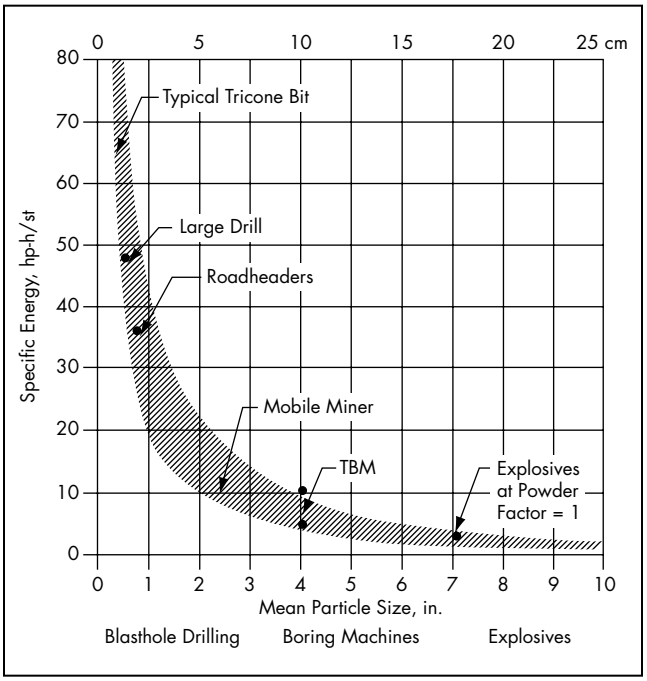
Water monitors, which consist of low-pressure, high-volume water jets, are still used in the mining of alluvial deposits and softer ground, but they are not capable of excavating rock. For rock-cutting applications, higher-pressure, lower-volume jets are preferred. Many water jet systems are available on the market for various applications, and many attempts have been made to use water jets as the primary excavation system, but none has so far proven to be economical. Water jet systems include oscillating jet, vibrating jet, pulse jet, cavitational jet, and abrasive jets.



While water-jet cutting dominates the stone-cutting and stone-carving industries, its application in mining is limited to cutting large blocks of granite (in effect replacing line drilling or wire saws) in a few large quarries. In general, water jet systems are effective for high-precision cuts but are not energy-efficient for high-volume excavation. The specific energy of cutting with water jets varies from 100 to 1,000 KW·h/m^3, compared to 0.5-10 KW·h/m^3 for cutting rock using other machines. Thus, the use of water jets in mining and construction applications has been limited to mechanically assisted water jets, which improves the cutting efficiency of partial-face machines, reduces dust generation, and improves bit life. In such applications, lower-pressure jets of 5 to 10 MPa (700 to 1,500 psi) have been employed on various machines such as roadheaders, CMs, and drum shearers.

Lower-pressure jets do not require high-powered pumps, and the piping, seals, and connectors are simpler, cheaper, and easier to maintain. Water jet applications in mining and rock excavation are described in detail in Summers (1995).

Some novel and intriguing systems have been proposed for extraterrestrial or space mining in recent years. One of the most valuable ores is water, which is anticipated to be ice in frozen regolith at the poles and dark side of the moon. Recently some efforts have been made to develop surface mining equipment that can efficiently cut frozen regolith with different degrees of moisture. The cutting system is capable of changing bit spacing to cope with the various strengths of frozen regolith that can be encountered. A prototype model of this system was recently fabricated and tested in material ranging in strength from 3.5 to 50 MPa (500 to 7,000 psi). In practical application, the cutterhead would be mounted on a roadmilling-type machine or on specially designed chariots to excavate the material and load it into containers that could be transported to the base for processing.

PERFORMANCE ESTIMATES

Estimating the rate of production in mining applications and the rate of advance in tunneling or entry development is a crucial step in calculating the mining cost per ton, the cost per meter of tunnel, and the project completion time. In other words, justification of using mechanical excavators depends purely on the production rate and on accurate and reliable performance estimates. There are specific formulas and models available for the estimation of production rate for each machine; however, there is a general guideline calculation of machine performance, based on the SE of the excavation, that can be applied to any mechanical excavator.

Source: Rostami et al. 1994.

Figure 7.1-16 Typical specific energy of cutting for various excavation systems

Advance Rate Prediction Based on Specific Energy

If the SE of cutting for a given rock type and cutting tool and the installed cutterhead power for a machine are known, the instantaneous production rate (IPR) can be calculated as follows:

$$\text{IPR} = \frac{\text{HP} \times \eta}{\text{SE}}$$

where

IPR = instantaneous production rate, m^3/h (yd^3/h)
HP = machine power, kW (hp)
η = mechanical efficiency of the system
SE = specific energy, KW·h/m^3 (hp-h/yd^3)

Figure 7.1-16 shows the SE of cutting for the various sizes of muck particle generated by different drilling and excavation systems (Rostami et al. 1994). Table 7.1-1 provides typical values for SE and η for certain types of machines and rock types. Using this table and the installed cutterhead power of the machine, one can estimate relevant volumetric or mass excavation rates. After the production rate is calculated, the linear rate of advance of the machine can be determined by dividing the IPR by the cross-sectional area, as follows:

$$\text{ROP} = \frac{\text{IPR}}{A}$$

Table 7.1-1 Typical specific energy, mechanical efficiency, and machine utilization for various mechanical excavators*

Machine Types	Rock Type/Strength	Specific Energy, KW·h/m³	Mechanical Efficiency, η, %	Utilization, %	Bit/Cutter Cost, $/t
Tunnel boring machine	Soft (<100 MPa)	5–7	80–85	25–50	2–5
	Medium (100–200 MPa)	8–12			5–10
	Hard (>200 MPa)	12–17			10–15
Roadheader	Soft (<40 MPa)	2–5	80–90	15–40	1–2.5
	Medium (40–70 MPa)	5–8			2–4
	Hard (70–100 MPa)	8–11			4–7
Continuous miner	Soft coal	0.35–0.5	50–65	30–40	0.05–0.08
	Medium coal	0.5–0.8			0.1–0.14
	Hard coal (or soft evaporites)	0.8–1.5			0.15–0.25
	Stronger evaporites	1.5–2			0.25–0.4
Longwall drum shearer	Soft coal	0.3–0.5	60–70	25–40	0.05–0.08
	Medium coal	0.5–0.8			0.1–0.14
	Hard coal (or soft evaporites)	0.8–1.5			0.15–0.25
	Stronger evaporites	1.5–2			0.25–0.4
Road milling machine	Soft (<40 MPa)	0.5–1.0	55–70	35–60	0.05–0.05
	Medium (40–70 MPa)	1.0–1.5			0.10–0.15
	Hard (70–100 MPa)	1.5–2.5			0.20–0.30
Shaft and raise boring and drilling systems†	Soft (<100 MPa)	8–12	75–80	45–60	5–10
	Medium (100–200 MPa)	12–17			10–15
	Hard (>200 MPa)	17–20			15–20

*Notes:
- SE units in metric (KW·h/m³) and English (hp-h/yd³) are nearly the same.
- Estimated values in the table are very general and could vary greatly by ground condition, machine specification, and operator skills.
- Production rates can be impacted significantly by rock mass conditions and jointing.
- Production is also a function of machine mass and rigidity; machine weight typically matches installed power.
- Bit costs are affected by the abrasivity of the rock, design of the cutterhead, and machine weight.

†These results assume the use of strawberry or multi-row carbide cutters. If disc cutters are used, the SE values listed for TBMs are applicable to these machines, but utilization and mechanical efficiency should be slightly reduced.

where

ROP = linear rate of advance, m/h (ft/h)
A = cross-sectional area of opening, m² (ft²)

Obviously, the units used in the calculations should be consistent. The daily advance rate of the machine, which is the daily distance mined in a single heading, can also be calculated by multiplying the linear rate of advance per hour (ROP) by the percentage utilization of the machine per day and the total number of operating hours per day, as follows:

$$\text{AR} = \text{ROP} \times U \times N_s \times H$$

where

AR = daily advance rate
U = machine utilization in percent total time
N_s = number of shifts per day
H = number of hours per shift

Utilization of the excavation machines are estimated based on the ratio of the time that the machine is actually excavating rock to the total time per shift or day.

This estimation system is applicable to any and all mechanical excavation systems from a small drill bit to a large TBM. The system makes some assumptions that may not be valid if there is a mismatch between machine specifications. For example, if the machine has the correct installed power but has low thrust capacity or if it operates within a weak structure that cannot deliver a full load on the cutters, penetration decreases and the specific energy for breakage will increase significantly. Another assumption is that the cutterhead configuration is reasonable for the application; if it is not, specific energies will be underestimated. The given specific energies in Table 7.1-1 assume a reasonably well-designed cutterhead. In general, the production and penetration rates estimated using this method are the maximum achievable rates. Additional information on the SE of cutting can be found in Fowell and McFeat-Smith (1976), Copur et al. (2001), Acaroglu et al. (2006), Bilgin et al. (2006), and Tiryaki and Dikmen (2006).

The following are two examples of using this system for estimation of the production rate of mechanical excavation systems.

Example 1. A 5-m-diameter TBM is chosen to mine a tunnel in medium rock. The machine has 1,000 kW of installed cutterhead power and is assumed to be capable of delivering full cutterhead to the face. Assuming a machine mechanical efficiency of 80% and a utilization rate of 25%, what is the daily advance rate of the machine if the work schedule calls for three 8-hour shifts?

Assuming a 5.7 KW·h/m³ specific energy and machine mechanical efficiency of 80%, one has the following:

$$\text{IPR} = \frac{1{,}000 \times 80\%}{5.7} = 140 \text{ m}^3/\text{h}$$

At 5 m diameter, the area of the face is approximately 20 m² and the linear rate of advance is 7 m/h. With 25% utilization and 24 operating hours per day, the daily advance rate becomes 42 m/d as follows:

$$\text{ROP} = 140(\text{m}^3/\text{h})/20(\text{m}^2) = 7 \text{ m/h}$$

$$\text{AR} = 7 \times 25\% \times 3 \times 8 = 42 \text{ m/d}$$

Example 2. A continuous miner with a cutterhead power of 400 kW is selected to excavate coal in a mine. The coal is of

medium strength and the entries are 3.5 m high by 6 m wide. What is the daily linear footage of entries excavated by the CM? If the machine is used to develop a three-entry panel with 30-m-long, 15-m-wide square pillars, what is the net distance of panel advance? Machine utilization is nearly 40%, and the miners work two 10-hour shifts. What is total tonnage produced on a daily basis if the specific gravity of coal is 1.2 t/m^2?

If one assumes from Table 7.1-1 a 0.8 KW·h/m^3 SE for cutting medium-strength coal and a machine mechanical efficiency of 60%, the following rates can be calculated:

$$\text{IPR} = \frac{400 \times 60\%}{0.8} = 300 \text{ m}^3/\text{h}$$

At a 3.5-m width and a 6-m height, the area of the face, A, equals $3.5 \times 6 = 21$ m^2, and the linear rate of advance is 14.3 m/h (300 m^3/h/21 m^2). The daily linear advance rate then becomes 114 m/d, as follows:

$$\text{ROP} = 300/21 = 14.3 \text{ m/h}$$

$$\text{AR} = 14.3 \times 40\% \times 2 \times 10 = 114 \text{ m/d}$$

The development of one crosscut in the panel requires advance of the entries and connecting them via side entries or crosscuts. To advance the panel 36 m from the start of one crosscut to the start of the next requires an advance equal to the length of one pillar plus the width of one crosscut plus the widths of two pillars. With 30-m-long, 15-m-wide pillars, the total length of excavation in 36 m of panel advance is 138 m ($3 \times 36 + 2 \times 15$) or 3.8 m of entry per meter of panel advance. Thus, with a linear advance rate of 114 m/d, the panel advance rate becomes 29.7 m/d (114/3.8).

Advance Rate Prediction Based on Cutterhead Design

A whole family of estimation methods that are applicable to both full-face and partial-face machines are based on computer modeling of the cutterhead. These models utilize the following:

- Cutting forces acting on individual bits
- Geometry of the cutterhead
- Geometry of the cutting surface
- Bit to rock contact area, the depth of penetration of each bit
- Composition of normal and rolling/drag forces
- Direction of the bits relative to the cutterhead to calculate the overall resultant forces
- Moments acting on the cutterhead while cutting the rock

The calculated values are then compared to the machine capabilities to see how much production can be anticipated from the given machine configurations. The same models are also used for cutterhead design and design optimization to minimize eccentric forces and moments on the cutterhead for full-face machines and can help in minimizing cutterhead vibration on partial-face machines. An optimized design will reduce SE requirements, increase machine productivity, improve bit life, reduce maintenance, enhance machine utilization, and reduce production costs. Overall, it is a worthwhile practice to review the cutterhead design for a particular machine for each mining application to ensure optimal performance. Further discussion on cutterhead design and optimization can be found in Hekimoglu (1995), Rostami and Ozdemir (1996), Rostami et al. (1998), Rostami (2008), Goktan (1995), Cigla and Ozdemir (2000), and Tiryaki et al. (2001).

TBM Advance Prediction

There are several models available for prediction of the TBM performance in hard-rock excavation. One is known as the Colorado School of Mines (CSM) model, which is based on the cutting forces acting on the disc cutters. The CSM model uses rock compressive strength and tensile strength together with cutter tip width and diameter, cut spacing, and TBM specifications to estimate penetration rate. The TBM advance and penetration rate is a function of applied cutter load, rock strength, and the availability of sufficient machine power to rotate the cutterhead. More detailed information on this TBM performance prediction system can be found in Rostami (2008).

An alternative prognosis system was developed by the Norges Teknisk-Naturvitenskapelige Universitat (Norwegian University of Science and Technology) in Trondheim, Norway. The Norwegian model uses specialized rock indices such as drilling rate index, bit wear index, and cutter life index, in addition to joint spacing and orientation and machine specifications to develop an estimated rate of penetration. A more detailed description of the models and examples can be found in Bruland (2000). Overall, either of these models can typically predict machine performance to within ±15%.

Roadheader Production Estimation

Several advance/penetration-rate prediction formulas have been developed for roadheaders. One example is the following formula developed by Bilgin et al. (1996):

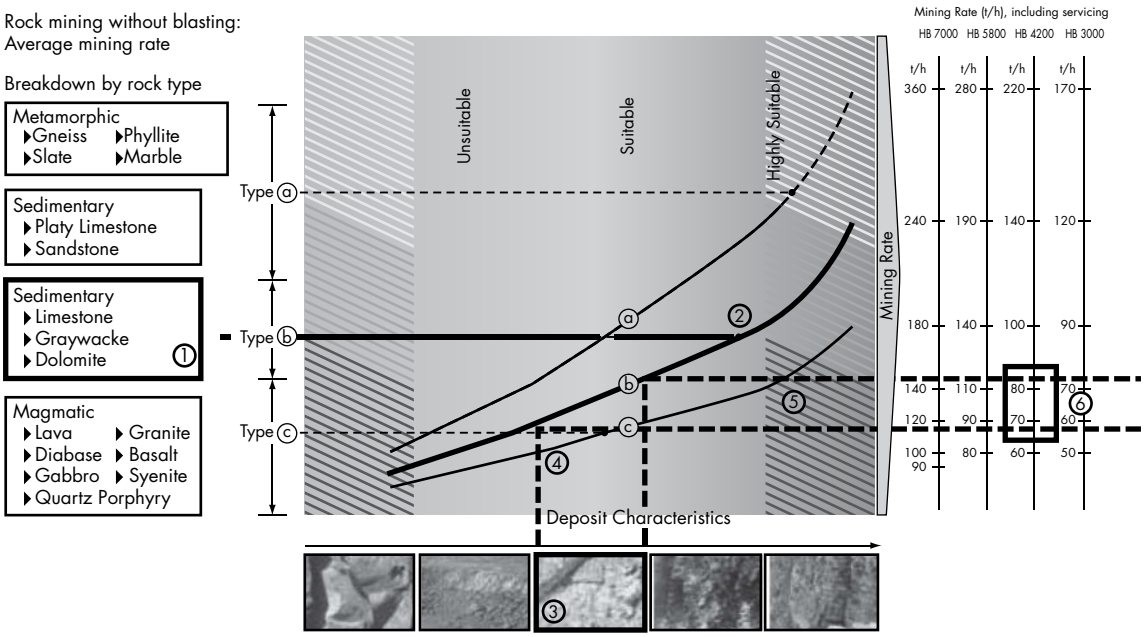
$$\text{ICR} = 0.28\text{HP}\,(0.974)^{\text{RMCI}}$$

$$\text{RMCI} = \sigma_c(\text{RQD}/100)^{2/3}$$

where

ICR = instantaneous cutting rate (m^3/h) or simply machine production rate
HP = machine cutterhead power (hp)
RMCI = rock mass cuttability index, MPa
σ_c = rock compressive strength, MPa
RQD = rock quality designation, %

With the ICR, the machine production rate can be estimated, and using the area of the face and the utilization factor as discussed previously, the linear rate of penetration and the daily advance rate can be calculated as was shown in the examples.



Other performance prediction equations for roadheaders based on compressive strength and specific work required for rock breakage were developed by researchers in Germany (Thuro and Plinninger 1998, 1999). Indeed, roadheader manufacturers generally have their own prediction methods and models.

Impact Hammer Production Rates

Production from impact hammers can be estimated using the chart in Figure 7.1-17.

Estimation of Cutter Life

Cutter and bit life has a direct impact on the economics of employing mechanical excavators. Consequently, the prediction of cutter cost is an important aspect of planning for projects involving hard-rock tunneling. Cutter costs typically range from $0.20 to $0.50 per metric ton for soft-rock mining (e.g., coal, salt, and potash) but could be as high as $1 to $2

Note: Circled numbers represent the steps in a production estimate.

Courtesy of Atlas Copco.

Figure 7.1-17 Impact hammer productivity

per metric ton in roadheader applications in moderately abrasive rocks, $3 to $10 per metric ton for TBM tunneling, and finally in the range of $10 to $20 per metric ton for very hard and abrasive rocks where strawberry cutters are used. A quick estimate of bit life for partial-face machines using conical bits can be found using the following:

$$L_B = 4 \times K_1 \times K_2/\text{CAI}$$

where

L_B = bit life in cubic meters of rock produced per bit change
K_1 = cutterhead speed factor, which varies from 0.8 to 1.2 for high to low cutterhead rotational speeds
K_2 = cooling factor, which varies from 0.9 for dry working condition of the cutterhead to 1.2 where water sprays are used on the head to cool the bits
CAI = Cerchar abrasivity index, which can be simply measured on rock samples in the laboratory

After the volumetric bit life has been estimated, bit cost can be determined from the cost of individual bits and their accessories. A totally different routine can be used to estimate the cost of disc cutters used in tunneling applications. Disc life in linear footage traveled over the face has been shown to have an inverse relationship with the CAI of the rock. That is, the life of a disc in a rock that has twice the CAI is cut by half. The life of the disc also increases linearly with disc diameter and tip width. After the linear footage of disc life is calculated, the overall life of the disc can be determined based on its location on the cutterhead and the number of rotations it can endure, which in turn can be translated to cutter life per hour for a given cutterhead rotational speed. More information on cutter life and cost issues can be found in Deering et al. (1991), Rogers and Roberts (1991), Rostami et al. (1994), Rostami (2001), and Roby et al. (2009).

ADDITIONAL SOURCES OF INFORMATION

A good source of additional information on mechanical excavation are the proceedings of the Rapid Excavation and Tunneling Conferences (RETCs), which are sponsored by SME and the American Society of Civil Engineers (ASCE) and which have been held every two years since 1972. Two journals whose papers are often related to mechanical excavation are the *International Journal of Rock Mechanics, Mining Sciences*, published by Elsevier, and *Rock Mechanics and Rock Engineering*, published by Springer-Verlag Wien. The *Handbook of Mining and Tunneling Machinery* (Stack 1982), which has recently been updated to an interactive CD, is also a great source of information, especially on the background of many of the machines used in the mining and tunneling industry.

Reports and other periodicals from certain government and research organizations are also a good source of information for some of the details on specific tools and applications. Among these are the Reports of Investigations of the Mining Research Group (formerly the U.S. Bureau of Mines) of the National Institute for Occupational Safety and Health (NIOSH) and similar publications by the Commonwealth Scientific and Industrial Research Organisation (CSIRO), Centre for Mining Technology and Equipment (CMTE), and Cooperative Research Centre (CRC) in Australia; the Council for Scientific and Industrial Research (CSIR) in South Africa; Canada Centre for Mineral and Energy Technology (CANMET) in Canada; and SveBeFo in Sweden.

CHAPTER 7.2

Blasthole Drilling

Jamal Rostami and Douglas F. Hambley

INTRODUCTION

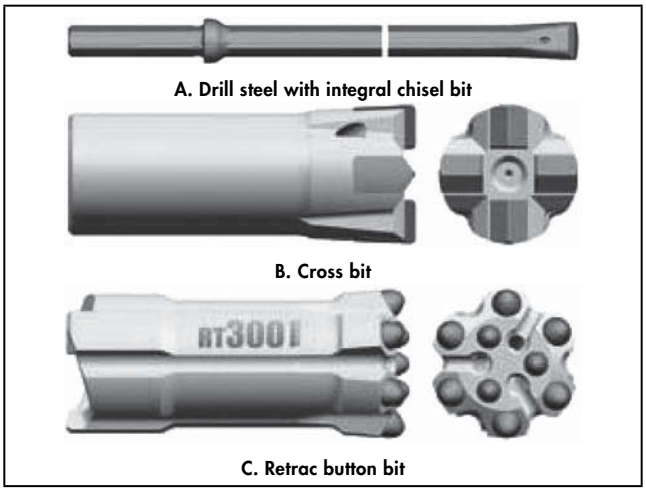
Drilling is an important unit operation in mining. Drilling is required for a variety of mining or mining-related activities including blasting, ground support installation, utility installation, dewatering, exploration, and much more. The term *drilling* is used for smaller-diameter holes, with a few exceptions such as shaft drilling and raise drilling, where larger excavations are created by special machines including cluster drills. This chapter is primarily concerned with mine production. Most boreholes drilled for mine production are blastholes for explosives. However, boreholes drilled for use in solution mining will also be discussed.

The majority of blasthole drilling is performed by two primary methods:

1. Percussive drilling
   - With smaller hole sizes (diameters up to 150 mm [6 in.]), the impact and rotation of the bit used to fracture the rock is transmitted from the drill (top hammer) to the bit through a drill rod or series of drill rods coupled together (referred to as a drill string).
   - With larger hole sizes (diameters from 75 mm to 508 mm [3 to 20 in.]), the hammer is located down-the-hole (DTH) or in-the-hole (ITH) at the bottom of the drill string immediately above the bit, and the impact is transmitted directly to the bit.
2. Rotary drilling
   - Drag bits are used for 75–250 mm (3–10 in.) holes in soft rock.
   - Tricone bits are used for 75–300 mm (3–12 in.) holes in medium and harder rock.
   - Larger roller bits are used for holes larger than 300 mm (12 in.).

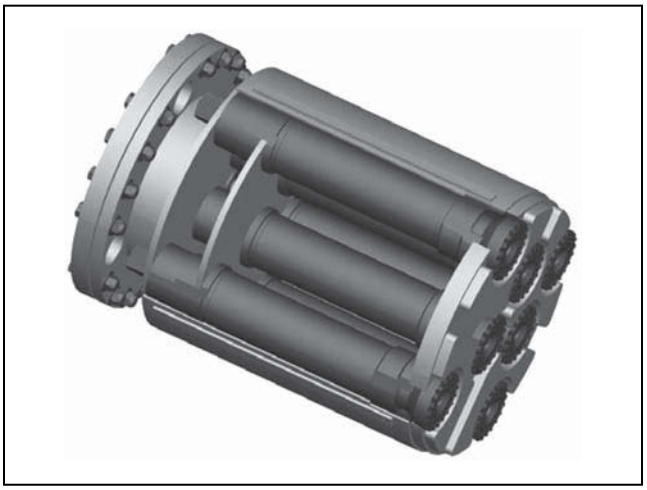
A third drilling method, jet piercing, which was formerly used to drill blastholes in taconites and other very hard, abrasive rocks, has largely been superseded by rotary drilling with tricone bits with tungsten carbide (TC) buttons.

PERCUSSIVE DRILLING



In percussive drilling, the rock is broken by a combination of rotation of the bit and high-frequency percussive impacts transmitted by the bit to the rock. The percussive impact is delivered by either pneumatic or hydraulic pressure. Percussive drills were originally powered by compressed air. Since the mid-1970s, however, hydraulically powered drills have supplanted pneumatic ones, except in the case of small, handheld equipment such as stopers and jackhammers. The advantages of hydraulic drills over pneumatic drills are the fewer moving parts and the significantly higher penetration rates. The depth of percussive drilling with top hammer drills is limited to approximately 76 m (250 ft), due mainly to losses in energy transfer at joints in the drill string. Larger and deeper holes can be achieved using DTH drills.

In DTH drilling, compressed air is supplied through the drill string to drive the hammer, which is located immediately behind the bit. The compressed air activates a hammer that delivers impact directly to the bit. This eliminates the loss of impact energy in joints and is a more efficient mechanism of percussive drilling. Rotation of the bit is provided by the motor at the top and transferred through the drill string. The diameter of the drill string, usually 150 mm (6 in.) or more, helps limit deviation of the hole, which improves drilling accuracy. As an example, at a Canadian uranium mine in 1978–1979, the second author of this chapter supervised the drilling with a DTH drill of 200-mm (8-in.) and 311-mm (12¼-in.) holes to depths of approximately 490 m (1,600 ft), with an error of less than 4.5 m (15 ft) at the target depth.



Percussion Drill Bits

Bits for top hammer percussion drills come in various shapes, as shown in Figure 7.2-1. The drill steel with an integral "chisel" bit and a single TC insert is used with handheld jackhammer (sinker) drills in shaft sinking. More common are the hammer-on or screw-on cross-shaped bits with four chisel-shaped TC inserts. However, in harder rocks especially, the chisel-shaped bits are being replaced with button bits, of

Figure 7.2-2 Cutaway view of a DTH hammer and bit

which the retrac bits are an example. (Retrac bits are designed to facilitate removal of the bit and steel from the hole, which is crucial in soft or squeezing ground.) The shape of the buttons is selected based on the application and the type of rock to be drilled. Longer, pointed inserts are used for softer rock, while shorter, rounded inserts are used in harder rock. A bit can be initially selected using charts from commercial bit manufacturers; however, optimum bit geometry and button shape is usually determined by trial and error at the job site.

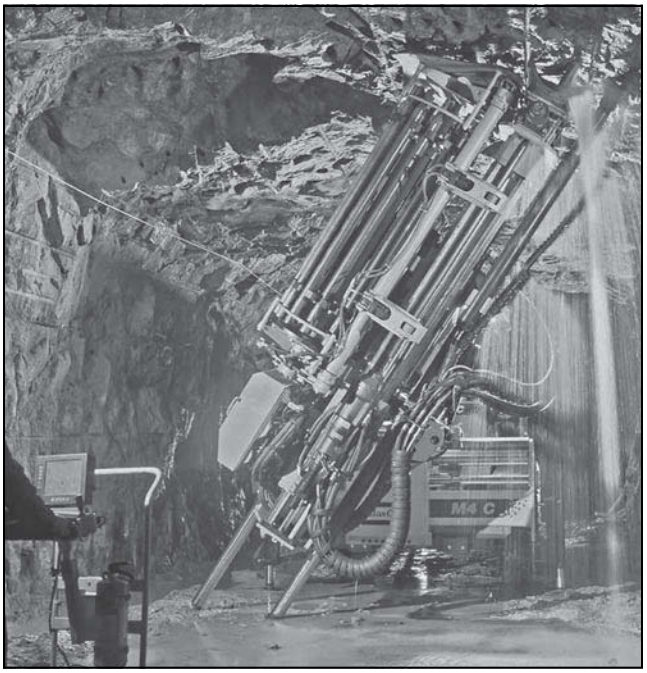
DTH drills were introduced by Ingersoll Rand Company in 1955, and the concept has changed little since then. Figure 7.2-2 shows a cutaway view of a DTH hammer and bit. The weak link in the DTH system is often the plastic foot valve between the piston and the bit, which can break easily if not seated properly.

Cluster drills are extra-large impact drill heads that incorporate a number of DTH hammers and bits. They can be as large as 2 m (6½ ft) in diameter. Depending on the size of the hole, the drills may have various numbers of hammers at the face, with the individual bits receiving impact energy from their individual hammers. The entire drill head is rotated via a drill string so that the hammers will cover the entire face. Cluster drills are often used in very hard and abrasive rocks, where a limited number of holes are planned, or in sinking small, shallow shafts less than 300 m (1,000 ft) deep. Figures 7.2-3 and 7.2-4 show a typical cluster drill.

Percussive Drilling Equipment for Underground Use

Handheld jackleg and stoper drills are lightweight percussive drills powered by compressed air. They are used for drilling small blastholes that are generally 35 mm (1.375 in.) or smaller in diameter. They are typically used to drill holes from 1.8 to 3 m (6 to 10 ft) in length, in 0.6-m (2-ft) increments, as that is the approximate extension of the piston in the air leg; holes up to 3.3 m (12 ft) long can be drilled by a skilled driller. Advance rates are generally inversely proportional to the rock strength and the cross-sectional area of the drill hole. Typical drilling rates for handheld drills range from 0.3 to 0.5 m/min (1 to 1.7 ft/min), depending on the rock mass properties.

Drilling rigs for underground mining applications can be divided into face drilling and production (or long-hole) drilling rigs. Face drilling is performed by mobile rigs equipped with drills mounted on one boom or multiple booms. A two-boom jumbo is shown in Figure 7.2-5. The number of booms and drills depends on the opening dimensions and rock mass properties, the number of holes to be drilled per blast round, and the number of faces to be drilled in a shift. In hard rock metal mining, two-boom or three-boom jumbos are used, whereas in limestone mining, two- or single-boom drill jumbos are common. Hole diameters typically range from 35 mm to 51 mm (1⅜ to 2 in.) with the exception of the reliever holes used in burn cuts, which are somewhat larger. Drill feeds are typically 3.7 to 4.3 m (12 to 14 ft); however, drill feeds of up to 6.4 m (21 ft) are available. Drill jumbos were historically powered by compressed air. Since the late 1970s, however, electric/hydraulic and diesel/hydraulic units have almost completely supplanted the older pneumatic (compressed air) units because of the much faster penetration rates that are achievable with the larger, more powerful hydraulic drills.



Ring-drilling production drills are used in underground metal mines to drill the long inclined or vertical blastholes (typically >6.1 m [20 ft] long) used in sublevel stoping, sublevel caving, and vertical crater retreat mining. Figure 7.2-6

Figure 7.2-6 Typical ring-drilling production drill for underground metal mining

shows a typical production drill unit in operation drilling an inclined uphole. In such operations, the drilling operation may include both long production blastholes and ground support installation (primarily cable bolts). To ensure good fragmentation, it is imperative for these holes to have the correct length and direction. To achieve this, it must be possible to easily rotate the drill boom to various positions, maintain the proper hole alignment, and minimize the deviation from the proper location. A bit with a flat or concave front face will create a straighter hole than a bit with a convex front face. Retrac bits with long bit skirts were introduced to improve drilling accuracy and reduce hole deviation. Another method to reduce hole wandering is to use larger-diameter drill strings, whereby the small difference between the diameter of the bit and the drill string limits the amount of bending of the drill string and thus keeps the hole straighter. Because of the need to flush drill cuttings from the borehole, the drill string on a noncoring drill cannot be the same diameter as the bit.

