B) Hysteresis in shallow lake Veluwe exposed to increasing and decreasing P-stress (x-axis, in mg L^{-1}). Adapted with permission (A) Faassen EJ, Veraart AJ, Van Nes EH, Dakos V, Lürling M and Scheffer M (2015) Hysteresis in an experimental phytoplankton population. *Oikos* 124(12): 1617–1623; (B) Meijer ML (2000) Biomanipulation in the Netherlands—15 Years of Experience. Wageningen University; Scheffer M, Carpenter SR, Foley JA, Folke C and Walker B (2001) Catastrophic shifts in ecosystems. *Nature* 413, 591–596.

resuspension by wind action and benthivorous fish. True lake-wide water clarity only occurred after substantially reducing numbers of benthivorous fish. This type of hysteretic behavior in which an intermediate recovery state or unstable clear state occurs is commonly observed in turbid, north-temperate shallow lakes on the road to recovery (Hilt et al., 2018). In those lakes, the stability and nature of the intermediate state depend on the type of restoration measures.

Overcoming hysteresis: Biomanipulation

Despite the lack of full insight into how ecosystem services change when a regime shift occurs (see "Foreseeing regime shifts" section), worldwide considerable effort is put into stimulating regime shifts, or in other words: to restore ecosystems to their original state. Lake Veluwe is just one of the many examples of inland waters where measures have been taken to reduce external and internal nutrient loading. Different measures and techniques are available (see e.g., Jilbert et al., 2020), but reaching a sufficiently low nutrient loading (i.e., below the value corresponding to tipping point F1 in Fig. 2) is often challenging and sometimes impossible. Biomanipulation may be used to "force" a shift to the desired state. Various biomanipulation techniques have been used to end a phytoplankton or floating plant dominated state and reestablish submerged vegetation. Well known examples are the removal of planktivorous fish to increase zooplankton grazing on phytoplankton, the introduction of piscivorous fish to achieve the same cascading effect, removal of benthivorous fish to reduce resuspension and uprooting of submerged vegetation, the introduction of filter feeders (fish or mussels) to remove phytoplankton and the introduction of submerged plants or the removal of floating plants (Jeppesen et al., 2012). Note that biomanipulation will only lead to the establishment of an alternative state when the environmental conditions are within the range that alternative states exist (i.e., between F1 and F2 in Fig. 2). Even then, biomanipulation is not always successful and sometimes repetitive actions are needed to keep the system in the desired state (Søndergaard et al., 2008).

Linking alternative states to ecosystem services

Regime shifts are large, persistent changes in the structure and function of ecological systems, with substantive impacts on the suite of ecosystem services provided by these systems (Folke, 2016). For aquatic systems the link between alternative regimes and ecosystem services are receiving increasing attention. It is clear that inland waters provide a wide range of ecosystem services, ranging from habitat provisioning for different types of organisms and nutrient retention to the provisioning of drinking water and recreational areas. Overview studies (Hilt et al., 2017; Janssen et al., 2019) indicate that alternative states differ in the services that they provide. Phytoplankton dominated systems, for instance, are much more suitable for navigation and different kinds of watersports, while engine propellers get stuck in aquatic plants. Aquatic plants (submerged and emergent) on the other hand stabilize the sediment with their roots, thereby protecting the shores or the bottom for erosion. The majority of studies report a higher biodiversity when a system is plant dominated as compared to systems that are dominated by phytoplankton, but notably

the opposite has also been found for instance for fish and phytoplankton communities. How regime shifts impact other ecosystem services, including greenhouse gas emission, carbon and nutrient retention, strongly depends on the system and so far no generalities can be distilled (see also knowledge gaps).

Foreseeing regime shifts

Foreseeing regime shifts ideally refers to identifying critical values in external conditions where a tipping point occurs. However, the identification of actual critical values is a daunting task. The alternative approach is to identify mechanisms and patterns that are related to the existence of alternative states and transitions between them (deYoung et al., 2008). These patterns can be used as criteria for detecting catastrophic regime shifts (Scheffer and Carpenter, 2003). Detecting regime shifts helps understanding their mechanisms and improves our ability to predict them. To achieve this, the most common approach is to identify discontinuities in time-series data using a breakpoint analysis (Andersen et al., 2009). Such identified breakpoints in long-term monitored aquatic systems are used to identify potential alternative states. Another approach is to infer the existence of alternative states from analyzing frequency distributions of state variables (Scheffer and Carpenter, 2003). A bimodal frequency distribution will flag the existence of alternative states and could even allow the reconstruction of stability landscapes (Fig. 2; Livina et al., 2010). However, both these approaches are performed post hoc meaning that a regime shift has already occurred.

To enable foreseeing tipping points and estimating the risk of an impending regime shift the use of different (or early warning signals) have been explored (Scheffer et al., 2009). The majority of these indicators stem from changes in the shape of the stability landscape of the system close and far from the tipping point (Scheffer et al., 2012; Fig. 5A and B), and they change in a consistent and predictable manner as the system is slowly approaching the tipping point. First, a system takes longer to recover back to equilibrium after a perturbation (Fig. 5C and E). Second, variability in the systems is rising (Fig. 5D and F), third the system states start to become more similar (autocorrelation increases Fig. 5G and I), and fourth the distribution of the system state becomes more skewed (Fig. 5 H and J). The prospects (Dakos et al., 2015) as well as the number (Clements and Ozgul, 2018) of resilience indicators have increased in recent years and there are complete statistical tools available for estimating such indicators in time series (Dakos et al., 2012) and in spatial datasets (Kefi et al., 2014). These tools have been applied using data from different types of

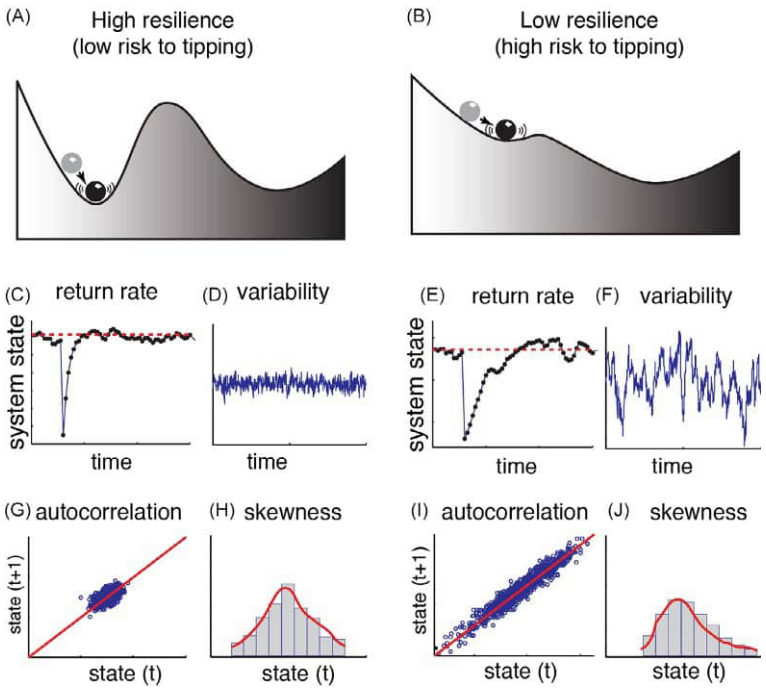

Fig. 5 Low resilience and high risk of tipping are fingerprinted by consistent changes in the dynamics of a system. Recovery rates upon perturbations (return rate, C and E) are slower when the basin of attraction is shallower (B) than when the basin of attraction is deeper (A). Increased slowness is reflected in stronger fluctuations in the state of the system measured as an increase in variability (compare D and F) as well as an increased temporal autocorrelation (G and I). Finally, the increasing asymmetry of the stability landscape close to the tipping point (B) leads to a skewed distribution towards values that reflect the direction of the future state of the system (H and J). Adapted from Scheffer M, Carpenter SR, Lenton TM, Bascompte J, Brock W, Dakos V, et al. (2012). Anticipating critical transitions. *Science* 338(6105): 344–348, with permission.

systems. Increased recovery rate has been manifested in a phytoplankton population prior to collapse in an experimental setup (Veraart et al., 2012), and rising variance and autocorrelation have been observed prior to trophic regime shifts in a whole lake manipulation (Carpenter et al., 2011). In addition, rising variance and skewness were found prior to eutrophication when analyzing sediment records in lake Erhai (Wang et al., 2012). However, estimating resilience indicators in five past well-documented regime shifts in aquatic systems showed divergent patterns among indicators (Gsell et al., 2016), highlighting that the practical application of resilience indicators for lake management is still challenging (Burthe et al., 2016).

Conclusion/Synthesis

Inland waters are facing numerous environmental stressors. In some situations, the resulting loss of ecological resilience causes small disturbances to trigger large shifts in the ecosystem state—a regime shift. When such shifted ecosystems are restored, hysteretic behavior triggered by new stabilizing feedback loops causes systems to shift back to their original state at much reduced levels of the original stressor. Therefore, successful restoration often consists of a combination of stressor reduction and biomanipulation—actively resetting dominant feedback loops. Regime shifts in inland waters strongly affect ecosystem functioning and the services associated with alternative regimes. Based on current insights, anticipating regime shifts remains a challenge.

Knowledge gaps

1. How to quantify resilience warnings that anticipate regime shifts and how to apply *them in order to take action before a shift occurs?* Whole-lake manipulation experiments and high-frequency continuous monitoring have demonstrated that resilience warnings could help to avert cyanobacteria blooms (e.g., Pace et al., 2017). Adoption of such approaches in lake management, however, remains a challenge.
2. *How to predict changes in ecosystem services related to alternative regimes*. Existing studies show contrasting results with respect to how ecosystem services, such as biodiversity provision and nutrient removal, change as a result of regime shifts (Hilt et al., 2017). A better mechanistic understanding is needed to predict changes in ecosystem services due to regime shifts.
3. *How to integrate spatial variation in resilience in our understanding of regime shifts*. First steps have been made in integrating spatial heterogeneity in models (e.g., Hilt et al., 2011 in streams; Janssen et al., 2017 in lakes), but further development of spatial ecosystem bifurcation analyzes and the validation and application in empirical studies are needed to, for instance, decide on spatially explicit restoration measures.
4. *How to apply knowledge on regime shifts and tipping points to inland waters other than shallow lakes*. Thus far, the main research focus has been on shallow lakes. However, we know little about regime shifts in other inland waters such as deep lakes, reservoirs, rivers and streams (Mesman et al., 2021).
5. *How to distinguish persistent regime shifts with alternative stable states from transient regime shifts with alternative unstable states?* Empirical work demonstrates that regime shifts may appear persistent, while in fact they are not. This is caused by slow ecological dynamics that lead in long-term transients following an abrupt change (e.g., Mushet et al., 2020). In a similar way, slowly responding systems may appear not shifting although in the long-run they would end up in a stable alternative state (e.g., Hughes et al., 2013). The theoretical and modeling framework of how persistent and transient regime shifts between alternative states occur is well-developed (Dakos et al., 2015), but identifying whether a regime shift will be persistent in practice remains a challenge.
6. *How to use knowledge on hysteretic behavior to optimize restoration?* Optimal restoration strategies need to take into hysteretic behavior into account as well as potential undesired new alternative states. Quantifying hysteretic effects, even when extensive system-specific knowledge is available, remains a challenge. In some cases, restoration does not result in the expected restored state (Chorus et al., 2020). For highly degraded systems, within-lake measures such as biomanipulation and geoengineering combined with stressor (nutrient) reduction show promise in restoration efficiency (Lürling and Mucci, 2020). Still, how to optimally design and execute restoration measures remains challenging as well.

Important case studies

A wide variety of studies has focused on alternative states in inland waters in different type of systems using different approaches with different foci. Below (Table 1) we mention several examples.

Table 1 Examples of case studies.

System	*Alternative states*	*Type of study*	*Main finding*	*References*
South African shallow lakes	Floating plants vs. invasive submerged plants	Field data	Biological control of floating invasive macrophytes can cause a regime shift between floating and submerged invasive plants	Strange et al. (2018)
Temperate, shallow lake (Lake Veluwe)	Clear, macrophyte dominated, turbid phytoplankton dominated and an intermediate state	Field data, long-term dataset	Clear hysteresis was observed during recovery from turbid-to clear in a shallow lake	Ibelings et al. (2007)
Shallow lakes in the Yangtze basin	Macrophyte vs. plankton dominated	Field data	Historic regime shifts were reconstructed using paleontological data and had different drivers in two different lakes	Xu et al. (2019)
Tropical shallow lake (Brazil)	Submerged vs. floating macrophytes	Field data	Phosphorus and light availability determine alternative state; floating plant dominance leads to a lower biodiversity	Moi et al. (2020)
Large shallow lakes	Submerged macrophyte vs. phytoplankton	Field data and modeling	Lake size, spatial heterogeneity and internal connectivity can explain the observed spatial presence of different states	Janssen et al. (2014)
Temperate, seasonally stratified lakes (Lake Vechten)	Oxic vs. anoxic—P dependent cyanobacteria-dominated vs. anaerobic microbial community with sulfur reducing bacteria and phototrophic sulfur bacteria	Field data and modeling	Feedbacks between biogeochemical processes and microbial-community dynamics drive shifts between oxic and anoxic states in seasonally stratified lakes	Bush et al. (2017)
Temperate Rivers and chains of lakes	Vegetated and clear vs. phytoplankton dominated and turbid	Modeling	Alternative stable states can only occur in systems with a high retention time and shift occurring upstream can propagate downstream	Hilt et al. (2011)
Shallow lakes in South America	Turbid vs. Clear	Field data and remote sensing	Turbidity is bimodally distributed in shallow lakes	Kosten et al. (2012)
Shallow lake (Gehu lake, China)	Turbid vs. Clear	Remote sensing	A regime shift from clear and macrophyte dominated to turbid was observed by remote sensing	Xu et al. (2020)
Large shallow lake (Lake Chaohu; China)	Submerged macrophyte vs. phytoplankton	Paleolimnology and modeling	Combined approaches showed interactive effect of two stressors (water level and nutrient loading) on regime shifts	Kong et al. (2017)

Invasive Species☆

Reuben P Keller[a] **and David M Lodge**[b], [a]School of Environmental Sustainability, Loyola University Chicago, Chicago, IL, United States; [b]Atkinson Center for Sustainability, Cornell University, Ithaca, NY, United States

This is an update of R.P. Keller, D.M. Lodge, Invasive Species, in *Encyclopedia of Inland Waters*, Edited by: Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00226-X.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Lars Rudstam.

Glossary

Ballast water Large ships and other boats have tanks in their hulls which hold ballast water. These vessels take on and discharge ballast water to compensate for changes in the weight of cargo being carried.
Canal Human-created channels that usually connect freshwater ecosystems that were not previously connected. Canals are generally built for the movement of water (e.g., from relatively wet to relatively dry areas) and/or to facilitate boat movement.
Established A species that is successfully reproducing to maintain a population beyond its native range.
Introduced A species that has been transported and then released beyond its native range.
Invasive A species that has at least one population established beyond its native range that is causing harm to ecosystems, economies, and/or human health.
Laurentian Great Lakes This system of lakes is made up of five individual lakes; Superior, Michigan, Huron, Erie, and Ontario. These lakes hold ~20% of the world's surface freshwater.
Nonindigenous A species is considered nonindigenous when it is found in a region outside of its native range.
Propagule pressure A measure of the number of organisms of a species that are introduced to a given region. Propagule pressure is composed of both the number of times that individuals of the species are introduced, and the number of individuals released.

☆*Change History*: October 2021. RP Keller prepared the update. Text has been modified with minor edits throughout for clarity and to update with current knowledge. "Impacts on Human Welfare" section has been added. Text in the examples has been updated to reflect current state of these invasions. Further reading section has been updated with newer references, and several older references deleted.

Species traits Characteristics of a species. This includes many factors like a species' size, fecundity, diet, and its tolerances to environmental factors like temperature and salinity.
Vector A process or object that moves organisms. For example, the pet trade is considered a vector because it is responsible for the movement of many thousands of individual organisms. Likewise, the ballast water of ships is a vector because many organisms are inadvertently moved with it.

Introduction

The introduction of nonindigenous species occurs as a byproduct of globalization. As human societies, and thus the ecosystems where humans live, have become more connected through trade and travel, species transfers have increased. In freshwater ecosystems around the globe a large number of nonindigenous species are already established and in many systems the rate at which new species are becoming established is increasing exponentially. The impacts that these species have in their new ecosystems can be very high, and invasive species are likely to remain one of the greatest drivers of losses in freshwater biodiversity and ecosystem services for the foreseeable future. Thus, the future biodiversity, productivity, and ecosystem function of freshwaters is dependent on how societies manage current invaders and on whether the arrival of future invaders can be prevented.

Freshwater invasion biology involves the study of a diverse range of taxonomic groups in a diverse range of ecosystems. In this article, we first provide an overview of invasion biology, especially as it applies to freshwaters and the general management and policy options available. Second, we present three extended case-studies: (1) the history of multiple species invasions in the Laurentian Great Lakes basin; (2) the Nile perch (*Lates niloticus*) invasion of Lake Victoria; and (3) the history of invasions by water hyacinth (*Eichhornia crassipes*) in tropical and sub- tropical regions of the world. These case-studies are representative of the impacts of many more species in many more regions. The 'Further Reading' section directs readers to longer and more thorough analyses of many of the topics covered here, and these include analysis of many more individual invasions.

Invasion sequence

To become invasive, a species must pass through three steps (Lodge et al., 2006). First, to be introduced, it must be transported by a vector to a region beyond its native range. Second, the species is defined as established if reproducing populations are found beyond human cultivation. Finally, a species is defined as invasive if it spreads and causes undesirable impacts to the environment, economy, and/or human health. In the following section, we describe each step more thoroughly.

Introduction of nonindigenous freshwater species

The globalization of trade and travel has created many vectors that transport species short and long distances across the globe (Table 1; Lodge et al., 2006). Some of these vectors, such as the aquarium and live food trades, intentionally transport species; we refer to these vectors as commerce in living organisms. Other vectors, such as shipping, transport aquatic species as a side effect of other human activities; we refer to these as transportation-related vectors. Later, we examine some of the most important vectors listed in Table 1, but we emphasize here that the number and diversity of vectors is far greater than displayed in Table 1, especially for transportation-related vectors. Furthermore, we emphasize that vectors differ in importance in different parts of the world, vectors have fluctuated over time in terms of the number of species that they introduce, and vectors differ in importance for different taxonomic groups.

Table 1 Important vectors of transport for the introduction of non-native freshwater organisms.

Category	*Vector*
Transportation related	Ship's ballast water
	Fouling organisms on the outside of boats
	Movement of recreational boats (e.g., on trailers and motors, in live-wells)
	Hitch-hikers (e.g., snails on plants) moved unintentionally with trade organisms
	Angling equipment (e.g., waders, fishing tackle)
	Canals
Commerce in living organisms	Pet/aquarium trade
	Watergarden trade
	Bait trade
	Live food trade
	Aquaculture
	Stocking for recreational/commercial fisheries
	Biological control

Commerce in living organisms

Stocking for sport and food

Throughout history, humans have intentionally moved freshwater organisms in attempts to generate new food resources and/or opportunities for sport. The most commonly transported taxa have been fish, crayfish, and mollusks, with introductions occurring across the globe. In the United States alone, for example, 128 fish species that are non-native to the country are now established, and a further 323 species that are native to the United States have become established in regions of the country beyond their native range. Rainbow trout (*Oncorhynchus mykiss*), a popular angling fish and probably the single most introduced sportfish in the world, has been introduced to over 100 countries.

Stocking for sport and food has been carried out by government agencies as well as by private organizations and individuals. Growing awareness of the impacts of nonindigenous species has led to tighter regulations, and introductions of new species have dropped in many countries. Despite this, the economic and social value derived from desirable fishes means that while new introductions have declined there are still many species being stocked. For example, although no new fish species have been intentionally introduced to the North American Great Lakes Basin in recent decades there are still large government programs which annually release millions of non-native salmonids including brown trout (*Salmo trutta*), rainbow trout, Chinook salmon (*Oncorhynchus tshawytscha*) and coho salmon (*Oncorhynchus kisutch*).

The aquarium trade

Thousands of species of fish and other aquatic organisms are moved around the world for the aquarium trade, and hundreds of these have been released and become established. When the sheer number of organisms involved in this trade is considered, it is easy to see why it is an important vector for new invasions. In the United States, for example, the aquarium trade in the early 2000s was annually introducing over 172 million individual freshwater fish (Smith et al., 2008). The vast majority of these fish were not identified at the species level so the diversity of species being imported is unknown. Although the trade is presumably smaller in countries with smaller economies, it is still an important vector for introductions, with, for example, 22 out of a total of 34 established nonindigenous freshwater fish species in Australia originally introduced as aquarium pets. Globally, the aquarium trade is growing so introductions and harmful invasions are likely to increase. An additional concern is that a large diversity of freshwater organisms can now be ordered online and quickly delivered (Keller and Lodge, 2007). This makes it difficult to fully understand and assess the risk from the aquarium trade vector because species sales and transport are less likely to be recorded.