For upholes, drills often use an ITH drilling system that delivers the impact directly to the bit. Combined with the larger-diameter drill tube, this allows for much higher accuracy and lower deviation. For example, in a hole that is 30 m (100 ft) long, drill-hole deviation may be as much as 3 m (10 ft), or 10%, when a top hammer and a conventional rod and bit are used. When the same drill is used with a retrac bit and guide tube behind the bit, the deviation can be reduced to 1.5 m (5 ft), or 5%. With an ITH hammer, however, that deviation can be reduced to 0.5 m (1.7 ft), or 1.7%. For very long holes, a stabilizer/reamer behind the ITH hammer will reduce deviation even further.

For shaft sinking applications, specialized jumbo drills can be used. Shaft drill jumbos use the same drilling equipment and bits as other drilling rigs—the only difference is that instead of a drill carriage, they are mounted on a work platform that hangs on a set of ropes. The jumbo is lowered

Source: Atlas Copco 2010c.
Figure 7.2-7 Crawler-mounted top hammer percussive surface drill

to drill at the face and raised a safe distance above the face to minimize damage from flyrock from the blast.

Typical hole diameters for production drilling with regular top hammer systems range from 50 to 100 mm (2 to 4 in.); with the ITH system, the range is from 100 to 254 mm (4 to 10 in.). The drill string diameter for regular rods varies from 38 to 51 mm (1½ to 2 in.), and the lengths of individual drill rods typically range from 1.2 to 1.8 m (4 to 6 ft), but can be up to 3.0 m (10 ft). For tube drilling in conjunction with ITH, drilling rods range from 45 to 87 mm (1¾ to 3½ in.) in diameter and from 1.5 to 3.6 m (5 to 12 ft) in length. (With ring drilling, the length of the rod is constrained by the height and width of the mine opening.)

Penetration rate is a function of the impact energy imparted to the bit, frequency of impacts, feed pressure, rotational speed, drill bit type, and rock mass properties. A typical drill unit is capable of delivering 10 to 25 kW of energy to the drill string with an impact frequency between 20 and 70 Hz (impacts per second). The drill rotational speed ranges from 0 to about 100 rpm, with the maximum for a given hole size defined by an angular speed at the bit perimeter of approximately 0.4 m/s (1.4 ft/s). Depending on the rock mass properties, penetration rates of 0.5–2.5 m/min (1.6–8 ft/min) can be achieved. It should be noted here that the penetration rates given previously in this paragraph do not account for the time required to retract the drill from a hole, reposition the boom, and collar a new hole, which can take from 30–60 seconds per hole, depending on the type of equipment.

For the sizes of blastholes normally encountered underground (35–100 mm [1⅜–4 in.]), jointing doesn't usually affect the ability to drill blastholes unless the rock is very closely jointed, as in a shear zone, or the drill hole is in the zone of back break behind the previous blast in the case of benching. Hence, other things being equal, the penetration rate in underground blastholes can be considered to vary inversely with the rock strength.

Percussive Drilling Equipment for Surface Use

Drilling equipment for surface mining applications can be categorized into two classes—percussive drills for small to medium-sized holes of up to 200 mm (8 in.) and rotary drills for larger sized holes of up to 450 mm (18 in.). Surface drilling units are generally crawler mounted. Older percussive drills (known as *air tracks*) may use compressed air as their power source; however, newer machines use hydraulic drills and are diesel powered. Percussive drilling for surface blasting typically uses holes ranging from 89 to 150 mm (3½ to 6 in.). Both top hammer and DTH drills are used. Figure 7.2-7 shows a crawler-mounted, surface percussive drill.

The lengths of drill rods used in surface drilling are selected to minimize the time for adding or removing the rods. Typical drill rods for percussive surface drilling range from 50 to 150 mm (2 to 6 in.) in diameter, and from 4 to 6 m (13 to 20 ft) long. The weight loading on the bits ranges from 1 to 4 t (1.1 to 4.4 st). Drilling rates for typical surface drills vary from 2 to 80 m/h (6 to 240 ft/h). They increase with increased power of the rig, and decrease with increasing hole diameter and rock mass strength.

Small, handheld drilling equipment has all but disappeared from surface mining applications, except for breaking oversize boulders or drilling sinking cuts for starting a bench in very inaccessible places in the mine. Most surface mines use impact hammers for breaking large or oversized boulders to avoid secondary blasting.

Percussive Drilling Penetration Rate

Typical penetration rates for various sizes and types of percussive drills are presented in Table 7.2-1.

ROTARY DRILLING

With the exception of special applications that use cluster drills, larger holes are typically drilled by rotary drilling. A typical rotary drilling rig used in surface mining is presented in Figure 7.2-8. With rotary drilling, the drill bit is rotated by applying torque at the end of the drill string, which results in removal of chips from the face of the hole. Power for bit rotation and penetration is either diesel or electric.

Since their introduction in the early 1900s by the Hughes Tool Company, tricone bits have been the traditional type of bits used in rotary drilling. They remain the most popular bits for blastholes ranging from 150 to 444 mm (6 to 17½ in.) in

Table 7.2-1 Comparison of different percussive drilling systems and their production rates

Drilling Method	Range of Diameter, mm	Typical Depth, m	Typical Drilling Rate, m/h*	Accuracy, % or cm/m	Application
Top hammer pneumatic jackleg	25–50	<4	60	2–5	Used in small tunnel and drift development, small-scale stoping, surface operations as starter, shallow trenching, bolt installation, etc.
Jumbo	37–100	4–10	100–200	1–3	Tunneling, stoping, fan drilling, bolt installation, and probe drilling
Surface crawler-mounted drills	50–150	5–30	20–150	1–3	Surface and bench drilling
Top hammer hydraulic jumbo drills	37–125	4–20	30–120	2–3	Tunneling, stoping, fan drilling, bolt installation, and probe drilling
Down-the-hole	75–150	10–50	20–80	3–5	Surface and bench drilling

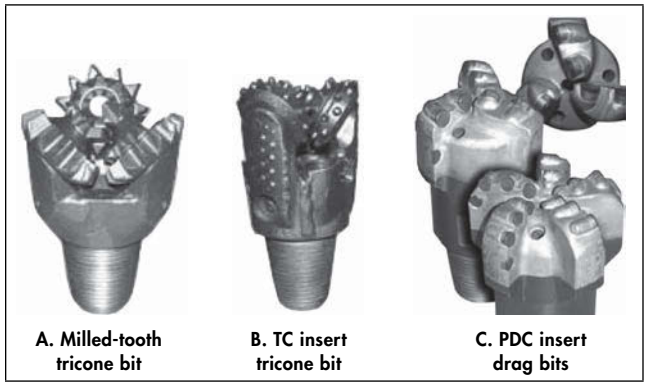
*Drilling rates are for actual drilling and do not include time for drill retraction, boom relocation, collaring, etc. Drilling rates decrease as rock mass strength increases and may increase or decrease depending on the number and orientation of joints/blocks.

diameter. Drag-type bits have gained an increasing share of the market since the introduction of polycrystalline diamond compact (PDC) bits in 1976 (Baker Hughes 2008). PDC drag bits are more expensive than tricone bits, but for relatively deep holes, the time saved due to longer intervals between bit changes may justify the price.

Bit selection is based on hole size and depth, rock type, and operational requirements. Sources of information to guide selection of the proper bit include manufacturers such as Atlas Copco and Sandvik for percussive drill bits, and Smith International and Baker Hughes for tricone and drag bits. Figure 7.2-9 shows typical drag and tricone bits used in rotary drilling. The weight loading on the bits ranges from 10 to 74 t (11 to 81.6 st).

The rate of advance for rotary drilling is a function of the rate of rotation, bit diameter, weight on the bit, and rock mass properties, and is well predicted by the following empirical equation (Calder 1973):

$$P = (61 - 28 \log_{10} S_c)\, W\, R/(250\, D) \qquad (7.2\text{-}1)$$



where
P = penetration rate (ft/h)
S_c = rock compressive strength (thousands lb/in.^{2})
W = pulldown weight of drill (thousand lb)
R = drill rotary speed (rpm)
D = hole diameter (in.)

In metric units, Equation 7.2-1 becomes

$$P\,(214 - 98 \log_{10} (0.145\, S_c))\, W\, R/(250\, D) \qquad (7.2\text{-}2)$$

Figure 7.2-9 Three types of rotary drill bits

where
P = penetration rate (m/h)
S_c = rock compressive strength (MPa)
W = pulldown weight of drill (t)
R = drill rotary speed (rpm)
D = hole diameter (mm)

Table 7.2-2 provides a general guide to surface blasthole drill productivity in various rock types. It is assumed that the work is performed on a reasonably prepared bench and includes the following operations:

- Moving the drill from prior hole to next hole location
- Jacking/leveling the drill
- Aligning the mast/feed for plumb or desired angle orientation
- Collaring and advancing the first rod
- Adding additional rods and advancing them until the required hole depth is reached
- Tripping out the drill string until it is clear of the hole
- Checking the hole/collar for depth/condition
- Retracting the jacks and making the drill ready to tram

Table 7.2-2 Generalized production rate of drilling units in surface mining

Drilling Conditions	Soft Rock	Medium Soft Rock	Medium Hard Rock	Hard Rock
Rock strength, MPa	70–100	100–175	175–225	225–300
Rock strength, 1,000 psi	10–15	15–25	25–35	35–45
Rock fabric condition	**Drilling rate, m/h***			
Stable, uniformly competent ground conditions	55	33.5	30.5	24.5
Competent rock, fractured collar zone (top 0.6 to 1.2 m of bench)	49.5	30	27.5	22
Rock with closed joints, fractured collar zone (top 0.6 to 1.2 m of bench)	42	25.5	23.5	18.5
Rock with open joints, fractured collar zone (top 0.9 to 2.4 m of bench)	33.5	20.5	18.5	15
Heavily jointed, poorly cemented rock, fractured collar zone (top 1.2 to 3 m of bench)	27	16.5	15	12

Courtesy of W. Hissem.
*To obtain drilling rates in feet per hour, multiply by 3.28.

The need for a stable drill setup with the jacks in place and activated cannot be overemphasized. In addition, for long holes, it is important to place centralizers at intervals in the drill string, especially if the rods are significantly smaller in diameter than the drill holes.

DRILL HOLES FOR SOLUTION MINING

Boreholes drilled for solution mining are not production holes in the same sense as blastholes; however, they are production holes in the sense that they are used to either inject or remove the fluid used to dissolve the rock and have a limited life span. Another difference is that after the holes have been advanced to their ultimate depth, they are cased and cemented and fitted with production tubing, a process known as *well completion*. Several different well-completion types are found in solution mines. The Frasch process for solution mining of sulfur utilizes concentric pipes, with hot water injected in one pipe and the sulfur-bearing pregnant solution removed in another.

In solution mining of salt and potash, concentric pipes are used to develop the injection and recovery wells. When the wells have reached the target depth and the sumps have been excavated, mining proceeds laterally until the two wells are connected. At this point, one well is converted to an injection well and the other becomes the recovery well.

Wells used for solution mining are generally drilled using oilfield equipment and mud-rotary drilling techniques. As with oil and gas drilling, selection of the proper chemistry and density of the mud is important. In evaporite zones, the saturated saline brines used for mud in normal oilfield drilling will dissolve potash minerals and should be replaced with oil-based invert mud. The outside diameter of solution mine wells typically ranges from 219 to 346 mm (8⅝ to 13⅝ in.) and depends on the completion configuration and tubing diameters required to transport the fluids.

NEW DEVELOPMENTS IN PRODUCTION DRILLING

The most important advance in drilling equipment since 1990 has been the development of computer-controlled drilling systems. These systems automatically locate and collar the holes, based on a preprogrammed blast round design, and incorporate real-time monitoring and optimization of the drilling. In surface mining, drill rigs have been fitted with Global Positioning Satellite systems, allowing for better control of the drill-hole locations.

Drills have been fitted with computer control systems that allow for optimization of drilling parameters such as feed rate, weight on bit, and torque to achieve the highest possible drilling rates. These systems allow for uploading of the drilling pattern into their computer via storage devices or, more recently, via wireless communication.

In underground mining, multiboom jumbo drills can be programmed to drill the desired blasthole patterns automatically, through coordination with an automated surveying and guidance system, and simultaneously monitor the drilling parameters and optimize the control parameters. Interfaces also exist that allow for ground characterization while drilling by comparing the current drilling rates and other parameters with stored data for drilling in similar rock types (Atlas Copco 2004; Schunnesson 1998; E. Tanner, personal communication). In this manner, the instrumentation system can provide an estimate of the rock properties.

Directional drilling has also made significant progress and is used with high speed and an advanced degree of accuracy for applications in oil well drilling, coal mine degasification, as well as civil engineering. Direction changes are effected using a bent sub together with a downhole mud motor drive unit to rotate the bits. The mud motor drive works in conjunction with rotary bits and receives the thrust force and torque reaction from the drill string, which in this case does not rotate.

Coil tubing, where the drill string is rolled on a reel and dispensed rapidly as needed, has been used extensively in oil/gas well drilling to eliminate the need for breaking and assembling the drill steels. This technique is only possible with mud motors, since there is no need to rotate the drill string. These systems are capable of making bends with radii as tight as 6–10 m (20–30 ft) in holes 75–100 mm (3–4 in.) in diameter. Because of this capability, coil tubing is commonly employed on workover rigs used to rehabilitate wells used for solution mining and oil production.

CHAPTER 7.3

Explosives and Blasting

Braden Lusk and Paul Worsey

INTRODUCTION

Noise, dust, and vibrations created by blasting are objectionable to many in our modern society; however, blasting is generally necessary to break large volumes of rock, especially if the rock is medium to high strength. An indication of the importance of blasting is that more than 1 billion kg of explosives are used annually in Australia and 3 billion kg in the United States for rock breakage, more than 85% of which is used in the mining industry. Explosives are the first choice of mining engineers for primary fragmentation and will continue to be so for the foreseeable future.

The blasting industry saw substantial changes since 1985, with many traditional techniques now verging on obsolescence while the explosives themselves have changed dramatically. Since 2000, the use of emulsions and ANFO (ammonium nitrate and fuel oil)/emulsion blends has expanded to meet the needs of almost every mining and construction situation. This is linked with the development of a full understanding of emulsion systems and their limitations and with the development of new techniques that allowed these systems to be optimally used.

This chapter concentrates on modern blasting techniques; explosives and initiation systems; concepts of fracturing and fragmentation; basic blast design for surface and underground mining; common misconceptions concerning blasting; estimation of blasting costs; description and control of blast effects; and trends, automation, and the future of blasting. The environmental effects of blasting and their control are discussed in depth in Chapter 16.3.

EXPLOSIVE AND INITIATION SYSTEM CLASSIFICATIONS

Primary and secondary explosives are distinguished based on their sensitivity to impact, heat, electrostatic shock, and friction. Secondary explosives normally require at least a primary explosive for initiation, whereas primary explosives are used as initiators. Nobel's original design for a detonator utilized mercury fulminate, a primary explosive, for successful and repeatable detonation of dynamite. Most modern detonators still employ primary explosives as the initiator for the base charge (a secondary explosive), which is usually pentaerythritol tetranitrate (PETN). Most commercial detonators use lead azide or diazodinitrophenol as the primary explosive in the detonator; however, other primary explosives include mercury fulminate, lead styphnate, and tetracene. Some manufacturers are now inserting PETN into a stainless-steel delay element directly against the pyrotechnic compounds that burn to create the delay timing. In this confined condition, the PETN can detonate without the use of primary explosives.

Classification of Explosives

Classifications of practical importance to mining engineers include the basic separation of types of explosives and their classification by regulatory agencies, which are represented in each state and territory, for commercial use in the mining industry.

An explosive is defined as a compound or a mixture of compounds, which, when initiated by heat, impact, friction, or shock, undergoes a rapid decomposition, releasing tremendous amounts of energy in the form of heat, gas, and shock. To define the different classifications used by regulatory agencies, an understanding of the distinction between detonation and deflagration is required. Detonation occurs when the rate of reaction in the explosive product exceeds the speed of sound (sonic velocity) in the product, thus creating a shockwave. Detonation velocities for commercial explosives range from 1,500 to 7,830 m/s, which is much higher than the sonic velocities. Deflagration is a process where the reaction occurs at rates much lower than the sonic velocity of the explosive material, so that no shock (primary pressure wave) is produced within the explosive material.

Regulatory authorities classify explosives into the three groups shown in Table 7.3-1. The distinction between high and low explosives by regulatory authorities closely follows the scientific definition; that is, high explosives detonate and low explosives deflagrate. Regulatory authorities identify a third explosive classification, blasting agents, in defining explosive storage requirements. Most blasting agents are capable of

Braden Lusk, Assistant Professor, Mining Engineering Department, University of Kentucky, Lexington, Kentucky, USA
Paul Worsey, Professor, Mining and Nuclear Engineering Department, Missouri University of Science and Technology, Rolla, Missouri, USA

Table 7.3-1 Regulatory authorities' classifications and definitions

Classification	Definition
High explosives	Explosive materials that can be caused to detonate by means of a blasting cap when unconfined (e.g., dynamite)
Low explosives	Explosive materials that can be caused to deflagrate when confined (e.g., black powder, safety fuses, igniter cords, fuse lighters, and "display fireworks")
Blasting agents	Materials that can be detonated but are not a detonator (e.g., ANFO and certain water gels)

Source: Adapted from CFR 2009.

detonation; however, regulatory authorities reserve a separate classification for these explosive products due to a relatively lower sensitivity than other high explosives. Regulatory authorities define blasting agents as explosive products that cannot be detonated by a Number 8 blasting cap. A Number 8 blasting cap is defined as one having 0.4 to 0.45 g of PETN base charge as discussed in the "Classification of Modern Detonators and Initiation Systems" section. In the mining and blasting industries, an explosive product is termed *detonator sensitive* if it can be detonated by a Number 8 test detonator. According to this definition, blasting agents are not "cap sensitive." The regulatory authorities' classification in Table 7.3-1 determines the requirements for the storage of explosives on-site.

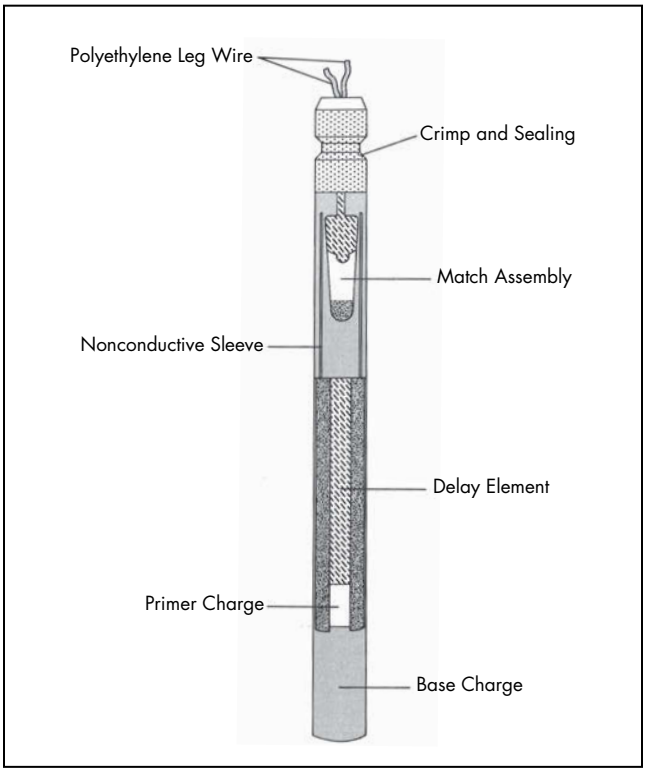
The transport classification is another important explosives classification system that is useful to mining engineers. This classification is primarily used for the transportation of explosives, but certain aspects of it are used by the regulatory authorities for regulation of explosives storage. The transport regulations classify explosives as Class 1 Hazardous Materials (CFR 2008). Class 1 is subdivided into six subclasses, 1.1 through 1.6, from most sensitive to least sensitive, respectively. The transport hazard classification is used for placarding vehicles that transport explosives (and other hazardous materials) on public roads and highways. The mining industry generally uses products from Subclasses 1.1, 1.4, and 1.5. Table 7.3-2 presents the transport classifications for explosives and examples of each class. In addition to the six subclasses, explosives are further separated into different compatibility groups identified by letters following the subclass number. The classification systems are changed periodically as new products emerge and as changes within the industry take place.

The classifications described in Table 7.3-2 are established by the respective regulatory agencies to guide policies in regard to storage and transportation of explosives. The classifications are also useful in the application of explosives. For example, the classifications can be useful for the selection of products for priming blastholes. A majority of mining operations use blasting agents (Subclass 1.5) for production blasting. Blasting agents require high explosive (Subclass 1.1) boosters to function at an optimum level because they are not detonator sensitive. Manufacturers also provide product technical information that includes minimum priming recommendations. This information will be the most reliable source for primer selection. Several options, ranging from dynamites to pentolite cast boosters, are available for priming. When a booster is combined with a detonator, it becomes a primer. Several regulatory authorities and Mine Safety and Health Act regulations concern the proper use, creation, transportation, and storage of primers. Note, especially, that primers are not to be prepared until they are ready to be placed in the blasthole.

Table 7.3-2 Department of Transportation's classification of explosives

Subclass	Definition of Subclass	Examples
1.1	Explosives with a mass explosion hazard	High explosives, boosters, dynamite, TNT, C4
1.2	Explosives with a projection hazard	Ammunition
1.3	Explosives with a fire hazard and a minor blast hazard or a minor projection hazard, but not both	Commercial (display) fireworks
1.4	Explosives with no significant blast hazard; effects largely confined to the package	Specially packaged explosives for prevention of mass detonation (e.g., packaged detonators)
1.5	Very insensitive explosives; mass explosion hazard but little probability of initiation during transport	Blasting agents such as ANFO and emulsions
1.6	Extremely insensitive articles with no mass explosion hazard	None at this point

Source: Adapted from CFR 2008.



Explosives can also be classified according to their packaging: cartridge versus bulk. Cartridge explosives must be smaller in diameter than the hole. Therefore, until tamped, they will not fill the hole. In contrast, bulk explosives come in bulk containers and are less labor intensive during loading. They also fill the entire hole diameter, making them more efficient to use. The majority of explosives that are used in mining today are bulk explosives, which are blasting agents such as ANFO, emulsions, and blends of ANFO and emulsion. In 2008, dynamite represented only 0.5% of all the explosives used in the United States, and there was only one remaining dynamite manufacturing plant in North America.

Classification of Modern Detonators and Initiation Systems

Three basic types of initiation systems are available for use in commercial blasting: electric, nonelectric, and electronic. There are many variations of each type of system, but all modern initiation systems fall into at least one of these categories. For many years, electric detonators dominated the industry, and cap-and-fuse initiators for many years before that. Electric detonators were used because of their availability and reliability. Other systems were not used as extensively until the introduction of shock-tube initiators. By 1990, shock-tube initiation systems became the majority of initiation products in use. Throughout the 1990s and 2000s, shock-tube initiation systems gained progressively more market share due mostly to their immunity to accidental initiation caused by two-way radio transmissions and stray current sources. With mining operations using radio dispatch systems for hauling and loading cycles, the need to turn off two-way radios in the presence of electric initiation systems was not acceptable. The three major types of initiation systems are discussed as follows.

Electric

Electric products were versatile and allowed for significant advances in blast design through the use of in-hole delays. There is a large variety of electric detonators, but the commercial

Source: Atlas Powder Company 1987.

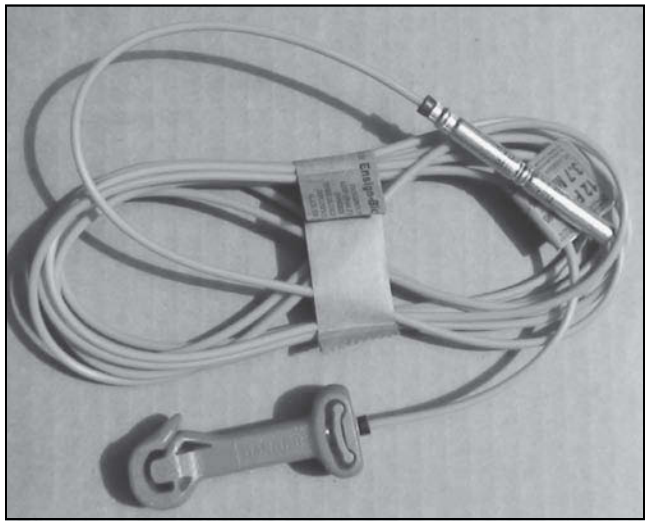


Figure 7.3-1 Inner workings of a typical electric detonator

blasting industry typically utilizes low-firing-current electric detonators. These detonators are initiated when a small amount of current is introduced to a bridge wire within the detonator shell via two leg wires. This bridge wire heats up and ignites a pyrotechnic match head or bridge wire embedded in a pyrotechnic compound. The match head ignites the delay element, which is manufactured to burn for a specific amount of time prior to reaching the primer charge consisting of a primary explosive such as lead azide and a base charge usually made of PETN. Figure 7.3-1 shows the inner workings of an electric detonator as described in this chapter.

Sequential timers were created for use with electric detonators to increase the number of design options available for delaying blastholes. For electric blasting caps, sequential timers allowed for several series of electric delay detonators to be purposefully staggered by electronics within the sequential timer. This allowed for many design options while still only using a minimal amount of individual delay caps. Sequential timers are no longer used extensively, but the idea of programmable detonators probably began with these devices.

Nonelectric

There are many types of initiation systems that could be considered nonelectric: detonating-cord (usually referred to as "det-cord"), cap and fuse, and nonelectric shock-tube detonators. The shock-tube type detonator is now the most common form of nonelectric initiation system. Nonelectric shock-tube detonators are responsible for the demise of electric detonators as the preferred initiation system. Although they are sometimes used in conjunction with a detonating cord, the majority of mining operations using nonelectric detonators utilize a combination of in-hole and surface delays.

Courtesy of Ensign Bickford.

Figure 7.3-2 An EZDet nonelectric detonator. The narrow metal cylinder (top) is the in-hole cap and the plastic connector (bottom) is the surface delay.

There are two common ways to use shock-tube systems. One method uses downhole delays that are completely separate from the surface delay detonators. Nonelectric shock-tube detonators are also produced in a dual-delay system where the downhole delay and the surface delay are attached at opposite ends of a single shock tube (Figure 7.3-2). These provide a similar design advantage to sequential timers. They are offered by all of the major manufacturers for use in blasting. The concept consists of a 200-to-500-ms delay in the hole with a much shorter (17 to 109 ms) surface delay between holes. The surface delay detonators are simply daisy-chained, which allows for a much larger number of delays than with single-delay detonators.

Electronic

Electronic detonators utilize microchip technology to provide delays for blast designs. Most electronic detonators consist of wires, a detonator shell that looks similar to electric and nonelectric detonators, a microchip, a capacitor or capacitors, and a primer charge/base charge similar to electric and nonelectric detonators. In most cases, the detonators will communicate with a logger/machine, and individual detonators can be checked prior to firing. At firing time, the blasting machine sends out a code to initiate the electronic timing devices within the detonators. When the detonators reach their programmed time, the electronics within them transfer the remaining current to the fuse head after which the process is similar to an electric detonator. The difference between electronic and electric detonators is the replacement of the pyrotechnic-delay element by a microchip. This allows for much greater accuracy in firing times. Unlike electric detonators, there can be a great deal of variation on how different manufacturers' systems function.

System Comparisons

Electric detonators and nonelectric shock-tube detonators are manufactured with several delay times. All major delay detonator manufacturers have a specified series of delay timings that they produce. The delay series can be generally separated

into the following two groups: millisecond (MS) series and long-period (LP) series. The MS series usually consists of 20 to 40 delay detonators having a separation of 25 ms between each two successive delay periods. Available are No. 0 delay (0 ms or instantaneous) through No. 20 (500-ms delay). The delay interval is approximately 25 ms but may vary by up to ±10 ms or more. With LP series detonators, most manufacturers have approximately 20 LP delays with varying times between delay numbers. Generally, the time between delay numbers for LP systems is between 200 and 400 ms but varies with the manufacturer. Current product information should be sought prior to making design decisions.

Programmable electronic detonators provide the most flexibility in delay design. Most systems allow for a large number of detonators to be programmed in a circuit to fire at any time between zero and 10 to 20 seconds. System capabilities vary, but most manufacturers claim accuracies to ±1 ms or ±0.1%, whichever is greater. This is a substantial improvement over conventional pyrotechnic detonators, both electric and nonelectric, which are usually only accurate to within ±5%. These accuracy figures are approximate and may not apply to all available systems; however, in general, electronics are at least an order of magnitude more accurate. The most obvious downside to electronic detonators is their higher cost per unit—although some systems have also displayed higher misfire rates and may be more complex to use than shock-tube alternatives. In some cases, better blasting results, and thus better overall processing costs, outweigh the initial high cost of the individual detonators. Many case studies have been performed to show their overall cost advantages, and their use is steadily growing. Electronic detonators are especially cost-effective in larger-diameter holes, where their added cost represents only a very small portion of the investment in drilling and explosives.

FRACTURING AND FRAGMENTATION

The obvious first question in considering blasting is, Why should one use explosives to break rock? There are two answers: ease of fragmentation (i.e., break the rock to make it easier to dig, load, haul, and crush) and ease of stripping (i.e., move overburden or waste rock overlying a seam by explosive means to reduce the mechanical work required to achieve the same result). Of these, fragmentation is the most important item for many mining operations. However, no two mining operations are identical and neither are their fragmentation requirements, where fragmentation refers to the size distribution of the broken rock within the muckpile.

As a result, a vast range of powder factors is used. The average powder factors for production mining in underground operations overall may be up to about twice that of surface operations, simply because underground workings are by definition more confined, and as a result, oversize material is quite difficult to deal with and displacement of rock into a loose muckpile may require more energy. Oversize material is usually avoided by using a higher powder factor (i.e., the explosives required to break a unit measurement of rock).

An additional item that is often misunderstood is the difference between fragmentation and fracturing. Well-fragmented rock has to be closely fractured and "jumbled up" by the associated movement of a blast, so that it can be easily dug. The movement is essential, and as this movement is in progress, bulking occurs as the chunks (or cubes) of rock are randomly reoriented so that void spaces are developed. The voids between the larger rock fragments make it easier for the teeth of buckets to penetrate and dig. The degree of rock mass bulking after a blast can be as much as 50%, depending on the shape and size distribution of the rock fragments. In stark contrast, soil when dug generally only bulks 10%.

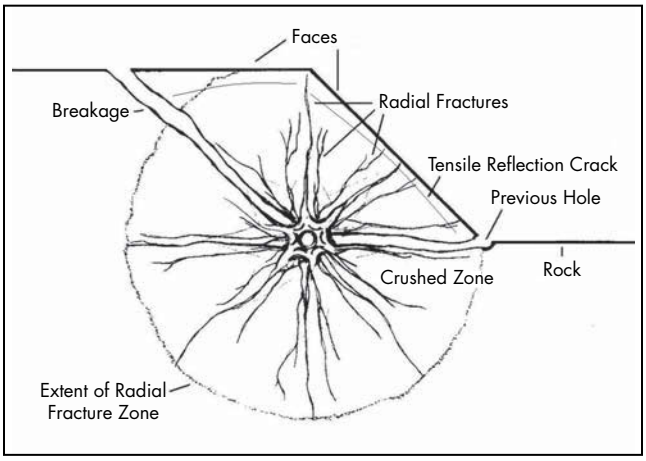

Figure 7.3-3 Processes of rock fracturing during fragmentation

The discontinuities in the rock mass, which includes bedding, jointing, and partings, are the main items that dictate how a rock fragments. The closeness of the separation of these determines the maximum block size in the muckpile. The effect of blasting is to reduce the size distribution of those preblast blocks. In closely jointed ground, there will be little change in the size distribution after blasting, though the rock mass may have been "moved."

The major elements of the fragmentation process include shock, gas production, extension of fractures, and rock mass movement. To start with, the shockwave from the explosive causes the creation of new fractures around the blasthole by the extension of microflaws orientated in a radial direction. Close to the hole there may be an extremely dense zone of small fractures (often referred to as the crushed zone). The wave travels outward, opening up and loosening the existing joint system, and when reflected from a free face, may cause minor tensile spalling. Hot on the heels of the shockwave is the pressurization of the blasthole by the explosion gases. This causes the small fractures around the hole to coalesce and grow due to the created tensile stress field. When these fractures connect with the blasthole, they are opened, and explosion gases are then able to penetrate. As these radial fractures extend, the compression bulbs that are created at their tips cause shorter fractures to slow, making the longer ones dominant. The width of the radial fracture zone caused by the shockwave is extended generally six times by the gas pressure. This is both forward and backward in blasting, preconditioning the rock for the next row of blastholes or the next blast. When the radial fractures reach a free face, major rock movement may occur, as shown in Figure 7.3-3.

The radial fractures may be replaced by a preexisting joint system. The explosion gases then act as a propulsion agent and accelerate the rock forward. This acceleration occurs over a brief period as the size of the initial blasthole is very small, and thus, as the void increases, the gas pressure drops very quickly. As the rock mass moves out it also expands, and this allows the rotation of fragments in the muckpile. Further fragmentation

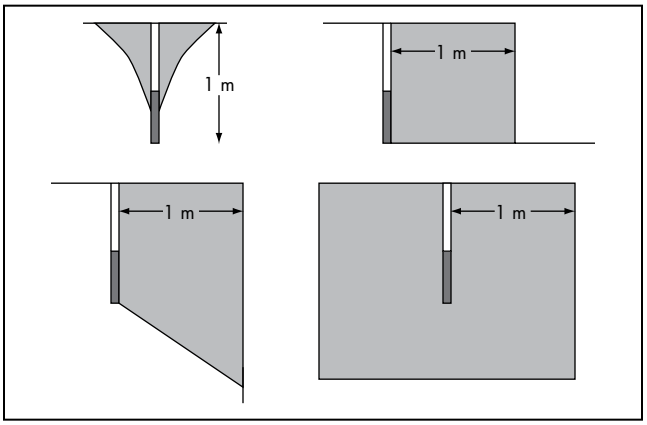

Figure 7.3-4 Effect of increasing degrees of freedom on volume fragmented using identical holes

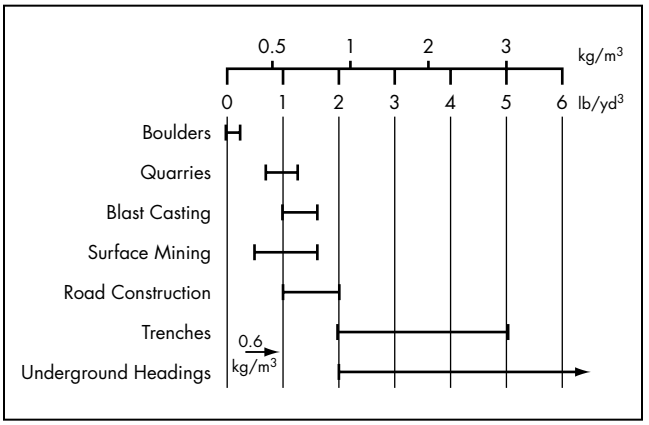

Figure 7.3-5 Typical range of powder factors for different types of blasting

occurs during this process because of the collision of fragments, the grinding of corners, grinding at the interface of the moving muckpile and the floor, and the impact of fragments as they come to rest. In low Young's modulus moderately to highly jointed rocks, significant compression may occur behind the bench during a confined blast, and when the pressure is released, rebound may occur, which can significantly loosen the back of the bench, causing overbreak and large cracks. The fragmentation process is very complex, especially when considering the complexity of geology.

ELEMENTS OF BLAST DESIGN

Importance of Free Faces

In blasting, a free face provides a direction for movement and, thus, a degree of freedom. As the number and extent of free faces located near the blasthole increases, the amount of rock that can be fragmented from that blasthole also increases, as shown in Figure 7.3-4. Because of such geometric considerations, as well as the properties of the rock and discontinuities, proper blast design requires more than simply adopting a reasonable powder factor.

It is simple to see that the easiest means of fragmentation in a repetitive fashion is bench blasting where the holes are parallel to the free face. In most instances, the fact that the face and hole are vertical also enables the easiest method of drilling. Because of this, in the most economical blast designs for both surface and underground, it is best to develop a bench-blasting configuration. The bench is not limited to a vertically down configuration; it can be at any angle (i.e., it is orientated to suit the mining method). Methods that incorporate burns or cratering are now normally only reserved for developing relief (called sinking blasts) for successive bench blasting. Although the term *bench blasting* is generally only used for surface applications, it exists in other forms, with appropriate titles, throughout underground blasting (such as long hole, breasting, and stoping holes) and is the basic production method for both surface and underground blasting.

The aim of good blast design is to produce the desired fragmentation with the minimum of back break and environmental effects such as flyrock, high air blast, and ground vibrations. Flyrock and elevated air-blast levels indicate inadequate confinement, whereas elevated ground vibrations suggest excess confinement. Excessive flyrock, air blast, and ground vibration all indicate inefficient use of explosive energy.

In mining, no single fragment size distribution satisfies every need. For example, in some operations, fine fragmentation is preferable because the rock is eventually going to be ground down to powder, as with copper ore or limestone (for cement). However, in iron ore mining and the quarrying of aggregates, fines (screenings) are usually a less valuable by-product. Also, in large mining operations, larger equipment such as crushers are used, so they can generally handle larger rock than smaller operations.

To get coarser rock, less explosive is used, which means expanding the drill pattern, whereas to get finer rock, more explosives are used, which means a tighter pattern. The amount of explosive used per unit of volume or weight of rock blasted is called the powder factor. Blast design equations and guidelines define the starting point that is designed to provide reasonable, rather than optimum, fragmentation. The equations, although based on different theories and empirical details, yield very similar powder factor results.

The range of powder factors for different types of mining and construction are given in Figure 7.3-5. The range of applications, and thus the range of appropriate powder factors, is large.

Surface Blast Design

The nomenclature used for bench blast design is shown in Figure 7.3-6. The following discussion presents some guidelines for blast design. The guidelines provide initial estimates from which to design a blasting pattern. However, the properties of the rock mass and of the explosive should also be considered. There are guidelines that have been established over the years for blast designs. In the following subsections, guidelines are presented that the authors believe represent common practice.

Hole Diameter and Burden Versus Face Height

This is an important item that is often overlooked. The face-height-to-burden ratio should be at least 3:1 to 4:1 for good fragmentation. Short faces are stiff and resist breakage. Also, the amount of stemming required to seal the hole increases as the face shortens, leaving less room for explosive in the hole, increasing the proportion of the bench interval remote from adjacent explosive columns and the hole utilization and powder factors drop, as illustrated in Figure 7.3-7.

As the face height decreases, because the stemming height is proportional to the hole diameter and burden, the

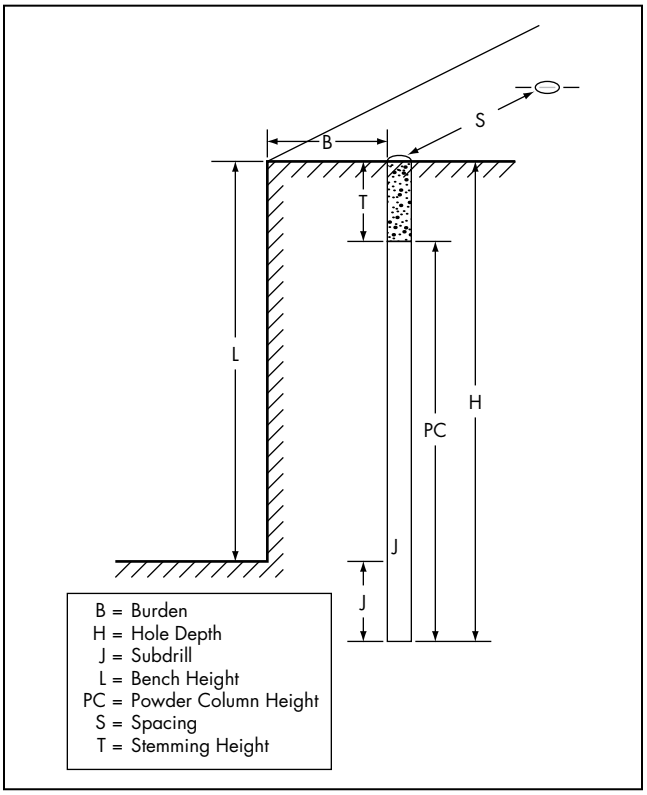

Figure 7.3-6 Nomenclature for bench blast design

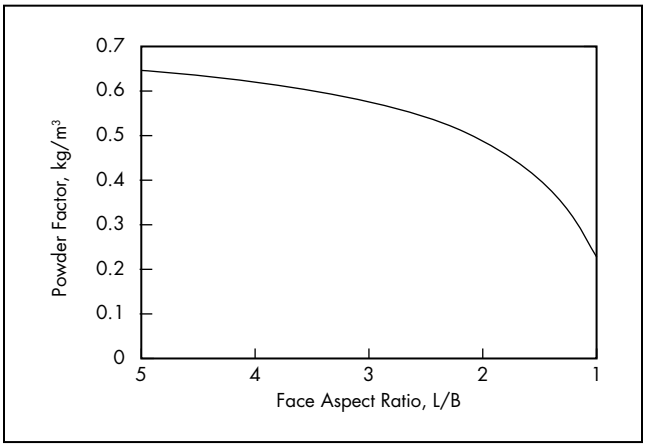

Figure 7.3-7 Effect of face height on powder factor using a constant burden and spacing

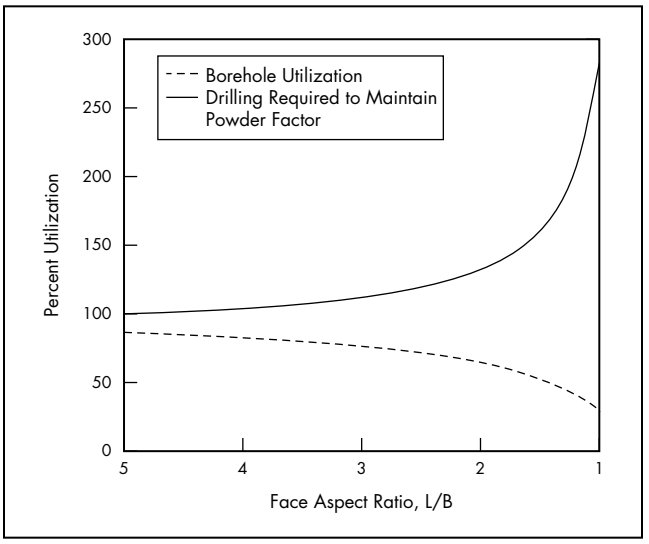

Figure 7.3-8 Effect of face aspect ratios on blasthole utilization and how much extra drilling is needed to maintain powder factor compared to when face height is used

powder column height decreases disproportionally, resulting in reduced borehole utilization (explosive-filled portion). To maintain powder factor, the pattern has to be shrunk, and this requires the drilling of more holes, increasing drilling costs. These concepts are illustrated by Figure 7.3-8.

Hole utilization curves for shots designed using the guidelines are given in Figure 7.3-9, where the upper curve represents holes with subdrilling (metal mining) and the lower curve is holes without subdrilling (limestone quarrying). In many metal mines, ore-body configurations dictate smaller bench heights for ore selection. Strangely, the same inefficient bench heights are often used for large areas and volumes of waste removal where there is no ore, and this does not make sense.

In contrast, when the face height is excessive, drill deviation occurs, which means a variation in the distribution of explosive energy at the bottom of the blastholes. In areas where holes wander excessively away from each other, inadequate breakage will occur, which often leads to pockets of high (or hard) toe. When blastholes come too close to the face, excessive flyrock and air blast can occur (Figure 7.3-10).

A good range for face height is 100 to 120 times the hole diameter. Going to extremes such as 50 or 200 times will most certainly result in problems. The excavation equipment should not dictate the face height unless regulations control the face height.

Burden and Spacing

For bench blasting, most equations produce similar results to the guidelines in Table 7.3-3 for rock in the specific gravity range of 2.2 to 2.8. There are basically two specific gravity divisions for modern bulk explosives. These are 0.8 to 0.87 for ANFO and 0.65 to 1.3 for emulsions and blends. As illustrated in Table 7.3-3, two sets of burden and spacing rules are used that result in a powder factor of approximately 0.6 kg/m^3. These are for rocks of "average strength" and where the required level of fragmentation is medium to coarse.

In bench blasting it is accepted practice that a burden-to-spacing ratio of about 1.15 to 1.4 for bench heights greater than four times the burden should be used on a staggered pattern. The reason for this is that repeatable faces are developed with equal burden on both faces of relief (see Figure 7.3-11).

Subdrilling

Subdrilling is necessary when blasting massive rock where there is no suitable horizontal bedding plane to maintain floor grade. In rocks such as granite, subdrilling is essential to maintain grade, otherwise the floor will rise. The accepted amount of subdrilling is one-third of the burden. Some operations may range from 0.2 to 0.5 times the burden (Morhard et al. 1987), but one-third is a good guideline. Subdrilling can

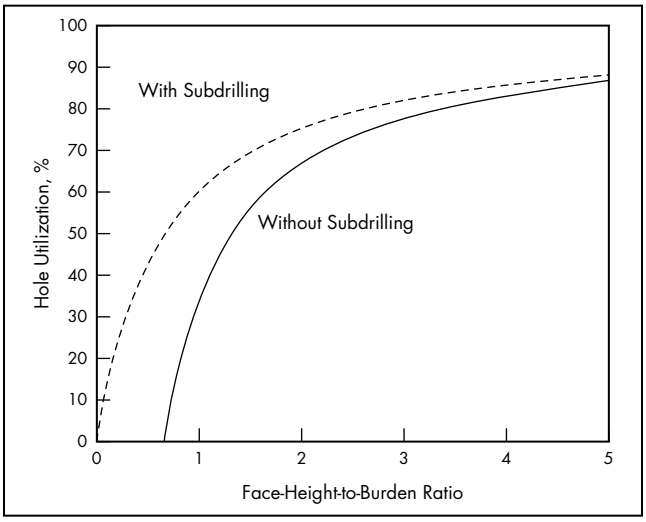

Figure 7.3-9 Hole utilization curves with and without subdrilling

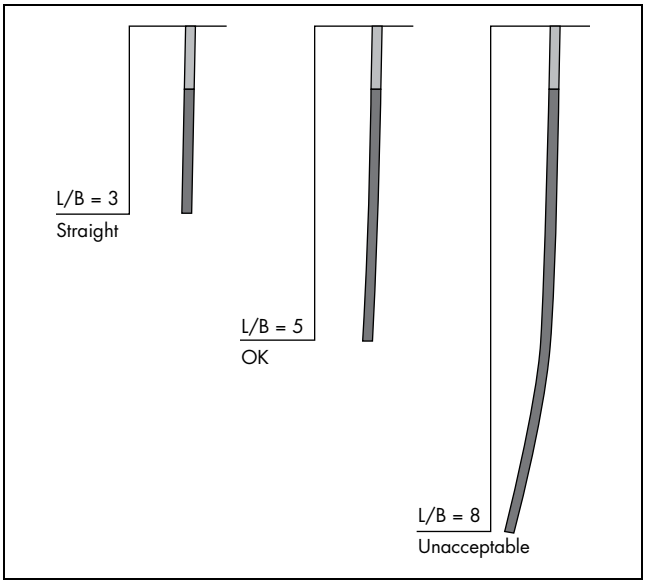

Figure 7.3-10 Effect of drill deviation with increasing face height (deviation is unacceptable with excessive bench height)

Table 7.3-3 Guidelines for burden and spacing as a multiple of hole diameter in bench blasting

	ANFO		Blends and Emulsions	
	Metric	U.S.	Metric	U.S.
Burden	× 25	× 24 (2 ft/in.)	× 30	× 30 (2.5 ft/in.)
Spacing	× 35	× 36 (3 ft/in.)	× 45	× 42 (3 ft/in.)

also be calculated as 5 to 8 times the diameter of the hole. One should beware that excessive subdrilling results in the smashing of the bench below, which makes drilling difficult and generally requires extra stemming to hold this later blast in place. In addition, the explosive energy from excessive subdrilling has nowhere to go, and not only is this energy wasted, but extra ground vibrations are created. The negative effects of subdrilling are best controlled by offsetting holes from one

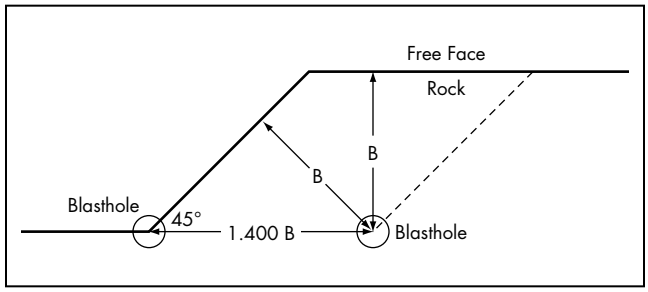

Figure 7.3-11 Plan view of the geometry for a burden-to-spacing ratio of 1.4 (S = 1.4B) showing breakout angle and the burdens for each face being equal

bench by half the spacing and half the burden when laying out the next bench. This hole offset also reduces the risk of drilling into a misfired "butt."

Subdrilling hould not be used in horizontally bedded sediments that have well-defined bedding planes, as these can be used as shear planes at the bottom of the blast to provide easy relief and a smooth floor.

In coal mining when blasting overburden, it is appropriate to use negative subdrilling, where the drill hole stops above the coal to prevent coal loss and excessive fines.

Stemming

Stemming is necessary to confine the explosives column to prevent explosive energy from escaping and reducing the effectiveness of the blast. If the stemming is ejected prematurely, not only is costly energy lost, but also a sonic boom is often generated along with flyrock. Unfortunately, stemming reduces the amount of explosives that can be placed in the hole, thereby, reducing the utilization factor of the hole. For example, with large-diameter blastholes and short benches, hole utilization can be 60% or less, whereas with benches with normal height-to-hole-diameter ratios, the hole utilization is often 85% or more. To minimize the length of a blasthole containing stemming, stemming materials should be carefully chosen for their size and gradation. The optimum stemming material has a diameter of about one-eighth the hole diameter for small- to medium-diameter holes. This is to maximize the potential for interlocking and also to avoid bridging when pouring the material in the hole. For example, a 150-mm (6-in.) hole would call for 19-mm (¾-in.) stemming. Stemming material locks best when it is "clean" (i.e., free of fines) rather than well graded. The guidelines for stemming are

$T = \frac{2}{3}$ B for clean stemming material ⅛ of the hole diameter
$T = \frac{4}{3}$ B for drill cuttings

Based on the above-mentioned relationships, drill cuttings are only half as effective as clean gravel when used as stemming. It is especially important to keep stemming to a minimum for large-diameter holes, as large lengths of face at the top of the blast may otherwise have no explosives to fragment them, and serious oversize (sometimes the size of small houses) may occur.

Powder Column Length

The powder column length is simply the amount of hole left over after subtracting the stemming. The hole utilization is the percentage of the hole used for powder. Normal hole utilization values of 80% or more can be expected.

Decking

Decking is the separation of the explosives column in a blasthole into two or more parts with stemming between them. The thickness of the deck material should be 6 times the hole diameter for dry holes and 12 times the hole diameter for wet holes. Decks are used for the following reasons:

- The first reason is to fill voids so that excessive explosive is not used. Even medium-sized voids can result in the excessive concentration of explosive energy. It is normal to measure the rise of decking in the hole until a normal rise is established and then to reprime and continue loading. In the case of voids, the same in-hole delay is used for each deck. Also a mud seam or other weak spot in the rock column has to be decked through to avoid flyrock.
- The second reason is to reduce the kilograms per delay when blasting close to residential structures to ensure that regulated limits are not exceeded. In this case, the stemming deck is used to divide the explosive column into two smaller decks. A delay (typically 25 ms) is used between decks so that two small "thumps" are provided rather than one large one.
- The third reason is to reduce the amount of explosive in the hole. In this case, air decks are used where an air void is placed either above or below the explosive. This is a way of decreasing the explosive load without the use of excessive stemming, which tends to lead to blocky ground on top of the muckpile and oversize.

Powder Factor

The powder factor is usually determined by taking the amount of rock to be fragmented to grade and dividing it by the weight of explosives used. It can be calculated for each hole or for a complete shot/round. In some mining, the powder factor is often quoted as weight of explosive per unit weight of rock (kilograms per metric ton); however, in certain quarry markets in the United States, the powder factor is quoted in tons per pound, but in construction, the weight of explosive per unit volume of rock is used (kilograms per cubic meter). The difference between construction blasting and mining is that in construction the excavated volume is the quantity of importance, whereas in mining the excavated tonnage of ore, and so forth, is of concern. The volumetric powder factor is also used in mining in connection with contract excavation overburden removal and waste stripping. For normal surface-mining operations, such as quarrying, a powder factor of 0.6 kg/m^3 is a good initial estimate. The weight of explosive, W, per hole is calculated as follows:

$$W = PC \times C_\rho$$

where

PC = powder column height
C_ρ = column density

Column density, C_ρ, is dependent on explosive diameter and explosive density and can be found using a manufacturer's chart or using one the following equations:

$$C_\rho = (D_e^2 \times \rho)/1{,}275 \text{ kg/m}$$

where

D_e = diameter of the explosive
ρ = density of the explosive

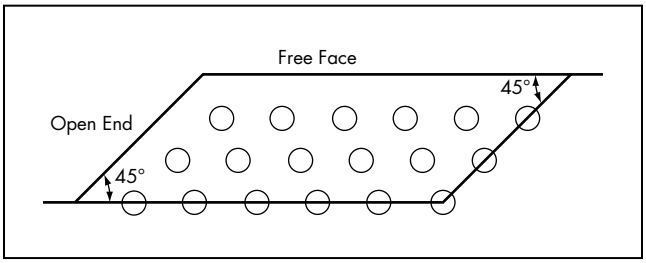

Figure 7.3-12 Staggered pattern (three rows with six holes per row)

Both equations are approximate because the diameter of the drill hole is often larger than the diameter of the drill bit. Also, drill bits wear considerably over their lifetime, and it is not usually possible to measure the diameter of the hole at the depth of the explosive column.

Choice of Patterns

A number of different patterns can be chosen, including square, staggered, en echelon, and diamond. It is normal to use a staggered pattern in bench blasting, firstly, because the hole in the row behind is blasting into more solid rock rather than a weakened pocket and, secondly, because holes tend to break at 45° to the free face, making a square end to a bench almost impossible (Figure 7.3-12). In some cases staggered patterns are avoided where angled holes are utilized. The staggered pattern creates logistical problems with drilling where the drill operator is forced to realign the boom angle rather than backing up perpendicular to the face and drilling subsequent rows with the same angle.

A square pattern is more appropriate for a confined shot, such as sumps used for dewatering the next bench level. A square pattern may also be appropriate in sinking cuts when developing a new level. In construction blasting, a square or rectangular pattern helps maintain straight sidewalls, especially in road cuts.

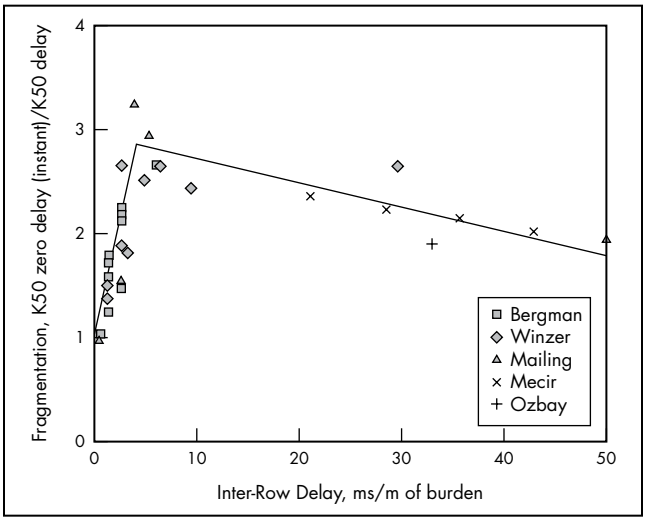
Number of Rows

The number of rows depends on what one wants to achieve. For small production shots, a single row may be appropriate if it is easy to maintain good face profiles. If it is difficult to maintain good face profiles, then multiple-row shots mean fewer drilling and loading issues. In quarry blasting, it is normal to shoot three rows or more, with only special loading consideration necessary for the front row. Multiple-row shots also afford less exposure of workers to highwall falls and failures. If employing more than three rows, the blast starts "piling up on itself," resulting in a high muckpile unless the timing pattern compensates for this. Otherwise to compensate for this, a higher powder factor is required. Excessive rows without the compensation of an increased powder factor often result in excessive back break, especially at the crest of the bench, and a muckpile that may eventually be higher than the original face height. Taking the number of rows to the extreme, one has a trench shot, which requires a powder factor of at least 1.2 kg/m^3 for successful fragmentation and reasonable digability.

Delays

There are two main types of delay in a blast pattern. These are the hole-to-hole (also known as "inter-hole") delay and the row-to-row (or "inter-row") delay. The optimum hole-to-hole

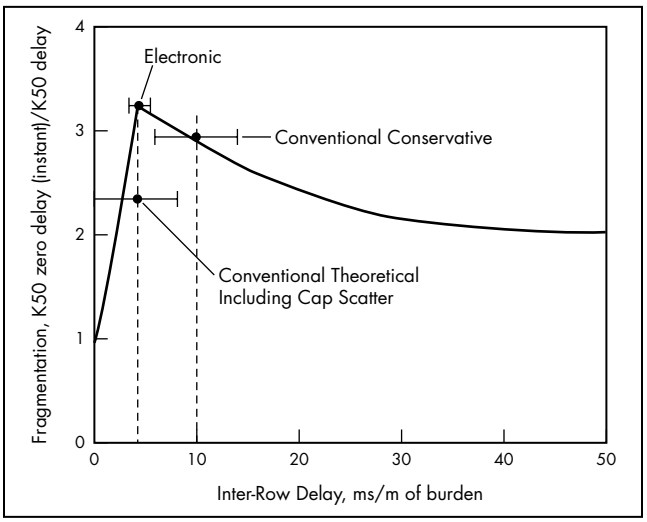
delay for fragmentation has been determined by a number of different researchers, including the U.S. Bureau of Mines (Stagg and Nutting 1987). The general consensus is that the delay is 3 ms/m of burden. However, maximum fragmentation is not always desired. In some cases, maximum throw is of primary importance, such as in blast casting (e.g., the explosive casting of overburden from above a coal seam).



The effect of hole-to-hole delay on fragmentation is shown in Figure 7.3-13, where fragmentation is expressed as the ratio of the median fragment size (K50) for zero delay to that for increased delay between holes. The data were combined from five different sources. As shown in Figure 7.3-13, fragmentation improves up to a delay of approximately 3 ms/m of burden and then gradually worsens.

When using delays, the accuracy of the delay time is also important. As shown in Figure 7.3-14, delay timing with conventional detonators is subject to scatter, and accurate detonation delay times are most likely to be achieved when using electronic detonators. Because of the potential for inaccuracy in detonator timing, it is recommended to use a delay interval within a row larger than the 3 ms/m optimum. Large delay intervals between holes result in reduced fragmentation.

Insufficient delay between holes is also not recommended and generally results in excessive throw (Figure 7.3-15), increased back break/wall damage, and inadequate fragmentation. The firing of neighboring holes together results in splitting of the rock between them and the premature propulsion of the rock mass forward, resulting in poor fragmentation. In blasting, it is normal to use a spacing-to-burden (S/B) ratio of 1.15:1 to 1.4:1, which means that delays are a necessity for fragmentation but a penalty in blast casting where burden and spacing are often reversed to achieve less fragmentation but more throw. The splitting effect is shown in Figure 7.3-16.



The dramatic loss in fragmentation before the "sweet spot" means surplus energy, which is consumed in throw, as shown in Figure 7.3-15.

The row-to-row delay to provide good movement and fragmentation is a minimum of 3 ms/m of burden. As the number of rows increase to more than three, this value should be increased to provide good movement and to reduce back break. Often significant "back splatter" (rock thrown backward on the bench) is a sign of insufficient delay between rows or excessive burden distance.

Application of Basics of Blast Design to Underground Blasting

Underground blasting uses the same principles as surface bench blasting, except that with underground blasting there is less space, and thus oversize cannot be so easily handled. Therefore, with underground blasting it is common to use double the powder factor to ensure fine breakage. Modern underground blasting can be separated into four types: headings, long-hole stopes, mass blasts, and pillar recovery.

Headings

Heading blasting is used for tunnels, development drifts, adits, and room-and-pillar (R&P) mining. Heading blasting has no free face parallel to the blastholes; therefore, it must create one. This is done by separating the blast into two parts: the cut and the main blast. The cut is designed to provide a free face perpendicular to the face to provide relief for the rest of the blast (bench blasting using horizontal holes). These first holes are collectively called the "cut," of which there are the following three principle types used in modern underground blasting: the burn cut, the V-cut, and the fan cut (often called slashing). These three types of cuts are illustrated in Figures 7.3-17 through 7.3-19, respectively.