Aquaculture and the live food trade

Freshwater aquaculture, the captive propagation of freshwater organisms, is growing rapidly across the globe. Approximately 46% of all seafood (freshwater and marine) production globally came from aquaculture in 2018 (the most recent year for which statistics are available), and the largest portion (60%) of this is freshwater fish (FAO, 2020). Introduction and invasion often accompany these benefits because the aquaculture industry usually selects species that thrive in local conditions, that are tolerant of a wide range of environmental conditions, and that are fast growing. These qualities also predispose species to become invasive if they escape, and aquaculture has led to numerous invasions across the globe. Although the potential for invasions from this industry is now well known, few measures have been taken to prevent escapes. Several fish species, collectively known as tilapia species, for example, are being promoted to developing countries through international aid programs, despite the fact that many of these species have a long record of escape and harm to native species and ecosystems. In the United States, bighead (*Hypophthalmichthys nobilis*), silver (*Hypophthalmichthys molitrix*) and black (*Mylopharyngodon piceus*) carp have escaped from aquaculture facilities in the last three decades and have invaded the Mississippi River and tributaries. These species now threaten to invade the Laurentian Great Lakes via a canal that connects these waterways.

Transportation-related vectors

Canals

The construction of navigation canals has connected many isolated freshwater ecosystems and allowed many species to cross barriers that previously restricted their range. For example, the construction of the Rhine-Main canal means that there is now a navigable water connection from the Black Sea in Eastern Europe, along the Danube River and through to the Rhine River, which eventually flows into the North Sea. Similarly, in North America, the Chicago Sanitary and Ship Canal connects the Laurentian Great Lakes—St Lawrence River biogeographic region with the Mississippi River basin. As well as allowing species to expand their ranges through their own propulsion, canals facilitate the movement of species via ships and other transportation-related vectors.

Shipping: Ballast and hull fouling

Ships take on and discharge ballast water to compensate for changes in the mass of cargo carried. Organisms become entrained when water is taken on and can be released far from their native range when the ballast is discharged. Many other species, referred to as fouling organisms, are transported when they attach to the hulls of ships. Both ballast and hull fouling are important vectors of freshwater, as well as marine, organisms. Hull fouling is likely to be a strong vector especially for ships and barges that travel through freshwaters, but may also be significant for other voyages given the broad environmental tolerances of many species. Because global shipping is increasing rapidly, and because the movement of ships now effectively links all ports on earth, the number of invasive species moved by ships is likely to continue to increase.

Establishment of nonindigenous freshwater species

Three factors interact to determine establishment success for introduced freshwater species: propagule pressure, traits of the introduced species, and the suitability of the receiving habitat.

Propagule pressure

The number of organisms released into a new habitat, and the number of times that releases occur, is referred to as propagule pressure. Species are more likely to become established if many individuals are released simultaneously, and if multiple introductions occur over long periods of time. When propagule pressure is low, too few individuals may survive long enough to establish, and for sexually reproducing populations, this makes individuals unlikely to find mates. With multiple introductions during a year, conditions most favorable for survival and reproduction are more likely to be encountered by the species. Although propagule pressure is clearly important, records of the number of individuals and introduction events are rare. Hence, although it is known that propagule pressure is positively related to risk of establishment the exact relationship between these factors is not well known.

Species traits

The establishment success of a species also depends on the traits of that species. A good example is that a broad diet and fast growth rate increase the likelihood of an introduced fish species establishing in the Laurentian Great Lakes (Howeth et al., 2016). Similar relationships have been quantified for fishes introduced into California (Moyle and Marchetti, 2006), and for other taxonomic groups introduced to many freshwater regions of the world. Not surprisingly, the traits associated with establishment differ across species and across freshwater ecosystems.

Habitat suitability

Because each species can survive and reproduce under a limited range of environmental conditions, it is often straightforward to predict where and when certain introductions will fail to establish populations. Good examples come from fish in the aquarium trade, which are mostly of tropical or sub-tropical origins. In the temperate Laurentian Great Lakes basin, only two species from the aquarium trade have established. In contrast, Florida, a sub-tropical state in the Southern United States, has over 40 established fish species that were introduced for the aquarium trade. Habitat suitability includes the potential effects of native species which may increase (e.g., by serving as prey) or decrease (e.g., by preying upon) the probability that introduced species will become established.

Impacts of invasive freshwater species

The final step in the invasion sequence occurs when established species spread and cause negative impacts. It is notable that most established species do not cause any measurable harm. Despite this, the sheer number of species that are introduced and become established means that the number of species that do cause harm is very large. These species are referred to as invasive. The same factors associated with species passing from introduced to established are important at this step, with species whose traits are well matched to their receiving environment being more likely to reproduce rapidly and spread. Propagule pressure may remain important at this step if new propagules increase genetic diversity that enhances local adaptation to the new environment. Below we discuss some of the major impacts caused by invasive freshwater species. First, we describe the ways in which invasive species harm ecosystems and economies. Finally, we describe damages to human welfare which have only recently begun to receive more research and attention.

Impacts on ecosystems

Invasive species often have large impacts as predators, herbivores, competitors, and ecosystem engineers. Additionally, when an invasive species is closely related to native species, hybridization with the native species can cause a loss of native genetic diversity. Although these are the same mechanisms by which native species interact with each other, the impacts of invasive species are often very large because they either introduce a novel function to their recipient ecosystem, or they prove more capable of exploiting resources than native species.

Freshwater invasive species impacts can be particularly severe when the invader becomes established as a 'trophic dead-end.' For this to occur a species must consume a large portion of total ecosystem productivity but not be susceptible itself to high levels of predation. Thus, resources become concentrated in the invading species. An example is the New Zealand mudsnail (*Potamopyrgus antipodarum*) that is invasive in Australia, North America and Europe. In a study of a stream in Wyoming, United States, this species was found to consume 75% of gross primary production through its herbivory (Hall et al., 2003). The main predators of New Zealand mudsnail are fish, but other studies have shown that the snails can survive gut passage. Hence, a large portion of total system productivity has been lost to the native food web. In this example, the primary impact of the invasive species is through

herbivory (grazing on algae), but secondary impacts may spread throughout the food web and ecosystem. Similar impacts are caused by the invasion of North American and European waters by zebra (*Dreissena polymorpha*) and quagga (*Dreissena bugensis*) mussels, and by invasions by crayfish (e.g., red swamp crayfish *Procambarus clarkii*) in many parts of the world.

Competition between freshwater species is often difficult to demonstrate. Nevertheless, it is likely an important mechanism by which many invasive species impact biodiversity. Some well-known examples are invasive macrophytes, especially floating plants such as water lettuce (*Pistia stratiotes*) and water hyacinth (*Eichhornia crassipes*), many of which establish thick mats of vegetation on the water surface that deprive the native species below of light.

North America is recognized for a diverse freshwater biota. Many of these species are recently evolved under conditions of geographic isolation. The construction of canals, release of aquarium and bait organisms, and other mechanisms that overcome natural isolation have produced many opportunities for hybridization and subsequent loss of biodiversity (Perry et al., 2002). For example, rainbow trout were introduced extensively for decades in the Rocky Mountain region of the U.S. to establish populations for sport-fishing. In many areas these non-native rainbow trout hybridize with the native cutthroat trout (*Oncorhynchus clarkii*). The hybrids produced are fertile and introgression of rainbow trout genes into cutthroat trout genomes means that across much of its historical range the native species has been replaced by the invader and hybrids (Muhlfeld et al., 2017).

In addition to strong direct impacts on biodiversity via food web interactions, invasive freshwater species often change physical and chemical conditions in their recipient ecosystem. For example, invasive macrophytes can reduce light and oxygen levels in the water column, thus altering opportunities for other species. Invasive crayfishes (e.g., red swamp crayfish) can burrow into the substrate and cause increased erosion and water turbidity, and some invasive fishes (e.g., common carp *Cyprinus carpio*) cause similar impacts through their feeding activities.

Introduction of parasites and diseases

Parasites and diseases are often transported in association with nonindigenous species, and these may have large impacts when native organisms have little or no resistance. Because the introduction and impacts of parasites and diseases are difficult to recognize and study, it is reasonable to believe that they are more common and larger than available results suggest. One well-known example is crayfish plague (*Aphanomyces astaci*), a fungal disease endemic to North America that was transported to Europe with American crayfish introduced for aquaculture. European crayfish species have no resistance to the disease, and in both Scandinavia and the United Kingdom whole populations of the only native crayfish species (white-clawed crayfish *Austropotamobius pallipes*) have been eradicated by this disease.

Economic impacts

Loss of valuable species

Many of the highest profile invasive freshwater species achieved notoriety by harming species that humans exploit. Sea lamprey (*Petromyzon marinus*) has invaded the Laurentian Great Lakes and caused large declines in commercial fish stocks, and Nile perch (*L. niloticus*) has greatly reduced populations of endemic cichlids in Africa's Lake Victoria that were once captured for the aquarium trade (each of these examples is detailed further in the *Case-Study* section below). Other species have had similar impacts. For example, concern about the spread of the algae *Didymosphenia geminata* in New Zealand is largely focused on its potential to reduce food resources for trout, and thus to decrease the value of recreational fisheries.

Fouling of industrial systems

Many industries around the world are sited on lakes and rivers to provide easy access to water, and several species have become serious pests by fouling water intake structures. The highest profile of these are the zebra and quagga mussels. Each of these has a planktonic juvenile stage during which individuals can be entrained into pipes where they settle and grow, eventually restricting water flow through the pipe. In response, whole industrial systems, such as nuclear power stations, may need to cease operations to clean out their pipes on a regular basis. In the United States portion of the Great Lakes alone, it is estimated that zebra mussels caused losses of over $200 million annually during the early part of their invasion through direct costs for cleaning and lost production. Recent impacts may be lower as industrial facilities have altered equipment and practices to reduce the impacts of these species. Dreissenid mussels have similar impacts across much of Europe and the United Kingdom. While these impacts are costly, the filtering activity of dreissenid mussels has made water clearer in many lakes. Clearer water is considered more desirable by many people and in some cases this impact of mussels has been linked to higher property prices.

Impacts on human welfare

Most research on the impacts of invasive freshwater species has occurred in relatively wealthy countries and has focused on how ecosystems, industrial economies, and recreational opportunities are affected in those countries. Because these countries generally have good infrastructure the direct impacts of invasive species on human welfare—for example by reducing water supply to subsistence farmers—have largely been overlooked. Several recent studies have begun to address this and made clear that some invasions lead to very severe impacts for human welfare. For example, Wular Lake in Kashmir (India) was recently invaded by two floating aquatic plant species. These plants now cover much of the lake for much of the year and reduce access to fisheries and water. The human population in the area experiences high levels of poverty, low levels of education, and relies heavily upon resources

extracted from the lake. As those resources have been reduced by the invasive plants many people have had to leave their villages to seek work elsewhere (Keller et al., 2018). A similar example comes from South Africa where dense populations of invasive plants—including aquatic invasive plants—transpire more water than native plants and lead to reduced streamflow in regions that are already water-stressed. This leads to less water availability for municipal purposes and agriculture (van Wilgen and Wannenburgh, 2016). Because these and other impacts on human welfare have received relatively little attention it is likely that they are much greater and more widespread than is currently known.

Managing established freshwater invaders

Two things are generally true about the detection and management of invasive freshwater species. First, most species are well established by the time that they are detected, and second, established populations of aquatic species can rarely be controlled or eradicated without using broad spectrum poisons that cause large nontarget effects. For example, with rare exceptions (e.g., the sea lamprey example below) the best option for controlling invasive fish populations is to use the poison rotenone, which kills all fish in the waterbody. Likewise, efforts to control or eradicate macrophytes often rely upon broad spectrum herbicides that kill all aquatic plant life. Because of the unintended effects on native species these methods are most commonly used in heavily human altered ecosystems (e.g., impoundments, canals) where the value of native biota is generally considered to be lower than in more natural systems. In very large or flowing systems (e.g., large lakes, rivers) the use of poisons is usually impractical because they disperse too quickly. Thus, preventing introduction of species and preventing further spread once a species is established in a region are the most cost-effective management strategies.

Interactions with other mechanisms of global environment change

The number of established invasive species, as well as their impacts, are magnified by a host of other mechanisms of global environmental change (Kolar and Lodge, 2000). In many cases environmental changes favor nonindigenous species over native species adapted to the previous conditions. Regulation and impoundment of rivers, for example, favors lentic over lotic species. Similarly, eutrophication, a globally common environmental change, creates similar conditions across continents that facilitate establishment, spread, and impacts of the same invaders like common carp.

Global climate change is altering conditions in freshwater ecosystems across the globe, including flow rates and volumes in rivers and patterns of drought and flood. In many cases the resulting changes are reducing populations of native species and allowing non-native species to become established (Rahel and Olden, 2008). The situation in freshwaters is complicated, however, because although rivers and lakes may become warmer, there is usually no opportunity for invaders to naturally disperse over land among these systems. The exceptions are lakes that are large enough that some species can presently survive in some but not all parts, and rivers that flow on a north south orientation. Because humans continue to transport and introduce invasive species, however, invasive species ranges are likely to grow as species that would previously not have persisted where they are released will be able to establish under the new conditions.

Case study 1: Invasions of the Laurentian Great Lakes

Europeans settled the Laurentian Great Lakes basin in the early 1800s, and ever since the lakes have been a focus for navigation, commerce, and recreation. These activities have caused the establishment of at least 188 non-native species (Fig. 1; Ricciardi, 2006; Sturtevant et al., 2019). Many of the earliest species introduced to the Great Lakes were fish released by private individuals and government agencies with the aim of providing new commercial and recreational fisheries (Fig. 1). Records of these releases were not well kept, and because lake ecology was not well studied at the time, little is known about the impacts of these introductions.

The first nonindigenous species to attract widespread attention was the sea lamprey, which entered the Great Lakes through the Welland Canal. This canal was constructed in the 1830s to allow boats to bypass the Niagara Falls and directly access the upper Great Lakes. It has also allowed for biotic transfer between the two previously isolated ecosystems. Sea lamprey are a parasitic fish that feed off larger fish, including the native lake trout. At the time that sea lamprey arrived there was a large commercial fishery for lake trout and populations of lake trout were already declining due to over-fishing. Sea lamprey greatly accelerated this decline and many stocks of lake trout were completely lost, along with the commercial fishery and many jobs. Sea lamprey persists in the Great Lakes to this day, although it is effectively controlled by lampricide applications to its breeding streams (Fig. 2; Heinrich et al., 2003). These lampricides can be implemented with acceptable levels of non-target effects because lamprey are susceptible to poisons that are not toxic to other species, and because lamprey breeding streams have been identified so that general application of the lampricide is not needed.

As oceangoing ships have gotten larger and faster, ballast water has become the dominant source of new introductions, and is the likely vector for 65% of the approximately 70 species that have become established since the enlarged Welland Canal opened and oceanic shipping to the upper lakes began in 1959. As the number of established species has grown, so too have the total impacts of invaders. The invaders that have achieved the greatest notoriety are probably the closely related zebra and quagga mussels, which

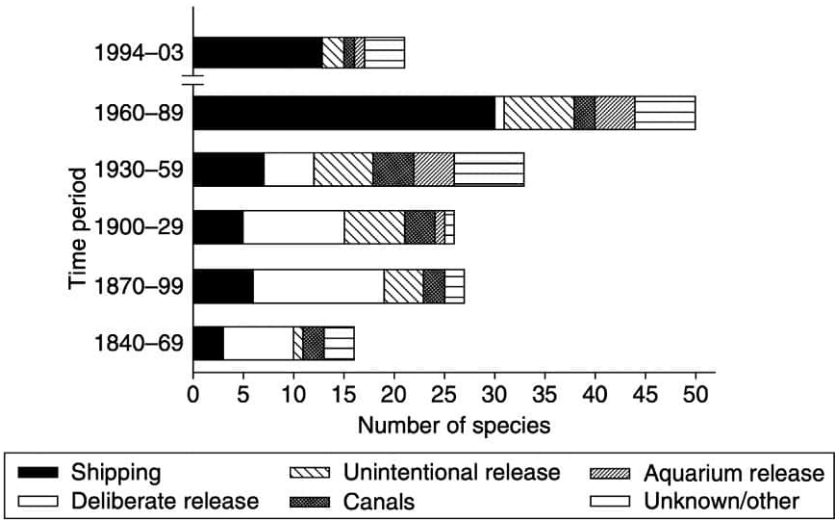

Fig. 1 Number of species introduced, and vectors of transport, for the Laurentian Great Lakes from 1840 to 2003. Reproduced from Ricciardi A (2006) Patterns of invasion in the Laurentian Great Lakes in relation to changes in vector activity. *Diversity and Distributions* **12**: 425–433.

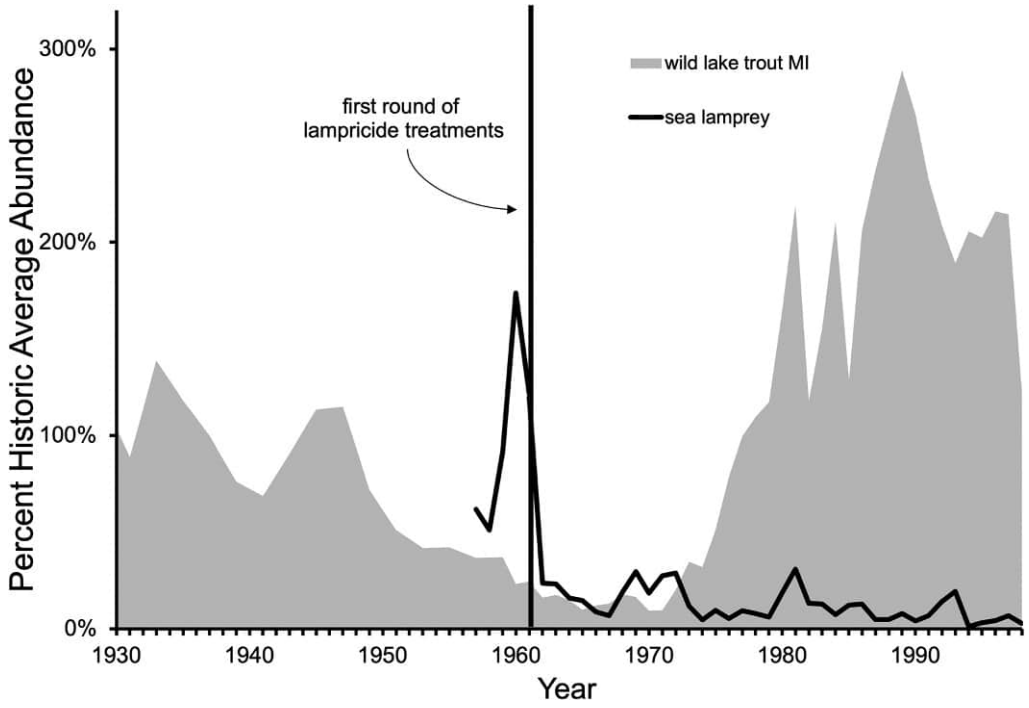

Fig. 2 Population fluctuations (expressed as relative abundance) of lake trout and sea Lamprey in the Michigan waters of Lake Superior from 1930 to 2000. Lake trout populations were already in decline due to overfishing when sea lamprey achieved high populations, and sea lamprey parasitism contributed to further lake trout population declines. Lake trout populations have since recovered, and sea lamprey populations are now kept down by applying a lampricide to their natal streams. Source: Great Lakes Fishery Commission.

were introduced in ballast water and discovered in the mid-1980s. Although the zebra mussel was initially dominant, it has largely been replaced in the five Great Lakes by the larger quagga mussel in recent years. Quagga mussel are larger and live across a greater range of depths, and they now consume a vast amount of the primary production of the lakes. Although one impact of zebra and quagga mussel establishment has been positive—its filter feeding has improved water clarity—these species have caused enormous economic damages and extensive ecological changes to the Great Lakes (Karatayev et al., 2015).

Efforts to reduce future impacts of Great Lakes invaders are focused on preventing the further spread of known invaders and the arrival of new invaders. Ships are now required to exchange ballast water in the open ocean before they can discharge it into the Great Lakes, and efforts are being made to address invasions from trades. A drop in the rate of new species discovery indicates that these efforts may be having some success (Sturtevant et al., 2019). Overall, however, further invasions should be expected through trade, shipping, and canals because many of these pathways and vectors remain active.

Case study 2: Nile Perch in Lake Victoria—Good intentions gone wrong

Perhaps the best-known example of biodiversity impacts from a freshwater invasive species is the introduction of Nile perch to Lake Victoria (Africa) in 1954 (Pringle, 2005). This introduction was intended to augment fisheries in the lake, and thus to provide an extra source of protein, jobs, and income for locals. For a number of years the species thrived, and to this day it supports a large, mainly export, fishery. Although the original intentions for introduction were initially met, they have come at a large cost to biodiversity and indigenous fisheries.

Lake Victoria is famous for its enormous diversity of endemic cichlid fish, which although never fully counted probably once numbered around 450 species. These cichlids were captured and reared for the aquarium trade, but it is estimated that approximately half of these species have been driven to extinction—or at least to undetectably low abundances—by Nile perch predation. Additionally, because many of these cichlid species were algae eaters, it is likely that the Nile perch introduction is at least partly responsible for an increased incidence of nuisance algal blooms in the lake. These algal blooms reduce visibility, which further interferes with mate recognition for the endemic cichlids and leads to hybridization and genetic introgression.