In the burn cut (Figure 7.3-17), uncharged open holes that are often larger in diameter than the regular blastholes are used to provide relief for the loaded holes. For proper fragmentation, rock must be allowed to swell up to 50% in volume. For this to occur, the center-to-center distance between the loaded and relief holes must be of the order of 1.5 times the diameter of the relief hole. When the broken rock has swelled, it is propelled from the resulting enlarged hole by the blast gases, creating a free face. As successive holes fire, the "free face" is enlarged and greater standoffs can be employed using the same design criteria. This continues until the desired burden is reached. Because the same sized burn cut is used for

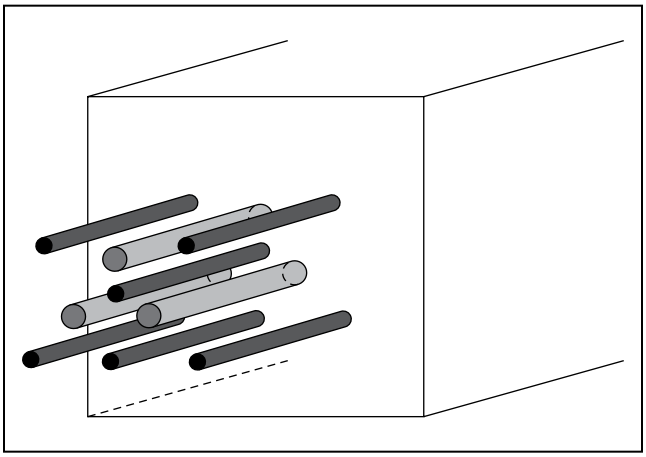

Figure 7.3-17 Example of a burn cut (rock's eye view). Light-gray (larger) holes are empty and dark-gray (smaller) holes are charged.

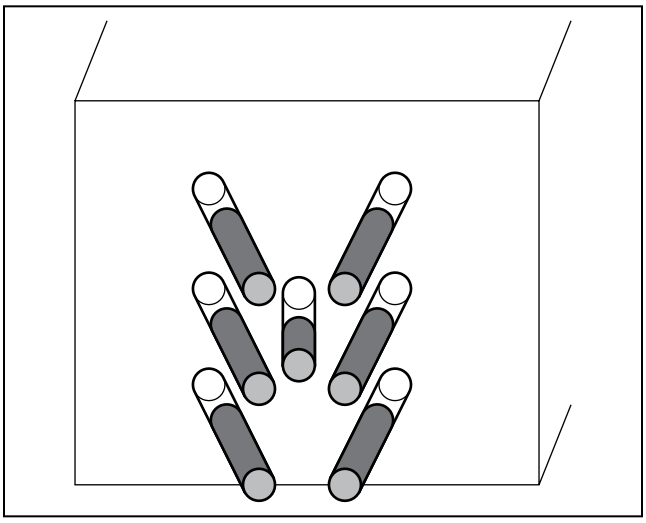

Figure 7.3-18 Example of a V-cut with a center "buster hole" (rock's eye view). This "V" is designed for modern bulk explosive, and the backs of the holes are purposely separated to avoid dead pressing.

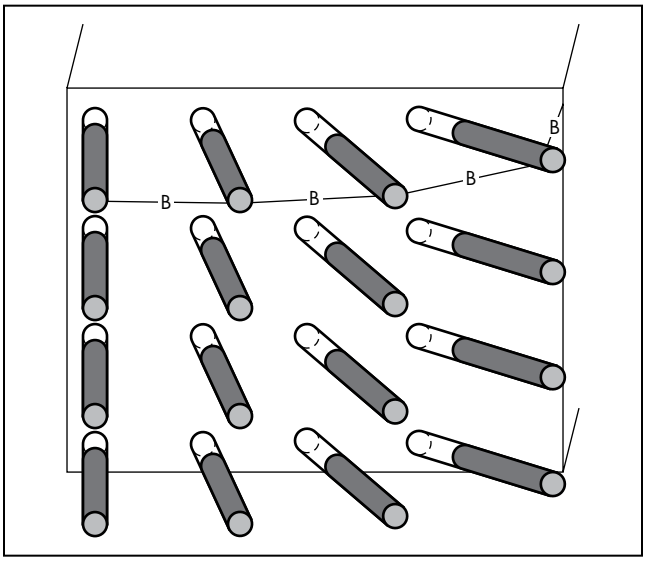
a small-diameter tunnel or a large R&P heading, the powder factor drops from around 6 kg/m^3 for a very small heading to 1.2 kg/m^3 for a large heading. Because burn rounds use parallel holes drilled straight into the face, they can be used on any width face.

V-cuts (Figure 7.3-18) use angled holes and can only be used in headings whose width is four or more times the depth of pull. Traditional V-cuts do not work well with modern explosives because the bottoms of V-holes come close together. In such cases, dynamites tend to sympathetically detonate, and emulsions and ANFO can easily dead press. A blasting agent is dead pressed when it is compressed/crushed enough to collapse a sufficient quantity of voids, thus losing sensitivity and resulting in a failure to fire. To overcome this, the bottoms of the V-holes are usually spaced 0.3 to 0.4 m apart. When using V-cuts, it is common to find a huge wedge of rock well in front of the muckpile when reentering the heading after blasting. To avoid this, "mini" V-cuts have been used, but these are very wasteful and they can be replaced by less-expensive buster holes, which may be fired before or after the V.

Fan cuts (Figure 7.3-19) have for some reason lost popularity. This is probably because their advance rate is less or because they are more complicated to drill. Because burn cuts end up with considerable fines, they are normally used in metal mining, whereas in underground quarries it is normal for V-cuts to be used because fines are generally a waste in crushed-stone operations. One measure of a blast's effectiveness is the length of the hole sockets left after the blast, signifying a reduction in maximum pull. In most cases it is not possible to totally eliminate sockets because this is the same phenomenon known as subdrill in surface bench blasting, and a maximum socket length of one-third of the burden can therefore be expected.

Long-Hole Stope Blasts

Long-hole stope blasting is used in narrow to wide vertical and subvertical ore bodies. It has replaced most of the short-hole techniques, and it has been made possible by the development in the 1970s of equipment that can drill long, straight holes. It is used to achieve high productivity but without the



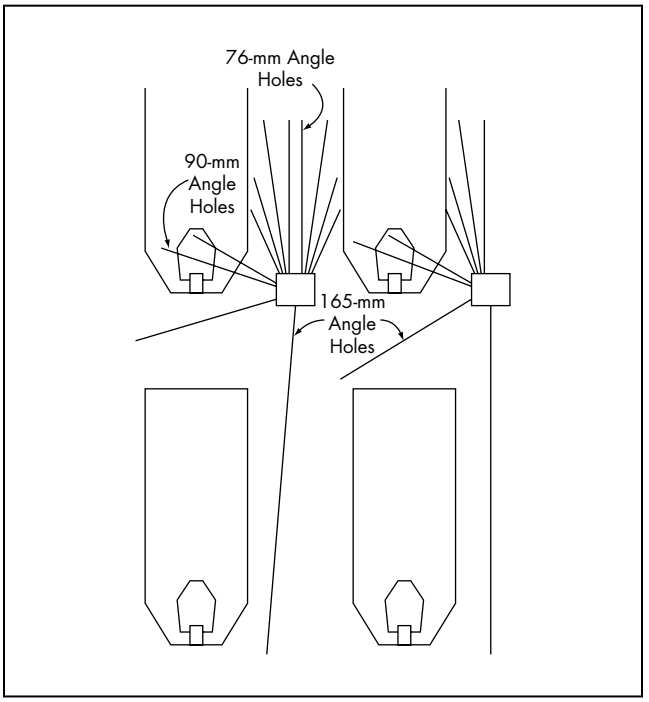


Figure 7.3-19 Example of a fan cut/round showing swing of holes (rock's eye view). The bottoms of the holes are at a constant burden between rows.

Source: Irvine 1982.

Figure 7.3-20 Mass blast design illustrating development drifts in pillars, partial drill patterns, and the use of abandoned stopes for swell

associated development costs and is basically a form of underground bench blasting. However, it relies on having a free face to blast into, which is usually provided by a raise that has been previously drilled between levels. These raises, in turn, rely on long-hole drilling, usually from the upper level and the use of multiple relief holes or vertical crater retreat (VCR). The technique of VCR started in the mid-1970s (Lang 1977). The use of large-diameter holes and down-the-hole hammers now ensures long-hole accuracy.

Mass Blasts

Mass blasts are large blasts that might take months to drill and weeks to load and that provide production for as much as a year. They require volume for expansion, and development drifts do not usually provide this. They are often used in older sublevel stoping operations in massive ore bodies, where large openings already exist and a high percentage of valuable ore deposit remains in horizontal and vertical pillars between the stopes. Blasting is often accomplished through the drilling and placement of explosives in rings of long holes located in development drifts excavated through the center of pillars, as shown in Figure 7.3-20.

An important factor in design is the adequate distribution of explosives. In a typical ring, the holes are designed to be at the appropriate spacing at their furthest extent. However, in the development tunnel the holes are rather close together. Consequently, many holes are often not loaded along their full length, as shown in Figure 7.3-21.

In addition, there are usually a limited number of delays available when using traditional initiation systems. Because of this, whole rings are usually shot on one delay. To limit splitting between holes, resulting in decreased fragmentation, the far ends of the holes are usually designed such that the spacing is at least twice the burden while the required powder factor is still maintained.

In mass blasts the production of air blast is also massive. As a result, fully activated sequential timing is required, otherwise detonating cord can be ripped apart and large-scale misfires may occur.

In the past several years, there have been record-sized mass blasts made possible through the use of electronic detonator systems that overcome many of the disadvantages outlined previously.

Pillar Recovery

For many mining techniques, a significant proportion of the resources are left at the end of the mine's life, especially in areas of high grade. In R&P mining, it is often possible to recover pillars, although the resulting large spans of unsupported roof may be too dangerous to allow. Often, cemented fill may be used to provide artificial pillars or cable bolting used to provide roof support. As pillars are taken out, stress redistributions occur, making neighboring pillars potentially unstable for drilling. As such, pillar scaling is required, and pillars should be drilled at least two pillars away from any pillar-extracted area. Pillars are best drilled from the side furthest from extraction (i.e., from the side of supported ground and least stress). Horizontal holes fired in rows parallel to the vertical sides of the pillar provide the best fragmentation. The initiation sequence is most efficient from one side to the other. Remote-controlled loading is the preferred method of removing the broken reserves.

In mass blasting and pillar removal, holes may be required to be loaded for some considerable time before they are blasted. It is, therefore, important that the explosive selected will both perform after being loaded for the required time and be compatible with the ore (some sulfide bodies are reactive, requiring special explosive).

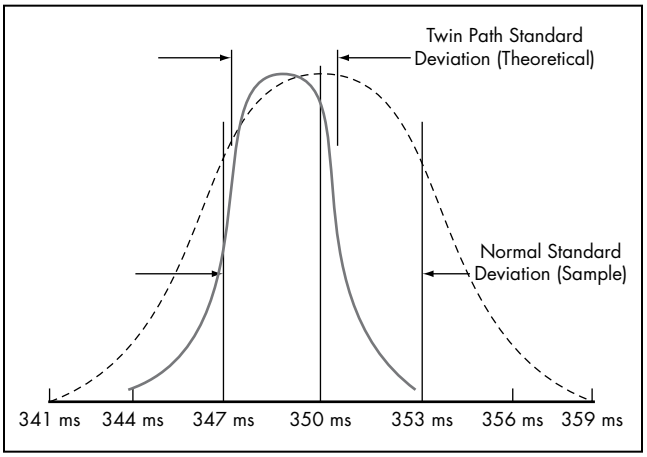
Figure 7.3-22 A modern repump emulsion system (Dyno Miner underground explosive loading system from Dyno Nobel) set on a Getman charging rig

Modern delivery systems underground comprise pumped emulsion systems and blown ANFO. High-shear pumps may be used to ensure that emulsions stay in vertical holes. Repump emulsion systems (as shown in Figure 7.3-22) allow for the rapid loading of high-energy bulk explosives, make optimum use of expensive drilling, and result in a significant reduction in the number of holes required. This type of system is now widely used in underground mines.



COMMON MISCONCEPTIONS

There are four common misconceptions about blasting. The first misconception is "high-gas" versus "high-shock" explosives. This concept gives the impression that some explosives are all gas and some are all shock. In all commercial explosives, the fraction of energy liberated in the form of shock is low compared to the gas energy. Thus, high-gas explosives should be called "higher-than-average-gas" explosives. In addition, blastholes have a fixed volume, so the bulk (volume) strength of an explosive can be used rather than its weight strength. For example, even though emulsion contains 15% to 22% water, which is inert, a hole filled with emulsion will have a higher gas pressure than one filled with ANFO because of the significantly higher density of the emulsion.

The second misconception is that one should not put a detonator in a hole. The assumption is that a cutoff could result, leaving an uninitiated detonator in a primer assembly in the hole, which could then be set off during excavation. Such occurrences were common when blasting caps were initialed by a slow-burning safety fuse, but these occurrences are rare when blasting with short-period electric detonators or electronic detonators. With such initiation systems, the problem of cutoffs is caused by not using a fully activated circuit (where all of the detonators are activated before the first hole detonates). Blasting circuits that are not fully activated are usually caused by a combination of bad blast design and overly large blasts.

The third misconception is that all holes have to be double-primed and that the top primer needs to be on a higher delay (Figure 7.3-23). Holes are usually double-primed for the following reasons: the hole is unusually long, the downline may be damaged during the stemming operation, rock slippage is expected along bedding planes and along low-angle discontinuities, and there is a large investment in each hole (the extra detonator and cartridge explosive represent a very marginal investment compared to the cost of a loaded hole). The mining industry has traditionally assumed that a blasthole has to be initiated from the bottom—it does not. However, if a rock-shift cutoff occurs, the toe will be hard to excavate. Therefore, for single priming, initiation at the bottom of the hole is the common practice. In top and bottom initiation, the top detonator is rarely put on the very top of the column but rather at a distance from the top. Putting the backup primer on a delay more than 25 ms longer than the bottom primer increases the chance of holes firing out of order with all the associated problems.

The fourth misconception is that in large-scale mining with a shovel, the face height is limited by the length of the stick on the shovel. This is a very simple and easy mistake—one digs the muckpile resulting from the blast and not the face. Thus, it is the height of the muckpile that should not exceed the stick height. The height of the muckpile is not necessarily the height of the face. For instance, in quarry blasting, the height of the muckpile is often only a third of the face height for higher benches with a limited number of rows. Mine operators often argue that when loading with shovels, the blast pile needs to be concentrated rather than spread out, as shovels are not as mobile as front-end loaders. However, with proper blast design, face heights can be doubled, even tripled while still maintaining the same muckpile height. In large-scale operations, the trend over the years has been toward drilling larger-diameter holes, because they are more economical; however, face heights have not increased accordingly, resulting in reduced face-height-to-burden ratios and stiffer faces, resulting in poorer fragmentation. In addition, because the

Courtesy of Ensign Bickford.

Figure 7.3-23 Effect of dual capping on standard deviations in nonelectric detonator delays

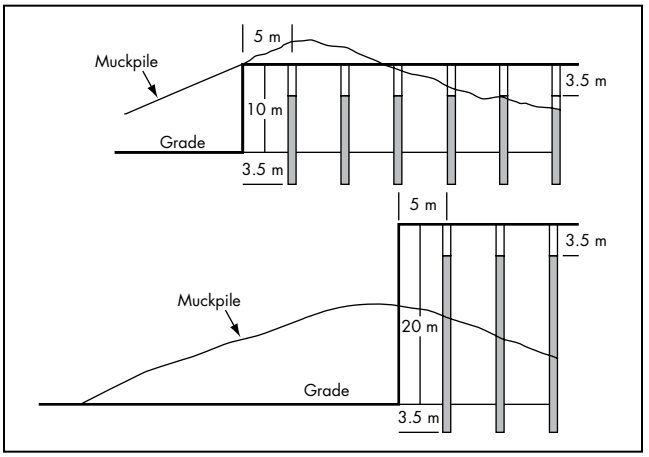


Figure 7.3-24 Example of increased efficiency from doubling face height and halving the numbers of rows

face heights have not increased proportionally to drill diameter, hole utilization has decreased by as much as 30%. This means significantly higher drilling footage to get the job done.

In the example shown in Figure 7.3-24, increasing the face-height-to-burden ratio from 2 to 4 results in a slightly lower muckpile, drilling is reduced by 23% (13% due to reduced hole footage and 10% due to an expanded blasthole spacing to maintain the powder factor), and the proportion of powder above grade is increased from 65% to 82.5%.

Mining engineers will often accidentally end up with "the tail wagging the dog" if they are not careful. The engineer cannot let one factor govern design, as economy and production will subsequently suffer.

THE COST OF BLASTING OPERATIONS

Unfortunately, many operators consider that the optimum cost of blasting is the lowest one that they can get away with. However, blasting is not an independent or standalone operation; it affects many other downstream operations, such as digging and haulage, as well as, more importantly, crushing/milling and handling oversize. Crushing and milling can be a bottleneck for many operations, and typically these parts of the operation cost much more per ton of rock than drill-and-blast. Reducing blasting costs can easily result in reduced fragmentation, which makes crushing and milling slower. Conversely, increasing the investment in blasting by increasing the powder factor generally results in an increase in fragmentation. This will normally result in an increase in throughput. Obviously, this is a complex subject, and because many mines and quarries are configured differently, with different needs and objectives, site-specific analysis is necessary. The lowest blasting cost may not (and usually does not) equate with the lowest overall mining cost. More and more companies are becoming interested in mine-to-mill cost studies, where it is necessary to track material blasted using different designs and account for costs in all stages.

Table 7.3-4 shows the costs that should be considered when analyzing a blasting operation. The table provides a starting point for gathering cost information on blasting costs and can be used to assign an estimated cost to each cell in the table. For example, explosive cost can be estimated on a per-hole basis by using the design equations given previously. After the weight of explosive per hole is established, explosive cost is calculated using the price per kilogram obtained from a manufacturer. Engineers should seek quotations from manufacturers when estimating explosives costs, which can vary greatly depending on quantity purchased, shipping distances, and proximity to manufacturers. When a critical mass of data is collected, trends should become evident and optimization analysis can begin.

Direct costs are almost directly proportional to powder factor. As in blasting, one deals with loaded holes, and the only realistic way to increase powder factor without changing the explosives is to use more loaded holes. In many quarrying operations, fines represent a waste material that not only results in lost revenue but also results in costly waste-handling costs. The opposite applies in some types of metal mining operations where fines are readily used. In both extremes, the production of fines has to be balanced with that of oversize.

After basic and complete information is gathered concerning a blasting operation, analysis can be undertaken to allow informed decisions to be made on issues such as product selection. Explosive selection is an important task requiring thorough consideration.

An old axiom predominates: "if drilling costs are low, then use ANFO, but if drilling costs are high, then use emulsion for better hole utilization with the denser emulsion." However, with the introduction of blends, replacing emulsions is a better cost alternative in dry holes of 100 mm (4 in.) in diameter or more. In many situations, the only reason not to use blends is their limited water resistance or minimum hole diameter requirements (see the manufacturers' technical data sheets). The costs of operational decisions regarding blasting should be thoroughly evaluated. For example, emulsions may provide a higher-density product where less drilling is required. However, in most rock types, higher powder factor will be required to compensate for the water in emulsions and the poorer energy distribution inherent to these expanded patterns. A simple analysis can determine the breakeven point where a certain percentage of wet holes can be most cost-effectively loaded using ANFO, an emulsion, or a blend.

The importance of blasting economics is best illustrated using examples, even though costs vary with time and location. The following examples use costs typical for the

Table 7.3-4 Summary of actual blasting costs

Drilling Costs	Loading Costs	Explosives Costs	Indirect Costs
Amortization or lease of drill rig	Dewatering	Explosives	Clearing the blast area—loss of production
Fuel	Accessories	Boosters	Stabilization and cleanup
Operator	Stemming materials	Initiation system	Compliance, litigation, and insurance
Lubrication	Transportation	Product enhancers (stemming plugs, additives, etc.)	Explosives storage
Maintenance	Loading equipment		Parts inventory
Drill steels	Maintenance		Drilling and fragmentation assessment
Drill bits	Labor		Permits
			Documentation

Midwest United States in 2006. The costs were provided by a drill-and-blast contractor. In the examples, 100-mm holes are drilled on a 12-m-high bench in limestone. The costs of bulk explosives delivered and loaded in the hole are $0.68/kg for ANFO and $1.06/kg for gassed emulsion. Costs of $4.50 per hole for the initiators and $3.00 per hole for cast boosters are also budgeted. The cost of contract drilling is $6.23/m. Comparative costs are estimated for the tonnage that would be produced from a 100-hole blast using ANFO. The rock tonnage and powder factor are held constant for both blasts. The number of holes in the emulsion and blend shots are reduced accordingly to achieve this.

The cost of drilling affects the economics of a dry pattern, as shown in Figure 7.3-25. For the cost of drilling at $6.23/m, the total shot cost is only 3% lower for ANFO at $13,172 compared with emulsion at $13,563. This small differential decreases to zero as drilling costs increase to $7.45/m, at which point the cost of using ANFO or gassed emulsion is the same at $14,650. As drilling costs exceed $7.45/m, emulsion is cheaper on a per-shot basis, but the margin of difference in this range of drilling cost is not very large. If a 70/30 ANFO/emulsion blend were used instead, then the cost would be reduced to below $12,000, which would give an overall cost savings of nearly 11% over ANFO. A 70/30 ANFO/emulsion blend is not sufficiently waterproof to be loaded into wet holes. Drilling costs must be less than $2.26/m before ANFO becomes more economical than a 70/30 blend.

The previous example shows the effect of drilling costs on a per-shot basis for dry holes. Additional analysis is required to determine the economics of encountering wet holes. On some shots, a percentage of holes may be wet while others are dry. Likewise, in certain mines, some shots may be entirely dry and others entirely wet. In these situations, it is common practice to drill an ANFO pattern and then deal with wet holes as they are encountered by loading a water-resistant (and thus more expensive) product. Wet holes cannot be loaded with ANFO and usually require bulk emulsion or, more commonly today, a high emulsion percent blend. This increases cost in two ways: first, a more expensive explosive is used, and second, because of the greater density, more explosives weight is required in the hole to bring the column up to the correct level.

Figure 7.3-26 graphically illustrates the effect on cost of having to use emulsion in wet holes on a pattern designed for ANFO. The solid line represents the cost of a shot designed for emulsion. The cost is constant for dry or wet ground. The dashed line represents the cost of encountering wet holes in a pattern designed for ANFO. As the percentage of wet holes increases, the cost increases because the more expensive emulsion product is required for the wet holes. As can be seen, the cost of loading emulsion in an entirely wet pattern that was drill-designed for ANFO represents a dramatic increase in cost (dashed line). The example also illustrates that if only 10% of the holes are wet, it is more economical to use emulsion with a drill pattern designed for emulsion. The bottom line is where a 70/30 ANFO emulsion blend is used to replace the emulsion (in the expanded/wet-hole pattern, solid line) where dry holes are encountered. In this case, the same weight of explosive is used in each hole as the densities of blend and emulsion are very similar and the pattern is already a "wet pattern" (i.e., expanded pattern suitable for emulsion). It is plainly evident that the cost of using a blend (bottom line) as the baseline explosive is far more attractive than that using ANFO, and it is cheaper than using only emulsion. This is why the use of blends continues to increase.

Another important economic factor is the size of drill appropriate for an operation. This is a simple question that may sometimes produce a rather complex answer because of issues such as the proximity of neighbors and ground vibration limits. Even without considering these issues, all equipment at a mine should be matched in productivity so that no one piece is overutilized (thereby providing some slack for expansion and to cover production problems) or severely underutilized. For example, a modern hydraulic 100-mm-diameter drilling rig is capable of providing more than 2 Mt of production per year, and a 150-mm-diameter drilling rig can provide 5 to 6 Mt/yr in limestone. Obviously, buying a 150-mm drill for a 0.75-Mt/yr quarry will result in severe underutilization of the equipment, and an 89-mm-diameter drilling rig would make more sense. In addition, this quarry would not be expected to have a very large primary crusher, so that problems with oversize could be expected with the expanded pattern size and consequent less uniform energy distribution of a 150-mm-diameter drilling rig.

Shot service affords many economic advantages, not just in the direct cost of blasting, but also, because these companies specialize in blasting, they have a far higher level of expertise. Blasting contractors, who often provide their own vibration-monitoring equipment and insurance, can usually reduce blasting problems, improve fragmentation and wall conditions, and reduce or eliminate explosives storage on-site. Relying on companies with expertise in blasting allows the management of small companies to concentrate on other items specific to their mining operation.

DESCRIPTION AND CONTROL OF BLAST EFFECTS

The use of explosives in mining creates several effects that can be detrimental to the operation if they are not properly controlled through proper design and application. Most operations are concerned with controlling flyrock, ground vibrations, air blast, overbreak, and so forth. This section provides some basic troubleshooting for the blast effects mentioned and shows connections between the design elements and respective blast effects.

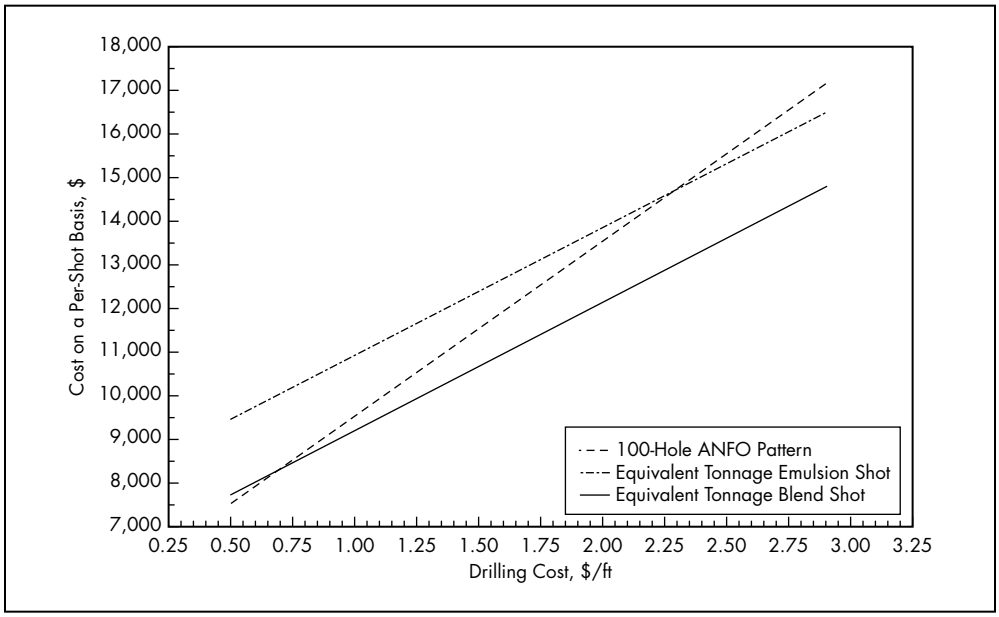

Figure 7.3-25 Effect of drilling costs on economic selection of ANFO versus emulsion and blend

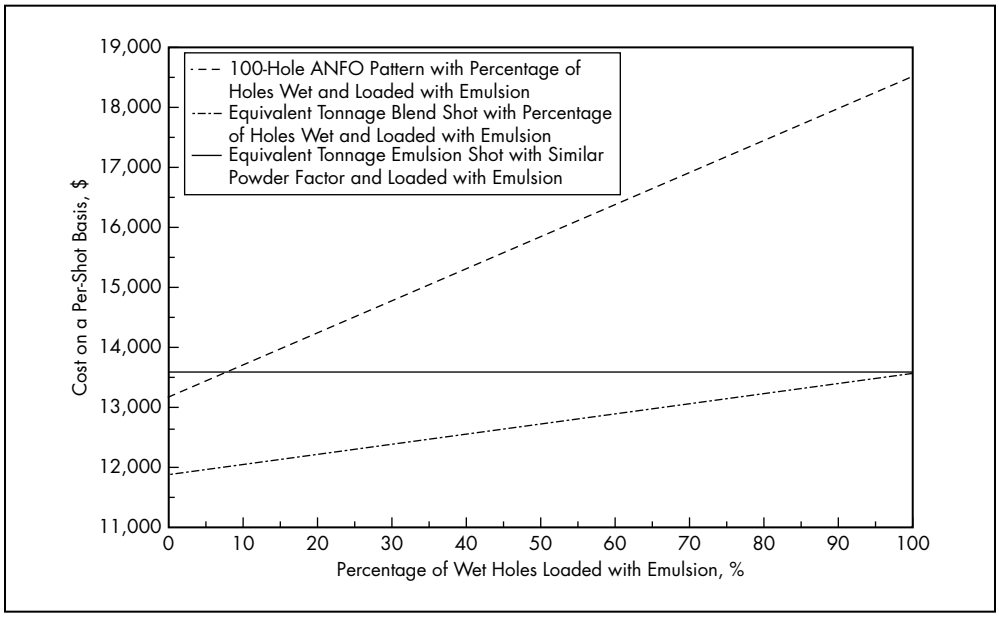

Figure 7.3-26 Economic analysis for using a 70/30 blend on an expanded pattern using emulsion for wet holes

By using proper blast design, the energy in an explosive product is harnessed to produce the desired result. Mining operations usually wish to use the majority of the energy to break rock and move it, thus fragmenting it into pieces of manageable size. The optimum scenario is to minimize the explosive energy that is converted into undesirable blast effects while maximizing the use of energy to provide the desired fragmentation and movement.

Flyrock is a significant issue that has plagued the mining industry since the inception of blasting as a method for excavation. The definition of flyrock is "any rock from a blast that goes where it is not intended to go." Various regulatory agencies have developed their own specific definitions for flyrock for the protection of residents. For example, Kentucky regulation KRS 351.330 states that "flying rocks shall not be allowed to fall greater than one-half the distance between the blast and a dwelling house, public building, school, church, commercial, or institutional building…" (Kentucky Revised Statutes 2009). A majority of injury-causing blasting accidents have been caused by flyrock that occurred when the blaster intentionally fired the shot. In contrast, it would be very difficult to find cases where individuals were injured by

ground vibrations or air blast from commercial blasting. For this reason, flyrock remains a focus for safe design. There are several potential sources of flyrock. In most cases, flyrock is generated from specific points in a blast where the burden is insufficient. Reasons for such occurrences include insufficient stemming, poor drilling, irregularities in the face, and a high charge density caused by loading through voids. In cases where flyrock must be well controlled, the practice of drilling holes adjacent to muckpile *before* it is excavated should be avoided as the reduced control of face hole burden can and has produced faceburst and long-range flyrock incidents. Other cases exist where a satisfactory design burden becomes insufficient. For example, mud seams or clay seams and loading explosives through these seams is a potential cause of flyrock. Identifying mud seams and voids is much easier during the drilling cycle, and such occurrences must be communicated to the shot blaster by the driller.

Accurate drilling and recording of drill logs is imperative to eliminating flyrock. In fact, poor drilling or poor driller communication are usually to blame for the majority of the blast effects. Modern tools, such as face and hole profilers and drill automation, can be used effectively to ensure consistent and appropriate burden, but nothing can replace a properly trained and experienced driller.