Nile perch support a valuable fishery in Lake Victoria, and even if the will existed it is unlikely that they could be eradicated. Indeed, most efforts to remove populations of invasive fish rely on general purpose fish poisons, so the consequences of such attempts would be unacceptable. Recent declines in the Nile perch population have, however, allowed for a recovery of some cichlid species. As these declines in Nile perch may be due to overfishing, the future of many of the remaining cichlid species may depend on future management of the Nile perch fishery.

Case study 3: Water hyacinth—An attractive invader

One of the most popular species in the global ornamental plants trade, and one of the most invasive, is water hyacinth. This species is native to Brazil, but is now widely established in tropical and subtropical regions around the world. Water hyacinth is popular for both aquarists and water gardeners because it is one of only a few floating aquatic plants, it reproduces extremely quickly (a population can double its biomass every 6–18 days), and because it produces large numbers of attractive purple flowers. It is also highly invasive and forms monospecific mats on invaded lakes and rivers (Fig. 3). This leads to a number of ecological impacts, including reduced light and oxygen levels in the water column, which in turn reduces native macrophyte diversity and can lead to fish kills, and to the loss of waterbird habitat. Water hyacinth populations have large negative impacts on human society by clogging lakes and waterways and impeding navigation and fishing, by providing breeding areas for mosquitoes and thus exacerbating vector-borne diseases, and by reducing opportunities for recreation. It is considered one of the world's most costly and damaging species.

As well as introducing water hyacinth beyond its native range, humans have altered the hydrology and chemistry of many tropical and subtropical freshwater ecosystems in at least two ways that encourage this species. First, the conversion of flowing rivers to impoundments has provided habitats ideal for this floating species. Second, eutrophication resulting from agricultural runoff leads to much higher water hyacinth growth rates, and subsequently much higher impacts.

Fig. 3 Water hyacinth (*Eichhornia crassipes*) infestation in Hawaii. Courtesy Forest and Kim Starr, Starr Environmental, Bugwood.org.

Although water hyacinth is a well-known invader, it remains valuable for trade and easy to purchase, creating an obvious tension with the large amounts of money spent to manage the species. In the United States, populations are often broken up with large, floating chopping machines. This method reduces the current size of an infestation, but does not eradicate the plant. It can also have the unintended consequence of encouraging further spread because the fragments created are relatively easy to inadvertently transport (e.g., on boat trailers) and may remain viable. In Africa, a number of infestations have been controlled through the release of insect species that preferentially feed on water hyacinth. Elsewhere, manual removal of infestations is favored because it reduces the possibilities of fragments founding new populations, and does not involve the risks from introducing new species. Despite the successes from these methods, however, water hyacinth will undoubtedly remain a serious invader across the globe for the foreseeable future. New populations are likely to become established as a result of further releases from the ornamental trades, and it is likely that climate change will enable the establishment of water hyacinth in regions where it was previously too cold for the species to survive.

Ecosystem Engineers in Freshwater Ecosystems

Christine M Mayer, Lake Erie Center and Department of Environmental Sciences, University of Toledo, Oregon, OH, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Lars Rudstam.

Glossary

Allogenic engineers Organisms that modify the environment by transforming material (other than themselves).
Autogenic engineers Organisms that modify the environment by their own physical presence.
Bioturbator An organism that disturbs sediments.

Introduction

The term Ecosystem Engineer was first coined in to describe "organisms that modulate the availability of resources (other than themselves) to other species by causing physical state changes in biotic or abiotic materials. In so doing they modify, maintain and/or create habitat" (Jones et al., 1994). Prior to 1994, when the term's definition was published, researchers were studying cases of specific species that changed their environments, e.g., Darwin wrote extensively on soil formation by earthworms (Darwin, 1892) and beavers have long been known to alter streams (Naiman et al., 1988). However, the lack of a term for an idea makes it difficult to discuss. For example, consider trying to discuss "organisms that share the same function in the food chain and the same nutritional relationship to the primary sources of energy" (Oxford Languages) instead of discussing "trophic levels." Ecosystem engineering is a fundamental concept for understanding how organisms interact with and modify their environment. The citation rate of the term 'ecosystem engineer' has increased since 2010 (Emery-Butcher et al., 2020). Despite increasing citation of this term, many textbooks on ecology don't include the term in their table of contents (e.g., Begon and Townsend, 2020; Sher and Molles, 2022). It is true that the citation rate increase has been slower in freshwater than terrestrial and marine systems; this relative inattention to ecosystem engineering in freshwater research does not reflect the actual importance of ecosystem engineering in inland waters.

Types of ecosystem engineers

Ecosystem engineers were categorized as one of two primary types by Jones et al. (1994):

1. *Autogenic engineers* modify the environment by their own physical presence via their living or dead tissues. Note that habitat modification by an organism's body differs from the energy that their tissues may contribute to the food web. Examples include submerged aquatic vegetation (SAV) that define the littoral zone, or dreissenid mussels (*Dreissena polymorpha* and *Dreissena bugensis*) that create hard surfaces with many interstitial spaces.
2. *Allogenic engineers* transform living and nonliving material (other than themselves) from one physical state to another. Examples include beaver (*Castor canadensis*) which construct dams (Fig. 1) that can alter the flow of rivers, and phytoplankton which shade the water column and can outcompete SAV and benthic algae for light.

Ecosystem engineers in different freshwater habitat types

Open water: The open water zone lacks hard physical structures and therefore autogenic ecosystem engineering is not likely to be prominent in this habitat. However, spatial structure in open water zones is often be defined by gradients in temperature, oxygen, and light which can be influenced by allogenic ecosystem engineering.

Organisms that control light are a major category of ecosystem engineers (Berke, 2010). Phytoplankton frequently control water clarity, thereby regulating light penetration, and are consequently a common ecosystem engineer in the open water. Regulation of light penetration by phytoplankton can control the depth to which other primary production is possible. The depth of SAV is controlled by light availability (Duarte et al., 1986) although plants are adapted to different light conditions and therefore the actual

Fig. 1 Beaver family near entrance of their lodge at Old Woman Creek National Estuarine Research Reserve. Photo by E. Kuzmick.

depth limit is species-specific (Middleboe and Markager, 1997). Some phytoplankton such as *Microcystis* spp. control their buoyancy with gas vacuoles (Reynolds et al., 1987) and can therefore maintain their position near the water surface and shade light away from other phytoplankton species. Consequently, phytoplankton acting as light engineers may influence the distribution of all other primary producers in aquatic habitats.

Phytoplankton also produce oxygen as a byproduct of photosynthesis and therefore affect oxygen gradients, especially in lakes. Oxygen is required by all animal life and therefore defines where animals and aerobic microorganisms can live. Although physical mixing with the atmosphere also contributes oxygen, as one of the major producers of oxygen, phytoplankton are important ecosystem engineers controlling this essential element. The ancient marine ancestors of freshwater cyanobacteria evolved the ability to photosynthesize and released large amounts of molecular oxygen into the atmosphere early in Earth's history (Buick, 2008). The appearance of oxygen in the atmosphere literally changed the world and altered the course of the evolution of life. Therefore, the marine precursors of freshwater phytoplankton were the original, and global-scale ecosystem engineers.

Bottom: Submerged Aquatic Vegetation (SAV) provides a structured habitat to other organisms ranging from algae to fish. Algae, microbes, and small animal live on the surfaces of SAV stems and leaves. Many of these organisms can also live on inert substrates, but the presence of SAV vastly increases the amount of substrate available meaning that SAV acts as autogenic engineers. SAV may additionally supply attached algae with nutrients, especially in oligotrophic waters (Eminson and Moss, 2007) and consequently SAV can also function as allogenic engineers. Attached algae themselves may also be considered ecosystem engineers, albeit at a much smaller spatial scale than SAV because they form a structural matrix that is inhabited by microbes and small animals such as rotifers. At a larger spatial scale SAV provides habitat for littoral fish species, such as sunfish (family Centrarchidae). The presence of SAV transforms an aquatic area via autogenic engineering in the same way that trees transform a terrestrial area and define it as a forest. The cover created by SAV can modulate foodweb interactions (Carter et al., 2010) and SAV density can affect commercial fishery landings (Giacomazzo et al., 2020). The littoral zone, which is defined by growth of SAV is therefore an area that is highly impacted by both autogenic and allogenic engineering.

Bioturbators physically restructure sediment and act as allogenic ecosystem engineers in the same way that earthworms engineer terrestrial soils (Le Bayon et al., 2017). Even relatively small burrowing invertebrates such as chironomid larvae affect the physical properties of sediment (Baranov et al., 2016). Mayflies of the genus *Hexagenia* construct U-shaped burrows and maintain high oxygen concentrations in their area (Wang et al., 2001). *Hexagenia* burrowing activity can release phosphorus from sediment and contribute to internal loading (Chaffin and Kane, 2010). Large bivalves such as those of the Unionidae family may restructure sediment at a more bulk-scale than do insect larvae. Unionids physically alter sediment by increasing water content and homogenization and they may also alter carbon and other nutrient content via biodeposition of waste (Vaughn and Hakenkamp, 2001). Consequently, the effect of engineering by bioturbators depends on the species, and can affect the structure and chemistry of the sediment as well as the coupling between the benthic and open water habitats of inland waters.

In contrast to bioturbating bivalves which churn sediment, other bivalves cap sediment and form a hard substrate (autogenic ecosystem engineering), qualitatively altering the type of bottom present. Zebra (*D. polymorpha*) and quagga (*D. bugensis*) mussels, introduced and invasive ecosystem engineers (Karatayev et al., 2002), have restructured bottom habitats outside their native range. They grow in clusters (Fig. 2) with interstitial spaces that provide habitat for invertebrates, which can increase locally in density (Mayer et al., 2002; Stewart et al., 1998). In addition to autogenic engineering, where they create hard substrate, *Dreissena* are also allogenic engineers as filter feeders that clear the water column and modulate the availability of light to other organisms. *Dreissena* can sharply increase water quality and this effect occurs at a lake-wide spatial scale (Mayer et al., 2014). Alteration of the light environment connects directly to a number of trophic levels rather than being transmitted through a series of links as in a trophic cascade. Increased light increases the photosynthetic rate of plants and algae, and also directly alters the environment for visual

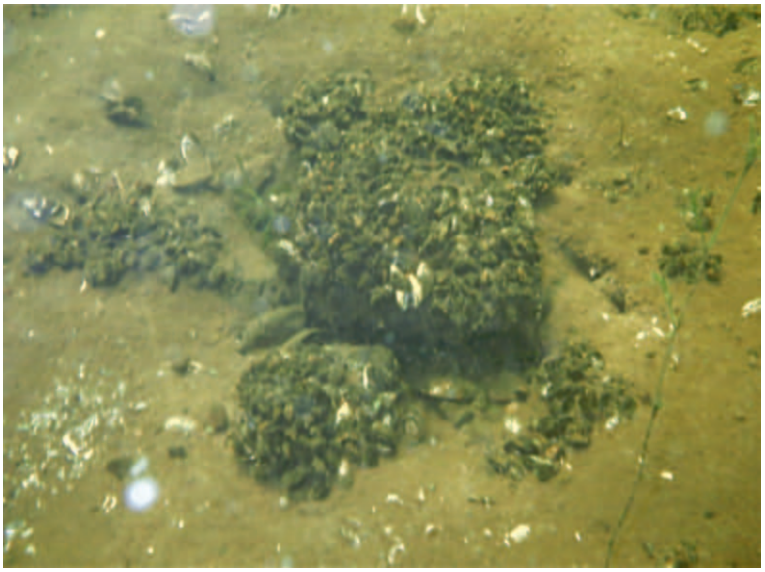

Fig. 2 Zebra mussels forming clusters surrounded by silty sediment in Oneida Lake. The largest cluster is formed on a rock. The smaller clusters are spreading out from smaller stones or other hard objects. Photo by K. Schulz, SUNY-ESF.

predators and prey. Additionally, *Dreissena* shift the spatial distribution of nutrients towards shallower areas where they are more abundant in large lakes, a process called the Near Shore Shunt (Hecky et al., 2004). The combination of multiple types of engineering coupled with large populations have made *Dreissena* a highly influential invasive ecosystem engineer.

Moving Water: In streams engineers also affect stream flow in addition to the effects on bottom structure and light penetration. This activity can dramatically change habitats. Beavers construct dams that make pools out of streams; probably the most well-known example of an ecosystem engineer (Jones et al., 1994). But other species also change stream flow. One of the most striking types of ecosystem engineering is gravel nest building. For example, fish of the genus *Nocomis* build mounds of gravel by transporting individual stones in their mouths (Frimpong, 2018) (Fig. 3). These nests often provide habitat used by nest associate species which benefit from spawning on the constructed nests (Johnston, 1994) and likely benefit the host species in a mutualistic association (Peoples and Frimpong, 2013). This form of allogenic ecosystem engineering is similar to dam construction by beavers in that both animals are purposefully moving materials to construct nests that happen to cause larger habitat modifications.

Applications to management and conservation

Invasive ecosystem engineers may disrupt ecosystems more than non-engineering invasive species because they modify habitat (Emery-Butcher et al., 2020). It is true that not all the impacts of invasive engineers are negative. For example the roots of an invasive species of SAV may stabilize sediment similarly to a native species (Emery-Butcher et al., 2020) and zebra mussels enhance habitat availability for native benthic invertebrates (Mayer et al., 2002). Nonetheless, status as an ecosystem engineer may be an important consideration in assessing the risk a potential invader poses. Conversely, for species that are managed for conservation, ecosystem engineer status may increase the perceived value of conservation since that species effect on the overall ecosystem via habitat modulation is likely to be great.

Knowledge gaps

One challenge in research on ecosystem engineers is that there is less basis for making predictions about the outcomes of interactions than there is when studying other processes such as predation or competition. In a predation event, there is a clear winner (predator) and loser (prey). In contrast, changing habitat may favor some organisms while disadvantaging others. For example, as *Dreissena* increase water clarity and light penetration fish species that forage efficiently in low light may experience a relative disadvantage, whereas some visually feeding species may forage more successfully. Consequently, focusing on approaches that describe and quantify the magnitude of interactions in addition to direction may help study of ecosystem engineering continue to move beyond case-studies.

Nutrient Stoichiometry in Aquatic Ecosystems

RW Sterner, University of Minnesota, St. Paul, MN, United States

This is an update of RW Sterner, Nutrient Stoichiometry in Aquatic Ecosystems, In *Encyclopedia of Inland Waters*, edited by GE Likens, Elsevier Inc.,2009 https://doi.org/10.1016/B978-012370626-3.00113-7 with revisions made by the Editor.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor, Lars Rudstam.

Introduction

In chemistry, the term 'stoichiometry' refers to the number of atoms of elements on both sides of a reaction. Stoichiometry tells you how many different molecules of each type of reactant you need to generate a specific product or set of products. Ecologists and limnologists can use these same principles of stoichiometry to understand aquatic ecosystems because individual species, like molecules, have defined chemical composition. The elemental formula of an individual species is normally not as strictly defined as the kinds of molecules we are most accustomed to thinking about, those with specific, unvarying composition. However, stoichiometry can still be a very useful approximation. Stoichiometry has much to say about the linkage of cycling of different elements and about patterns of nutrient limitation in primary producers and other parts of food webs. It bridges studies on individual species with studies dealing with the flow of matter and energy in ecosystems.

In this article, we first consider some of the patterns in elemental content of particular aquatic organisms and then we consider the ecological consequences of those patterns.

Stoichiometric homeostasis

Homeostasis is one of the hallmarks of life. Homeostasis is a resistance to change. For example, homeothermic organisms maintain a constant body temperature in spite of fluctuating environmental temperature. There are many other examples of homeostasis in biology, like the pH of blood and the concentration of ATP in a cell. Homeostasis results from negative feedbacks. In ecological stoichiometry, we use this same term to refer to the tendency of an organism to maintain its chemical content in spite of variation in the chemical content of its resources (Fig. 1). The figure illustrates the general principle. Mathematically, stoichiometric homeostasis (H) is defined as

$$y = cx^{1/H}$$

where y = organismal elemental content (e.g., moles P per dry mass of animal), c = a constant, x = elemental content of resources (measured in the same units as 'y'), and H (the Greek letter 'eta') is the measure of homeostasis. If homeostasis is so strong that organismal content is constant no matter what the chemical content of the organism's food is, the stoichiometric coefficient H approaches infinity and we refer to that as a 'strict homeostasis'.

Not all species maintain stoichiometric homeostasis to the same degree, and within any given species not all resources are regulated equally. These differences will be elaborated upon later, but in terms of nutrients such as nitrogen and phosphorus, primary producers generally have more variable chemical content than animals. Algae and macrophytes, like other 'plants' and many microorganisms, can store nutrients by assimilating them at rates much larger than immediate requirements. Later, these organisms can then tap into these reserves for future growth. Animals have more limited capacity for nutrient storage. Differences in mean chemical content between plants and animals have also been suggested recently by analysis of selected proteomes (all of the proteins produced by a species) of these groups; animals had about 7% higher number of N atoms per amino acid side chain than did plants.

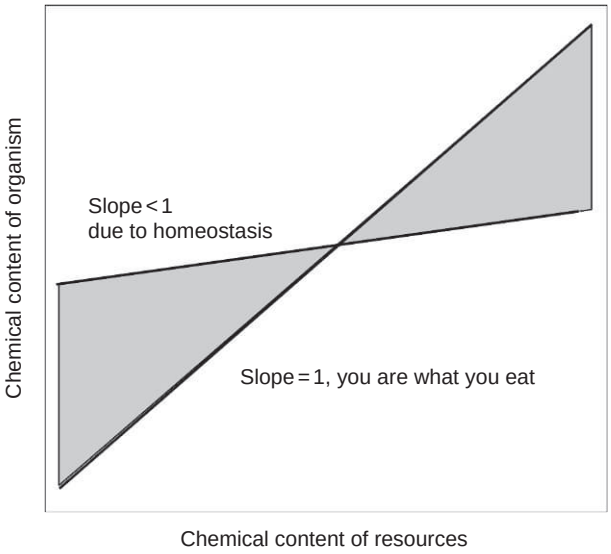

Fig. 1 Stoichiometric homeostasis deals with the question of whether organisms 'are what they eat'. Organisms have varying strengths of regulating their own content of different elements. If the chemical content of organisms passively reflects the resources they take in, their own chemistry would match the chemistry of their resources, and observations would lie along the 1:1 line marked 'you are what you eat'. This would be an absence of stoichiometric homeostasis. Stoichiometric homeostasis reduces the slope of the relationship below the 1:1 line (shaded regions). Different organisms and different chemical resources produce different degrees of homeostasis (see for example Table 1).

Table 1 Coefficients of variation (CV) of content of different elements (log10-transformed) measured over a season in a single pond.

Organism	*Content of elements*									
Amphipod	C	N	P	Cu	Zn	Se	As	Pb	Hg	Cd
	0.004	0.005	0.007	0.009	0.018	0.019	0.021	0.059	0.079	0.124
Damselflies	C	N	P	Cu	Se	Zn	As	Hb	Cd	Pb
	0.004	0.004	0.016	0.024	0.025	0.030	0.035	0.05	0.053	0.074
Snails	C	N	P	Se	Zn	As	Cu	Cd	Hb	Pb
	0.002	0.005	0.007	0.018	0.018	0.018	0.019	0.040	0.045	0.085
Zooplankton	C	P	N	Zn	Se	Pb	As	Cu	Cd	Hg
	0.003	0.003	0.006	0.007	0.017	0.02	0.026	0.035	0.041	0.059

Within an animal taxon, variation in element content is lowest for macronutrients, intermediate for essential micronutrients, and highest in nonessential metals (Table 1). Animals apparently regulate macro-elements most strictly and they regulate elements with definite biological function more than those elements that are incorporated into cells even though they are not essential for growth or survival.

There has been progress recently in defining patterns of homeostasis across elements and across organisms, but we are still a long way from a comprehensive understanding of all the potentially important patterns and contrasts. Homeostasis is an important concept in ecological stoichiometry because the stricter the homeostasis the closer the more an organism's chemical composition resembles a molecule with defined composition. Maintaining a given chemical content in spite of the composition of resources has some detrimental effects on fitness. As we will see later, homeostasis makes organism growth sensitive to the composition of the food that is eaten. Without homeostasis, organisms would 'be what they eat' and there would be no slowing of growth when an individual element becomes scarce. There must be substantial benefits to homeostasis to make up for the easily observed costs, but much less is known about the nature of these benefits.

Stoichiometry at the organism level

Let us now examine some of the stoichiometric patterns for particular aquatic organisms. Organisms vary in nutrient content for many reasons because there are many functions of different elements in biology. Several fundamental causes for organism-level variation in stoichiometry are phylogeny (closely related species are more likely to resemble each other in terms of stoichiometry as well as many other phenotypic traits), structure (especially for large organisms or those with major investments in support or

defense), allometry (effects of body size), and life histories (high rates of growth have a unique stoichiometric signature). In considering these factors, we will start at the base of the food chain, the primary producers.

Primary producers

As is apparent from many examples given throughout this article, stoichiometric variability is the hallmark of primary producers. This variability arises because nutrient uptake and biomass gain can be decoupled. For example, if one exposes a nutrient-limited algal cell suddenly to high concentrations of nutrients, within minutes it can replenish cellular nutrient stores. It then puts those stores to work over time scales of hours to days as the cell gains organic carbon via photosynthesis and eventually divides by fission or mitosis. Cells also may take up nutrients for more than any immediate growth needs, resulting in higher nutrient content than seen in long-term, high growth-rate situations. These cellular nutrient stores sometimes are in the form of specialized storage compounds such as polyphosphate (for P) or cyanophycin (for N). The autotroph cell can also divert resources among different functional pools, for example photosynthetic pigments are N-rich and often cells growing under low light and excess N will be very rich in these pigments. If that cell moves to a high light but low N environment, those pigments can be broken down and the N moved into different pools. In this way, photosynthetic pigments serve as an N reservoir, even though they are not storage compounds per se.

The general model used to describe the linkage between cellular stores and cell growth was proposed years ago by M.R. Droop. Droop's model applies under conditions of a single limiting chemical resource. Droop performed experiments with algae in continuous culture and suggested that growth rate was negatively and linearly related to ratio of biomass to nutrients within the cells (Fig. 2). The Droop relationship ties a stoichiometric quantity (C:P) to a dynamic variable (growth rate).

The higher the CV, the more variable is the element in the given organism relative to the element's mean concentration. Elements are arranged left to right by increasing CV. Macronutrients are unshaded. Essential micronutrients are lightly shaded. Non-essential trace elements are darkly shaded.

Aquatic primary producers come from deeply branched evolutionary lineages. Some of the stoichiometric variability across diverse algal forms was recently described. Two of the major lineages, the 'red superfamily' and the 'green superfamily' can be separated on the basis of their patterns in trace metal composition. Members of the red superfamily (e.g., diatoms) tend to be higher in Cd, Co, and Mn whereas members of the green superfamily (e.g., green algae) tend to be higher in Cu, Zn, and Fe. Quite possibly these differences reflect major geological events such as the relative concentration of ocean oxygen during the evolutionarily origin of these groups.

This straight-line model is normally written algebraically as:

$$\mu = \mu'(1 - (Q_{\min}/Q))$$

where μ = cellular growth rate (time^{-1}), $Q_{\min}$ = the cell quota at zero growth, and Q is cell quota (in this case, P:C or N:C). The term 'quota' refers to the nutrients per cell or per biomass in the cell, e.g., P:C or N:C. In the Figure, a is $1/Q_{\min}$ and b is μ'. The parameter μ' is a theoretical (high) growth rate that would be reached at infinite quota. The thick part of the line represents a range where one would expect to see actual observations. The narrow part of the line would be growth rates that were never observed.

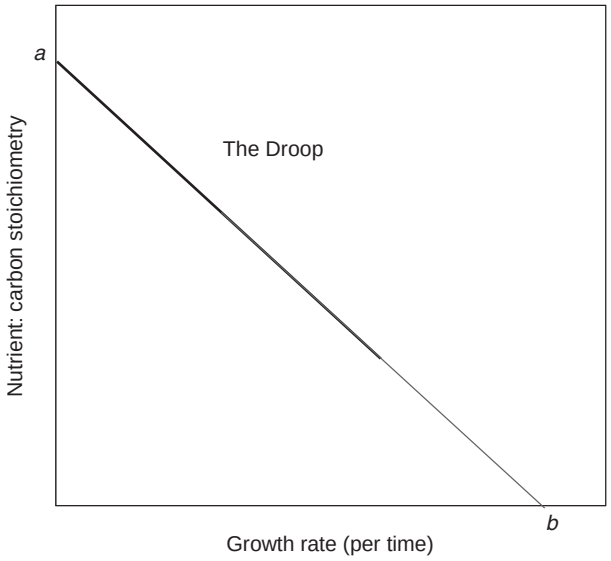

Fig. 2 The functional coupling between organismal stoichiometry (e.g., C:P or C:N, vertical axis) and growth (per capita rate, time-1) is often linear when one resource is limiting. Adapted from Karimi R and Folt CL (2006) Beyond macronutrients: Element variability and multielement stoichiometry in freshwater invertebrates. *Ecology Letters 9*: 1273–1283.

Freshwater algae attached to substrates include microscopic forms ('periphyton') living in close association with other microbes and nonliving organic materials, all collectively forming a biofilm. These biofilms are the main source of autochthonous production in streams and sometimes in nearshore lake habitats as well. Living algae are often a minor contributor to the total carbon within such biofilms. Especially in streams, the stoichiometry of the entire biofilm is made up by living and nonliving components. In order of decreasing N and P content, those include wood, leaf litter, green leaves, and both periphyton and fine particulate organic matter (Fig. 3). Stoichiometric variability at the base of stream food webs is probably more dependent on the relative contributions of these different components than it is on variation within any one component.

Zooplankton

Moving up the food chain from primary producers, we encounter a variety of herbivores. In water columns, these herbivores are members of the zooplankton. The freshwater zooplankton is not a particularly taxonomically diverse group; protozoans, rotifers, cladocerans and copepods as well as juvenile insects are common members. Cladocerans and copepods both belong to the Crustacea, and they plus the insects are all Arthropods. Though species from any number of these several major taxonomic groups may coexist, may have overlapping diets, and may share many other aspects of their ecology such as predators, they nevertheless can have divergent stoichiometries. In particular, some species, such as *Bosmina*, have low P content, whereas others, such as *Scapholeberis* or *Daphnia* have P content several times higher. All of these species, diverse from the standpoint of their elemental content, are members of the same taxonomic order. Homeostatic regulation of element content is highly variable, even within

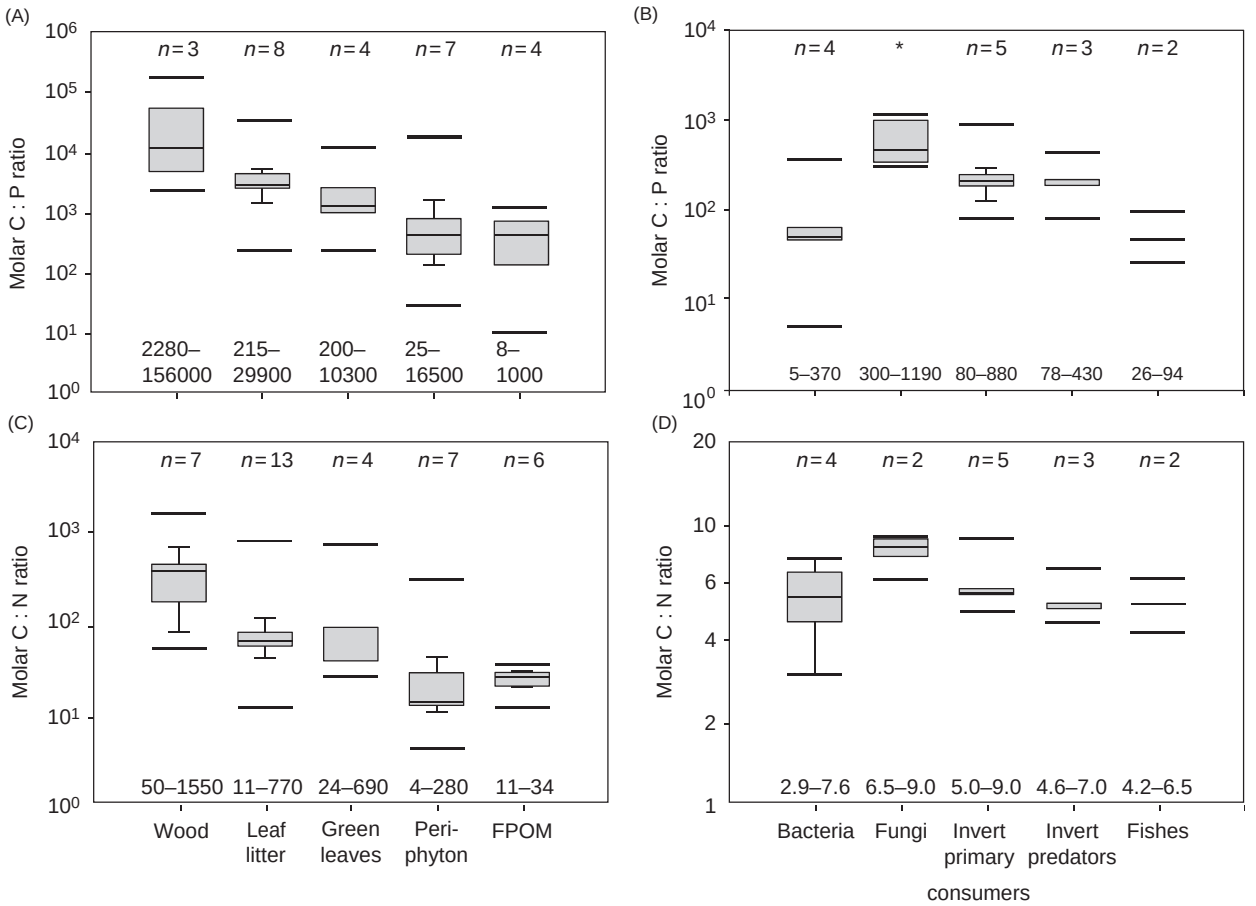

Fig. 3 Means and variability of C:N:P stoichiometry in common freshwater benthic resources and consumers. FPOM: fine particulate organic matter. Boxes and whiskers give the median, 10th, 25th, 7th, and 90th percentiles of the data within each category. Original sources of data include 49 literature studies. Ranges are given in text below the boxes. Reproduced from Fig. 1 in, Cross WF, Benstead JP, Frost PC, and Thomas SA (2005) Ecological stoichiometry in freshwater benthic systems: Recent progress and perspectives. *Freshwater Biology* 50: 1895–1912, with permission from Blackwell Publishing.

members of a single genus of zooplankton. Thus, stoichiometric patterns include not just average nutrient content but also the degree of variation within the taxon. We have made much progress in understanding the importance of average nutrient content, which will be apparent later in this article, but we have a very poor understanding of the ecological relevance of differences in homeostatic regulatory ability. Why some species are very homeostatic in element content and others are less tightly regulated is not at all understood yet.

Cross-species variability in average phosphorus content has been linked to life-history differences because biochemicals responsible for growth have a distinct elemental signature. Species with a potential for rapid biomass growth rates must contain large complements of P-rich biosynthetic machinery. This machinery is dominated by ribosomes, subcellular organelles involved in protein synthesis and which have distinctly high P content. The Growth Rate Hypothesis (GRH) proposes that elevated P demands caused by increased allocation to P-rich ribosomal RNA under rapid growth drives variation in whole-organism P content and thus whole-organism C:P and N:P ratios. Through the GRH, there may be very strong couplings between life histories and stoichiometry and therefore nutrient and energy flow. One example of couplings between growth and P content is given in Fig. 4. Note that the GRH coupling exists when overall food concentration is high. When food concentration is low, animals are likely mainly energy limited and couplings to nutrient content are muted or absent. Linkages among growth rate and stoichiometry seem to depend upon the nature of growth limitation, what resource is limiting at any given time.

Other aquatic invertebrates

The stoichiometry of stream and lake benthic invertebrates has been explored, and wide chemical variation among the diverse members of this group has been observed. In one such study, %P ranged from 0.2% to 1.5% and the N:P ratio ranged from <20 to >100. Trichoptera and Ephermeroptera were lower in %P and %N than Diptera, Odonata, and Plectoptera. When examined as a function of feeding group, predators were found to have higher P and N than other feeding groups. This is an impressive amount of stoichiometric variation. Not many studies have examined the consequences of this stoichiometric variation in streams, but perhaps some of the same processes we describe later relative to planktonic systems hold as well in streams.

Bacteria and protozoa

Heterotrophic microorganisms include bacteria and Protozoa. Not much work has been done yet on the stoichiometry of freshwater Protozoa. Freshwater bacteria are often found to have relatively high N and P content (low C:N and C:P) compared with other aquatic organisms. Studies suggest that bacterial N content is very homeostatic but P content varies with the availability of P for uptake as well as the growth rate of the bacteria. One study on *E. coli* that varied the chemistry of the growth substrate and the growth rate itself found a range in C:P from 40 to 75, a range in N:P from 11 to 18 and a very constant C:N of 4. At high growth rate, bacteria

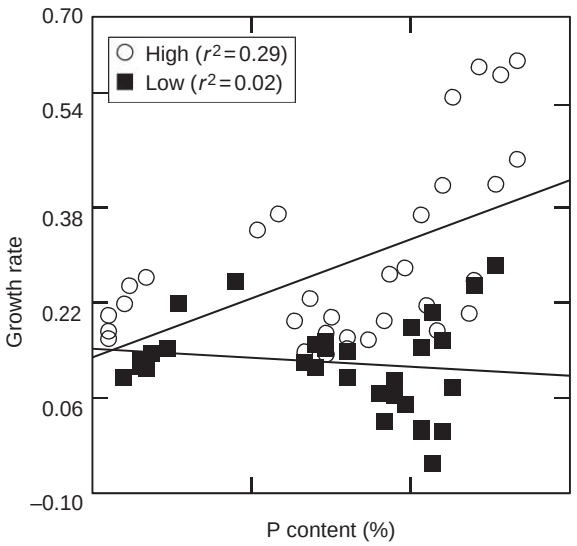

Fig. 4 In a laboratory bioassay study involving four species from three genera of cladocerans, growth rate and P content were positively related when food concentration was high (open circles) but not when it was low (closed squares). At low food concentration, animals were energy limited, but at high food concentration they were likely P limited so that growth was linked to P levels in the animals. Reproduced from Fig. 2 in Ferrão-Filho AS, Tessier AJ, and DeMott WR (2007) Sensitivity of herbivorous zooplankton to phosphorus-deficient diets: Testing stoichiometric theory and the growth rate hypothesis. *Limnology and Oceanography* 52: 407–415, with permission from American Society of Limnology and Oceanography.

had low C:P and elevated RNA content. In comparing the results for *E. coli* with literature findings, this same study suggested that individual bacterial strains were strongly homeostatic whereas in nature bulk bacterial communities varied much more widely, suggesting that varying dominance of individual strains may be responsible for much of the variation in bacterial C: N:P composition in the field. In this respect, stoichiometric patterns in the bacteria have a resemblance to other organisms, including freshwater zooplankton.

Fish

Fish are often the ecologically dominant vertebrates in aquatic ecosystems. Fish can be herbivores as well as carnivores or even detritivores or omnivores. Fish have numerous effects on aquatic ecosystems and at times they can be so abundant that they channel great quantities of nutrients in and out of their own biomass through feeding, excreting, etc.

This group too is characterized by wide stoichiometric variation and the ecological consequences of such a wide stoichiometric variability are just beginning to be understood. Phosphorus content of fish ranges from less than one to over 4%. Low-P fish include minnows in the Cyprinidae family. High-P fish occur in both temperate and tropical ecosystems; they are bony and are typical of the Percidae, Centrachidae and Loricariidae families. In fish, evolutionary patterns associated with structure (boniness) account for most of the stoichiometric variation. We see this in a very strong correlation between fish Ca and fish P (Fig. 5). Fish skeletons can account for from one to more than 5% of body mass. Bony skeletal material is made of a calcium phosphorus mineral called apatite with chemical formula $Ca_5F\ (PO_4)_3$ where other anions may replace F. This large quantity of mineral has a great effect on the stoichiometry of individual species of fish—the slope of the line in Fig. 5 is almost exactly as predicted from the stoichiometry of apatite mineral.

We will now consider the ecological ramifications on these stoichiometric properties of species.

Food quality

Consumers rely on organic food resources that may or may not closely match their own chemical requirements for survival and growth. The idea of a 'balanced' diet is familiar to everyone from the standpoint of human nutrition—it means that the chemical composition of food matches closely an ideal composition. Stoichiometry helps us understand how balanced vs. imbalanced a particular diet may be for any given aquatic consumer. Natural ecosystems often present highly imbalanced diets to consumers. Effects of many different nutritive substances such as vitamins, amino acids and fatty acids are known. Here, we will focus solely on individual chemical elements.

To help understand how different elements may limit consumer growth, we use a tool called a 'Threshold Element Ratio' (TER). A TER is the ratio of elements in an organism's resources where that organism is equally limited by both elements. When the ratio of elements (e.g., C:P) in the food exceeds the TER, the element in the denominator (P) limits consumer growth. Likewise, when the ratio is lower than the TER, the element in the numerator (C) limits growth. TERs are determined by two main things: the nutrient content of the consumer organism, which we considered earlier, and growth efficiency, which we will consider next.

Growth efficiency is defined as the amount an organism gains divided by the mass it ingests. Growth efficiencies based on carbon for aquatic consumers average around 0.3 with large variation around that average. Stoichiometry helps explain some of that

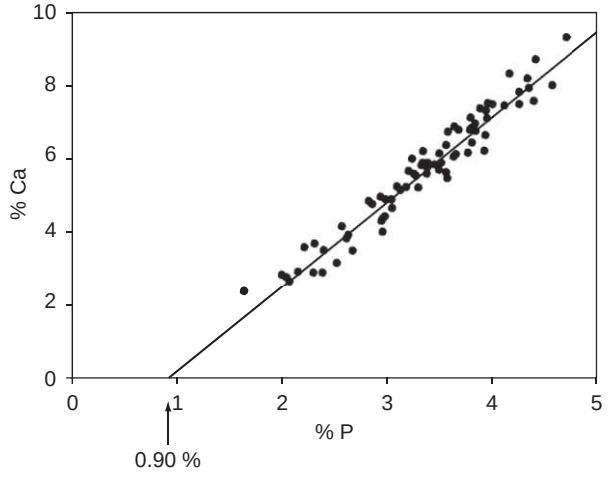

Fig. 5 Ca vs. P for 18 species of fish. The line has equation $y = 2.31x - 2.09$ ($r^2 = 0.95$). Reproduced from Fig. 4 in Hendrixson HA, Sterner RW, and Kay AD (2007) Elemental stoichiometry of freshwater fish in relation to phylogeny, allometry and ecology. *Journal of Fish Biology* 70: 121–140, with permission from Blackwell Publishing.

variation. The growth efficiency of a strongly homeostatic organism must adjust to the composition of the food, otherwise the consumer would not be able to maintain its homeostasis. There are many well studied examples where decreased growth efficiency on poor quality (low nutrient) foods has been observed in aquatic systems. A good example is heterotrophic bacteria where growth efficiency is typically well above 50% for growth on substrates with C:$N < 5$, but declines to 10% or less on substrates with C:N ratios >30. Because bacterial processing of organic carbon is often a very big part of the organic carbon cycle in lakes, these stoichiometric modulations of C shunted into cell growth versus loss as CO_2 or organic C can play a very large role in the biogeochemical cycling of carbon.

TERs have been calculated for many aquatic organisms (Fig. 6A). Fish have low C:P TERs (typically about 100–200), a reflection of their P-rich skeleton. The highest C:P TERs (about 500) are found for aquatic insects, which of course do not have bony skeletons but still require P for making RNA and other biomolecules. In fact, within the invertebrates, there is a statistically significant negative relationship between maximal potential growth rate and the C:P TER (Fig. 6B, open symbols). Here we see the elemental requirements for the machinery for growth affecting whole-organism ecology, consistent with the Growth Rate Hypothesis described earlier. There have been numerous studies on stoichiometric dimensions to food quality in zooplankton. One example comes from the study of a model organism in ecological stoichiometry, *Daphnia*, the water-flea. *Daphnia* are keystone herbivores in planktonic systems; they merit special attention because of the role they can play in decreasing algal biomass. Above, we discussed how *Daphnia* are generally high in P content. As one would therefore expect, *Daphnia* growth is sensitive to the P content of their food (Fig. 7). Algae with high C:P ratio (and thus low P content) dramatically lowers *Daphnia* growth rate, in this case lengthening by three-fold the time to double biomass. Other studies on zooplankton stoichiometry have shown: (a) low P zooplankton such as *Bosmina* are much less affected by the C:P of algal food than are high P zooplankton like *Daphnia*; and (b) particular life stages of some zooplankton may be particularly sensitive to C:P of food; thus, an overall effect on the animal may be determined most at specific points in its life cycle One recent study showed that hybrids of two *Daphnia* species performed better on high C:P food than the two parental species, suggesting that success in stoichiometrically imbalanced systems might be responsible for maintenance of hybrids in the ecosystem.