Operators generally want to minimize overbreak. In surface operations, overbreak/back break can create unstable highwall conditions. Likewise overbreak/fracturing to the bench below can cause problems when drilling and preparing lower benches. Overbreak in underground operations can lead to unstable conditions and more extensive and/or more complicated roof-control programs. Overbreak in bench blasting is usually caused by either too much powder in the last row, firing of choked/buffered or otherwise overconfined blasts next to walls, or by insufficient delay timing. In underground operations, overbreak usually occurs from overloaded holes too close to the planned perimeter of the opening. A number of perimeter-blasting techniques can reduce the amount of overbreak to an acceptable level. In surface operations, the application of presplit blasting is commonly used to generate stable highwall conditions. Other common techniques include line drilling, buffer blasting, and smooth walling. The concept is similar for each technique and generally involves closely spaced holes with lighter explosive loads than the main part of the blast. One of the most important aspects of a successful overbreak control program is the knowledge and analysis of geology. Many geologic features can enhance or reduce the effects of the perimeter blasting techniques.

Ground vibration and air blast are common blast effects that are almost impossible to completely eliminate. There is generally some form of both generated from every mine blast. Regulations govern the amount of vibration and air blast permissible at nearby structures. Although state and local ordinances concerning air blast and ground vibration vary, a majority of these regulations will closely resemble the content of Office of Surface Mining blasting regulations.

If scaled-distance limitations require a lower amount of explosive per delay than can physically fit into a blasthole with stemming, decking must be employed. Holes can be loaded where two or more powder columns are separated by inert stemming material and fired on separate delays. This is a common practice for surface blasting where nearby structures impose explosive weight restrictions per delay due to scaled-distance calculations.

Improper stemming or insufficient burden often leads to high air blast, which is usually accompanied by flyrock. Other causes of excessive air blast include the use of detonating cord on the surface and gas venting from the face. The need to use detonating cord on the surface has been superseded by modern advances in initiation systems. Air blast overpressure levels can be estimated using scaled-distance relationships. More complete coverage of ground vibration and air blast can be found in Chapter 16.3.

Another potential cause for excessive ground vibration, air blast, and flyrock is improper timing. Delays are used in blasting to provide optimum fragmentation and movement. There must be sufficient delay between holes to provide adequate relief for subsequent holes. A delicate balance exists between sufficient and excessive delay. In some cases, too much delay can remove the burden of holes that are in rows further away from the bench crest, leaving the holes underburdened and causing flyrock and high air blast. If insufficient delay is utilized, holes risk becoming overburdened and high ground vibrations can result. Overburdened holes can also generate flyrock in the form of stemming ejection. Similarly, if insufficient timing is used, the gas pressure is likely to eject the stemming and crater the blasthole. In bench blasting, insufficient timing on the back row is evident by fragmented rock heaped on the bench behind the blast. In a properly timed bench blast, the bench behind the blast should be clean and clear of shot rock.

Gas fumes are produced as a normal by-product of blasting operations regardless of the types of the explosive materials used. Common gases produced by explosives include ammonia, carbon monoxide, carbon dioxide, oxygen, water vapor, nitrogen, nitrogen oxides, sulfur dioxide, and hydrogen sulfide. Sulfur dioxide and hydrogen sulfide can be generated if sulfur is used in the explosive formulation. Currently, no products in the United States use sulfur as an ingredient. Every explosive product fumes on detonation. These fume volumes are generated under ideal conditions and do not consider the effects of adverse field conditions, including water, dilution of explosive products, and low-order detonation as a consequence of underpriming. These conditions can cause excessive fumes and can create other operational problems. ANFO is particularly susceptible to fume generation because of water infiltration. When blasts are confined, such as in trenching or lift-shot applications, fumes are likely to seep through the strata to nearby neighborhoods and developments. Blasters should be wary of these conditions and apply preventive measures to ensure that fumes do not cause dangerous situations. For example, when blasting in wet conditions near residential areas, a waterproof low-fume class product is necessary.

With all of the blast effects discussed in this section, it is apparent that attention to detail is of utmost importance. Designing a proper blast involves relatively simple calculations. However, the application of this design in a mine environment is much more difficult. Assurance of proper burden, spacing, loading, and timing is imperative to a successful blast.

TRENDS, AUTOMATION, AND THE FUTURE

Blasting techniques are constantly evolving with technology. In general, changing trends in the explosives industry are most evident to shot service companies and explosives manufacturers.

The explosives product of choice for many years has been ANFO, which replaced dynamite as the dominant explosives

product many years ago. Dynamite is still a viable product for a few niche applications, but it has only a very small share of the market. Most operations have also moved away from bags and cartridges to bulk. Explosives supply contractors have highly automated bulk trucks that are capable of creating variable blends of ANFO and emulsions. Advances in bulk truck technology allow the storage and transportation of oxidizers that become blasting agents when they are gassed by the bulk truck during loading into the blasthole. Because of the regulatory authorities' storage regulations, this ability has prompted many companies to adopt this technology. Several shot service companies have started using these gassed emulsions almost exclusively. Even large underground operations utilize bulk emulsions.

Small quarries and surface mines often use shot service contractors for off-site storage of explosives and complete blasting services. To keep a shot crew employed and to justify the purchase of new-technology bulk-loading equipment, an operator needs to be undertaking a lot of blasting. For smaller operations, full shot service not only offers direct monetary efficiency, but it also reduces the issues associated with compliance, insurance, dealing with complaints, and so forth. Even quarries producing 6 Mt/yr often use shot service for delivery of bulk explosives products from the manufacturer to the bench while using their own shot crew to help load, connect, and fire the blast.

The same can be said for drilling, and as such, there has been a rapid increase in the amount of drilling that is contracted out. For a smaller operation, this can be far more cost-effective in the long haul. One added reason for the sudden increase in contract drilling between 2003 and 2006 was the introduction of noise limitations on drilling by the Mine Safety and Health Administration. The only way that drilling manufacturers have been able to reduce driller noise exposure in an acceptable manner is to provide soundproofed cabs. However, this requires drill operation to be automated with drill steel carousels and so forth. Also, because hydraulic drills are less noisy, mines have been forced to convert to hydraulic drills and abandon their air-track drills. The high purchase cost of new equipment has forced them to investigate the contract drilling option. Quarry companies with multiple sites now often own high-productivity hydraulic drill rigs, which are shared and transported among their operations. This in turn has forced them to shoot bigger, more infrequent blasts, which has lent itself to the economics of shot service. Shot service is now the norm in the United States.

Advances in drilling technology have allowed for the use of Global Positioning System (GPS) locators for drill holes. This ability allows engineers to design blast patterns in real time with the advance of the mine. If used properly, a GPS has the potential to increase the quality of many blasting programs. In underground situations, drilling jumbos now have GPS technology to start from a reference point and drill a round autonomously. The drill operator is still required to ensure quality control and to adapt patterns to changing conditions, but the drilling cycle is becoming more automated and efficient.

The most recent advances in initiation systems have taken place in electronic detonators. More operations are utilizing electronic detonators and are benefiting from this newer technology. Cost has been the major disadvantage, but costs are gradually becoming competitive with nonelectric systems. The advantages of electronic initiation in fragmentation and control are becoming more evident, and many operations are beginning to quantify the economic advantages of switching to electronics. It is likely that electronics will take an increasing share of the market in the coming years.

PART 8

Ground Mechanics

CHAPTER 8.1

Introduction to Ground Mechanics

Russell Frith and Mark Colwell

The nature of the geotechnical environment and the resultant geomechanics (i.e., how the ground responds) during excavation is one of the primary influences on mining—for example, whether to commence mining in the first place, the choice of mining method, the design of the mine layout, or the need for ground control measures during and subsequent to mining. After a deposit of ore or coal has been found and a market for its subsequent sale identified, understanding the various mining constraints, as a result of the nature of the geotechnical environment, becomes a key mining consideration throughout the entire life of the project.

There is little doubt that mining efficiencies are materially affected by geotechnical aspects of the mining environment. For example, as the immediate rock mass surrounding an ore body becomes less competent, ground support requirements to maintain a suitably stable and safe excavation will inevitably increase. Increased ground support translates to increased mining costs but, more importantly, will decrease the rate of roadway or tunnel advance. In almost every underground mining scenario, the rate of tunnel development is a key business performance parameter.

In surface mining, slope angles are strongly linked to the geotechnical nature of the overburden or waste. The less competent the overburden, the lower the slope angle must be to maintain an adequately stable and safe pit wall. As the slope angle decreases, the amount of overlying material that needs to be removed to access each ton of mining product correspondingly increases. This, in turn, increases the mining cost and so detracts from business performance.

As early as possible in the mine feasibility assessment process it is vitally important to understand and fully consider the interrelationships between the local geotechnical environment and the mining process. In both surface and underground mining, the geotechnical environment is a material mining consideration, well summed up in the following quotation by Napoleon Hill: "Nature cannot be tricked or cheated. She will give up to you the object of your struggles only after you have paid her price."

Part of "her price" is understanding and adequately controlling the geotechnical environment in all of its facets. This section of the handbook covers many such aspects in a technical sense, while this chapter is intended to provide a general overview with some appropriate examples.

MINING FEASIBILITIES

The objective of every mining feasibility study is to make a prudent capital investment with the expectation of making a suitable return over time. As with all things in life, there are no guarantees when making such an investment, but the focus should be on achieving the highest possible level of confidence that the feasibility predictions on which the decision is made become reality. This is no trivial exercise, and ignoring or underplaying the geotechnical environment's influence on mining is a serious feasibility oversight. Plenty of failed mining projects around the world substantiate this particular point.

The irony of such failed projects is that eventually most deposits become economically viable due to either improved mining technology or significantly higher commodity prices as a result of increased demand and/or increasing scarcity of the resource. Investing in mining projects prematurely has both short-term and long-term adverse consequences. As the custodians of the earth's natural resources, miners have a duty to invest only in those projects that make good economic sense at the time of mining. Understanding the impact of the geotechnical environment on mining is a key part of this.

Larger mining companies are typically owned by shareholders, many of whom invest via either private equity or through retirement funds. Mining companies have a duty to invest the shareholders' hard-earned savings wisely, with the feasibility study being the primary vehicle for such decision making. Different companies take varying approaches to the mining feasibility process. Although this chapter is not aimed at discussing how financial viability is measured, in general terms, mining feasibilities should have three basic stages: concept study, prefeasibility assessment, and feasibility assessment.

Russell Frith, Adjunct Professor, School of Mining Engineering, University of New South Wales, Sydney, New South Wales, Australia
Mark Colwell, Principal, Colwell Geotechnical Services, Queensland, Australia

Concept Study

This stage simply establishes that certain minimum requirements are met to allow a feasibility study to take place. For example, it is important to know the likely quality of the deposit and, in the case of the geotechnical environment, whether any obvious "showstoppers" would immediately preclude any form of economic mining.

For example, in underground longwall mining at high depth (>500 m), the presence of a thick and strong (>100 m thick) dolerite sill just above the target coal seam, with the potential to prevent overburden caving, would be an obvious geotechnical showstopper to efficient and indeed safe longwall extraction, as longwall mining relies heavily on the regular caving of the overburden. A dolerite sill of such thickness so close to the extraction horizon would prevent regular caving of most of the overburden and instead would store significant amounts of potential energy through spanning across one or more longwall panels. With such a feature present in even a small number of boreholes, it would obviously raise the questions as to whether to proceed any further and, if so, whether other mining methods would be better suited to mining the resource.

Prefeasibility Assessment

Fortunately geotechnical showstoppers are rare, and most projects at least get to the prefeasibility stage. The aim of the prefeasibility assessment is to develop several credible mining options that could conceivably be used to exploit the deposit. These can be compared on a net present value (NPV) basis, as well as associated technical risk, with the outcome a preferred mining option to take into the feasibility assessment.

Feasibility Assessment

With a preferred mining option identified, the focus of the feasibility stage is to evaluate the option in sufficient cost and technical detail so as to provide a suitable basis for a prudent investment decision. If the decision is made to invest, the project proceeds to the construction and final operational phases. If not, it remains as a prospect that may be revisited in the future when technology and market forces are more favorable.

In geotechnical terms, the credibility of the feasibility study process relies heavily on two aspects that need to be in place:

1. Availability of a suitable amount of relevant geotechnical information. Clearly one cannot make quality decisions without quality data, and this encompasses both the type and quantity of such data.
2. The use of appropriate geotechnical assessment or design methods that establish reliable mine design parameters and identify geotechnical risks and their mitigation. For example, there is little point in designing tunnel or roadway strata support in great detail at this stage when all that is required is a credible estimate of likely average support quantities to gauge the impact of such support on the rate of advance and mining costs.

The type of geotechnical data collected for a given mining prospect clearly varies according to the type of mining being evaluated and, most importantly, the geotechnical assessment methods used. It is vital at the project's start that likely assessment methods are defined and that exploration protocols are targeted to the collection of the necessary input data. Keeping in mind that such projects may be subject to peer review by individuals and groups using different methods of assessment (some proprietary), the need to be clear at the outset on the required range of geotechnical data is critical. Because much geotechnical data emanate from either logging or testing of fresh bore core, the ability to revisit incomplete boreholes later in the feasibility study can be limited.

In terms of the density of the available geotechnical data, no hard and fast rules exist, and different mining companies apply different corporate standards. One could argue that the various standards of resource reporting (e.g., *The Australasian Code for Reporting of Exploration Results, Mineral Resources and Ore Reserves* [AusIMM 2004]) should provide some specific guidance in this regard. Most standards recognize that as a resource goes from *inferred* to *measured* or a reserve moves from *probable* to *proven*, the level of geological and geotechnical knowledge and associated confidence must increase. This makes logical sense.

The SME Guide for Reporting Exploration Information, Mineral Resources, and Mineral Reserves (SME 2007) provides the following quotation in regard to the reporting of mineral reserves:

> Mineral Reserves are those portions of Mineral Resources which, after the application of all mining factors, result in an estimated tonnage and grade which, in the opinion of the Competent Person making the estimates, can be the basis of a viable project after taking account of all relevant mining, metallurgical, economic, marketing, legal, environmental, social and governmental factors.
>
> The term "economic" implies that extraction of the Mineral Reserve has been established or analytically demonstrated to be viable and justifiable under reasonable investment and market assumptions.

In discussing coal reserves, the 2007 *SME Guide* makes the following comments in regard to geotechnical matters:

> Geological similarity between neighbouring coal deposits can greatly simplify demonstration of a new Coal Resource, as well as reduce the technical and economic study requirements needed to demonstrate a Coal Reserve next to an operating mine. Geological similarity must be demonstrated by means of drill holes, mapping or other deposit-specific geoscientific evidence to a suitable level of confidence required to declare Measured and/or Indicated Resources. Mere inference of the continuity of coal thickness and quality from an operating mine onto a neighbouring block or property is not sufficient to declare Measured and Indicated Resources and subsequently a Reserve.
>
> It is the responsibility of the Competent Person to ascertain that there is sufficient information to demonstrate geological similarity and to determine which additional factors must be taken into account to demonstrate technical and economic feasibility with a reasonable level of confidence.

Clearly then, the definition of adequate mine feasibility input data requirements should be determined by a competent person and not governed by statute or standards. Obviously, the person responsible for undertaking the geotechnical assessment

of a mining prospect should have a leading role in determining what constitutes suitable quantities of geotechnical data, as opposed to what is required for simply estimating the volume of the reserve base.

One point worth making is that if the economic measure of a mining project is its NPV, the bulk of that value relates to the first 15 years of mining, beyond which mining outcomes have a significantly diminished effect on the investment decision. Therefore, on the basis that all exploration budgets have limits, it makes sense, particularly with very large projects, to ensure that the initial mining areas for the majority of the NPV, and hence investment risk, contain a higher quantity of exploration data than those that are longer term.

Geotechnical design methods will be discussed in more detail later in this section, specifically that all methods, regardless of how they are named (e.g., analytical, numerical, or empirical) are in fact or certainly should be empirical in nature at some level because they refer back to, and rely on, previous mining experiences. In terms of the feasibility stage of a project where the objective is to make an investment decision with confidence, a highly valuable feasibility finding is demonstrating that another mining project achieved certain mining outcomes in geotechnically similar conditions to the one under consideration, which is far more valuable than predicting future ground support densities or mining geometries to high levels of accuracy. By definition, this means that well-constructed empirical methods of geotechnical assessment and design within an overall assessment strategy should have a key role in mining feasibilities in which a mineability estimate is the key focus.

All mining investment decisions contain some level of residual or undefined risk, particularly in the area of geomechanics, because, unlike most other engineering disciplines, the engineer does not have control over the nature of the material involved (i.e., soil or rock). Because this is controlled by Mother Nature, it is impractical to know at the feasibility stage the full range and distribution of mining conditions to be faced. Furthermore, much of the capital investment will be sunk before the true impact of the geotechnical environment is experienced in actual operations, at which time abandoning the project would be costly in terms of both cash losses and business reputation. Therefore, mining feasibility studies should be undertaken on a prudent rather than overly optimistic geotechnical basis, because experience shows that, as more geotechnical information and mining experience becomes available, the geotechnical outlook generally either worsens or, at a minimum, becomes more complex.

MINING OPERATIONS AND STRATA MANAGEMENT

When a mining project proceeds to an operational status, the geotechnical focus changes to

- Striving to improve mining efficiencies within geotechnical constraints,
- Promoting safe mining practices, and
- Identifying and controlling those geotechnical conditions that were previously unknown but are encountered during mining.

Whether formally or informally, this is all covered by what is termed colloquially in the Australian underground coal industry as the *strata management process*, which is now defined in local mining legislation.

The strata management process has been implemented, in fact, since historic mining operations. Even though the earliest miners had little or no geotechnical data or sophisticated measurement methods, they could still use their own judgment (typically gained from previous successful and unsuccessful mining experiences) as to whether a mine area was safe and hence whether to continue mining or not. Unfortunately, a combination of inexperience and/or an optimistic outlook can lead to poor judgments, the result being inadvertent unsafe mining practices. Personal judgment (via observation) in isolation is not always sufficient to optimize mining practices and maintain suitable stable and safe mine workings. Geotechnical design and continual operational control of the geotechnical environment need to work hand in hand in order to achieve the highest standards of both mine safety and economic performance.

In the 21st century, unsafe mining, while morally and legally unacceptable, is also not good business. One has only to consider the rigor to enforce recent corporate safety initiatives of the major mining houses (e.g., BHP Billiton's Fatal Risk Control Protocols [BHP Billiton 2005]) to prove this point. It is also gratifying to know that different countries are tending to cooperate with each other at the highest levels in the effort to improve mine safety. The Australia/China Coal Mine Safety Demonstration Project is one such example of this (Queensland Government 2009).

The strata management process during operational mining has three basic elements:

1. Geotechnical design
2. Exploration and input data
3. Implementation and management of residual risks (i.e., those risks remaining despite all defined controls being in place)

Each of these will be discussed in detail, but it is worth making the initial point that the overall process hinges (or should) around geotechnical design. Geotechnical design requirements will govern what information needs to be collected as part of the exploration program and subsequent mining activities.

Similarly, geotechnical design outcomes, particularly the residual uncertainties involved, will influence what measures need to be taken to safely implement the design and ensure its ongoing suitability during operations. A pillar design with a high factor of safety (FoS) will require little or no ongoing operational vigilance (other than related to the immediate skin of the pillar or ribs) to ensure that it remains suitably stable. However, if a wide mine roadway, for example, needs to be excavated with a relatively low FoS against roof instability occurring, implementing an effective monitoring and response regime to ensure that roadway's ongoing stability becomes quite critical.

As a result of this realization, geotechnical design will be discussed first followed by exploration, then implementation and management.

Geotechnical Design and Design Methods

Design is an intrinsic component of effective engineering, including geotechnical engineering, in mining. Whether underground or surface, a mine represents an engineering structure where persons are required to work and shareholder value is to be realized. It is common sense that mining ventures will almost certainly be safer and more profitable if

controlled by credible mine design according to the specific set of geotechnical circumstances faced.

The Coalbrook disaster of 1960 in South Africa, where 437 miners lost their lives in the world's largest coal pillar collapse, demonstrates the inherent consequences of inadequate geotechnical design (van der Merwe 2006). In 1960, few if any credible coal pillar design methods were available to mine operators, and the occurrence of such a tragedy was probably inevitable. The same is not true today when duty of care requires that credible and prudent geotechnical design be applied to mining operations.

Undertaking geotechnical design in mining does not in itself guarantee that the required outcome will be achieved in practice. However, the likelihood of achieving it increases considerably with the effort of undertaking a meaningful and risk-based design evaluation.

Mine design in general should consist of three primary considerations:

1. Safety
2. Reserve recovery
3. Rate, or unit cost of production

The fundamental dilemma is that, if taken for granted that all mine design needs to result in a safe working environment, a compromise may be required between reserve recovery and rate/cost of production. For example, leaving pillars behind clearly reduces reserve recovery, but they can improve general mining conditions and thus promote safety and assist mining rates. It is not always possible for any given mining environment to allow 100% of the ore to be mined safely and cheaply, particularly in underground mining. Therefore, a strategic decision needs to be made as to which parameter (reserve recovery or rate/cost of production) is to be compromised in favor of promoting the other.

There are no universal rights and wrongs in this, because much will depend on the primary objective of mining. Any commercial mining operation will want to extract as much of the reserve as possible but only within a strict cost range. However, in a number of government-controlled mining industries, the focus is on extracting all of what is considered a precious national resource, almost regardless of cost. Both of these are legitimate mining strategies. This is where prudent geotechnical mine design has a role to play, ensuring that the balance between safety, reserve recovery, and mining efficiencies is kept within tolerable levels.

Specifically, the primary objective of geotechnical mine design is to provide mine operators with either benign or, more typically, inherently manageable conditions during operations. The design is ineffective if the manifestation of geotechnical problems is either so rapid that mine workers cannot take effective remedial action or vacate an area (e.g., coal mine bumps or rock bursts), or so sensitive to the actions of mine operators that minor mistakes on their part result in catastrophic failures.

It is obvious that effective geotechnical design cannot be undertaken without reliable design methods. This section will provide some of the fundamental requirements for a design method to be considered credible:

- It must be of direct relevance to the problem being addressed.
- It must provide risk-based design outcomes to allow mine decision makers to consider their mining options and associated risks.
- Wherever possible, the method should refer to and make use of known documented mining experiences (either locally or industry-wide), either through the use of empirical design methods or the back-calibration of analytical or numerical methods.
- The method should have a proven track record via previous use or at least be published in the public domain.
- The basis of the design and methodology must be understandable by mine-site personnel, particularly decision makers.
- The method should be transparent and fully auditable.
- Design should always be undertaken by suitably competent personnel.
- Design outcomes must fit with the mining process in use and be able to be installed as intended in a safe manner.
- The design method must include relevant geotechnical parameters.

Mining personnel can judge for themselves as to whether geotechnical design in use at their mine meets these credibility requirements. However, it is important to include geotechnical parameters in the design process; the potential limitations of relying on "rules of thumb" can be found in various sources.

For example, it may be a general rule of thumb that the length of a rock bolt should be one-half to one-third the heading width. However, without considering the ground stresses, structural competency of the host strata, the required excavation serviceability and service life, or indeed the type of rock bolt being employed, it would be imprudent to heavily rely on such a rule for design purposes when considering rock bolt length. It may be convenient to use such general rules in mining as initial estimates, but current duty-of-care considerations require a far more professional approach.

Mining legislation may also stipulate that a geotechnical design process is in place, even if the word *design* is never actually used. The following is an excerpt from the Australian New South Wales Coal Mine Health and Safety Regulation 2006 (NSW Government 2006) about the Strata Failure Management Plan (Section 32 of the regulation):

> [The plan] must make provision for the following matters:
>
> a. the estimation of the geological conditions likely to be encountered in roadway development
> b. the assessment of the stability of roadways to be developed in those geological conditions
> c. the recording of geological conditions that may affect roadway stability
> d. the development of support measures that will provide roadway stability in those geological conditions
> e. calculations (including maximum roadway width and the minimum dimensions of coal pillars) to determine the probability of instability to be assigned to any coal pillar, consistent with the pillar's role or roles over its life.

Without ever using the terminology of *geotechnical design*, this legislation clearly states that coal pillars and roadway strata in coal mining need to be controlled based on a logical design process rather than simple rules of thumb or local mining precedent. Furthermore, the design process needs to be proactive in an attempt to predict geological conditions before they are

encountered, rather than reactive via defining control measures once discovered. That is not to say that unexpected geological conditions will not be encountered during development, simply that the mine must make all efforts to minimize the potential for this happening, because safety hazards are inevitably heightened when unexpected ground conditions are intersected.

Clearly, mining legislation varies around the world, and no hard and fast rules exist for the prescribed need for geotechnical design. However, it is important for practicing mining personnel to be fully aware of what the local mining rules prescribe in this regard and so ensure that minimum geotechnical design requirements are met.

At a basic level a good deal of geotechnical design in mining can be encapsulated by the following equation that incorporates the well-known concept of FoS, even if a particular design methodology does not directly utilize the concept as the design output:

$$\text{FoS or risk-based measure of stability} = \frac{\text{load-bearing capacity}}{\text{applied load}}$$

The point is that most geotechnical problems in mining can be simplified for the purpose of illustration to (1) a driving force, (2) a resistive force, and (3) a risk-based outcome that can be used in making informed and prudent decisions.

On many occasions, using a form of this equation for actual geotechnical design results in inevitable complications, and in these situations the design approach should typically provide a credible range to work within as part of a management process. Ground support associated with mine roadways (as opposed to permanent tunnels) is a classic example. In this situation, instead of the outcome being an FoS, it is a credible range for the level/type of support that can be installed in conjunction with an appropriate monitoring program to manage the risk.

Where an FoS or risk-based design approach is adopted, everything to the right of the equal sign should be predominantly within the domain of the geotechnical engineer, whereas everything to the left should be ultimately that of the mine-site decision maker who is the custodian of acceptable levels of risk. In this instance, it is important that geotechnical inputs and risk-based design outputs do not get confused or indeed considered as one, specifically as their custodians are different. The geotechnical designer should provide mine-site decision makers with various mining options, each containing a defined level of risk. It is the responsibility of the decision maker to consider those options along with non-geotechnical considerations and come to a holistic risk-based decision.

It is understandable that mine operators wish to minimize costs and maximize resource recovery in their efforts to improve mining efficiencies. However, geotechnical input parameters should never be modified as part of this endeavor. The only design variable that allows optimization of the design outcome is the level of acceptable risk. This ensures that mine-site decision makers are fully informed of the potential ramifications when they make their decisions, particularly the need to institute specific operational controls to manage the inherent residual risks.

Generic design methods in geotechnical engineering are commonly referred to as

- Empirical—based on mining experiences, ideally analyzed in a statistically rigorous manner;
- Analytical—involving some form of closed-form solution utilizing discrete equations;
- Numerical—using computer codes;
- Local experience—referring to what has worked previously at a given mine; and
- Rules of thumb.

The choice of geotechnical design method rests with the engineer undertaking the design. Publications such as industry standards on quality control in engineering design (e.g., AS 3905.12-1999, *Guide to AS/NZS 9001:1994 for Architectural and Engineering Design Practices*) mandate processes but not *how* to undertake design or what methodologies should be used. This makes sense as every geotechnical designer brings his or her experience into the design, and it is important to utilize those methods that best complement that experience base. This may include the use of several independent methods to address the same problem, which is commonly considered to be good practice.

Local experiences at a given mine site can be a source of significant design guidance but as an isolated or limited number of case histories only, because reliance on such guidance can lead to problems when geotechnical conditions depart significantly from previous local experiences. It is only by giving due consideration to the primary geotechnical drivers at work in case studies that geotechnical design can attain high levels of reliability; and for this, one is forced to move to either empirical, analytical, or numerical design.

It is beyond the scope of this chapter to provide a detailed comparison of these three design methodologies. In fact, it comprises a book in itself if one wishes to delve deeply into the specifics of individual design methodologies. However, what is worth stating is that regardless of whether a design method is described as empirical, analytical, or numerical, all are by definition empirical at some level. Empirical design methods are self-evident in this regard. However, the highly common practice of calibrating analytical or numerical design methods to known or measured outcomes in the field is an obvious and unequivocal form of empirical design.

It would be nice to believe that geotechnical engineering has progressed to a point where we have at our disposal infallible geotechnical models that can make accurate predictions for how strata will behave under given conditions and how best to go about controlling the resultant manifestation. The reality is that no *first principles* design approaches come close to achieving this, and all design methods need to or should refer back to known experiences prior to making future predictions.

In relation to empirical modeling, Salamon (1989) states the following:

> The main advantage of this approach is its firm links to actual experience. Thus if it is judiciously applied it can hardly result in a totally wrong answer. Also in our legalistic world it has the added advantage of defensibility in a court of law. After all it is based on actual happenings and is not just a figment of imagination.

It is important for a mine-site employee with any form of responsibility for geotechnical design to be satisfied that designs used in operations are credible, and one significant aspect of this is the credibility of the design method in the first place.

If it is accepted that almost all current geotechnical design methods are empirical at some level, this gives the mine-site employee a basis for interacting with the geotechnical

engineer. For example, it would be unreasonable to expect a general mining engineer to hold a sensible discussion on the application of the associated flow rule for plasticity within a numerical code. However, it is reasonable and, in fact, important that mining engineers charged with operational decision making in the area of geomechanics are conversant with the empirical or experience base that underpins the use of any given geotechnical design method at their mines.

In the same way that mining legislation develops over time via learning from mining outcomes (usually accidents), so geotechnical design methods should always be based on and continually updated from relevant mining experiences. Without reference to such experiences, the credibility of geotechnical design requires significant scrutiny before being implemented in mining operations where the safety of workers and the financial security of the mine are at stake.

One final aspect of geotechnical design is having a clear view about the design output. Geotechnical matters rarely completely define the entire focus of geotechnical design, because in the final analysis it is all about supporting a mining process. Therefore, for geotechnical design to be as effective as possible, the geotechnical engineer must be geotechnically competent and have a sound understanding of the mining process and mine operators' needs. For example, mine operators may need one or more of the following non-geotechnical aspects of mining included and considered by the geotechnical design process:

- Exposure of mining personnel to geotechnical risks and associated safety hazards
- Service life of the excavation or mine opening
- Business consequences of inadequate ground control during mining
- Whether the mining work is a critical path activity (i.e., detracts directly from mine production levels)
- Costs involved
- Mining equipment to be used and its limitations
- Ability to install remedial measures if problems occur
- Dilution of run-of-mine product or grade control
- Needs of the mine budget and forecasts

This list clearly demonstrates that an effective geotechnical designer in mining must have a good working knowledge and understanding of the various needs of the mining process and the people who manage and operate the mine. Conversely, it is important for mine operators to clearly define their requirements so the geotechnical engineer can duly consider them as part of the engineer's work.

Exploration and Input Data for Geotechnical Design Purposes

The subject of geotechnical data for design purposes is vast and varies according to the geotechnical issue being addressed (e.g., shaft wall stability, open-pit slope stability, or pillar design for underground mining). Each geotechnical design approach will have its own particular input data requirements and, as stated earlier, it is vital that the exploration program provides the geotechnical designer with the data he or she needs.

Geotechnical data for assessment and design purposes inevitably comes from a variety of sources; no single preferred source of data is preferred. However, the following are typical sources of input data for geotechnical design purposes:

- Surface boreholes: core, chip logs, observations, geophysics, in-hole measurements
- Surface geophysics: seismics, magnetics
- Surface mapping: highwalls, cliffs, lineaments
- Underground mapping: roadways, previously mined-out areas, falls of ground, adverse mining conditions
- Underground boreholes (i.e., upholes and in-seam drilling)
- Underground monitoring data: stress measurement, deformation monitoring (e.g., extensometers, tiltmeters), borescope or fiberscope observations, seismic monitoring systems, and so forth
- Mining experiences: falls of strata, trapped mining equipment, safety statistics, production statistics
- Published technical literature: technical papers, industry bodies, documented case histories
- Informally obtained information: from adjacent mines, mining personnel, third-party consultants

One common theme about geotechnical data collection is consistency of method. Whether it be something as simple as a laboratory test for the uniaxial compressive strength of rock or the calculation of a rock mass rating parameter, consistency is critical. No matter who is undertaking the test or evaluation, the numerical outcome should not be sensitive to the individual concerned. This leads into the area of standards, protocols, and the competency of persons, and it is therefore no surprise that groups such as the International Society for Rock Mechanics (ISRM) have gone to great lengths to develop and publish standards for the characterization of the geotechnical environment. This is summarized in what is known as *The Blue Book*, available from the ISRM (2007).

Quality decisions in geotechnical matters are strongly linked to the quality and quantity of the input data that supports the decision. Therefore, there is great mining value in committing resources to the collection and (just as importantly) the formal storage of geotechnical data relating to the mining project. This is a vast subject area.

Implementation and Management of Residual Risks

After a geotechnical design is signed off, it is transferred to mine operators for implementation. This is one area in which mining is different from, for example, civil construction activities and where many geotechnical problems can occur.

In civil construction projects, the designer (or design team) is usually intimately involved throughout the entire construction project on a day-to-day basis. The designer has the ability to monitor the construction as it proceeds, review and sign off various stages, and collect samples for testing to confirm that his or her original design assumptions have been achieved in practice. A key feature of major civil construction is that it is built consistent with the intent of the design and the assumptions made in its derivation.

In mining, such a process in which the designer is involved throughout the construction phase is far less common and is rarely carried out in practice. Many mines do not have full-time geotechnical professionals on-site, and even if they did, design is often carried out by third parties that do not reside on-site. Therefore the designs are handed over to mine operators for implementation without the day-to-day involvement of the geotechnical design person or team.

The strata management plan in Australian underground coal mines provides a reasonable framework to illustrate the important elements that ensure the associated residual risks are adequately addressed. Once again, Section 32 of the NSW Coal Mine Health and Safety Regulation 2006 (NSW Government

2006) addresses the terms of provisions that relate to the implementation of geotechnical designs in the mine:

f. the preparation and distribution of support plans that clearly describe the following:
   (i) the type of support,
   (ii) the dimensions of the support,
   (iii) the locations where the varying types of supports are in use,
   (iv) the distance between supports,
   (v) the maximum distance roadways can be advanced before support is installed,
   (vi) the means of roadway support required to be installed, in a manner that they may be readily understood by those required to install the roadway support,
g. other information necessary to enable an employee to install support according to the requirements of the management plan,
h. safe, effective and systematic work methods for the installation and subsequent removal when required, of roadway support (including support in connection with carrying out of roof brushing (or baring down) operations or the recovery of plant),
i. the availability of adequate plant and resources to effectively install or remove roadway support,
j. the monitoring of the stability of roadways after development and support installation,
k. the training of employees in support design principles, support plan interpretation, placement and removal of support, understanding the need for and the importance of the various support systems, and recognition of indicators of change that may affect roadway stability,
l. the recording of strata failures that have the potential to cause serious injury to people,
m. a description of the following features and any special provision made for them
   (i) any multiseam workings
   (ii) any mining that has the potential to cause windblast or rapid stress change
   (iii) any mining at depths of less than 50 metres
   (iv) any coal pillars with a pillar width-to-pillar height ratio of 4:1 or less
n. a prohibition on people entering an underground place that is not supported in accordance with the management plan, unless the person does so for the purpose of erecting support, in which case temporary support must be used,
o. a prohibition on mining taking place unless there is sufficient support for the place in accordance with the requirements of the management plan,
p. a statement that nothing in the management plan is to be read as preventing the installation of more strata support or support installation at more frequent intervals than is required by the management plan.

The excerpt about the strata failure management plan illustrates the number of areas that need to be addressed in order for geotechnical designs to be implemented effectively during mining operations. Specifically, it addresses all of those areas in which a well-founded geotechnical design could become compromised and fail in practice. This includes

- Competency of mining personnel in geotechnical matters related to their job functions;
- Need for effective communication with mining personnel about what is precisely required of each geotechnical design;
- Need for the mine to provide adequate resources and fit-for-purpose mining equipment;
- Need for safe systems of work, including consideration of temporary support;
- Need for formal monitoring of mining excavations over time to ensure ongoing and adequate stability or conversely to identify the need for additional support in a timely manner;
- Recording of failures in order to aid the learning process for future mining;
- Identification of issues that have a high associated safety threat and hence the need for special mining provisions;
- Recognition of the right of all mine workers to install strata support necessary to ensure the safety of their workplace; and
- Need to control access to mine areas to ensure that mine workers are not exposed to unacceptably high geotechnical safety threats.

Many of these subject areas have been in place in the mining industry for many years. However, the focus in the 21st century is to incorporate them into a formalized management process rather than simply an informal set of customs and practices, because a formalized and controlled process will yield better overall outcomes in all areas.

SUMMARY COMMENTS

Because the technical aspects of mining geomechanics are many and complex, geotechnical engineering in mining is a specialist discipline. Although mining engineers specializing in mine planning/scheduling or in operational management roles are not expected to be as knowledgeable about geotechnical matters as the geotechnical engineer, such mining professionals should at least have a working knowledge of the relevant subject areas and be able to ask questions of the geotechnical engineer, which add value to the project.

The commonality between all geotechnical disciplines is process rather than technical content. It does not matter whether it is surface or underground, or coal or metalliferous, optimum control of geotechnical hazards in mining can only be achieved if a comprehensive process is in place, covering exploration activities, geotechnical design, and the safe implementation and management of geotechnical design as part of operations.

As importantly, in any system of enabling legislation (which geotechnical matters almost always are), the judgment as to whether a mine has met its duty-of-care obligations will usually be based on the specifics of the processes and procedures that are utilized rather than specific design methodologies employed. Geomechanics is an earth science, and mining is always exposed to vagaries and uncertainties due to the semichaotic nature of the geotechnical environment. Therefore the outcome is not guaranteed, the focus being on minimizing the potential for unexpected occurrences via the application of best practice geotechnical methods within a prudent risk-based management process.

CHAPTER 8.2

Soil Mechanics

Ivan A. Contreras and Jedediah D. Greenwood

INTRODUCTION

Soil is a three-phase (solid, liquid, and gaseous) medium consisting of weakly bonded or unbounded material grains and voids filled with water and air. Mineral grains are more strongly bonded in rock than in soil, although in reality there is no sharp boundary between soil and rock. In particular, properties of weak rock bear many similarities to those of soil and are included in the discussion in this chapter. *Soil mechanics* refers to the fundamental principles that govern the behavior of soils as related to the design, construction, and performance of engineering works. The most significant engineering properties of soil and rock are permeability, compressibility, strength, and durability.

Principles of soil mechanics are applied toward the solution of a variety of problems, including the following:

- Seepage or water flow through soils
- Settlement of foundations and fills on compressible soils
- Swelling and slaking of clay shales in foundations
- Stability of slopes and underground openings

- Design of earth dams and retention ponds
- Bearing capacity of foundations and mine pillars on weak soils
- Tunneling in soils, weak rock, or fault zones

SOIL AND ROCK PROPERTIES

Soil and weak rock possess several characteristics that differentiate them from other engineering materials. The following sections discuss the various properties specific to soil and rock in addition to the manner in which these properties are typically determined by way of laboratory and in-situ testing.

Characteristics of Soils

Fine-grained soils interact with water in such a way that there is no resemblance between their dry and wet behavior, and their properties are largely influenced by the physicochemistry of the soil–water system. Fine-grained saturated soils are generally cohesive as a result of the net balance between attractive and repulsive inter-particle forces.

Soft or weak sedimentary rocks such as shale and other *rock–soil transitional materials* such as weathered rock or residual soils not only have strengths that may approach those of highly overconsolidated soils but also have behavior similar to soils, inasmuch as it is influenced by the physicochemistry of the solid–water system. Thus the principles of soil mechanics can be also used to explain the behavior of so-called *weak rock* whose pore water response, volume change behavior (e.g., swelling), and shear strength characteristics are similar to those of soil.

Stiff soils and weak rocks commonly contain fissures and joints that affect permeability, compressibility, strength, and durability of the soil/rock mass. Thus the principles used in rock mechanics for evaluating a discontinuous medium are also applicable to these materials.

The concept of *effective stress* is one of the most important principles of soil mechanics. Both soil compressibility and soil strength are controlled by effective stress. The concept establishes that, for a saturated soil–water system, the effective stress σ' applied to the soil skeleton is equal to the total stress σ externally applied minus the existing pore water pressure u:

$$\sigma' = \sigma - u \tag{8.2-1}$$

The maximum shearing resistance (shear strength) that a soil can develop is a function of the effective stress acting on the soil. The pore water pressure is positive when u is in compression (greater than atmospheric pressure). An increase in the pore water pressure for a given total stress reduces the effective stress and, consequently, the shear strength of the soil. The pore water pressure is negative, on the other hand, when u is in tension (less than atmospheric pressure). In the latter case, which occurs for saturated and partially saturated soils above the groundwater table, the effective stress is greater than or equal to the total stress. The concept of effective stress applies not only to soils but also to rock and other materials with continuous voids formed by pore spaces or joints.

Ivan A. Contreras, Vice President, Barr Engineering Company, Minneapolis, Minnesota, USA
Jedediah D. Greenwood, Senior Geotechnical Engineer, Barr Engineering Company, Minneapolis, Minnesota, USA

Saturated materials that are soft enough to undergo significant volume change upon application or removal of pressure (soil and many weak rocks) exhibit time-dependent consolidation or swelling, which is a manifestation of the principle of effective stress. Upon application of an increment of pressure $\Delta\sigma$ to a saturated soil, its volume does not decrease significantly until water is expelled from the pore spaces. Because the soil skeleton is more compressible than water, the pressure increment is initially applied to the water; thus $\Delta u \approx \Delta\sigma$, the excess pore water pressure. With time, as the water is squeezed from the pore spaces, the volume decreases, and the water pressure reduces to its original value ($\Delta u = 0$). The pressure increment is progressively transferred from the water to the soil skeleton, until finally the pressure increment becomes fully an effective pressure, $\Delta\sigma' = \Delta\sigma$. This time-dependent process is termed *consolidation* for the volume decrease resulting from an increase in effective stress, and *swelling* for the volume increase resulting from a decrease in effective stress. Excess pore water pressure dissipates rapidly for permeable materials such as sands, and slowly for low-permeability soils such as clay.

For a large mass of low-permeability soil, the process is so slow that significant changes in volume or water content may not occur over the period of loading, so the material remains undrained, and its strength and stiffness can be assumed to be unchanged from the initial condition before the load increment was applied. Upon application of load and over a long period of time, drainage occurs and the soil consolidates, with corresponding increases in strength and stiffness. Upon unloading, however, the soil swells with time, and strength and stiffness decrease.

In contrast, most sandy soils subjected to static loads are assumed to be loaded slowly enough that significant excess pore water pressure Δu does not build up; therefore the soil is drained, and the pressure increment is applied directly to the soil skeleton throughout the loading increment ($\Delta\sigma' = \Delta\sigma$; $\Delta u = 0$).

Index Properties of Soil and Weak Rock

The spatial distribution and properties of soil, rock, fluids, and air at a site should be investigated as they relate to local geology and information collected from field exploration. The results of field exploration should be used to log the distribution and changes in material properties, to index soil properties by means of in-situ tests, and to collect disturbed (remolded) samples for laboratory index testing or undisturbed samples for elaborate laboratory tests.

Soil and weak rock are classified for engineering purposes in terms of *index properties*, which are by definition significant (i.e., engineering behavior can be inferred from them), simple and quick to measure, reproducible, and easy to express (such as with a numerical value).

Grain size is an important property of all soils. A soil is considered *fine grained* (clay and silt) or *coarse grained* (sand and gravel) if its predominant grain size is smaller or greater, respectively, than the smallest particle diameter that can be identified with the naked eye (equivalent to passing through a No. 200 U.S. standard sieve, or 75 μm).

With little to no clay or silt, coarse-grained soils are generally cohesionless, and their properties remain practically unchanged whether the soil is unsaturated or fully saturated. Coarse-grained soils are indexed in terms of their grain size and grain-size distribution.

The Atterberg limits serve as an index test for measuring the characteristic of fine-grained soils, referred to as *soil plasticity*. The Atterberg limits define the range of water contents (percent ratio between the weight of water and the weight of solids) at which fine-grained soil passes from a liquid state (liquid limit) through a plastic state (plastic limit) and finally into a solid state (Atterberg 1911). The *shrinkage limit* is defined as the water content at which fully saturated soil cake stops decreasing in volume. Any further moisture loss simply starts emptying the soil pores. High-plasticity soils, having a large plastic range, are subject to high swelling and shrinkage.

Both grain size and plasticity form the basis for the categories in the Unified Soil Classification System shown in Table 8.2-1. These index tests are performed on disturbed samples, which do not retain the structure and density of the soil in situ.

Field Exploration

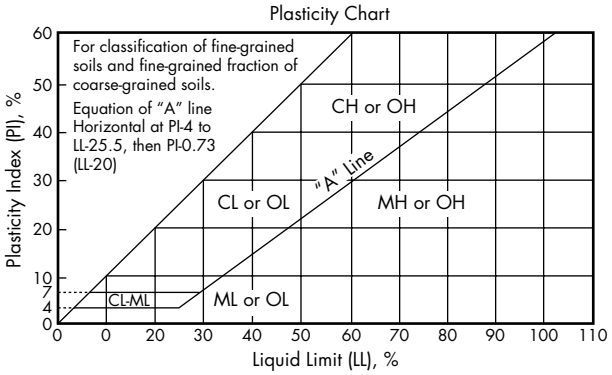
In order to collect disturbed samples for index-property testing and to evaluate in-situ soil properties (i.e., permeability, compressibility, and strength), it is necessary to perform a field exploration program. Index properties are determined on disturbed samples, because the properties are independent of sample disturbance. In contrast, in-situ properties are determined on relatively undisturbed samples in the laboratory or in the field, because the properties are highly dependent on sample disturbance.

The field exploration program generally includes soil borings with in-situ tests including but not limited to the following:

- Standard penetration test
- Cone penetration test
- Marchetti dilatometer test
- Pressuremeter test
- Field vane test

Standard Penetration Test

The standard penetration test (SPT) involves driving a 2-in.-(50.8-mm-) diameter split-spoon sampler into the ground using a 140-lb (63.5-kg) hammer dropped freely from a height of 30 in. (762 mm). The sampler is attached to drill rods and lowered to the bottom of the clean drilled hole. After the sampler reaches the bottom of the hole, the number of hammer blows is counted until it achieves three successive penetrations of 6 in. (150 mm). The number of blows to advance the sampler the first 6 in. (150 mm) is disregarded because of likely disturbance at the bottom of the hole. The number of blows "*N*" to advance the sampler for the second and third 6-in. (150-mm) increments into the ground is the standard penetration resistance of the soil.



During the SPT, the amount of energy actually transmitted to the drill rods by the hammer is influenced by several factors. The ratio of the energy actually transmitted to the rods to that theoretically delivered by the hammer is commonly known as the *energy ratio* or *efficiency* of the hammer system. In general, most correlations are based on N values corresponding to an efficiency of 60%, designated N_{60}. The energy correction factor C_E is given by the equation

$$C_E = \mathrm{ER}/60 \tag{8.2-2}$$

where ER is the energy ratio. The energy transmitted to the drill rods can be determined by direct measurement in the field

Table 8.2-1 Unified Soil Classification System

Criteria for Assigning Group Symbols and Names Using Laboratory Tests[a]			Soil Classification Group Symbol, Name[b]
Coarse-grained soils: >50% retained on No. 200 sieve			
Gravels: >50% of coarse fraction retained on No. 4 sieve	Clean gravels: <5% fines[c]	$C_u \geq 4$ and $1 \leq C_c \leq 3$[e]	GW, Well-graded gravel[f]
		$C_u < 4$ and/or $1 > C_c > 3$[e]	GP, Poorly graded gravel[f]
	Gravels with fines: >12% fines[c]	Fines classify as ML or MH	GM, Silty gravel[f,g,h]
		Fines classify as CL or CH	GC, Clayey gravel[f,g,h]
Sands: ≥50% of coarse fraction passes No. 4 sieve	Clean sands: <5% fines[d]	$C_u \geq 6$ and $1 \leq C_c \leq 3$[e]	SW, Well-graded sand[i]
		$C_u < 6$ and/or $1 > C_c > 3$[e]	SP, Poorly graded sand[i]
	Sands with fines: >12% fines[d]	Fines classify as ML or MH	SM, Silty sand[g,h,i]
		Fines classify as CL or CH	SC, Clayey sand[g,h,i]
Fine-grained soils: ≥50% passes No. 200 sieve			
Silts and clays: liquid limit <50	Inorganic	PI > 7 and plots on or above "A" line[j]	CL, Lean clay[k,l,m]
		PI < 4 or plots below "A" line[j]	ML, Silt[k,l,m]
	Organic	$\frac{\text{Liquid limit (oven dried)}}{\text{Liquid limit (not dried)}} < 0.75$	OL, Organic clay[k,l,m,n] or silt[k,l,m,o]
Silts and clays: liquid limit ≥50	Inorganic	PI plots on or above "A" line	CH, Fat clay[k,l,m]
		PI plots below "A" line	MH, Elastic silt[k,l,m]
	Organic	$\frac{\text{Liquid limit (oven dried)}}{\text{Liquid limit (not dried)}} < 0.75$	OH, Organic clay[k,l,m,p] or silt[k,l,m,q]
Highly organic soils		Primarily organic matter, dark in color, and organic odor	Pt, Peat

Source: Adapted from ASTM D2487-00.

a. Based on the material passing a 3-in. (75-mm) sieve.

b. If field sample contained cobbles, boulders, or both, add "with cobble, boulders, or both" to group name.

c,d. Gravels or sands with 5% to 12% fines require dual symbols such as "GW-GM well-graded gravel with silt" or "SP-SC poorly graded sand with clay."

e. $C_u = \frac{D_{60}}{D_{10}}, C_c = \frac{(D_{30})^2}{D_{10} \times D_{60}}$

f. If soil contains ≥15% sand, add "with sand" to group name.

g. If fines classify as CL-ML, use dual symbol GC-GM or SC-SM.

h. If fines are organic, add "with organic fines" to group name.

i. If soil contains ≥15% gravel, add "with gravel" to group name.

j. If Atterberg limits plot in hatched area, soil is a CL-ML, silty clay.

k. If soil contains 15% to 29% plus No. 200, add "with sand" or "with gravel," whichever is predominant.

l. If soil contains ≥30% plus No. 200, predominantly sand, add "sandy" to group name.

m. If soil contains ≥30% plus No. 200, predominantly gravel, add "gravelly" to group name.

n. PI ≥4 and plots on or above "A" line.

o. PI <4 or plots below "A" line.

p. PI plots on or above "A" line.

q. PI plots below "A" line.

Table 8.2-2 Correction factors for the standard penetration test

Factor	Term	Equipment Variable	Correction
Energy	C_E	Donut hammer	0.5–1.0
		Safety hammer	0.7–1.2
		Automatic-trip donut-type hammer	0.8–1.3
Borehole diameter	C_B	2.5–4.5 in. (65–115 mm)	1.0
		6 in. (150 mm)	1.05
		7.9 in. (200 mm)	1.15
Rod length	C_R	<10 ft (3 m)	0.75
		10–13 ft (3–4 m)	0.80
		13–20 ft (4–6 m)	0.85
		20–32 ft (6–10 m)	0.95
		32–100 ft (10–30 m)	1.0
Sampling method	C_S	Standard sampler	1.0
		Sampler without liners	1.1–1.3

*Standard penetration resistance corresponding to an efficiency of 60% blows/ft.

using dynamic pile testing equipment. Alternatively, energy corrections have been summarized based on factors such as hammer type, borehole diameter, rod length, and whether or not the sampler uses a liner. Correction factors corresponding to these factors are shown in Table 8.2-2.

The value of N corresponding to 60% efficiency, N_{60}, is given by the equation

$$N_{60} = N\, C_E\, C_B\, C_R\, C_S \tag{8.2-3}$$

where

N = standard penetration resistance measured in the field
C_E = energy correction factor
C_B = correction factor for borehole diameter
C_R = correction factor for rod length
C_S = correction for sampling method (with or without liners)

N_{60} indicates the relative density of in-situ granular soils and the consistency of fine-grained soils. Table 8.2-3 shows the relationship between the relative density of sand and the strength (consistency) of clay.

The relationship between N_{60} and unconfined compressive strength q_u in the table is a crude estimate of clay strength. The significant scatter in the values of unconfined compressive strength for a given N_{60} is attributed to the disturbance induced by the SPT sampler and procedure. As a result, the relationships in the table should be used with caution.

Similarly, the approximate relationship between N_{60} and the relative density of sand should be used with caution. When the sand is located below the water table and the water inside the casing is allowed to fall below the piezometric level, the sand at the test location may become quick and transform into a loose state, resulting in a low value of N_{60}. On the other hand, boulders or cobbles larger than the diameter of the spoon may give high values of N_{60}.

Because the standard penetration resistance increases with increasing effective overburden stress, an overburden-stress correction factor is generally applied (Seed and Idriss 1982). This correction factor, C_N, is typically applied for granular soils when performing liquefaction assessments and is calculated using the equation

$$C_N = (100\ \text{kPa}/\sigma'_{vo})^{0.5} \tag{8.2-4}$$

where σ'_{vo} is the effective overburden stress in kilopascals at the considered depth. C_N should not exceed 1.7.

The standard penetration-blow count corresponding to a combined efficiency of 60% and a normalized effective stress of 100 kPa is given by the equation

$$(N_1)_{60} = N_{60}\, C_N \tag{8.2-5}$$

This blow count is used in several SPT correlations and in liquefaction assessments.

Cone Penetration Test

The cone penetration test (CPT) has been extensively used in recent years to provide in-situ geotechnical information relatively quickly and inexpensively. It has gained wide acceptance in geotechnical practice since the late 1980s, and additional capabilities continue to be developed. CPT results are less operator-dependent than are SPT results, which makes the CPT more attractive because of its repeatability and the possibility of good correlations between test data and geotechnical parameters. However, the CPT has limitations in gravelly soils, cemented soils, and bedrock, which are unlikely to be penetrated with the equipment.

The test involves pushing a conical tip with a 60° apex angle into the ground at a constant penetration rate of 0.8 in./s (20 mm/s). During penetration, measurements are made of the cone-tip resistance (q_c), side friction of the cylindrical shaft behind the cone (f_s), and pore water pressure (u_2) generated by penetration. These measurements, collected virtually on a continuous basis, are used to infer lithological profiles based on interpreted soil-behavior types. They are used to assess liquefaction, slope stability, foundations, and groundwater flow characteristics.

The cone is also used to perform dissipation tests. A dissipation test is performed at the desired depth by stopping cone penetration and measuring the change in pore water pressure with time. The rate of pore water pressure dissipation depends on the horizontal coefficient of consolidation c_h, which in turn depends on the compressibility and permeability of the soil.

Cones equipped with geophones are commonly used to measure arrival times of shear and compression waves

in addition to the three basic measured parameters. These are commonly referred to as *seismic cones*. The shear-wave source usually consists of a beam pressed against the ground and a hammer with an electronic trigger. Shear waves are generated at the ground surface by hitting the beam ends with a hammer in the direction of the long axis. During a pause in penetration, typically at 3.3-ft (1-m) intervals, shear waves are generated at the ground surface and the arrival time of the shear waves to the geophone is measured. The shear wave is used to estimate shear deformation modulus (small strain) and to perform liquefaction assessments. Compression waves are generated and interpreted in a similar manner.

Some CPT equipment is outfitted with devices to obtain soil and water samples. The device is generally pushed into the ground using an offset sounding. Penetration is then stopped at the desired sampling depth. Soil and water samples are taken only at discrete locations.

New CPT equipment includes additional sensors for subsurface exploration. These include sensors to measure lateral stress, electrical resistivity, heat flow, radio isotopes, and density. They also include sensors for environmental applications such as temperature, conductivity, pH, and laser-induced fluorescence.

Dilatometer Test

The Marchetti, or flat-blade, dilatometer test (DMT) is another device often used to measure in-situ geotechnical properties of soils. It is primarily used to determine stiffness parameters and undrained shear strength of cohesive soils, but also has applicability for granular materials and in determining in-situ horizontal stresses. Soil stratigraphy and depth to the water table can also be determined from the test. Similar to the CPT, bedrock and gravelly or cemented soils may cause problems for penetration.

The test device consists of a flat blade 0.5 in. (14 mm) thick, 3.7 in. (95 mm) wide, and 8.7 in. (220 mm) long. A flexible stainless-steel membrane 2.4 in. (60 mm) in diameter is located in the center of one side of the blade. The blade is pushed into the ground with a CPT rig or drill rig and stopped at regular depth intervals (usually 7.9 in. [20 cm]), after which the membrane is inflated with nitrogen gas and then deflated. The operator measures and records the pressure required to produce expansion of the membrane into the soil at two preset deflections. The first reading is taken when the membrane starts to lift off; the second is taken after a deflection of 0.4 in. (1 mm). An optional third reading is taken when the membrane reaches the original lift-off position to measure pore water pressure.

Pressuremeter Test

The pressuremeter test (PMT) is used to determine in-situ stress–strain characteristics in soil and weak rock. The PMT is typically used in materials that are too stiff for the DMT. The PMT provides information about the stress–strain properties and strength of the soil or rock by expanding the walls of a drill hole while the radial pressure and corresponding deformation are measured.

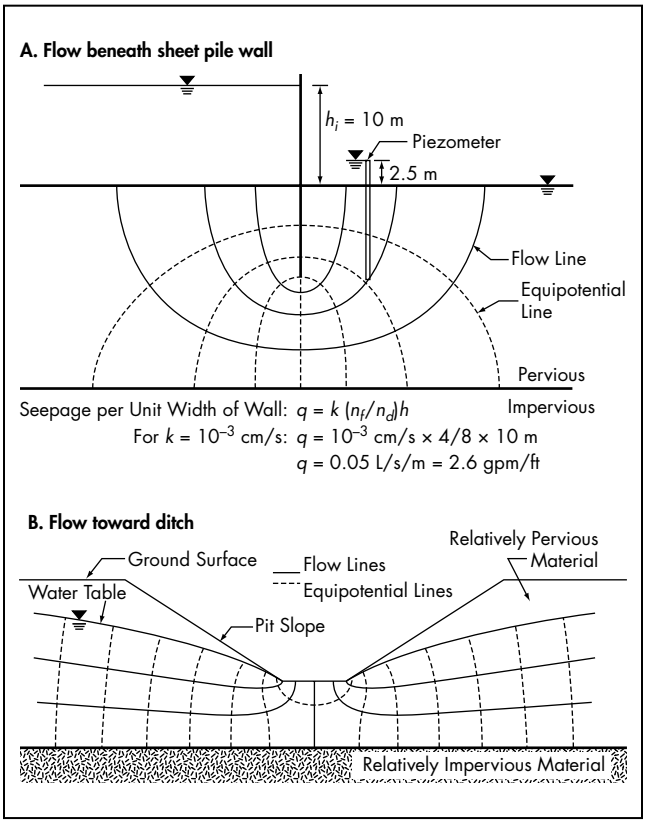
The test device consists of an assembly of three cells with flexible walls. The upper and lower cells are guard cells; the middle cell is used as a measuring cell. The assembly is lowered into a drill hole similar in size to the pressuremeter apparatus and the cells are then inflated. The measuring cell is inflated incrementally using water pressure. The water pressure is measured to indicate the radial pressure against the soil or rock, and the volume of water is measured to indicate radial displacement during the increment. The guard cells are also inflated to ensure a nearly cylindrical two-dimensional (2-D) state of stress with the purpose of reducing the end effects on the measuring cell. Some corrections are applied to account for expansion of the measuring tubing under pressure.

The measured cell pressure and cell volume are used to generate a stress–strain curve for the in-situ soils. The slope of the pseudo-elastic portion of the curve is used to compute the pressuremeter modulus, which is a measure of the stiffness of the soil or weak rock.

Field Vane Test

The field vane (FV) test is widely used to measure the undrained shear strength of soft clays. The test device consists of a four-bladed rectangular vane fastened to the bottom of a vertical rod. The standard vane has a height/diameter ratio of 2:1, with a height of either 4.3 or 5.1 in. (110 or 130 mm) and a diameter of either 2.2 or 2.6 in. (55 or 65 mm). Some models have a protective casing or sheath for the vane and others do not. The vane is pushed into the ground to the desired test depth and rotated at a rate of 0.1°/s by a crank handle while the torque is measured. The vane is then advanced to the next depth and the process is repeated. Tests are typically conducted at intervals of 1.6 ft (0.5 m). The shearing resistance is computed from the torque and the dimensions of the vane. If the vane is rotated rapidly several revolutions, the soil remolds and the remolded strength can be computed.

Table 8.2-4 Coefficient of permeability



Material	k, cm/s
Clean gravel	1 to 10^2
Coarse to medium sand	10^{-2} to 1
Fine sand	10^{-4} to 10^{-2}
Silt	10^{-6} to 10^{-4}
Natural clays	10^{-8} to 10^{-6}
Highly overconsolidated clays and shales	10^{-12} to 10^{-8}

Source: Cording and Cepeda-Díaz 1992.

Permeability

Permeability k, expressed in units of length per time, indicates the discharge velocity with which water under a unit hydraulic gradient flows through soil and rock. Procedures are available for measuring permeability in the field and in the laboratory. Results depend on the direction of the water flow during the test because soil and rock generally have direction-dependent permeability or anisotropy. In a bedded deposit, horizontal permeability k_h usually exceeds vertical permeability k_v. For example, for homogeneous soft clay, typical ranges for horizontal permeability are $k_h = 1.0–1.5\ k_v$; for varved clay, typical ranges are $k_h = 1.5–5.0\ k_v$. Much greater ratios of k_h/k_v apply to bedded deposits having alternating layers of clay and sand.