Stoichiometry predicts that consumers of high element content should be rare in environments where that element is scarce. A large Norwegian study showed a strong relationship between the abundance of *Daphnia* and seston C:P ratios (Fig. 8). In this study,

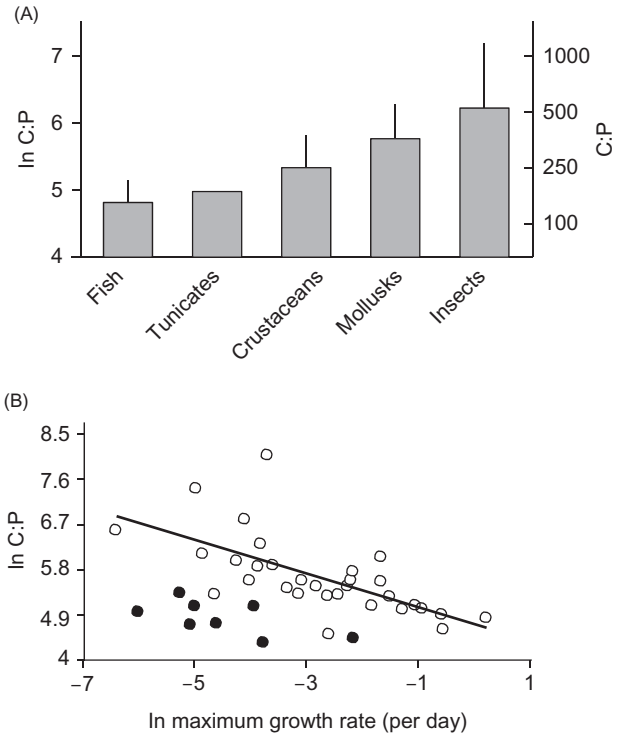

Fig. 6 Ratios of C:P (moles C per moles P), where different kinds of aquatic animals switch between growth limitation by carbon vs. growth limitation by phosphorus. When food C:P exceeds an animal's TER, the animal is limited by P and when food C:P is less than an animals's TER, carbon limits growth. (A) Their higher TERs (mean ± SD) indicate that less food P is required per unit food carbon for mollusks and insects relative to fish, tunicates, and crustaceans. (B) A higher growth rate depresses the C:P TER in invertebrates (open circles), a signal consistent with the growth rate hypothesis. Further, at any given growth rate, high P content depresses fish C:P TER (closed circles) below that observed for invertebrates. Adapted from Figs. 2 and 4 in Frost PC, Benstead JP, Cross WF, Hillebrand H, Larson GL, Xenopoulos MA, and Yoshida T (2006) Threshold elemental ratios of carbon and phosphorus in aquatic consumers. *Ecology Letters* 9: 774–779, with permission from Blackwell Publishing.

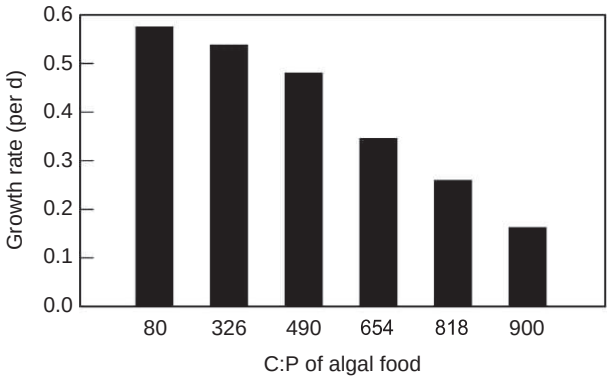

Fig. 7 The planktonic herbivore, *Daphnia magna*, has much reduced growth rate when it feeds on algae of high C:P ratio (low P content). All algal food treatments in this study were the same species of algae, *Scenedesmus acutus*, grown under different conditions to get a stoichiometric range from 80 to 900. Converting from growth rate units one can find that at low C:P, these *Daphnia* double their biomass in 1.2 days, whereas at high C:P it takes 3.8 days, or more than three times as long. Adapted from DeMott WR, Gulati RD, and Siewertsen K (1998) Effects of phosphorus-deficient diets on the carbon and phosphorus balance of *D. magna*. *Limnology and Oceanography* 43: 1147–1161, with permission from American Society of Limnology and Oceanography.

all sites with high *Daphnia* abundance had seston C:P well below this organism's C:P TER. Seston C:P ratios were the most important variable in explaining the abundance of *Daphnia*. In general, physiological studies of TERs, laboratory growth studies, and field studies all point to a consistent conclusion, that high P herbivores like *Daphnia* are affected by stoichiometric imbalances between food and consumer.

There are some other very high imbalances between consumer and resource stoichiometry in streams and lake benthos. Certain consumers in those habitats subsist largely on nutrient-poor detritus. An example of stoichiometry affecting a stream invertebrate is given in Fig. 9. In this study, snails were given two quantities of periphyton food that had been grown under different nutrient treatments. Periphyton grown with added P (treatments + P and + N + P) had C:P of about 200 whereas C:P was 400 or more when P was not added (treatments Ambient and +N). The snails were strongly homeostatic and they showed pronounced stoichiometric effects on growth at low but not high periphyton quantity.

Although most studies of food quality have emphasized what happens when food is deficient in some element, recent studies have also shown that food may be imbalanced when it is too high in a particular element. Whether reduced food quality at high nutrient content is due to overt toxicity or because very high content of some element indicates some other chemical imbalance is not yet understood.

Nutrient recycling

Next we consider stoichiometric aspects of nutrient cycling. In particular, we consider processes that deliver nutrients to the dissolved pool. Nutrients enter the dissolved pool in inland ecosystems from the air, the surrounding land, the sediments or substrate, and also from the organisms living in the water, which release nutrients as waste products. There are stoichiometric aspects to all of the above, but here we will focus on biological resupply, or nutrient recycling by consumers. Consumers here can range from Protozoa to fish.

The stoichiometry of nutrient recycling is related to food quantity, considered above. When an organism's food is deficient enough in a particular element for it to be limited by that element, a great premium is placed on not wasting that element. In order to maintain a stoichiometric homeostasis, organisms must efficiently retain elements in short supply in their food relative to stoichiometric requirements. For the same reason, they must either not assimilate or they must release upon assimilation, elements that are in surplus to their own requirements. Stoichiometric homeostasis thus has a highly constraining effect on patterns of nutrient recycling by consumers.

Many studies on many organisms have considered the N:P ratio of release by individual aquatic organisms. In Fig. 10 we see data gathered from freshwater and marine zooplankton. Other studies with similar results have been conducted on bacteria, Protozoa, and vertebrates including fish. Fig. 10 illustrates the two principal stoichiometric effects on nutrient recycling. First, the N:P recycled is positively related to the N:P in the food ingested. Note that because of the log scale in this Figure, the N:P released is not directly proportional to the N:P eaten. Instead, as N:P in the food increases slowly, N:P released increases very quickly. This upward trajectory was predicted mathematically, and it has been shown repeatedly in different nutrient cycling studies. When feeding on food of low N:P, a homeostatic consumer must keep the N for itself but recycle excess P, so that N:P released is very low. Likewise, when feeding on food of high N:P a homeostatic consumer must release excess N but keep relatively scarce P, making N:P recycled high. The second principle stoichiometric effect on nutrient recycling comes about because of the chemical variability among

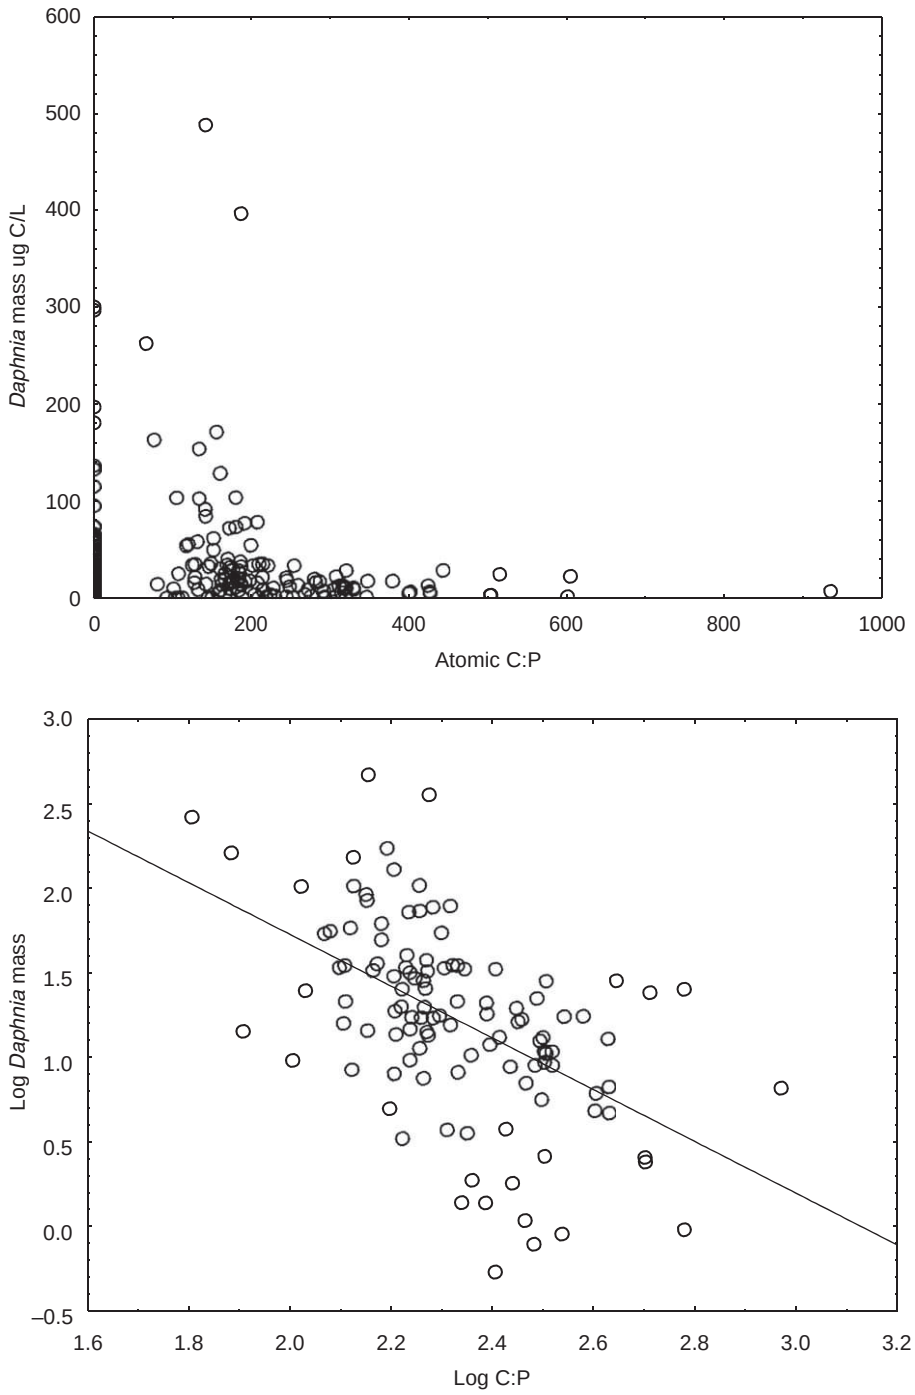

Fig. 8 Consistent with predictions of stoichiometric theory, lakes with high C:P in their seston have lower abundance of the high-P, keystone genus, *Daphnia*. Data are from a survey of 400 Norwegian lakes. The upper panel shows the data plotted on linear axes and emphasizes how large populations build up only at C:P below the *Daphnia* TER, which typically is about 300. The lower panel shows the same data plotted on logarithmic axes and shows a strong consistently negative slope. Replotted from data published in Hessen DO (2006) Determinants of seston C:P ratio in lakes. *Freshwater Biology* 51:1560–1569.

consumers. Consumers that are low in N:P will recycle at high N:P ratios and organisms that are high in N:P will recycle at low N:P. Given that many studies point to the critical importance of N:P loading as determining algal community structure, this example illustrates how ecological stoichiometry integrates species-level information with ecosystem-level processes. It is remarkable that something as potentially complicated as the rates of nutrient release by living animals relates so strongly to simple measures such as nutrient content.

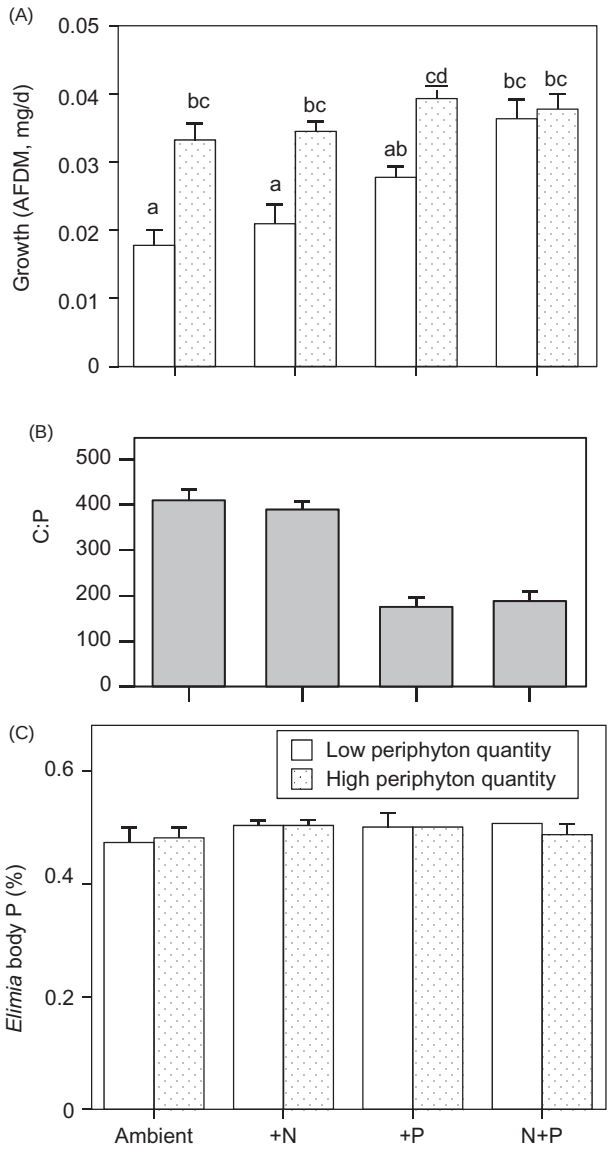

Fig. 9 Effect of nutrient addition on periphyton and snail stoichiometry. Snails (*Elimia livescens*) were reared in experimental streams (flumes) and fed periphyton on clay tiles. An approximately similar periphyton biomass (low or high) was given to snails in all treatments. The experiment lasted 34 days. (A) Snails growth varied with nutrient treatments at low periphyton quantity but not high periphyton quantity. At low periphyton quantity, additions of P stimulated snail growth. (B) The C:P of the periphyton under different nutrient treatments. (C) The %P of the snails under different nutrient treatments. Note that the periphyton have more flexible nutrient content than the snails. Adapted from Stelzer RS and Lamberti GA (2002) Ecological stoichiometry in running waters: Periphyton chemical composition and snail growth. *Ecology* 83:1039–1051, with permission from Ecological Society of America (ESA).

Community dynamics

The separate effects of stoichiometry on animal growth and nutrient cycling considered above combine to influence community dynamics. One long-term culture study found two markedly different outcomes. In one, cultures had high abundance of algae but low abundance of grazers (a 'green' world). This first outcome was seen in the cultures with high algal C:P ratio. In the other outcome, cultures had low abundance of algae but high abundance of grazers (a 'clear' world). This second outcome was seen where algal C:P ratios were low. There was a sharp threshold between the two outcomes near the threshold, small differences in growth conditions promoting different stoichiometric ratios had large effect on community dynamics. Stoichiometry played a role in separating the green and the clear world. A second interesting aspect of this study was that high grazing promoted high food quality so that zoo-plankton had a positive demographic effect on their own populations—more zooplankton meant better food and therefore higher zooplankton growth. This kind of positive feedback between population size and population growth contrasts markedly with classical ideas about population regulation.

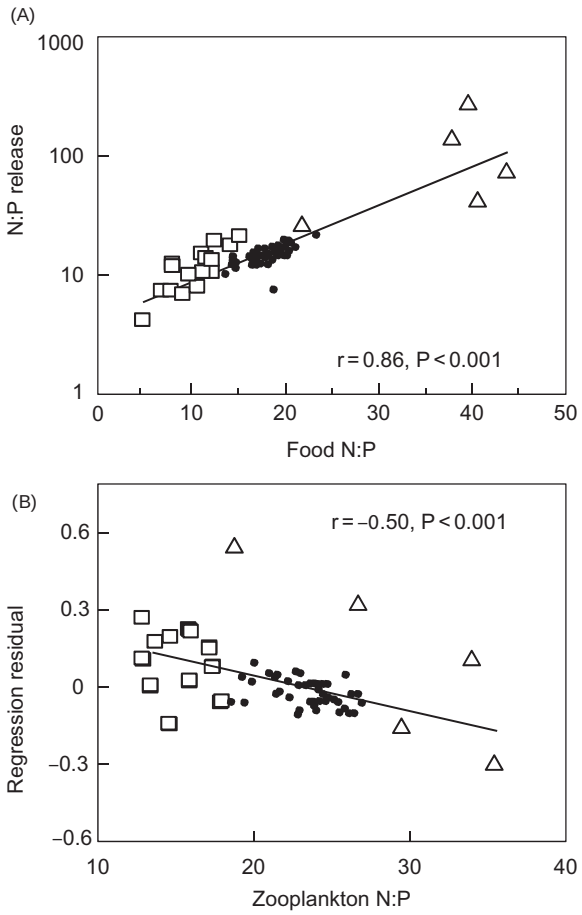

Fig. 10 Two aspects of stoichiometry altering nutrient fluxes through organisms. (A) The N:P released by zooplankton is positively related to the N:P of the food they are eating. (B) After accounting for the trend in (A), the consumers' own N:P ratio is negatively related to their N:P release (B). Reproduced from Fig. 4 in Elser JJ and Urabe J (1999) The stoichiometry of consumer-driven nutrient recycling: Theory, observations, and consequences. *Ecology* 80:735–751, with permission from Ecological Society of America (ESA).

Mathematical, theoretical analyses have uncovered other surprising aspects of community dynamics associated with stoichiometry. Stoichiometrically explicit models of grazers, algae and nutrients suggest the existence of complex dynamics, including steady population changes through time, irregular, even chaotic, nonrepeating cycling of populations, and, in some versions of models, deterministic grazer extinction.

These different community dynamics emerge quite easily and naturally from models that explicitly incorporate stoichiometry. They suggest that classical, nonstoichiometric, ideas about population regulation, dynamics, and competition may be far off base when stoichiometric effects are important.

Whole-system scale

These many stoichiometric patterns and processes that we have considered so far operate simultaneously to form aggregate stoichiometric properties of entire ecosystems. A touchstone for understanding ecosystem-level stoichiometry is the Redfield Ratio, a concept put forward by the oceanographer A.C. Redfield in the 1930s-1950s. Redfield noticed a correspondence between the C:N:P ratio in particulate matter of the surface ocean and dissolved nutrients in the deep ocean. The atomic ratio he observed was C_{106}:N_{16}:P_1, which is now called the Redfield Ratio. From this similarity he deduced that the entire global ocean had its nutrient content determined mainly by the biota. His argument was that both C and N come into stoichiometric balance with P, as set mainly by the demands of the oceanic biota. If either C or N are in short supply, the biogeochemical processes of primary production or N fixation can tap into atmospheric sources of these elements. Likewise, excesses of C or N can be vented to the atmosphere by respiration or denitrification. Phosphorus lacks an important gaseous phase, and its supply to the oceans is set by geological (or, now, human) action on the continents, which controls the rate of runoff from major river systems. The Redfield Ratio is similar to the ratios that many phytoplankton obtain when growing at either high growth rate or light limitation. The variation among species is such that if one takes an average of many different species, a C:N:P of 106:16:1 emerges. The Redfield ratio thus describes an overall mean of many species growing without strong single-element nutrient limitation.

The same kinds of measurements can be made for inland waters, but lakes, ponds, streams and rivers exhibit a greater degree of variability in their stoichiometric C:N:P ratios than do the oceans. This variability across sites can be due to many factors. Inland ecosystems are subject to widely varying inputs of elements from the atmosphere and from their watershed. They flush relatively rapidly compared with the time scales necessary for Redfield balancing mechanisms. Individual lakes, ponds, streams or rivers may be more homogeneous in terms of the many variable factors that determine biogeochemical potentials than the entire world's oceans; for example, highly unproductive lakes may lack anoxic zones that would support high levels of denitrification. They may be dominated by a small number of species during bloom conditions. There is a potentially large but variable detrital pool, poor in N or P, which may be found. Finally, they may be strongly limited by a single element, whether it be P or N or perhaps even some other nutrient. Given this large number of factors that can perturb C:N:P ratios away from Redfieldian balance, it is not surprising to see that freshwater systems are generally more stoichiometrically variable at the ecosystem level than are oceans (Fig. 11). This great

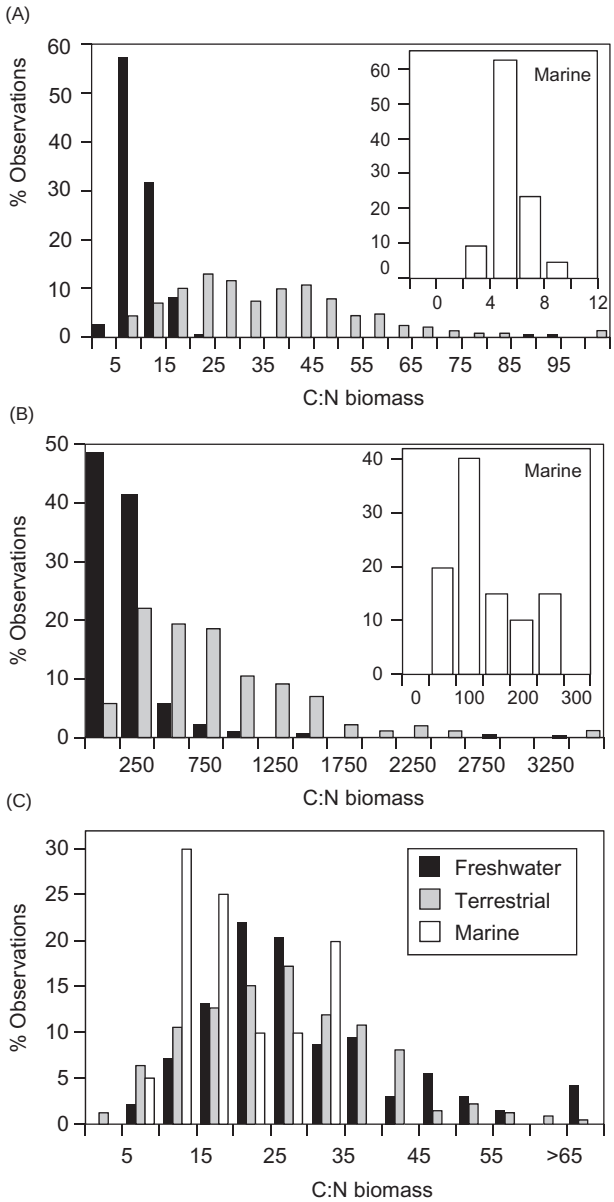

Fig. 11 Variations in C:N:P stoichiometry at the base of marine (white), freshwater (black), and (for reference) terrestrial (gray) food webs. Data for lakes and oceans represent values of seston, including all particles living and dead, whereas data for terrestrial habitats reflect values for individual leaves. Note that freshwater systems have more variable C:N, C:P, and N:P ratios than do marine systems. This means the 'raw material' for stoichiometric determination of growth rate, nutrient cycling, etc. is greater in freshwater than marine systems. Though outside the scope of this article, this Figure also shows that terrestrial systems too have great stoichiometric variability at the base of their food chains. Reproduced from Fig. 3.13 in Sterner RW and Elser JJ (2002) *Ecological Stoichiometry: The Biology of Elements from Molecules to the Biosphere*. Princeton, NJ: Princeton University Press.

stoichiometric variability is the primary force that sets into motion many of the processes already described in this article, such as food quality constraints or stoichiometric determination of nutrient recycling patterns. Let us therefore now further analyze some of this great stoichiometric variability.

One explanation for this variation is the Light: Nutrient hypothesis. Light stimulates photosynthesis and thus is related to the input of carbon into particulate matter in inland ecosystems. As we discussed earlier, rates of carbon and nutrient acquisition in autotrophs are not tightly linked. When light is plentiful but nutrients are scarce, photosynthesis can be high compared to nutrient uptake and thus there develops a high C:P or C:N ratio in autotroph biomass. Characteristics of high light environments are clear water, shallow mixing or, in the case of benthos, shallow depth. The Light:Nutrient hypothesis suggests that stoichiometric variation at the base of food chains results from the relative balance of energy (light) and nutrients (N and P) available for primary producers.

Support for the Light:Nutrient hypothesis is accumulating. C:P ratios in 65 European lakes generally declined with increasing mixing depth (and zooplankton biomass correspondingly increased, as one would predict from food quality constraints). An elegant mathematical model of how mixing depth should affect lakes by way of stoichiometric shifts corresponded to the same patterns in the data. In another study, experimentally incubating phytoplankton from three Ohio lakes at different light levels and different nutrient levels caused seston C:N:P to shift in ways predicted by the Light:Nutrient hypothesis. C:P and C:N went up at higher light and down with increased nutrients. Third, seston in 112 Norwegian lakes covering a C:P from 24 to 1842 was related to measures of nutrient availability and it showed several different effects of decreased light owing to shading by algae in more productive water columns. Seston C:P in these Norwegian lakes declined strongly with increasing phosphorus (Fig. 12). No effects of lake area, season or latitude on C:P were detected. Particulate C did not correlate with C:P. The highest C:P ratios occurred in low P, therefore unproductive, lakes. C:P increased with increased values of the ratio of Secchi depth:total P and similarly C:P increased with the POC:chlorophyll ratio (representing the relative proportion of particulate detritus; Fig. 5). As we saw earlier (Fig. 8), high P *Daphnia* in these lakes were less abundant when seston C:P was high. There is mounting evidence that inland aquatic ecosystems do respond to relative availability of light vs. nutrients and thus these abiotic factors influence ecosystem dynamics in a way that is strongly mediated by stoichiometry.

One final stoichiometric aspect at the whole ecosystem scale relates to carbon fluxes in ecosystems. The fate and cycling of carbon in ecosystems is a topic of increasing concern in today's world. The human economy is run in part on cycling of carbon and nutrients for energy production, transportation, agriculture, etc. Fossil fuel combustion combined with land use changes have resulted in excess CO_2 building up in the atmosphere. Lakes often are carbon sources (not sinks) relative to global carbon cycling due to decomposition of terrestrially derived organic matter. However, lakes, and especially reservoirs, do build up significant reservoirs of carbon in their sediments. One early study suggested that lakes and reservoirs globally accumulated organic carbon at a rate of about 200 Tg year-1, more even than the world's oceans even though the oceans cover a much greater fraction of Earth's surface. The fate of carbon cycling through ecosystems is closely related to stoichiometric ratios. It has been noted that ecosystems that are high in C:P or C:N show more carbon cycled through detrital food chain pathways, whereas those ecosystems with lower C:P or C:N ratios show more carbon channelized through herbivore/grazing pathways. We can expect that lakes and reservoirs that are higher in C:P and C:N likely bury a larger fraction of their organic carbon than do lakes at the opposite end of the stoichiometric gradient. Thus, ecological stoichiometry can be an important aspect of how inland ecosystems fit into global carbon cycles.

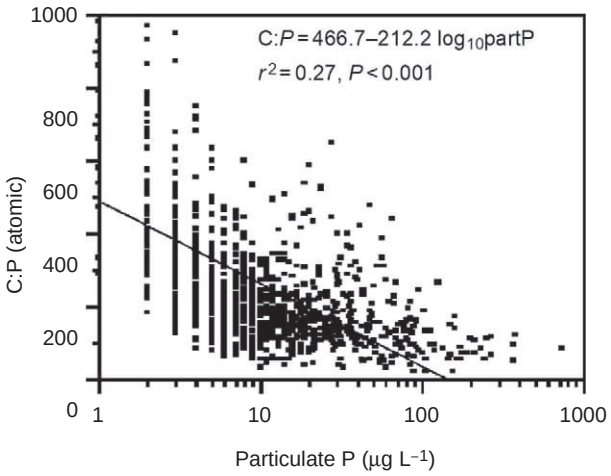

Fig. 12 Seston C:P ratios decline with increasing particulate P and therefore with overall productivity. Reproduced from Figure Hessen DO (2006) Determinants of seston C:P ratio in lakes. *Freshwater Biology* 51:1560–1569.

The Biomass Size Spectrum

W Gary Sprules, Department of Biology, University of Toronto Mississauga, Mississauga, ON, Canada

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor, Lars Rudstam.

Glossary

Abundance Spectrum Logarithmic numerical abundance per unit area or volume in successive logarithmic size intervals.
Biomass Spectrum Biomass concentration (on either a linear or logarithmic axis) in successive logarithmic size intervals.
Bounded Power Law (PLB) or Truncated Pareto Distribution A mathematical function that underlies size-frequency distributions that are strongly right-tailed and are bounded by minimum and maximum sizes.
Height The coordinate value of the size spectrum at the middle of the body size axis. It is a measure of overall abundance or biomass concentration.
Individual Size Distribution (ISD) This is recommended terminology for size distributions of organisms in nature described by a PLB. All forms of size spectra are mathematical variants of the ISD.
MLE Maximum Likelihood Estimation is a statistical technique superior to OLS Regression for estimating the size spectrum exponent in many instances.
Normalized Spectra As above except biomass or abundance concentration is divided by the width of the size intervals
OLS Ordinary Least Squares Regression is a statistical fitting criterion historically used to estimate size spectrum parameters.
λ-lambda The exponent of the ISD. It is mathematically equivalent to the slope of size spectra. Negative values indicate a preponderance of small over large organisms and positive values the opposite.

Introduction

A size spectrum is the relation between the numerical or biomass concentration and the body size of organisms in a community. As typically displayed on double logarithmic axes this is a roughly linear negative trend reflecting the fact that in nature small organisms are much more abundant than large ones. In a very general way size spectra are related to the "pyramid of numbers" introduced in the 1920s by Elton (1927) (Fig. 1, based on Trebilco et al., 2013) when ecologists were interested in what factors determined the great range of organism abundance found in nature. These pyramids typically, although not exclusively, had a broad base reflecting the great abundance of small organisms and smaller upper layers for the decreasing abundance of progressively larger organisms. Elton argued that the pyramid results from the ecological interactions of larger predatory species feeding on smaller prey. Regular patterns occur because predators cannot consume prey that are too large (pack animals are an exception) nor can they acquire enough energy by hunting prey that are too small. There are limits to the heights of the pyramids because only a fraction of a prey population can be consumed by its predators until eventually there are no predators that could survive on the meagre energy supply at the top. Of course, there are exceptions to these patterns caused by the population dynamics of interacting species in temporally and spatially variable habitats, but the general concepts are robust.

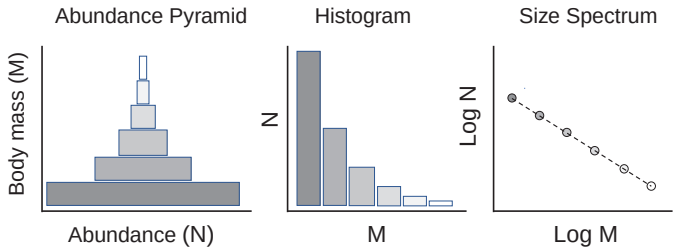

Fig. 1 The relationship among abundance pyramids, size-frequency histograms and size spectra. Redrawn from Trebilco R, Baum JK, Salomon AK and Dulvy NK (2013) Ecosystem ecology: Size-based constraints on the pyramids of life. *Trends in Ecology & Evolution* **28**: 423–431.

Shortly after Elton's ideas about organism numbers emerged, ecologists became increasingly interested in the trophic rather than size structure of communities of organisms. Expressed as "trophic" pyramids the bottom layer comprised primary producers (typically plants) with higher layers consisting of primary consumers (invertebrates, rodents, ungulates), secondary consumers (birds of prey, larger fish, big cats), etc. Studies of productivity and energy flow through food webs were based primarily on species as the study unit and their classifications by trophic position. The population dynamics of component species was an important element in field and modeling studies of this trophic "revolution."

By the early 1960s some biological oceanographers considered that progress in quantitative studies of the productivity and structure of plankton communities was limited by the common methods of characterizing organisms using taxonomic and chemical (including pigment ratios) criteria. Interest grew in the use of automated particle counters that facilitated field measurements of the size and abundance of planktonic organisms—measurements considered advantageous for developing mathematical models of energy flow through food webs. Beginning in the 1960s Ray Sheldon and his mentor Tom Parsons used a Coulter Counter to make extensive measurements of the size distribution and biomass of planktonic particles from 1 to 100 μm diameter in surface waters of the Atlantic and Pacific oceans (Sheldon and Parsons, 1967). They noted peaks of biomass reflecting variation through space and time of characteristic planktonic size groups in response to underlying physical and ecological processes in these communities. The relative ease of collecting observations on the size-based abundance of organisms, and the strong dependency of many ecological processes on body size (growth, mortality, feeding selectivity, reproduction, metabolism) facilitated a new size-structured view of communities—particularly in aquatic systems—of which the size spectrum is an integral part.

In what follows I will outline the methods used to construct size spectra, offer a brief discussion of underlying theory, and present some practical applications of size spectrum concepts in ecosystem management and modeling.

The power law

It is well known that the size-frequency distribution of organisms in nature is strongly right-tailed reflecting the rapid decline in abundance from the smallest to largest individuals (Fig. 2, based on Vidondo et al., 1997). Like many other phenomena with strongly skewed frequency distributions (e.g., sizes of moon craters, frequencies of words in a language, papers written by scientists) the one for organism size follows a Power-law distribution:

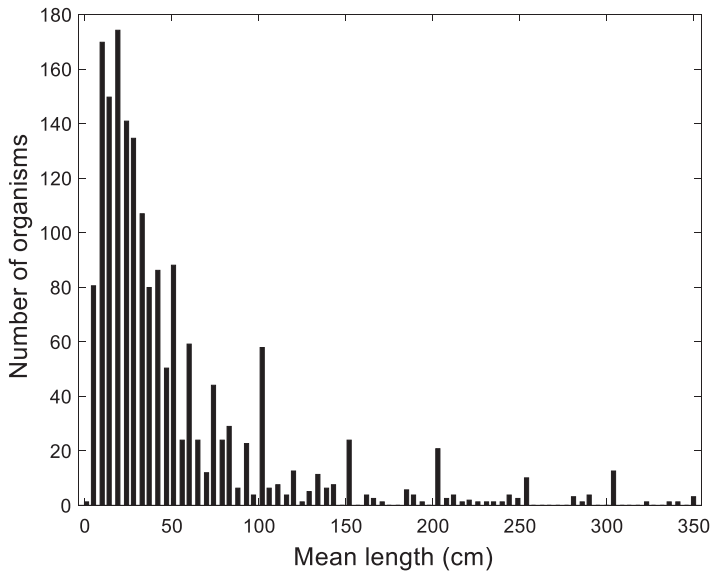

Fig. 2 Length-frequency distribution of a large mixed-species sample of Atlantic Ocean fish illustrating the long right tail typical of body size distributions in nature. Redrawn from Vidondo B, Prairie YT, Blanco JM and Duarte CM (1997) *Limnology and Oceanography* 42: 184–192.

$$f(m) = c \cdot m^{\lambda}, 0 < m_{\min} < m < m_{\max} \quad (1)$$

where m is a random variable (body mass in this case) and c and λ are constants to be estimated when fitting the function to specific data. With minimum and maximum values of mass specified, as is typical for size spectrum studies, the function is a "Bounded Power Law" (PLB) which is also known as a "Truncated Pareto Distribution." The exponent λ must be negative if abundance decreases with size. In the precise language of mathematics this is a probability density function which gives the probability that a random value of m will fall within a specified interval. To standardize terminology in size spectrum studies it is recommended that when the PLB is applied to organisms in nature it should be called the "Individual Size Distribution" (ISD). The ISD lies at the root of all abundance and biomass size spectra that vary only in how samples of organism size are measured, grouped and plotted. The ISD and its derivatives are mathematical models of abundance-size relationships in nature that can be used to make predictions such as of large organism concentration from that of more easily measured small ones, provide fitted parameters to be used as indicators of community structure, assess the structural effects of size-specific harvesting on a community, or motivate simulation models to better understand the dynamics of size-structured communities.

A primary goal of size spectrum studies is to estimate the two parameters of the ISD as will be described below. The exponent, λ is a measure of the size structure of organisms in a community. In both empirical and modeling studies of size spectra it has been found that values of λ are typically $\approx$–2 (= –1 or 0 for other presentations of size spectra, see below). Values <–2 indicate a relatively greater abundance of small than large organisms in a community (e.g., due to the harvesting of large organisms) whereas more positive values indicate the opposite (relaxed harvesting). The scaling coefficient c is typically a measure of the overall abundance or biomass of organisms at a standardized body mass.

Graphical representations of size spectra

To illustrate the variety of ways in which the ISD of organism sizes can be displayed, a simulated data set of 100,000 body masses was randomly selected from a bounded power law distribution with exponent $\lambda = -2$, minimum mass = 1, and maximum mass = 1000 using techniques described by Edwards et al. (2017). The large sample size is necessary to avoid statistical curve fitting problems because large values of the random variable (= large organisms) are extremely rare in power law distributions. For a realistic context, imagine this to represent a random sample of the abundance (#L^{-1}) of freshwater zooplankton ranging in individual body mass from 1 to 1000 μg fresh weight.

In the next sections the various forms of the ISD are illustrated. In each case estimates of the ISD are presented based on non-linear curve fitting, ordinary least squares linear regressions (OLS), or maximum likelihood estimation (MLE). MLE can be based either on the 100,000 raw masses (White et al., 2008) or when the raw data have been binned into mass intervals (MLEbin, Edwards et al., 2020). There is some debate about the statistical rigor of OLS versus MLE and this will be addressed below in Section "Slope". All calculations were done using MatLab (2020).

Histograms

An initial visualization of the pattern in such a large sample of body masses would typically involve "binning" them into a series of linear mass intervals and plotting these against the frequency of observations in each interval. This is the familiar histogram (Fig. 3A). A series of equal intervals on a *linear scale* is created and the frequency of organisms in each interval plotted against either the interval midpoint or one of the interval boundaries—typically the lower one. In linear size bins the upper boundary is the lower boundary *plus a constant*, and the width is the difference between the boundaries. The typical pattern of very abundant small organisms rapidly declining for progressively larger ones is observed and of course is well fitted by the power law from which the data came (Fig. 3A). For curve-fitting purposes this histogram has much smaller size intervals than would ever be used in practice; the power law is a continuous distribution for which accuracy of parameter estimates increases as the size interval approaches zero. A histogram with more "practical" size intervals of 20 μg is shown for comparison (Fig. 3B, Table 1).

Abundance spectrum

The researcher has an initial choice of binning their data into either linear or logarithmic mass intervals. Both have been used in the literature but as will be discussed below estimation of the parameters of the ISD and related size spectra is statistically much more precise and accurate for logarithmic intervals. The "Abundance Size Spectrum" is formed by binning the mass observations into equal logarithmic intervals and determining the frequencies per interval. Any logarithmic scale can be used, but the Coulter Counter used in early studies to measure the sizes of sampled marine "particles" grouped the data into $\log_2$-intervals and a precedent was established for this scale. Particles are grouped into classes with boundaries in a mass doubling sequence; 1–2, 2–4, 4–8, 8–16, 16–32, etc. μg which on a $\log_2$ scale would be equal intervals 0–1, 1–2, 2–3, 3–4, 4–5, etc. The $\log_2$ scale gives more mass intervals and hence greater spectrum detail than base 10 or natural logarithms, and, uniquely for this scale, the lower interval boundary is equal to interval width (e.g., interval 8–16 is 8 units wide) which will make calculations described below easier.