The coefficient of permeability k is a function of the size, shape (tortuosity), and number of pores or joints (channels) in the soil/rock mass. Table 8.2-4 presents typical values of k for various soil and weak rock materials. For a given soil or weak rock, k decreases with decreasing values of void ratio e (volume of voids per volume of solids) and therefore with increasing effective stress. The slope of the e–log k relationship is

Source: Cording and Cepeda-Díaz 1992.

Figure 8.2-1 Flow nets for medium soil with homogeneous, isotropic permeability

generally referred to as $C_k = \Delta e/\Delta \log k$. For soft clays, C_k = 0.5–2.0; for shales, $C_k < 0.5$.

For granular soils, Hazen (1892) performed a number of experiments from which he established an empirical formula to estimate the permeability of saturated filter sands. The relationship is $k = C_H(d_{10})^2$ where k = coefficient of permeability (m/s), C_H = Hazen empirical coefficient, and d_{10} = particle size from a sieve analysis for which 10% of the particles are finer (in units of millimeters). Figure 8.2-1 shows permeability and grain-size data from Louden (1952). Caution should be exercised in using the Hazen empirical correlation because of its simplicity and because the C_H coefficient (average value of 0.01) can vary by orders of magnitude. Other more complex relationships (such as the Kozeny–Carman semi-empirical/semi-theoretical formula [Kozeny 1927; Carman 1938, 1956]) have been proposed that are more accurate, but require more input parameters.

Permeability is particularly sensitive to heterogeneities such as stratification, fissures, and joints. Thus their presence determines either the minimum specimen size required in the laboratory for a representative sample or the need for in-situ testing to obtain valid measurements. Disturbance of the soil during boring or sampling can also affect permeability measurements. In many cases, laboratory-measured permeability is not comparable to in-situ permeability. In the field, the local permeability surrounding a borehole can be assessed by a water pressure test in which a quantity of water is pumped into or extracted from a section of a borehole under a given pressure. More comprehensive results, indicative of the performance of a larger portion of an aquifer, are obtained by pump tests in which piezometric levels are monitored in several borings, with time, as a nearby well is pumped.

Darcy's empirical equation (Darcy 1856), initially established for the flow of water through coarse-grained soils, has also proven to be valid for water flow through fine-grained soils, including heavily overconsolidated clays and shales (Mesri and Cepeda-Díaz 1987). Darcy's law states that the discharge velocity v_s in a direction s is equal to the coefficient of permeability in the s direction k_s times the hydraulic gradient i:

$$v_s = k_s\, i \tag{8.2-6}$$

where the dimensionless parameter i is equal to the change of total hydraulic head Δh in the distance interval Δs along the macroscopic or apparent flow path s ($i = \Delta h/\Delta s$). Therefore, the time rate of flow q (volume flow rate) through an area A perpendicular to the direction of the flow is given by

$$q = k_s\, iA \tag{8.2-7}$$

which is used to directly evaluate one-dimensional (1-D) steady-state flow.

A modified version of the previous equation is used to calculate the quantity of flow for 2-D steady-state flow through soil. The solution to the mathematical problem can be obtained graphically in the form of a scaled flow net (Cedergren 1967). For a homogeneous, isotropic medium ($k_h = k_v$), the flow net consists of two mutually orthogonal families of curves (flow lines and equipotential lines) forming curvilinear "square" cells within the boundaries of the problem, thus also forming both a number of flow channels n_f and a number of equipotential drops n_d for a given head loss h_l (Figure 8.2-1). Since each flow channel carries the same flow rate as the others and continuity of flow (conservation of mass) must be satisfied, fluid motion can be described at the individual-square-cell level where the hydraulic gradient i times the discharge area of the channel is equal to h_l/n_d per unit of width and thus iA (per unit of width for the entire flow net) = $(h_l \cdot n_f)/n_d$. For 2-D steady-state flow, therefore, the time rate of flow ($q = k_s iA$) is given by

$$q = k_s(n_f/n_d)h_l \tag{8.2-8}$$

per unit of width perpendicular to the plane of the flow net. A flow-net solution enables the hydraulic gradient and the pore water pressure to be calculated at any location within the hydraulic boundaries considered. Thus, pore water pressures developed as a result of water seepage can be determined along potential surfaces of sliding in order to evaluate the stability of a soil mass.

In materials such as jointed rock or bedded soils, permeabilities are not uniform. As a result, the flow net is distorted, and the flow lines and equipotential lines do not form squares.

Computer modeling programs have simplified the computation of groundwater flow regimes, and many programs allow computed pore water pressures to be imported into slope-stability analyses.

Compressibility and Volume Change Characteristics

The compressibility or expansibility of a soil or weak rock can be separated into several components:

- Initial "elastic" deformation
- Time-dependent hydrodynamic volume change (primary consolidation or swelling)

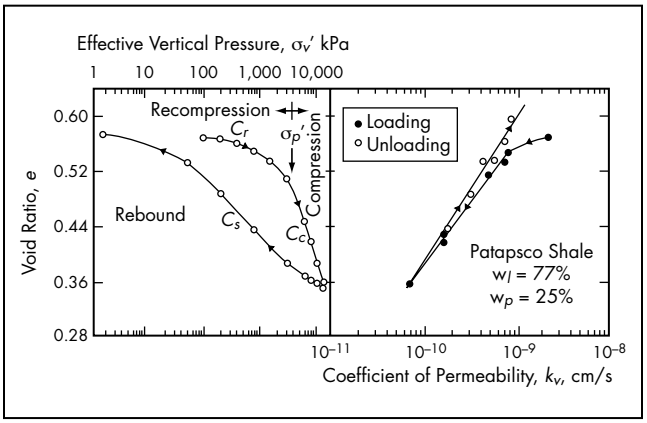
- Time-dependent volume change (secondary consolidation or swelling) and/or time-dependent deformation (creep)

Initial "Elastic" Deformation

Immediately after the application or removal of load, a fine-grained saturated soil deforms without any change in volume or water content, referred to as the *undrained condition*. In an unsaturated soil or a coarse-grained soil, the initial elastic deformations may include some volume changes and distortion.

Assuming that the material has not yet failed, the amount of strain for a given pressure increment can be estimated using a modulus of deformation that is equivalent to a modulus of elasticity E, but represents a tangent or secant to a stress–strain curve that is usually nonlinear. The deformation modulus E_u of a sample is determined in the laboratory from unconfined or triaxial compression tests in which the specimen is subjected to increasing axial stress σ_1 while the all-round confining pressure σ_3 is kept constant. The slope of the curve relating the stress difference $\sigma_1 - \sigma_3$ to the axial strain ε represents the modulus of the sample, and $(\sigma_1 - \sigma_3)_{max}$ is the compressive strength. The unconfined compressive strength is generally referred to as q_u. For most soils and weak rocks, E_u = (50 to 300) q_u.

For the modulus of deformation, values measured in-situ are expected to differ from those measured in the laboratory. For most soils, sample disturbance reduces soil stiffness significantly, and thus laboratory measurements are generally lower than in-situ measurements. In contrast, for soil and rock masses that contain fissures or joints, a laboratory sample usually does not contain a representative number of fissures or joints, and thus laboratory measurements are generally higher than in-situ measurements.



The greater the stiffness of the soil or rock, the more significant is the initial deformation with respect to the overall deformation experienced with time by the soil or rock mass.

Primary Consolidation or Swelling

In a saturated fine-grained soil, the initial elastic deformations described previously occur with very little volume change in the soil matrix. With time, as the load remains in place, water is squeezed out of the soil matrix and the soil volume decreases. This process is called primary consolidation. In soft clays, primary consolidation is responsible for most of the settlement that the clay undergoes upon application of a load. Compression that occurs with time, after the effective stress σ' has reached its final value, under either isotropic loading or 1-D deformation conditions, is called secondary consolidation and is a creep phenomenon.

Upon unloading, as water is sucked into the soil, soil volume increases and effective stress decreases. This time-dependent process is called primary swelling. Swelling that occurs with time after σ' has reached its final value, under either isotropic unloading or 1-D deformation conditions, is called secondary swelling.

The magnitude of settlement or heave during primary consolidation or swelling is determined for fine-grained soils in the laboratory by means of the 1-D consolidation test, in which a sample is restrained so that lateral strains are zero as vertical load is applied. As each load decrement or increment is applied, water is allowed to flow into or out of the soil through porous stones at the top and bottom of the sample, and the vertical deformation of the specimen is measured with time. The change in the void ratio of the sample is proportional to the vertical displacement. The end of primary consolidation or swelling, at time t_p, occurs when the excess pore pressure that is generated upon application of each load increment has completely dissipated, which can be determined graphically.

Source: Cepeda-Díaz 1987.

Figure 8.2-2 Typical plots of void ratio for soil and weak rock as a function of effective vertical pressure (stress-volume) and as a function of coefficient of permeability

For a homogeneous soil layer of thickness H and initial void ratio e_o, settlement or heave ΔH is given by

$$\Delta H = \{(e - e_o)/(1 + e_o)\}H \tag{8.2-9}$$

where e is the void ratio at any particular vertical stress σ'_v and/or time t.

The magnitude of settlement or heave at the end of primary consolidation or swelling is generally obtained for fine-grained soils from a plot of the void ratio e versus the logarithm of the effective stress σ'_v applied to the sample. Figure 8.2-2 shows the typical e–log σ'_v relationship. For a heavily overconsolidated clay, it consists of three parts: recompression, compression, and rebound (Patapsco shale). The preconsolidation pressure σ'_p = 38 tons/ft^2 (40 MPa). The slope of the curve, $\Delta e/\Delta \log \sigma'_v$, for each distinct portion is identified as the recompression index C_r, compression index C_c, and swelling index C_s. In the recompression range, the corresponding settlement is significantly smaller than that resulting when σ'_{vf} (final σ'_v) is in the compression range. Loading of soft clays, whose preconsolidation pressure σ'_p is relatively small and compression index C_c is relatively large can result in large settlements when the applied pressures exceed the preconsolidation pressure. The magnitude of heave can be estimated using the rebound curve whose slope is C_s. Figure 8.2-2 also shows direct measured permeability data at various σ'_v and the corresponding e in the form of an e–log k_v plot for parallel examination with the e–log σ'_v plot.

The time rate of settlement or heave, which is controlled by the rate at which pore water can be expelled (or taken in), is a function of the permeability k and the compressibility (or swellability) of the soil, $a_v = \Delta e/\Delta\sigma'_v$, as expressed by the coefficient of consolidation (or swelling) $c_v = k(1 + e)/a_v\gamma_w$, according to the Terzaghi theory of consolidation (Terzaghi et al. 1996). The mathematical solution of the theory provides the relationship between the average degree of consolidation (or swelling) U in % = $\Delta H/\Delta H_p$ and a dimensionless time factor T whose numerical value is equal to $c_v t/H^2$, where t is real

Table 8.2-5 Values of C_α/C_c for geotechnical materials

Material	C_α/C_c, ± 0.01
Granular soils including rock filling	0.02
Shale and mudstone	0.03
Inorganic clays and silts	0.04
Organic clays and silts	0.05
Peat and muskeg	0.06

time and H is the maximum drainage distance. Therefore, after c_v is evaluated (usually by fitting Terzaghi's theory to the observed deformation time data in the 1-D consolidation test), the settlement ΔH at any time $t < t_p$ during the consolidation process can be predicted. For example, according to the Terzaghi theory of consolidation (or swelling), the time factor for U = 95% is T_{95} = 1.12. Therefore, the (real) time for a 95% average degree of consolidation (or swelling) to occur is $t_{95} = 1.12\ H^2/c_{cv}$. For a maximum drainage distance H = 20 ft (6.1 m) and a coefficient of consolidation (or swelling) of 10 ft^2/yr (0.93 m^2/s), the time for end-of-primary to occur t_p is approximately $t_{95} = 1.12\ (20\ \text{ft})^2/(10\ \text{ft}^2/\text{yr}) = 45$ years.

In soils containing lenses of sand with a clay or silt, the effective drainage distance is difficult to determine, and hence the time to achieve consolidation or swelling is difficult to estimate. One of the most effective means is to monitor the settlement of test fills.

The horizontal coefficient of consolidation c_h can be estimated in situ using CPT dissipation test results. During a pause in penetration, the decay of measured pore water pressure is recorded and an empirical correlation between c_h and t_{50} (time to 50% consolidation) has been proposed by Robertson et al. (1992). The values of c_h and c_v for settlement calculations can be related by means of the anisotropy relationship.

Secondary Consolidation or Swelling

The slope of the observed e–log t curve for $t > t_p$ is called the secondary compression index C_α for consolidation and the secondary swelling index $C_{\alpha s}$ for swelling. Since C_α/C_c is constant for any one soil, including shales, its value can be used in combination with the e–log σ'_v relationship to compute the secondary settlement at any $t > t_p$ (Mesri and Godlewski 1977). Table 8.2-5 shows typical values of the C_α/C_c ratio for various geotechnical materials. The relationship between $C_{\alpha s}$ and the OCR (final overconsolidation ratio after swelling $\sigma'_{max}/\sigma'_{vf}$) can be also obtained and used to compute the secondary swelling for any time $t > t_p$.

Shear Strength

The shear strength s or shearing resistance of a soil or rock is a function of the normal effective stress on the shear plane at failure σ'_{nf}. Thus s is controlled by the existing normal effective stress before shear ($\sigma'_n = \sigma_n - u$) and the excess pore water pressure induced during shearing up to failure u_{sf}, $\sigma'_{nf} = \sigma'_n - u_{sf}$. For $u_f = u + u_{sf}$, σ'_{nf} can be expressed as

$$\sigma'_{nf} = \sigma - u_f \tag{8.2-10}$$

During shearing, as a result of particle rearrangement, loose coarse-grained cohesionless soils and normally consolidated clays tend to compress, whereas dense cohesionless soils and overconsolidated clays and shales tend to increase in volume (dilate). Excess pore water pressures develop when water cannot move in or out of the pores fast enough to accommodate the volume changes induced during shearing. In this case, the soil is sheared under so-called undrained conditions.

Effective stress analyses can be used to evaluate the strength of a soil for either drained or undrained conditions. However, to use an effective stress analysis in the undrained case, the pore water pressures generated at failure must be known. This information is difficult to obtain or predict. Therefore, for soft clays subjected to short-term loading, an analysis for the undrained case is used, in which the undrained shear strength s_u is determined from unconfined compression tests, undrained triaxial tests, or in-situ vane shear tests.

Sand

With the exception of dynamic loading, clean coarse-grained cohesionless soils can be treated as shearing under drained conditions as a result of their high permeability. Their shear strength can be expressed as

$$s = \sigma'_{nf} \tan \phi' \tag{8.2-11}$$

where ϕ' is the drained friction angle (or friction angle in terms of σ' at failure). For granular soils, ϕ' is primarily a function of the relative density of the soil. Thus for loose sand $\phi' \approx 28°$ and for loose sand $\phi' \approx 44°$.

Loose saturated sands subject to dynamic loads such as earthquakes are apt to develop positive pore water pressures that reduce the effective stresses to zero and liquefy the sand.

Fine-Grained Soils

For fine-grained soils, their relatively low permeability is such that significant buildup of excess pore water pressure is expected to occur during the loading and unloading operations associated with construction. In a short period of time, the excess pore water pressures that are generated do not dissipate, and the clay does not change in volume or water content. Thus soft clays can be treated as undrained, with an undrained shear strength s_u that does not change from its original value. This condition is described later in the "Undrained Shear Strength" section.

Use of the undrained shear strength is simple, with application to several significant engineering problems. However, many failures have resulted from its inappropriate use, particularly in situations where negative pore water pressures were generated initially and then dissipated, resulting in reduced shear strength during the period in which the undrained shear strength was assumed to be applicable. This is most likely to occur for stiff, overconsolidated clays. In addition, the presence of sand seams or fissures in a clay can cause more rapid dissipation of negative pore water pressures than would be otherwise anticipated, leading to failure earlier during the construction period than expected. Thus, when using the undrained shear strength, it is important to recognize those conditions for which its use is unconservative.

For these reasons, it is always good practice to investigate the stability of fine-grained soils for both the short-term period (during and after the end of construction) when undrained conditions prevail and the long-term period when the material is drained.

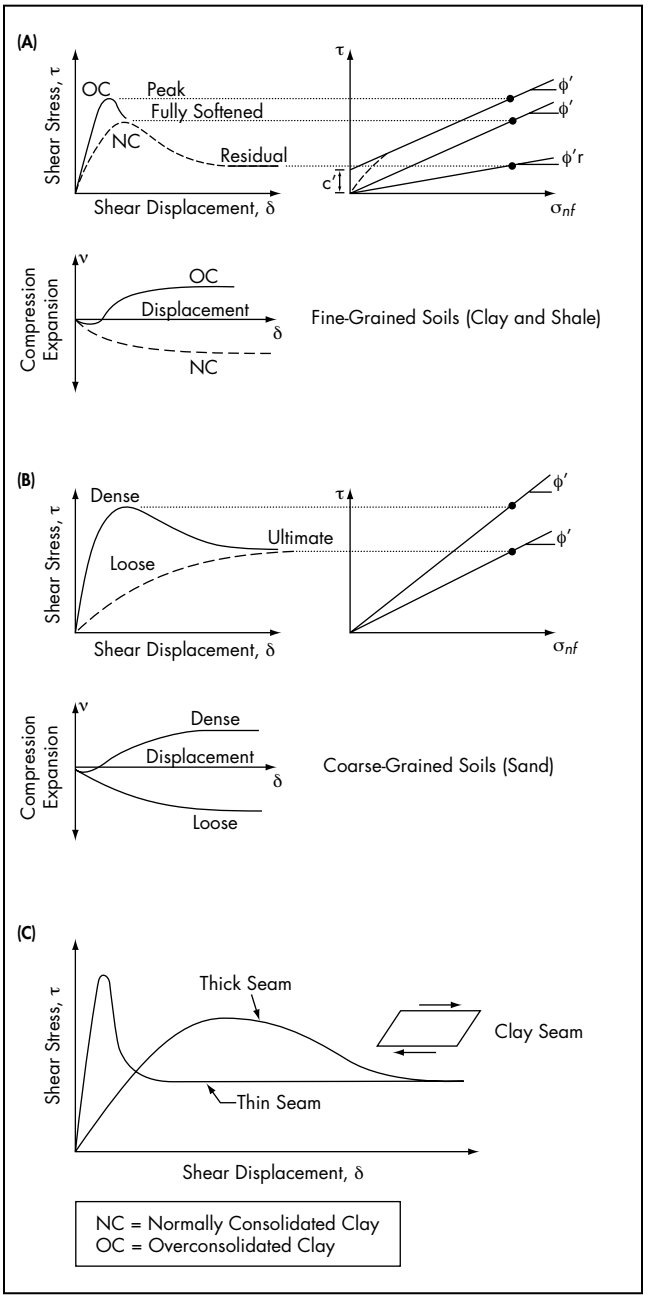
Shear Strength

The drained shear strength that a given clay or shale can actually mobilize (peak, fully softened, or residual strength) depends on whether the in-situ material is intact, is fissured, or contains discontinuities (such as bedding planes or shear planes) along which significant movements have occurred or will occur under the displacements imposed on the soil mass.

Peak shear strength. If in-situ fine-grained material is relatively intact, the peak shear strength is expected to be mobilized, and thus the failure envelope for the effective stress range considered can be characterized in terms of the effective-strength parameters c' and ϕ' by

$$s = c' + \sigma'_{nf} \tan \phi' \qquad (8.2\text{-}12)$$

where c' is the cohesion intercept. The greater the magnitude of the preconsolidation pressure σ'_p , the greater is the cohesion intercept c'. For normally consolidated clays, $c' = 0$. Values of ϕ' are typically in the range 22° ± 10° and reflect the capability of a random arrangement of clay particles (of particular size and shape) to interact and interlock with each other.



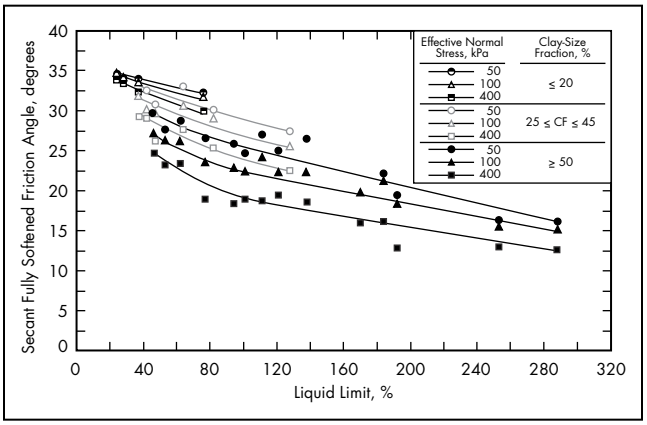
For overconsolidated clays, the typical shear stress–strain and strength curves shown in Figure 8.2-3A show that the peak shearing resistance is mobilized with no major structural rearrangement. Near the maximum shearing resistance, the changes in volumetric strain v are small and mainly in compression.

Fully softened shear strength. Additional shear displacement beyond the peak (intact) shear strength is accompanied by softening (volume increase as the disaggregated clay takes up water) and corresponding decrease in shearing resistance as c' decreases. By the time the softening process has been completed, only the fully softened shear strength is mobilized ($c' \approx 0$), and the material behaves as a normally consolidated clay. Long-term stability of cuts in overconsolidated, fissured clays has been determined to be related to the fully softened shear strength.

Skempton (1977) suggested that, for a first-time slide, the shear strength of a stiff fissured clay at failure can be approximated by the fully softened strength. After reviewing the failure of Carsington Dam (United Kingdom) and slides in highway cuttings and embankments, Skempton and Vaughan (1995) stated that "residual strength can indeed play a part in first-time slides in clay fills and cuttings." Stark and Eid (1997) concluded that residual shear strength can influence the stability or behavior of slopes that have not undergone prior sliding. They indicated that mobilized shear strength can be estimated as an average between the fully softened and residual. More recently, Mesri and Shaien (2003) showed that, for many first-time slope failures, part of the slip surface is at the residual condition.

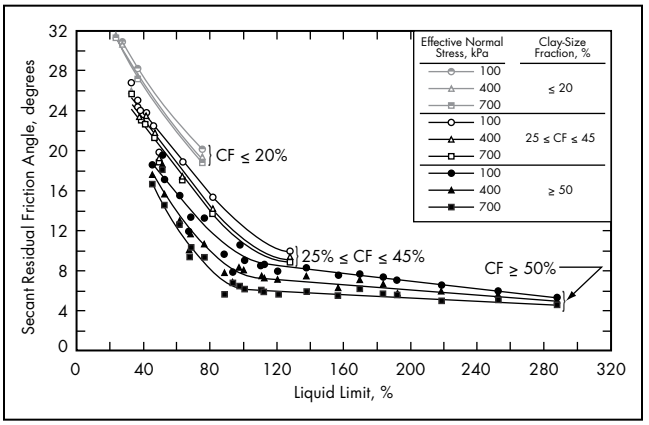
The typical shear stress–strain and strength curves for a given sand in both dense and loose states (Figure 8.2-3B) show to what extent the behavior of dense and loose granular soils is similar to that of overconsolidated and normally consolidated clays, respectively. For nonplaty granular soils, there is no possibility of particle alignment during shear, and thus the ultimate shear strength of the dense sand (which loosens after reaching its peak strength) corresponds to the maximum shear strength of the loose sand (which densifies during shear).

Figure 8.2-4 shows plots of drained fully softened secant ϕ' as a function of liquid limit, clay-size fraction, and effective normal stress for clays and shales (Stark and Eid 1997).



Source: Cording and Cepeda-Díaz 1992.

Figure 8.2-3 Typical plots of stress vs. displacement (strain) and strength characteristics for soils and weak rock



Higher liquid limits and higher clay-size fractions yield lower shear strengths, with ϕ' ranging from 34° (liquid limit $w_l \leq 25\%$ and clay-size fraction CF ≤ 20%) to about 15° (liquid limit $w_l \geq 280\%$ and clay-size fraction CF ≥ 50%).

Residual shear strength. Additional shear displacement, if concentrated along a narrow shear zone, causes further decrease in shearing resistance, below that of the fully softened case, as the plate-shaped particles in the relatively narrow shear zone increasingly align in the direction of shear. In this configuration, the soil or rock is able to mobilize only the residual shear strength or minimum s that it can ever have, or

Figure 8.2-4 Plots of drained fully softened friction angle vs. liquid limit for triaxial compression mode of shear

Source: Stark and Eid 1994.

Figure 8.2-5 Plots of drained residual friction angle vs. liquid limit

$$s = \sigma'_{nf} \tan \phi'_r \qquad (8.2\text{-}13)$$

The residual friction angle ϕ'_r is an index property of the natural soil composition, and reflects the size and shape of the soil particles (Mesri and Cepeda-Díaz 1986). Figure 8.2-5 shows the correlation of drained residual secant friction angle ϕ'_r as a function of liquid limit, clay-size fraction, and effective normal stress for clays and shales developed by Stark and Eid (1994). It can be seen that higher liquid limits and higher clay-size fractions yield lower ϕ'_r values, with ϕ'_r ranging from 31° (liquid limit $w_l \leq 25\%$ and clay-size fraction $CF \leq 20\%$) to about 5° (liquid limit $w_l \geq 280\%$ and clay-size fraction $CF \geq 50\%$).

In materials that contain thin seams of soft material or preexisting planes of weakness, such as bedded shales or shear zones, residual shear strengths are reached with much smaller displacements than those required to reach residual strength for a thicker material. Figure 8.2-3C compares the different shear displacements observed in direct shear tests on thick and thin seams of clay (Nieto 1974). In practice, residual strengths are likely to be more representative of thin-bedded materials, such as a bedded shale, rather than of massive clay with indistinct bedding. Small displacements along the bedding planes can rapidly reduce peak strength to the residual value. Additionally, any excess pore water pressures generated in the bedding seam during shear rapidly dissipate so drained conditions may prevail. If the soil or rock mass presents evidence of discontinuities along which significant movements have already occurred, such as bedding or shear planes, then only the residual shear strength is expected to be mobilized and the failure envelope can be characterized in terms of the residual friction angle ϕ'_r.

Undrained shear strength. The undrained shear strength of a clay can be obtained in terms of c' and ϕ' as long as u_f can be determined; however, this is often difficult in the field and sometimes infeasible in the laboratory. Therefore, the undrained shear strength s_u is usually determined or approximated from direct and simpler measurements such as FV test or CPT, laboratory unconfined compression tests, or unconsolidated undrained triaxial tests on undisturbed samples.

Cone penetration testing can also provide a valuable measure of undrained shear strength by means of the following equation:

$$s_u = (q_t - \sigma_{vo})/N_{kt} \qquad (8.2\text{-}14)$$

where

q_t = corrected cone tip resistance
σ_{vo} = in-situ total vertical stress
N_{kt} = empirical cone factor

N_{kt} can be determined on a site-specific basis by collecting and testing undisturbed samples in the laboratory. For small projects where extensive laboratory testing is not possible, typical values of N_{kt} can be taken as 16 ± 2. Some researchers have proposed a correlation between N_{kt} and the plasticity index, but other researchers have found no such correlation.

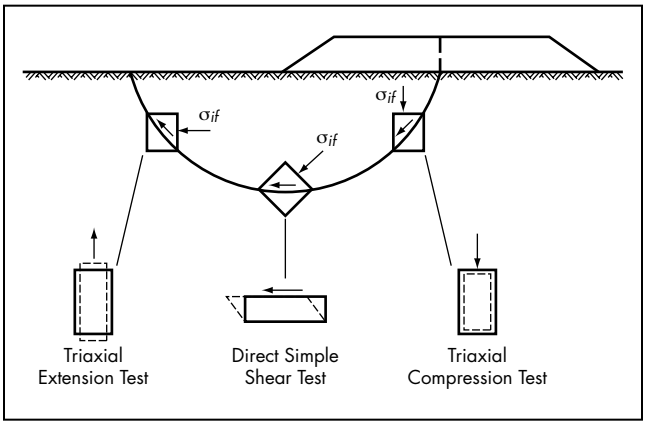
The *unconfined compressive strength* ($q_u \approx 2s_u$) is a measure of the consistency of fine-grained cohesive soils and has been used for classification purposes (Table 8.2-3).

Back-calculation of the mobilized shear strength $(s_u)_{mob}$ in a number of slope and foundation failures in various soft clay deposits indicates that, for the cases investigated, $(s_u)_{mob} \approx 0.22\,\sigma'_p$ (Mesri and Godlewski 1977). Typically, s_u determined from laboratory unconfined compression tests is less than $(s_u)_{mob}$ largely because of sample disturbance. Corrections are also applied to the measured laboratory undrained shear strength to account for field conditions that are not exactly duplicated in the tests, such as mode of shear, strength aniso tropy, influence of shearing rate, and progressive failure.

Undrained shear strength depends on the mode of shear and differs in different directions in the ground. The values of undrained shear strength mobilized in different directions can be measured in the laboratory by means of shear tests that simulate distinct modes of shear. The most widely used tests are the following:

- Triaxial compression (TC)
- Triaxial extension (TE)
- Direct simple shear (DSS)

Figure 8.2-6 shows the relevance of these tests along a circular failure surface in the field. The relationship between the undrained shear strength and the effective stress before shear can also be investigated by means of TC tests on undisturbed samples that are first consolidated to the various effective stresses selected and then sheared under undrained conditions; such tests are usually called consolidated undrained TC tests.



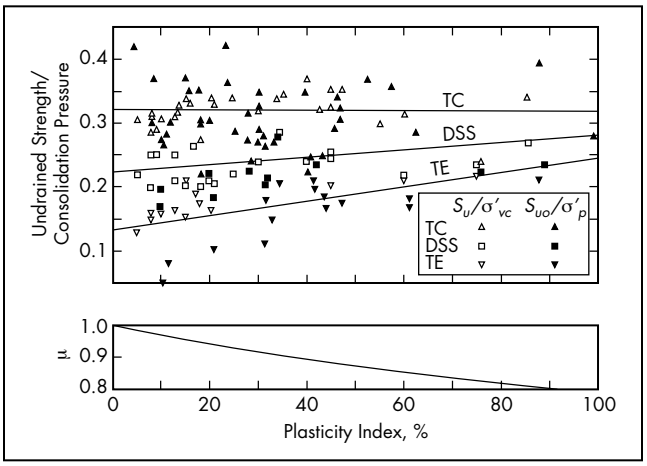


Figure 8.2-6 Undrained shear strength tests

Source: Terzaghi et al. 1996.

Figure 8.2-7 Plots of normalized undrained shear strength from laboratory triaxial tests vs. plasticity index

The TE test, which is similar, involves a sample that is consolidated to various effective stresses and then sheared due to a decrease in the vertical load. The DSS test also involves undrained shearing; its failure mode lies between those from the TC and TE tests.

Figure 8.2-7 shows an empirical correlation between the undrained shear strength s_u from triaxial and DSS tests (normalized by the consolidation pressure σ'_{vc} or the preconsolidation pressure σ'_p) and the plasticity index I_p (Terzaghi et al. 1996). At low plasticity values, the difference between the three failure modes is significant, with the undrained shear strength ratio for the TC failure mode being about 2.3 times the ratio for the TE failure mode. As plasticity increases, the difference between the three failure modes decreases until it is very small at I_p = 100%. The TC failure mode appears to have little or no correlation with I_p. The time to failure in laboratory shear tests is generally measured in hours, whereas mobilization of the undrained shear strength in the field requires weeks. The time to failure for instabilities is likely to increase with I_p. A correction factor has been developed to account for these differences and is included in the figure.