The 100,000 random body masses span 10 $\log_2$ intervals and the frequencies of observations in each are displayed in Table 1. These are plotted on double logarithmic axes in Fig. 3C as the Abundance Spectrum. A linear model fitted to these data using OLS

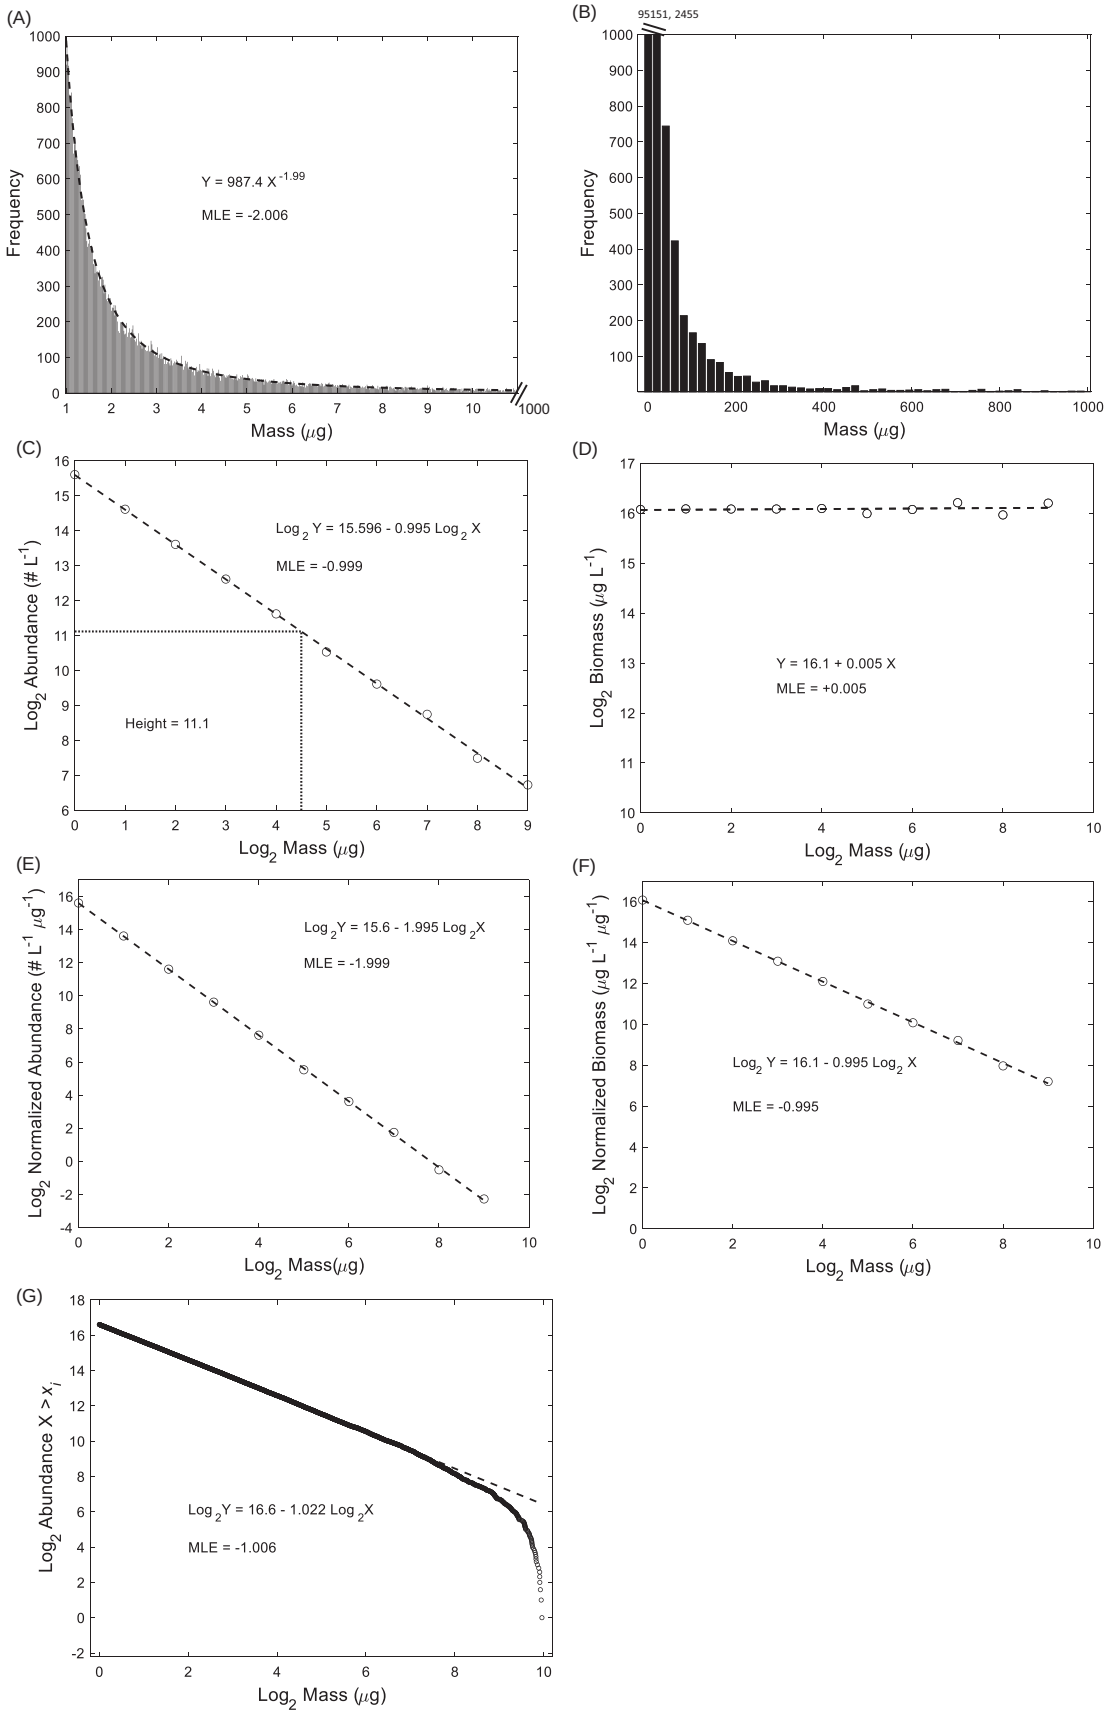

Fig. 3 (A) Length-frequency distribution of 100,000 body masses sampled from a Power Law distribution with exponent $\lambda = -2$. Fitted ordinary least squares line (OLS) and equation are shown, as is the Pareto maximum likelihood estimate of the Power Law exponent (White et al., 2008). Note the break in the X-axis extending out to the largest body mass of 1000 μg. (B) The data from Fig. 3 replotted with wider size intervals to for better visualization. Frequency values for the first two bars that extend well above the plotted area indicated. (C) The Abundance Spectrum of the random body masses in $\log_2$ mass and abundance intervals. Equation of OLS fitted line and the maximum likelihood estimate of the spectrum exponent (MLEbin method, Edwards et al., 2020) are shown. Height at the midpoint of the mass axis is shown as a standardized measure of community abundance. (D) The Biomass Spectrum with biomass plotted on a logarithmic scale. Equation of OLS fitted line and the MLEbin estimate of the spectrum exponent are shown. (E) Normalized Abundance Spectrum. Equation of OLS fitted line and MLE estimate of the spectrum exponent are shown. (F) Normalized Biomass Spectrum. Equation of OLS fitted line and MLE exponent estimate are shown. (G) Cumulative Pareto Distribution. Dashed line is an OLS fit to the linear portion of the distribution. The Maximum Likelihood estimate of λ based on all 100,000 individual mass values (–2.006) is also shown after scaling by addition of 1 for comparison with the OLS value of –1.022.

Table 1 100,000 randomly selected masses used in the construction of Fig. 3.

Mass (μg) Interval (a)[a]	*Abundance (No. L^{-1}) =# per interval (b)*	*Biomass ($\mu g\ L^{-1}$) =Σ mass per interval (c)*	*Normalized Abundance (# $L^{-1}\ \mu g^{-1}$) (b/a)*	*Normalized Biomass ($\mu g\ L^{-1}\ \mu g^{-1}$) (c/a)*
1–2	49,899	69,115	49,899	69,115
2–4	25,090	69,667	12,545	34,833
4–8	12,506	69,535	3127	17,384
8–16	6282	69,549	785	8694
16–32	3150	70,021	197	4376
32–64	1480	65,231	46	2038
64–128	783	69,091	12.2	1080
128–252	430	75,900	3.4	593
252–512	180	64,069	0.7	250
512–1024	106	75,444	0.2	147

Masses are grouped according to the form of the size spectrum, and calculations are indicated.
[a]For $\log_2$ scale interval width = lower boundary.

regression has a slope parameter b_a of −0.995 which is indistinguishable from the expected value of −1 given minor statistical error in the algorithm used to generate the sample of random masses. It can be shown mathematically that the linear parameter, b_a, of the Abundance Spectrum is one unit greater than λ, the ISD exponent, and hence can be used to estimate it ($\lambda = b_a - 1 = -2$). The MLE estimate of the ISD exponent (incremented by 1) is very close to the OLS estimate as would be expected for data simulation.

Biomass spectrum

The Biomass Size Spectrum is formed in a parallel manner except total mass rather than frequency is computed for each logarithmic mass interval (Table 1). With biomass plotted on a logarithmic scale the trend is a straight line with OLS slope $b_b = 0.005$ (within statistical error of the expected value of 0) indicating that biomass per mass interval is the same for all intervals (Fig. 3D). This is also mathematically consistent with a $\lambda = -2$ power law. The slope of the Biomass Size Spectrum is 2 units greater than λ and can be used to estimate it ($\lambda = b_b - 2$). The MLEbin estimate of λ is identical to the OLS slope. This spectrum is sometimes referred to as a "Sheldon" spectrum after Ray W. Sheldon who in 1972 wrote provocatively "that, to a first approximation, roughly equal concentrations of material occur at all particle sizes from 1 μm to about 10^6 μm, i.e., from bacteria to whales" (Sheldon et al., 1972). He expressed size as "equivalent spherical diameter"—the diameter of a sphere having the same volume as an organism—and plotted this on a $\log_2$ scale. He expressed biomass as parts per million by volume and plotted this on a linear scale. This form of the spectrum is now rarely used; however Sheldon's early observations stand as the primary motivation for all empirical and theoretical research on the Size Spectrum that followed.

Normalized abundance and biomass spectra

A problem with the Abundance and Biomass Size Spectra is that patterns depend not only on the total frequency or biomass per mass interval but also on the width of the interval which increases progressively across the logarithmic scale. This can be avoided by "normalizing" abundance or biomass values through division by the linear width of the intervals (Table 1) to give the "Normalized Abundance Spectrum" or the "Normalized Biomass Spectrum." The pattern of the Normalized Abundance Spectrum is well described by a straight line with a slope b_{na} of −1.995, close to the expected value of −2 (Fig. 3E), which follows analytically from the underlying power law. This is a direct estimate of the power law exponent ($\lambda = b_{na}$) and is close to the MLEbin estimate of −1.999. Similarly the Normalized Biomass Spectrum is a straight line with slope $b_{nb} = -0.995$ (identical to MLEbin) close to the expected value of −1 (Fig. 3F), one unit greater than λ ($\lambda = b_{nb} - 1$). This form of the spectrum is probably the one most frequently used in the literature.

Pareto distribution

Grouping measurements into intervals requires decisions about interval type and width making comparisons among studies difficult, and the choice of intervals can affect the accuracy and precision of estimates of the ISD parameter λ, a primary goal of size spectrum analysis. These problems can be avoided by analyzing the probability distribution of individual masses which requires no binning. Individual masses are ranked from smallest to largest ($i = 1 \ldots n$) and the probability of a random mass being $\geq m_i$ is estimated as $P = 1 - i/n$. The relationship between P and m is a "cumulative" distribution known as the "Pareto Distribution" which can take two forms—"Bounded" if both the minimum and maximum value of m are specified, and "Unbounded" if only the

minimum is specified. The random masses used here to illustrate forms of size spectra were generated from a Bounded distribution. P plotted against m on double logarithmic axes is a straight line for most of its range but curves down, or asymptotes, because it is bounded by the maximum mass value. A more "ecological" form of this distribution is to multiply the probabilities by the total sample size as has been done in Fig. 3G. The slope of a linear model fitted to the straight-line portion of the distribution, $b_p = -1.022$, is within fitting error of the expected value of −1. This is one unit greater than $\lambda = -2$ and can be used to estimate it ($\lambda = b_p - 1$). The MLE estimate of λ (−1.006) is very close to the OLS estimate for these data that precisely follow a Power Law.

Examples of size spectra

A selection of size spectra has been plotted in Fig. 4 to illustrate the variety of shapes and the variation in choice of units and axes. Sheldon's pioneering observation that biomass concentration is roughly equal across equal logarithmic intervals of body size is based partly on one of his early plankton spectra (Fig. 4A). Although clear peaks can be seen they are nevertheless roughly equal in maximum height (note the Y-scale is linear). The units Sheldon chose are no longer in use. The biomass spectrum for the whole food web of Lake Ontario shows peaks of biomass corresponding to the major organism groups (from left to right: phytoplankton, zooplankton, the amphipod *Diporeia*, and planktivorous fish (Fig. 4B, based on Sprules and Goyke, 1994). OLS and MLE parameter estimates are very similar. When these data are plotted as a normalized biomass spectrum (Fig. 4C, based on Sprules and Goyke, 1994) the biomass peaks are less obvious due to the logarithmic scaling and have been referred to as domes. Fitted parameters are similar for OLS and MLE. While the primary pattern for normalized spectra is linear there is generally residual variation around this "backbone" that can vary considerably in magnitude and pattern. The normalized spectrum for the Pacific Gyre (Fig. 4D, based on Rodriguez and Mullin, 1986) is very linear with residuals that appear random and are tightly clustered around the linear trend. There are no obvious domes. Lake Ontario is a much more productive system than the Pacific Gyre and the spectral patterns in these two systems accord with theory that indicates decreasing productivity of a system attenuates the domes which are caused by cascading top-down predation forces (e.g., Rossberg et al., 2019). The benthic marine biomass spectrum (Fig. 4E) also shows clear domes that span roughly two orders of magnitude in biomass. It is moot whether these are "roughly equal" but in contrast to pelagic environments the benthic habitat has a lot of physical structure that can affect the form of the size spectrum (Schwinghamer, 1981). In this case there is considerable discrepancy between OLS and MLE parameter estimates.

Size Spectrum parameter estimation

Slope

The most common method of analysis used to estimate size spectrum parameters has been to fit an ordinary least squares (OLS) regression to linear forms of the spectrum (Fig. 3) to obtain the slope (an estimate of λ after the appropriate corrections indicated above) and the intercept (an estimate of abundance or biomass). OLS regression works by choosing the parameters of a line that minimize the sum of squared deviations of Y around it. Recently White et al. (2008) and Edwards et al. (2017) have shown, using Monte Carlo simulation techniques, that the accuracy and precision of OLS parameter estimation is not uniform across forms of the size spectrum. Instead the most rigorous estimates of λ are obtained by Maximum Likelihood Estimation (MLE). MLE works by choosing a model and parameters that maximize the likelihood of obtaining the observed data. OLS analyses of spectra with *linear* size intervals results in inaccurate estimates of λ and should not be used for this purpose. OLS estimates of λ for abundance or biomass spectra (both unnormalized and normalized) with data binned into equal logarithmic intervals are generally close to MLE estimates (e.g., Fig. 4B and C) but may have wide confidence intervals. MLE estimates are both accurate and precise. This is especially true for the Pareto Function which is based on individual rather than binned observations. Edwards et al. (2020) have also shown that, if the data at hand are already in binned form giving no access to the raw observations, MLEbin estimation based on the assumption that the hidden observations *within* a bin follow a power-law distribution gives the best parameter estimates.

A possible weakness of the Monte Carlo simulations is the assumption that size spectra follow a perfect power-law distribution which gives linear normalized abundance and biomass spectra. However there is extensive evidence, both empirical and theoretical, that there is often secondary pattern in size spectra, most frequently manifest as sequential biomass "domes" reflecting the major interacting size groups in the community (Fig. 4). These effectively constitute non-random residuals around a linear spectrum model that could result in the MLE and OLS estimates of λ being different (e.g., Fig. 4E). Further research is required to resolve this matter.

Intercept

The intercept of a linear model is the value of Y where $X = 0$. In OLS analyses of size spectra the intercept has been used as a measure of overall biomass or abundance in the community at this standardized reference point. This is not recommended however because the slope and intercept are not statistically independent. One solution to this is to use 'height', the value of Y for the size interval in the middle of the X axis, as the measure of community biomass or abundance. This is independent of the slope. It works well for the Abundance Spectrum since height will be a direct estimate of the number of organisms per unit area or volume (Fig. 3C). For normalized spectra the units of height would have to be multiplied by the width of the central size interval to obtain abundance or

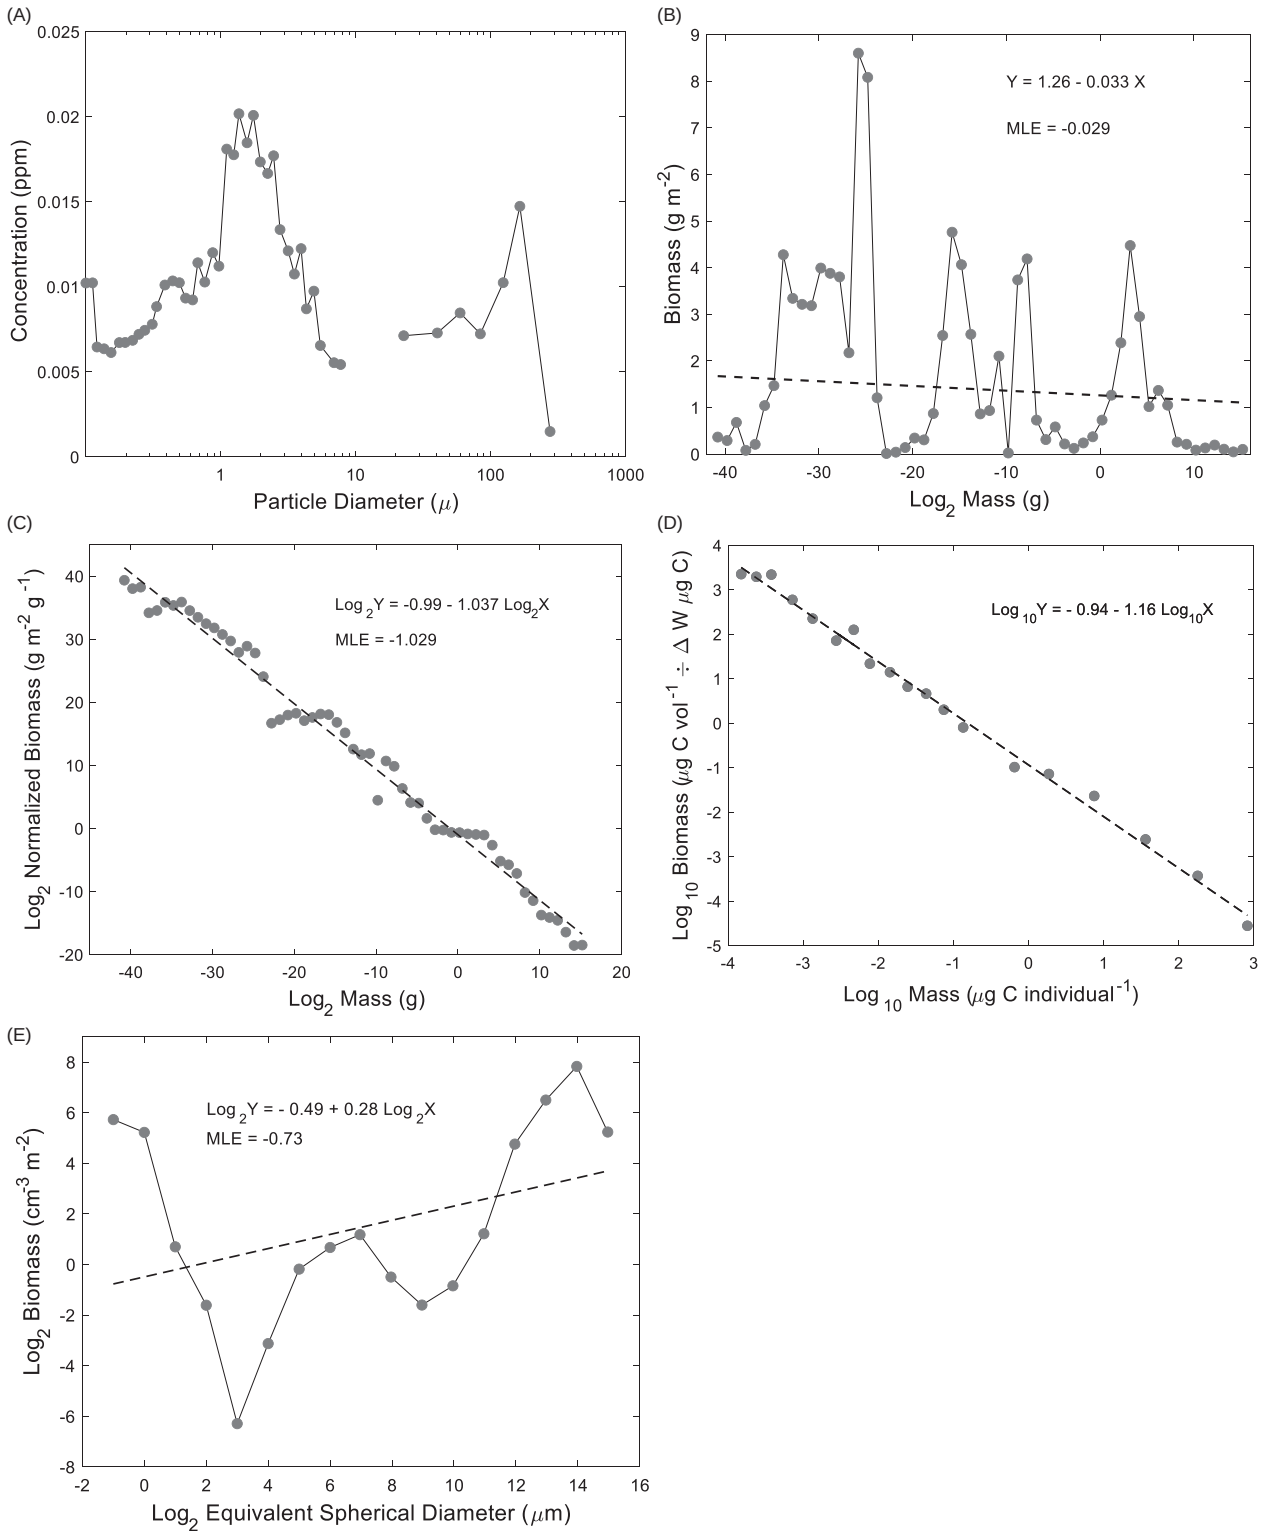

Fig. 4 (A) R. Sheldon's marine biomass spectrum comprises organisms less than 100 μm in diameter measured with a Coulter Counter and zooplankton above this range collected with tow nets. Size units presented here are no longer commonly used. (B) The biomass spectrum for Lake Ontario from bacteria to large fish averaged over seasons and spatial stations. Major biomass "domes" from left to right are phytoplankton and bacteria, zooplankton, the benthic amphipod *Diporeia*, and planktivorous fish. Equation of the OLS fitted line and the MLEbin exponent estimate are shown. (C) The Lake Ontario Normalized Biomass Spectrum from the same data as in (B). The biomass domes are attenuated in this presentation but are nevertheless visible as humps or waves. The OLS fitted line and the MLEbin exponent estimate are shown. (D) Normalized biomass spectrum for micro- and macro-plankton in the euphotic zone of the North Pacific Central Gyre with OLS fitted equation. The MLE exponent estimate cannot be computed because the unnormalized biomass data were not published. (E) Mean benthic biomass size spectrum from marine samples in the Bay of Fundy, New Brunswick and the south coast of Nova Scotia, Canada. The three domes from left to right comprise bacteria, interstitial meiofauna, and macrofauna. OLS fitted line and MLEbin exponent estimate are shown. (A) Redrawn from Sheldon RW, Prakash A and Sutcliffe WH Jr (1972) The size distribution of particles in the ocean. *Limnology and Oceanography* **17**: 327–340; (B and C) Redrawn from Sprules WG and Goyke A (1994) Size-based structure and production in the pelagia of Lakes Ontario and Michigan. *Canadian Journal of Fisheries and Aquatic Sciences* **51**: 2603–2611; (D) Redrawn from Rodriguez J and Mullin MM (1986) Relation between biomass and body weight of plankton in a steady-state oceanic ecosystem. *Limnology and Oceanography* **31**: 361–370; (E) Redrawn from Schwinghamer P (1981) Characteristic size distributions of integral benthic communities. *Canadian Journal of Fisheries and Aquatic Sciences* **38**: 1255–1263.

biomass concentration (Figs. 3E and F). MLE techniques only estimate the exponent λ but if the primary pattern in a spectrum is linear then the spectral height could be determined by solving the linear equation passing through the intersection of the means of X and Y.

Theory

Models of interactions within communities of organisms have traditionally been based on species as the focal units and have generally been complex given the need for species-specific data on many life history and ecological processes. They have nevertheless been instrumental in advancing our insights into the dynamics of communities in nature. By contrast, in size-structured community models the unit is an individual and its primary characterization is body size. Physiological and ecological processes such as metabolism, prey selection, feeding rate, and growth efficiency are strongly size-dependent and empirical estimates of the underlying parameters of these functions are extensive.

Early size-based models were motivated by a desire to understand the size-based ecological and physiological processes underpinning Sheldon's famous observation of roughly equal biomass in logarithmic size intervals from bacteria to whales. In the simplest terms this arises because the loss of energy through a sequence of inefficient transfers from small to large organisms is balanced by progressively lower turnover times of the biomass of ever larger individuals. Sheldon et al. (1977) modeled these concepts in order to make predictions about the biomass and production of larger marine organisms of commercial interest (e.g., Peruvian anchoveta, *Engraulis ringens* Jenyns) based on more easily obtained data on the abundance of small organisms (phytoplankton and zooplankton). Kerr (1974) similarly conceived of the production of a prey population constituting the ration of a large (by a fixed size ratio) predator used to support predator metabolism and growth at size-dependent rates. When fully parameterized both modeling approaches predicted ratios of standing stocks of prey and predators to be roughly equal as empirically observed.

Sheldon and Kerr envisaged energy being transferred across size gaps from smaller to large organisms. By contrast, Platt and Denman (1977) modeled a continuous spectrum with biomass moving through time across narrow "spectral" bands of body mass. The flux of biomass through a size band was modeled by the respiration rate and turnover time of the organisms both of which are size dependent. The result was a slope of −1.22 for the normalized biomass spectrum. This model did not include predation losses so can only be taken as a preliminary effort at modeling continuous spectra as Platt and Denman noted.

Boudreau et al. (1991) postulated that, in food webs classified by organism size only, biomass production occurs at two scales. At the scale of major predator groupings (e.g., fish feeding on zooplankton) predators can capture only a fraction of the total prey biomass and can convert only a fraction of that energy to predator biomass. This is a primary "physiological" scaling that determines the overall negative slope of the (normalized) biomass spectrum. By contrast, within major predator groups larger organisms feed on smaller ones and must continuously seek prey of suitable size, concentration, and spatial distribution to meet their growing energy demands. Size dependencies of these interactions define a secondary or "ecological" scaling that manifests as biomass "domes" along the primary spectrum axis (e.g., Fig. 4). Thiebaux and Dickie (1993) analytically derived the secondary domes from a mathematical analysis of Boudreau's model.

A major advance in size spectrum models by Hartvig et al. (2011) with modification by Rossberg (2012) was a formulation comprising multiple "species" each made up of many individuals of varying body size up to the species-specific maturation size. Species are linked through feeding interactions, the strengths of which are governed by the relative body sizes of predator and prey individuals. Acquired energy is partitioned into individual growth and maintenance until maturation size is reached. Then more and more energy is allocated to reproduction until growth eventually ceases. Predation is the primary source of mortality. Organisms grow as a function of how much they eat, and they die primarily because they are eaten. These processes closely simulate interactions among individual organisms in nature. The community spectrum is derived by summing individual species spectra and steady-state solutions match the basic Sheldon expectation of roughly equal biomass across equal logarithmic size ranges. Furthermore Rossberg et al. (2019) show that dome structures commonly observed in empirical size spectra are predicted by his theory as top-down cascades that are intensified by increases in overall system productivity.

Size spectrum models are relatively simple given that component organisms are characterized by body size alone and the few ecological and physiological processes required are size dependent. Parameter values of these size-dependent processes are well documented in the literature. The models predict emergent properties of communities that are commonly observed in nature. They apply specifically to pelagic aquatic communities in which predators feed on prey smaller than themselves. It remains to be determined whether terrestrial or other aquatic communities (e.g., benthic) can be similarly modeled. Given their ability to closely simulate observed patterns of community size structure it can be said that these models capture the fundamental organizing principles of ecological systems. On the other hand size spectrum models are not suited to predicting dynamics at the species level although trait-based versions of these models do capture key life-history characteristics such as maturation size and maximum body size. There is a trade-off between increasing model complexity to represent myriad interactions among species and simpler, more easily constructed models that are limited in predictive ability. Perhaps size spectrum models represent an intermediate solution, but it cannot be denied that a variety of modeling approaches can be useful for ecosystem management.

Applications

The earliest applications of the size spectrum were to make predictions of abundance or production of one size class of organisms from spectral information on a smaller size class. For instance Sheldon et al. (1977) used a model of the relationship among standing stock, body size, and growth efficiency of predators and their prey to estimate the annual production of anchoveta in a relatively simple pelagic food web off the coast of Peru. Field observations of biomass per logarithmic interval of phytoplankton were used to predict those for copepods and thence for anchoveta based on the model above. The estimated total anchoveta standing stock in the fishing area was then multiplied by an independently measured instantaneous population growth rate to predict the annual production available to the fishery. This estimation fell within the range of actual landed catches over a 6-year period.

Slopes of two common forms of the size spectrum—the abundance and the normalized biomass size spectra—have been observed to be close to −1 across a wide range of pelagic aquatic habitats. This has been interpreted to represent the steady state condition of the size structure of natural communities not subjected to major perturbation. It suggests that deviations of the slope from this "baseline" condition could be a signal of destabilization of the community due to external perturbations such as size-selective fishing or pulses of nutrient additions. In fact size spectrum parameters have been recommended as indices for monitoring the status and trends of marine ecosystem properties by both the European Commission and the Southern Ocean Observing System. The relative simplicity and availability of body size data and the demonstrated utility of the size spectrum as an indicator of system structure make size spectrum parameters particularly useful. The slope of the size spectrum has also been interpreted as an indicator of the efficiency with which energy is transferred through the community; shallower slopes indicate high efficiency because greater numbers of larger organisms can survive. Mehner et al. (2018) showed that empirical estimates of trophic transfer efficiencies between trophic groups in lake communities of bacteria to fish were correlated with the slope of their size spectra.

Several researchers have tracked the value of spectrum slopes through time as a way of monitoring ecosystems and identifying whether, and why, community size structure has changed. For instance Blanchard et al. (2005) used various metrics, including the slope of the normalized biomass size spectrum, to track changes in the size structure of the Celtic Sea groundfish community over multiple years and locations in relation to commercial fishing pressure and sea temperature. The spectrum slope decreased (became more negative) through time indicating a loss of larger organisms due to increased fishing pressure. Mazurkiewicz et al. (2020) studied abundance and biomass spectra of undisturbed benthic macro- and meiofauna communities across six Norwegian fjords varying in species composition and bottom water temperature. They found that size spectrum shapes of these communities did not vary across localities despite variation in species composition and environmental conditions suggesting stability of size structure and hence energy transfer through the food webs. Of four fish size indicators used to detect changes in fishing mortality in a multi-species marine fisheries model Thorpe et al. (2015) showed that the slope of the abundance size spectrum was the most responsive. Barth et al. (2021) showed that an abrupt change in a time series of normalized abundance size spectrum slopes coincided with the first detection of the invasive zooplankton predator *Bythotrephes longimanus* in a small Ontario lake, but slopes returned to normal values after the invasion suggesting a return to the baseline structure of this plankton community after the initial disruption.

Beyond slopes, dynamic size spectrum simulation models have now reached the point at which they can be applied in real ecological contexts—particularly marine fish communities. Model specification of the growth and mortality of fish "species" that are characterized by their body size and distinguished from others by maturation size make them especially suitable for use in fisheries management. These models differ from previous fisheries management models in that (a) the dynamics arise from growth and predation processes internal to the model (individuals grow by feeding and die by being eaten) rather than being controlled by external growth or yield-per-recruit functions, and (b) organisms are characterized by body size rather than age. Law et al. (2015) have remarked that removing the independence of growth and mortality assumed by yield-per-recruit models leads to ".. a surprisingly different perspective .." on management of fish stocks. Furthermore the data on organism size and abundance through time required to parameterize and test size spectrum models are more easily acquired than life history information on many fish species. This is not to say one approach is better than the other but rather that a variety of model formulations will enrich the knowledge of how fish communities function and how best to manage them by balancing exploitation with conservation.

Houle et al. (2016) used a size spectrum model of the 35 most common fish species in the Celtic Sea southwest of Ireland to evaluate the relative impacts of seal predation and commercial fishing on the fish community. As is typical of size spectrum models, species are distinguished solely by the key trait of maturation body mass with other life-history traits as allometric functions of this mass. The model was calibrated to historical data on the fish community and simulations indicated that seal predation was an order of magnitude less than commercial harvests principally because there was little overlap in preferred prey of seals versus the fishery.

Blanchard et al. (2014) developed a more complex size spectrum model of 12 common species captured by the North Sea trawl fishery. Physiological, life history and foraging parameters were specified for each species as were predator-prey mass ratios and spatial overlap among species pairs—all estimated from field data. The model was calibrated to the historical fishery. Simulation results indicated that biodiversity targets (minimum biomass of all species, specified minimum proportion of large fish, the slope of the community abundance spectrum of −1.1) were 60% more likely to be reached under the sustainable yield scenario than under status quo fishing.

Finally, forces other than fishing mortality have also been explored with size spectrum models. Yool et al. (2017) used a size-structured marine benthic biomass model coupled with an ocean biogeochemistry model to explore benthos response to variations in particulate organic carbon (POC) supply under varying climate warming and ocean acidification scenarios. Results indicated that with climate warming benthic biomass decreased more than surface ocean productivity, especially at deeper sites. The model indicated this was due to acidification effects on the chemistry of the POC flux and greater remineralization over deep oceans sites due to time taken for sedimentation.

Prospectus

The tremendous advances in the theory, practice, and application of size spectra, particularly over the last 10–20 years, have cemented these concepts in the very center of aquatic ecosystem ecology. It can also be argued that this size-based approach to studying the structure and functioning of communities in nature has motivated a broader trait-based approach across all types of ecosystems. That is not to say body size is a panacea but rather that it is a complement to species-centered studies that has enriched the tools and perspectives we can bring to bear on many difficult threats to the natural world.

Standardization of the data and analyses required to construct size spectra has also advanced considerably. This is necessary for comparisons of size spectrum parameters among studies—especially the exponent λ that is an index of both the structural integrity and the energy efficiency of natural communities. Recent studies have greatly advanced the statistical procedures that give the most robust estimates of this important parameter. International organizations are encouraging investigation of size spectrum parameters as key indicators to be applied to management of natural communities—especially marine fish. Size spectrum models have become more sophisticated with increasing success as platforms for testing ideas about harvesting approaches to marine fisheries, which should also be applicable to inland water fisheries. They have also become more complex as the simple trait of body size is being extended by addition of other life history and physiological species characteristics. There will eventually be a trade-off between the two extremes.

From bacteria to whales still stands as a remarkable insight into the structure and dynamics of ecological communities and will surely continue to motivate size-based ecology for many years to come.

Recommendations

1. Use mass as the measure of body size whenever possible—either directly measured or computed from a length-weight relationship.
2. Retain all individual masses for the most rigorous MLE estimates of λ. Compare Pareto or abundance spectrum plots of the data with fitted models to ensure good fits—especially if the spectrum contains non-linear portions (domes).
3. If the data comprise masses already allocated to bins use MLE bin methods to estimate λ and plot data and fitted models. Compare with OLS fits to the abundance spectrum, especially if domes are present in the spectrum.
4. Beware of generalizing based on size spectra data for limited organism size ranges (e.g., zooplankton only or fish only). Theory and application are based on the whole food web with interacting predators and prey spanning wide size ranges.
5. As much as possible include seasonal and spatial replication in size spectrum sampling programs. A single spectrum at a place and time is but a snapshot of a dynamic community of organisms operating on different temporal scales.

Paleolimnology: Long-Term Reconstructions of Environmental Change

John P Smol, Paleoecological Environmental Assessment and Research Lab (PEARL), Department of Biology, Queen's University, Kingston, ON, Canada

This is an update of J.P. Smol, Paleolimnology, In Encyclopedia of Inland Waters, Edited by: Gene E. Likens, Academic Press, 2009, https://doi.org/10.1016/B978-012370626-3.00207-6.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Lars Rudstam.

Introduction

The ecological and environmental conditions in lakes and rivers change on a variety of time scales. However, one of the greatest challenges faced by limnologists (as well as other environmental and ecological scientists) is the general lack of long-term monitoring data. A recent assessment of the length of typical aquatic monitoring programs concluded that about two-thirds of such studies were less than 1 year in duration, with over 80% of studies less than 3 years long (Smol, 2019). Without such temporal data, it is difficult to determine whether changes are occurring in an aquatic system and, if they are, then to identify the likely drivers of any ecosystem changes. Long-term data are especially critical in contrasting the effects of human activity versus natural environmental change on ecosystems.

Although direct instrumental data on limnological changes are often lacking, an important archive of past environmental and ecological conditions is preserved in the sediments of lakes and some river systems. The information preserved in lake sediments provides relatively comprehensive records of past limnological changes, as well as changes occurring in the surrounding terrestrial catchment and airshed.

Paleolimnology can be defined broadly as the multidisciplinary science that uses the physical, chemical and biological information preserved in aquatic sediments to track past changes in ecosystems (Cohen, 2003; Smol, 2008). Paleolimnology has enjoyed considerable progress over recent decades, with important advances in the ways paleolimnologists can retrieve and section sediment cores, new approaches to provide geochronological control for these sediment profiles, major advances in the quantity and quality of proxy information that paleolimnologists have learned to retrieve from sediments, as well as major improvements in the ways that paleolimnologists can interpret these stratigraphic changes in a statistically robust and defendable manner.

Examples using lakes will be emphasized throughout this contribution, however similar approaches are being used in wetland, river, estuarine and marine ecosystems (e.g. Weckström et al., 2017). The overall focus is on paleolimnological approaches with an emphasis on biological proxy data. Other contributions to this encyclopedia cover additional approaches.

Sediments

Lakes slowly fill up with sediments. Typically, 24 h a day, every day of the year, sediments are slowly accumulating at the bottom of lakes. The overriding principle in paleolimnology is that lake sediments accumulate in an organized fashion, with older material occurring deeper in the sediment core, and the most recent material at the surface of the core (i.e. the Law of Superposition). Not all sediment profiles are ideal for historical analyses, as some mixing processes, such as bioturbation (i.e. the mixing of the sediments by benthic organisms), may occur. Nonetheless, many of these potential problems can be assessed (e.g. using dating techniques) and it is now clear that the vast majority of lakes archive valuable records of past environmental change in a stratigraphically intact manner.

Lake sediments incorporate a tremendously rich library of information about lake processes and biological communities from both within and external to the lake. Paleolimnologists typically divide the sources of lake sediments into two broad categories: (1) allochthonous sources, which refer to material originating from outside the lake basin (e.g. soil particles, pollen grains from trees, pollution from industries); and (2) autochthonous sources, which refer to material originating from within the water body itself (e.g. dead algae or invertebrates, chemical precipitates). The amount of sediment that has accumulated can vary tremendously between lakes, and even within a single lake basin over time. A typical glaciated temperate lake may contain 4 or 5 m (or even 10 m or more) of sediment, representing the lake's history since the time of the lake's formation following the retreat of the ice sheets at the end of the last ice age (*ca* 12,000 years ago, but varies depending on location). In contrast, a lake of similar age from a polar

region may have far less sediment accumulated, as sedimentation rates are typically very low. In some regions, such as the Great Rift Valley lakes of Africa, records spanning several hundred thousand years are contained in 100s of meters of sediment.

A major advantage of paleolimnological approaches is that researchers can, to a large extent, set the time scale. For example, by taking longer sediment cores, a longer time frame can be studied. Similarly, the researcher has some control over the temporal resolution of the study. For example, by slicing the sediment core at finer intervals, more detailed records of past environmental changes can be inferred. Of course, there are also potentially serious limitations. For example, the sediment accumulation rate may be so low that even fine-resolution sampling will still not provide sufficiently fine temporal resolution to answer certain questions.

From the information preserved in sediments, paleolimnologists can reconstruct the history and development of aquatic ecosystems. There are two key steps involved in any paleolimnological investigation – (1) retrieval of the sedimentary material required for study, and (2) establishing the depth-time scale of the profile using geochronological techniques. These first two critical steps are described below.

Retrieving sediment cores

Many ingenious sediment samplers have been developed to collect sediment cores in an undisturbed manner, many of which are described in Glew et al. (2001). Each sampler has both advantages and drawbacks, and so it is first important to determine the scientific questions that researchers hope to address. For example, what time frame will be required for the paleolimnological study? Will the program include a detailed analysis of the more recent sediments, which may be used to study, for example, the influences of recent human interventions on the lake system, such as the effects of agriculture or acid rain? Or is the main focus on long-term changes, such as broad climatic shifts over millennial time scales? What temporal detail (e.g. annual, decadal, centennial) will be needed to answer these questions? The answers to these questions will determine which study lake(s) will be chosen for study, as well as what type of equipment will be required to retrieve and section the most suitable sediment samples.

The earliest corers were developed to answer questions related to long-term (centennial and millennial) scale changes in lake ontogeny. Many of the original designs were inspired by the work of M. Jull Hvorslev (1895–1989), whose seminal work on sampling soil profiles for the U.S. Army Corps of Engineers contains many of the basic principles that paleolimnologists still use today to collect sedimentary profiles (Hvorslev, 1949). Using some of these concepts, Daniel Livingstone (1927–2016) published a piston coring design (Livingstone, 1955) that is still widely used today (often with some minor modifications). The typical piston corer consists of three components: the piston and cable assembly, the core tube, and the drive head and drive rods. Many variations of the original design are available, including those that can be used on a rope. Piston corers can remove, sequentially, sediment profiles of about 1 m in length, until the required depth of sample penetration is reached (Fig. 1).

Since the mid-1980s, there has been an increased emphasis on using lake sediments to study more recent changes in lake histories, such as the effects of anthropogenic impacts on lake ecosystems. This requires the use of a corer that will carefully sample the most recent, watery sediment records, which may be disturbed or lost if collected using standard piston corers. Two major types of samplers are used: gravity corers and freeze crust corers.

A variety of gravity corers have been developed to specifically sample the most recent sediments. Many of these follow the general design of a benthic invertebrate sampler that Z. Kajak (1929–2002) developed, however significant modifications have been made to the original design, such as those developed and modified by John R. Glew (Fig. 2) or those developed by Uwitec in Austria. In its simplest form, a surface sediment gravity corer is a hollow coring tube that is carefully lowered into the recent sediments on a rope from the surface, using its own weight for penetration. However, when sampling stiffer sediments, additional weight may be

Fig. 1 Lake sediment coring on Lake Chala (Kenya), using a Livingstone-type piston corer (modified by Uwitec). Photograph courtesy of B. Cumming (Queen's University).

needed to achieve adequate penetration. The top of the coring tube is then closed off to create a seal, typically using a messenger that is delivered down the coring line. The gravity corer, with the tube of collected sediment, is then returned to the surface, the bottom of the core tube is plugged, and then set up for subsequent sectioning and sub-sampling.

Freeze-crust coring is another sampling method used for retrieving relatively undisturbed recent sediments. This process is also quite simple. A freeze-crust corer can take many designs, but most are either a metal box or tube that is filled with a coolant, such as frozen carbon dioxide (i.e. dry ice), as well as a fluid, such as ethanol. The filled freeze crust corer, which would now be very cold, is then slowly lowered on a rope into the sediments where in situ freezing of the sediments onto the corer will occur. During this time, the sampling rope must be anchored on a solid platform at the lake surface, such as the ice cover, to prevent it from sinking further into the sediments. After a certain period of time (the time that the sampler is left in the sediments depends on the design used, but typically from 10 to 15 min), a crust of sediment has been frozen onto the surface of the sampler. The sampler can then be retrieved, and the crust of frozen sediment can be removed and sectioned.

A large number of other coring designs are available, including those specifically developed to take long sediment cores in deep waters, such as the Kullenberg sampler. Other designs include corers designed to penetrate compact sediment profiles, such as hammer corer and vibracorers. Suffice to say that almost any lake system can now be sampled for its sediment history.