Drainage conditions and shear strength parameters in the field. The undrained shearing of highly overconsolidated clays and shales leads to a decrease in s with time as the induced excess negative pore water pressures gradually dissipate. Thus, for this type of material, the long-term drained condition is generally the least-favorable condition. For normally consolidated clays, on the other hand, the undrained shear strength (corresponding to a given σ'_n before shear) may be considerably lower than the corresponding drained shear strength as a result of the positive excess pore water pressures induced during undrained shearing. During foundation loading, for example, the least favorable condition for normally consolidated clays and slightly overconsolidated clays (OCR < 2) is generally the short-term undrained condition, and thus using the undrained shear strength for this latter type of material is usually conservative.

For unloading slope cuts and other excavations, excess pore water pressures resulting from unloading are superimposed on the excess pore water pressure generated by undrained shearing. This can result in a net negative excess pore water pressure, even for normally or slightly overconsolidated clays. With time, as the excess negative pore water pressure dissipates, shear strength decreases. Thus, the undrained shear strength is unconservative if used to estimate long-term strength of excavations, particularly for highly overconsolidated clays or shales.

For bedded shales or weak rock with joints, the strength along the discontinuity, rather than the unconfined compressive strength of the material, controls many of the failures. In some cases, the strength along the bedding surface or other discontinuity can be estimated using a peak friction angle, which may include a dilatant component to account for irregularities on the surface. However, the residual friction angle should be used if irregularities have already been sheared off or if they will be lost with small displacements.

For failure surfaces that cut at an angle to the discontinuity, the peak strength of the intact material may be applicable. However, combined failures, both through intact material and along discontinuities, often occur in shale and other weak rock, and the interaction of a discontinuity with the intact portion of the weak rock decreases strength to less than predicted for failure of the intact material alone.

Creep

Creep refers to the time-dependent deformation of soil or rock resulting from internal rearrangement of particles in response to the application of a sustained stress difference $(\sigma_1 - \sigma_3)$, which is generally smaller than the stress difference of the soil at failure $(\sigma_1 - \sigma_3)_f$, where σ_1 and σ_3 are the major and minor compressive principal stresses, respectively. Deformation during undrained creep results from shape distortion as the soil mobilizes a constant shearing resistance in response to shear stresses applied upon loading or unloading.

Creep models have been applied toward a variety of engineering problems, such as the closure of and loading on tunnels, chambers, and pillars in creep-sensitive materials such as salt, shale, and fault zones. Highly stressed and creep-sensitive ground encountered in underground excavations is described in tunnel-worker terminology as *squeezing ground*, inasmuch as it leads to a gradual closing of the opening under practically undrained conditions.

Undrained creep behavior is closely related to the drained creep behavior associated with secondary consolidation and swelling, inasmuch as the mechanisms that cause volume change for drained loading (at a constant effective stress) cor-

respondingly cause excess pore water pressures for undrained (constant volume) loading.

A fundamental approach to creep behavior, involving the response of soil to isotropic and deviatoric stresses, is quite complex and still in the development stage. For this reason, creep predictions have been traditionally based on semi-empirical creep models obtained through attempts to best fit the observed laboratory creep data of a variety of soils. Singh and Mitchell (1968, 1969) determined the interrelationship among creep strain rate $\dot{\varepsilon} = d\varepsilon/dt$, stress level with respect to a reference strength $D = (\sigma_1 - \sigma_3)/(\sigma_1 - \sigma_3)_f$, and time t. The interrelationship is widely applicable to both drained and undrained creep, and is expressed by

$$\dot{\varepsilon} = \frac{d\varepsilon}{dt} = A_1 e^{\alpha D}\left(\frac{t_1}{t}\right)^m \tag{8.2-15}$$

where t_1 is the reference time. The m parameter is the slope of the linear $\log \dot{\varepsilon}$ –$\log t$ relationship existing for any intermediate stress level D (approximately 30%–90% of the failure stress) for which m is also a constant. In other words, m establishes the rate of decrease of the strain rate with time. The α parameter gives the dependency of strain rate on stress level for $D \approx$ 30%–90% of the failure stress for a given time ($t_1 < t_2 < \ldots t_n$) for which α is also a constant. The parameter A_1 is the extrapolated value of strain rate at the reference time t_1 for $D = 0$. The creep potential of a clay is closely related to the value of m, which is in the range 0.5–1.3 for a variety of soils. As m decreases, creep deformations become more significant and the soil becomes more susceptible to creep rupture under sustained loads. For any one soil, there seems to be a maximum shear stress that the soil can sustain without creep rupture, called the upper yield strength.

Expressing the strain–stress model as a hyperbola provides a better physical representation of the creep parameters. The parameters in the hyperbolic model are the ratio of undrained modulus to undrained shear strength E_u/s_u and the axial strain at failure ε_f (Mesri et al. 1981) as given by

$$\varepsilon = \frac{2}{(E_u/s_u)_1}\,\frac{D_1}{1-(R_f)_1 D_1}\left(\frac{t}{t_1}\right)^{\lambda} \tag{8.2-16}$$

where $R_f = 1–[2/(E_u/s_u)\varepsilon_f]$ and all the pertinent parameters are evaluated at initial time t_1.

The creep parameter λ that controls time or strain-rate effects also correlates very roughly with E_u/s_u. Specifically, $\lambda \approx$ (1/6,000) E_u/s_u. Typical values of E_u/s_u are in the range 100–600 for clays and shales, and thus the values of λ are typically in the range 0.01–0.10 ($\lambda = 1 - m$).

Laboratory creep tests on samples of clay gouge can be used to determine creep rates and pressures anticipated around a tunnel in squeezing ground, as discussed later in the "Tunneling" section.

Deterioration

Deterioration of overconsolidated clays and weak argillaceous rocks in response to weathering, swelling, and associated softening is perhaps one of their most important engineering characteristics. Unstable shales, for example, have plagued the petroleum industry for many years; the washout experienced by shale formations in response to borehole drilling can be tolerable in some wells but uncontrollable in others. Deterioration of shale mine roofs has been a major cause of the time-dependent roof collapses that have troubled the coal-mining industry.

Disintegration of shale into relatively small pieces upon exposure to different humidity-moisture environments, including submersion, is usually referred to as slaking. For tunnels and other underground excavations, the slaking characteristics of shale affect stand-up time, overbreak, support loads, and construction and support procedures required to minimize deterioration. Successive disintegration and breaking away of loose material from the tunnel crown section results in a fresh rock surface that is exposed each time to a further cycle of weathering. Slaking also progresses along surfaces of fractures behind rock slabs, contributing to time-dependent instability of large blocks.

Wetting and drying are also known to significantly increase the expansion of exposed clay and shale strata (and thus the heaving of overlying structures) as compared to the magnitude of swell and associated softening caused only by unloading with access to water. The additional heave and expansion occurs in response to the further breakdown of diagenetic bonds and alteration of the shale structure. The rate of disintegration of the upper shale layers also controls the rate at which shale slopes are "worked down." The colluvium of disintegrated shale (which could be tens of feet or meters thick) often forms an unstable mass that slides along its contact with the underlying intact shale. Thus the overall strength and stability of slopes is frequently controlled by the strength of the softened and deteriorated material.

During drying, shale is often subjected to heterogeneous and anisotropic shrinkage that can cause cracks or microfissures to open, providing conduits for future moisture redistribution. Upon access to water, shear stresses resulting from differential swelling may also cause local failures and shale disintegration. Moreover, pore-air compression, resulting from immersion of unsaturated shale in water, can apply internal pressures that may eventually exceed the local tensile strength of the material and cause additional shale slaking.

The resistance of shale to deterioration upon exposure to drying and wetting cycles is frequently estimated by subjecting representative specimens to the standard slake durability test. In this test, 10 oven-dried lumps of shale 0.08–0.13 lb (40–60 g) each are rotated (20 rpm) for 10 minutes in a partly immersed drum of 0.08-in (2.0-mm) mesh. The slake durability index is the oven-dried weight percentage retained in the drum after two (oven drying–wetting) standard cycles. Shale slake durability is characterized as described in Table 8.2-6.

The deterioration response of shales encompasses a broad range because of the expansive assortment of shale compositions and the wide variety of field-humidity and moisture environments to which they are subjected. As a result, index tests and classifications based on limited, often severe testing environments do not permit a full evaluation of shale performance under field conditions. This is particularly true in underground excavations in which moisture changes may be caused by relatively small humidity changes rather than alternate soaking and drying.

A study of the deterioration of two dozen natural shales exposed to controlled temperature and relative humidity conditions revealed the following (Cepeda-Díaz 1987). In general, shales with natural water content w_o smaller than the shrinkage limit w_s are fissile, whereas shales with natural water content higher than w_s are massive. Fissile shales

Table 8.2-6 Shale slake-durability classification

Slake-Durability Index	Descriptive Term
>98	Very high
95–98	High
85–95	Medium high
60–85	Medium
30–60	Low
<30	Very low

Source: Cording and Cepeda-Díaz 1992.

(group F) deteriorate by opening along weak planes of stratification, followed by separation of thin slabs perpendicular to the stratification. In contrast, massive shales (group M) lack a preferred orientation of discontinuity and often break down to chunks and chips along random cracks, fractures, and slickensided surfaces. Fissile shales generally have natural water content of <15% and liquid limit w_l of ≤100% (using ball-mill disaggregated samples passing through a No. 200 U.S. standard sieve). Beyond this range of values for w_o and w_l, shales are generally massive.

Fissile and massive shales can be further subdivided into three groups (1, 2, and 3) depending on moisture-change response and deterioration behavior upon exposure and thus related to their equilibrium relative humidity (ERH). ERH is the relative humidity (RH), at a given temperature, in which freshly exposed specimens of a given shale remain at their natural water content. At RH > ERH, intact shale gains moisture from the air environment; at RH < ERH, intact shale loses water to the environment. Shales in the three groups react differently to humidity:

1. Shales in group 1 deteriorate when subjected to RH > ERH and include shales with $w_l > 40\%$ and $w_o < 0.2w_l - 8\%$ but natural water content ≤15%.
2. Shales in group 2 (75% ≤ ERH ≤ 97.5%) deteriorate when subjected to RH ≠ ERH and include shales with $w_l > 10\%$ and natural water content other than those characteristic of groups 1 or 3.
3. Shales in group 3 (ERH > 97.5%) deteriorate when subjected to RH < ERH and include shales with $w_l > 10\%$ and $w_o > 0.2w_l - 2\%$.

Shales that deteriorate when subjected to RH > ERH (groups 1 and 2) generally have natural water content lower than that corresponding to $w_o = 0.2w_l$. In contrast, shales that deteriorate only when subjected to RH < ERH (group 3) generally have natural water content higher than $w_o = 0.2w_l$. Thus it is consistent that shales with natural water content equal to both $w_o = 0.2w_l = w_s$ remain intact upon exposure to any RH environment. At such a moisture and structural state, the total volume change associated with moisture gain or loss upon environmental exposure may be relatively small, and thus the shale does not experience a significant amount of anisotropy and heterogeneous deformation—that is, it does not deteriorate.

For underground excavations such as tunnels and mines where field environmental control can be considered, the following guidelines are suggested for preventing the deterioration of various types of exposed shale strata (Cepeda-Díaz 1987).

- Shales in group 1 should always be maintained at environments drier than ERH and preferably not wetter than 75% RH. Dry environments not only avoid the damaging effect of humidity fluctuations at high RH but also discourage the chemical alteration of any iron sulfides that are present in the shale. Iron sulfides are known to oxidize in the presence of water and oxygen to form limonite and sulfuric acid. The sulfuric acid reacts with any calcite in the rock to produce carbonic acid and gypsum with resulting large increase in volume and shale disintegration.
- Shales in group 2 (75% ≤ ERH ≤ 97.5%) should always be maintained at relative humidities near ERH and preferably not exceeding ERH ± 2%.
- Shales in group 3 (ERH > 97.5%) should always be maintained at environments wetter than ERH, and thus very often close to 100% RH.

Because shales in group 3 rarely deteriorate upon immersion in water at their natural water content, the use of sprayers to keep the exposed shale strata from drying may be a suitable alternative to high-humidity control. For shales in groups 1 and 2, any direct contact with water should be suppressed to avoid severe deterioration. Independent of the initial type of shale deterioration upon initial environmental exposure, wetting as a result of water inflow, immersion, or spraying (rain in the case of open cuts) is likely to induce severe deterioration if the exposed shale strata has been allowed to dry before wetting.

MECHANICS OF BEHAVIOR

For many problems in both soil and rock mechanics, the stresses or interrelation of stresses and deformations in the soil or rock mass must be determined. A first step in approaching these problems is to consider the boundary conditions—the geometry of the mass and the distribution of loads or displacements applied to the mass.

These types of problems have traditionally been divided into two groups (e.g., Terzaghi 1943): (1) those in which the stresses in a region or a surface in the mass have reached a limit or failure condition, and (2) those in which the stress levels are below the limit condition, and changes in stress within the medium are a function of the deformations.

- **Limiting stress conditions.** The loads or the state of stress can be determined from the equilibrium of a portion of the mass, assuming that the stresses along a surface or region within the medium have reached their limit—the strength of the material. Slope-stability analysis, earth-pressure theory, and bearing-capacity problems concern the evaluation of the loadings upon the soil or rock mass when certain surfaces within the mass are at a limiting level of stress.
- **Stress-deformation conditions.** In many problems, it is assumed that changes in stress are a function of deformations. The simplest assumption is that stresses are proportional to strain—that is, the material is elastic. Closed elastic solutions are available for relatively simple boundary conditions, and often can be used to obtain a first approximation of the mechanics of the problem. More sophisticated stress-deformation models may assume that the material has a nonlinear stress–strain relationship that may even approach a limit at some strain level, and that energy losses occur as loads are cycled. Solutions for these models, as well as for elastic models with more complex boundary conditions, require the use of a computer and numerical methods such as finite-element or discrete-element models.

Stress-deformation relationships are used to evaluate not only foundation settlements but also the interaction between the soil medium and a structure—such as an anchored bulkhead, braced excavation, or tunnel lining—whose stresses and deformations are a function of relative stiffness with respect to the soil mass.

Another group of stress-deformation problems is that in which settlements or heave occur with time as water flows into or out of the soil matrix in response to changes in the state of stress—the process of swelling or consolidation, respectively. In soft soils, volume changes occurring as water flows into or out of the soil are the major cause of settlement, whereas deformation of the soil at constant water content is usually a minor portion of the total displacement.

LIMIT EQUILIBRIUM

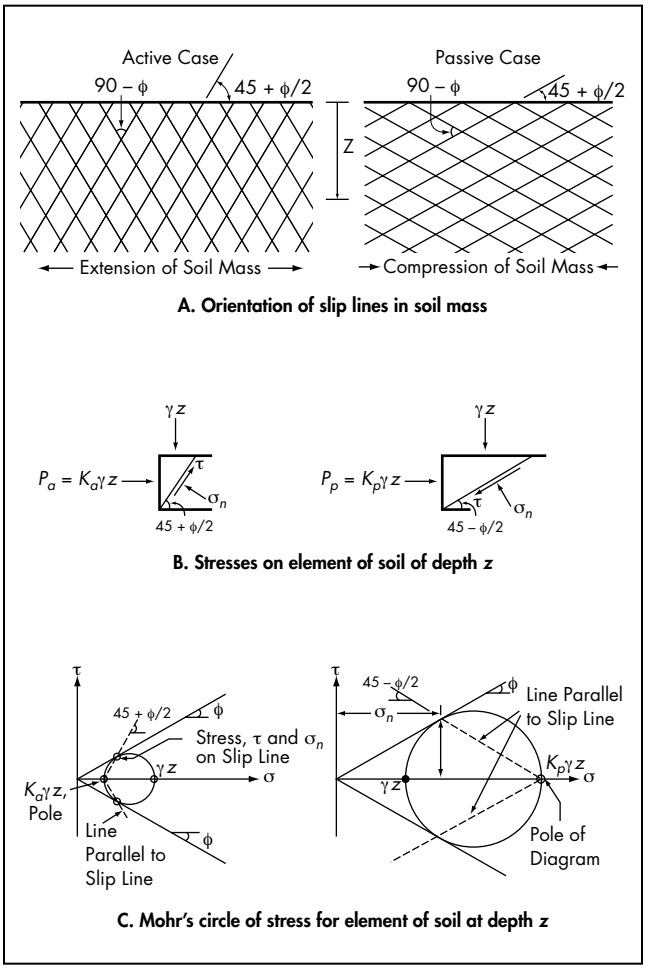
Limit equilibrium is a common approach for analyzing soil- and rock-mechanics problems. The following sections discuss how this method is used to analyze retaining walls, stability of slopes, and foundations.

Analysis of Active and Passive Earth Pressures

Lateral extension or compression of a soil mass decreases or increases, respectively, the lateral soil pressures until a limit is reached. The limits are termed the *active and passive earth pressures* and represent, respectively, the minimum and maximum possible natural lateral stresses that can exist in the ground. The active pressure P_a denotes the earth pressure acting behind retaining walls; the passive pressure P_p is the maximum pressure that can act at the toe of a wall embedded in the soil.

Figure 8.2-8 shows the active and passive pressures resulting from extension and compression of an infinite soil mass with a horizontal ground surface.

The magnitude of the active and passive stresses acting on a vertical plane is obtained from Mohr's circle of stress, recognizing that the vertical stress is equal to the overburden pressure z, and the soil element is at its limit, and therefore the circle of stress is tangent to the strength envelope, which is assumed to be a straight line, $s = c + \sigma \tan \phi$.



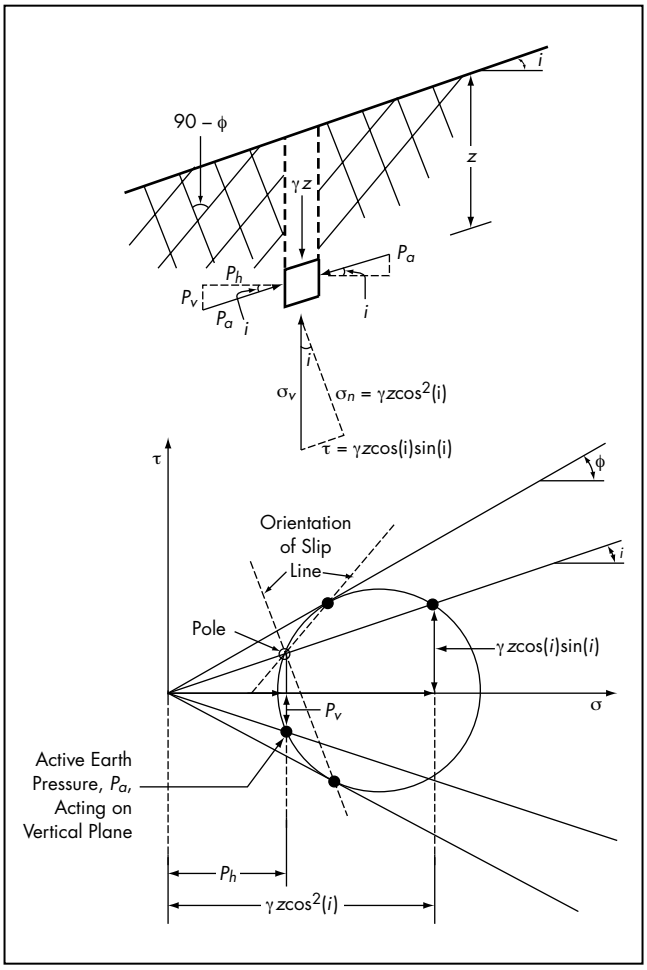
Rankine Analysis

Rankine (1857) provided the first solution to this problem. The principal stresses at the limit condition are related as follows:

$$\sigma_1 - \sigma_3 \tan^2 (45^\circ + \phi/2) + 2\, c \tan (45^\circ + \phi/2) \qquad (8.2\text{-}17)$$

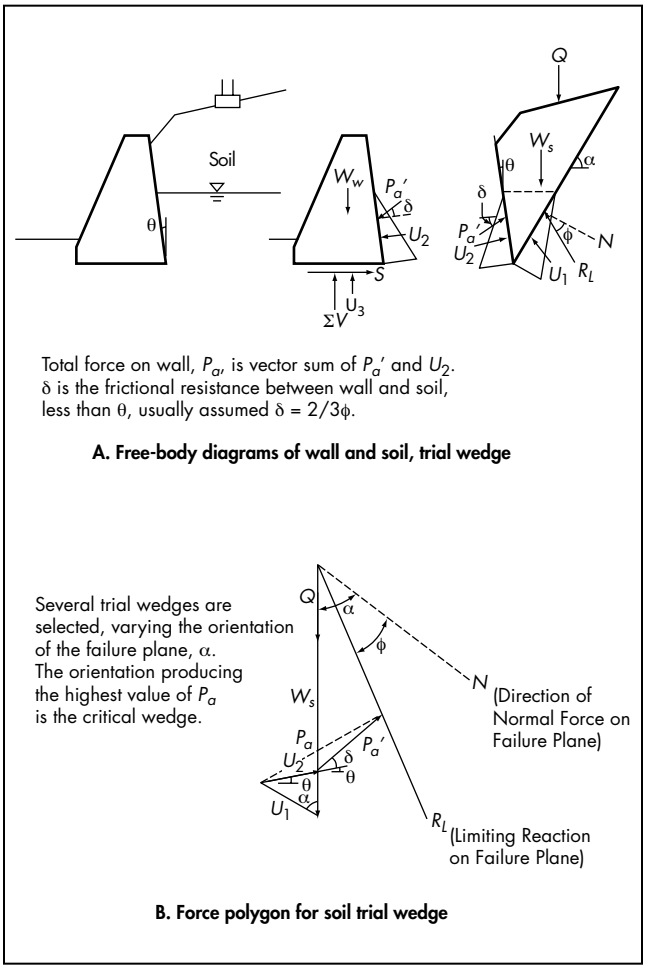
For lateral extension of the soil mass, the lateral stresses are reduced to their minimum value, and σ_3 equals the lateral stress, which is the active earth pressure. For a horizontal ground surface, the coefficient of active pressure $K_a = 1/\tan^2 (45 + \phi/2)$. For lateral compression of the soil, the lateral stresses are increased to their maximum value, and σ_1 equals the lateral stress, which is the passive earth pressure. For a horizontal ground surface, the coefficient of passive pressure $K_p = \tan^2 (45 + \phi/2)$.

The more general Rankine solution is for active and passive pressures that develop in an infinite slope. For an infinite slope, the vertical force on a plane parallel to the ground surface is equal to the weight of the overburden. The active and passive earth pressures are the stresses acting on a vertical plane. They are oriented parallel to the ground surface and thus have both a normal and shear component. Figure 8.2-9 illustrates the condition for active earth pressure. The magnitude and direction of the active earth pressure and the orientation of the shear planes can be obtained from Mohr's circle.



Source: Cording and Cepeda-Díaz 1992.

Figure 8.2-8 Rankine analysis of active and passive earth pressures for a vertical plane



If the entire soil mass is in a limiting state of equilibrium, as is assumed in the Rankine case, then the active and passive stresses acting on the vertical plane for a frictional material increase linearly with depth. The total active or passive force over a given height z acts at the lower third point and has a magnitude equal to $z/2$ times the active or passive pressure at depth z. This condition is obtained for a retaining wall when outward deflections at the top of the wall are on the order of 0.1%–0.5% of its height. Thus the validity of designs based on an assumed active state of stress behind the wall depends on the outward deflections that the retaining structure actually undergoes.

For walls in which the upper portion of the wall is not allowed to deflect outward, the distribution of stresses on the wall does not increase linearly with depth, even though movements of the lower portions of the wall may be sufficient to reduce the total forces on the wall to the active forces. This is the case with braced walls in which the upper portion of the wall is restrained early in the excavation process, usually in order to limit ground movements that could adversely affect structures and utilities adjacent to the wall. As a result, the center of pressure for the forces acting on the wall is at a higher

Source: Cording and Cepeda-Díaz 1992.

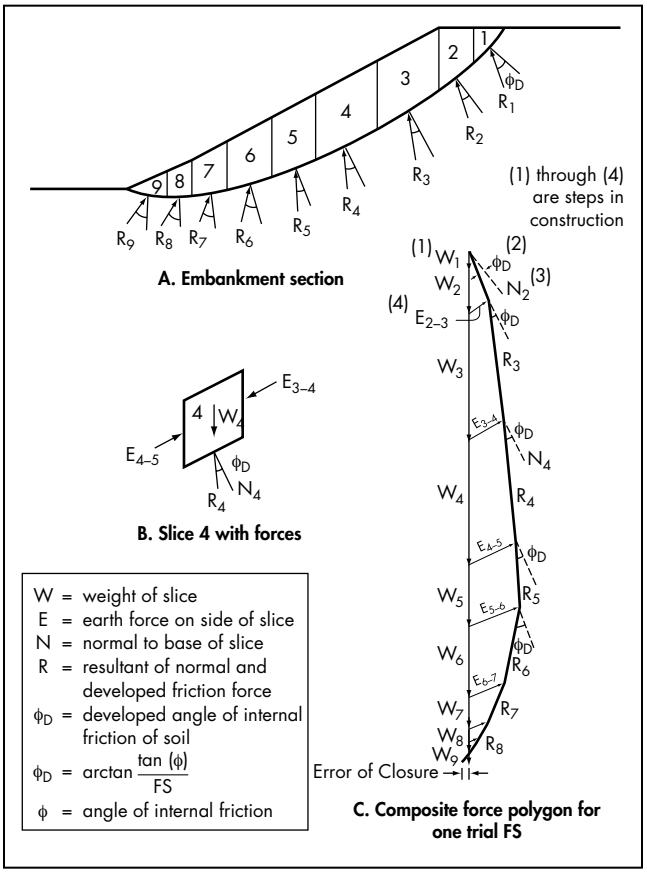
Figure 8.2-10 Coulomb wedge analysis of active earth pressure

elevation than the lower third point, although the total magnitude of the forces can be estimated using Rankine or Coulomb assumptions. Field measurements of strut loads for braced excavations are used to develop apparent earth-pressure envelopes for design. The envelopes, which encompass the variations that can be expected in strut loads due to construction procedures, provide an almost rectangular (constant) pressure distribution with depth and a magnitude of the total force under the envelope that is approximately 1.3 to 1.75 times the active Rankine or Coulomb pressure (Peck et al. 1974).

Rankine analysis, in which a ground surface of infinite extent is assumed, either horizontal or sloping, can be applied to real problems in which the ground surface is not of infinite extent, as long as the stresses on the vertical plane can be assumed to act parallel to the ground surface. Rankine analysis usually produces a conservative estimate of either the active or passive pressures on a wall because it usually does not fully account for the shear stresses that act on the wall.



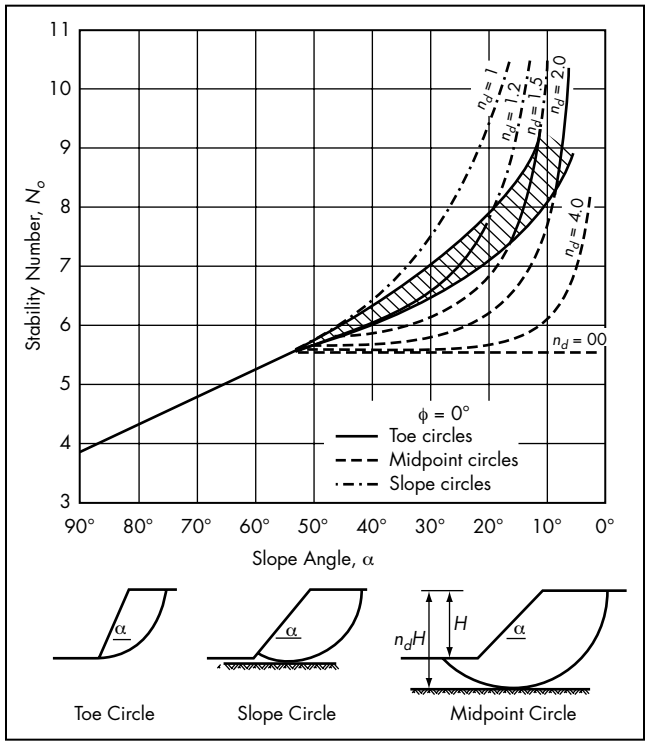
The magnitude and location of the total active or passive forces acting on the back of a retaining structure can also be determined using the assumptions involved in the Coulomb wedge analysis, described in the next section. Coulomb analysis is more general than the Rankine method in that any orientation of the forces on the back of the retaining wall can be assumed, and surcharges and irregular backfill slopes can be handled.

Coulomb Wedge Analysis

A more general solution for limiting conditions in a soil mass can be obtained by Coulomb (1776) analysis, which evaluates the forces acting on a wedge of soil. It is assumed that a planar failure surface has developed in the soil mass and that the soil wedge slides along a planar surface forming the back of the wall. The analysis is commonly used to evaluate active earth pressures behind retaining walls.

Figure 8.2-10 illustrates the procedure for a frictional material. As in most limit equilibrium problems, analysis is handled in a series of steps:

1. A free-body diagram of the wedge of soil is drawn, showing all forces acting on the boundaries of the wedge as well as the body forces (weight W_s and acceleration forces) acting in the free body. A failure plane forms one of the wedge boundaries. A trial failure plane is selected, oriented at angle α to the horizontal.
2. A force polygon is constructed to include all forces acting on the free-body diagram. The summation of forces is obtained either graphically or by trigonometry,



Source: Cording and Cepeda-Díaz 1992.

Figure 8.2-11 Method-of-slices analysis of slope stability

considering the geometry of the force polygon. Water pressures U_1 and U_2 acting on the boundaries of the wedge are included as external forces. Although the summation of forces equals zero, the assumption of a planar failure surface may result in the summation of moments not equaling zero.

3. Because the orientation of the failure surface is usually not known, several trial wedges are analyzed, each with a planar failure surface at a different orientation α. The largest value of the active force or the smallest value of the passive force represents the critical condition in which the first planar failure surface would develop.
4. For soil or rock containing preexisting planes of weakness of known orientation, the trial failure plane is set parallel to the plane of weakness for cases in which its orientation is close to the orientation of the critical failure plane. In this case, it is not necessary to search for the orientation of the critical failure plane by analyzing multiple trial wedges.

Coulomb analysis can be used for general retaining-wall problems, but with some limitations. For passive pressure, when there is a significant component of wall friction, a planar failure surface does not closely approximate the actual failure surface in the field, and thus Coulomb analysis is unconservative (i.e., it overestimates the passive pressure). In such cases, the critical plane is curved and passive pressure can be analyzed as described in the following section.

Figure 8.2-12 Stability chart for slopes in cohesive soil

Application of Wedge Analysis to Slope-Stability Problems

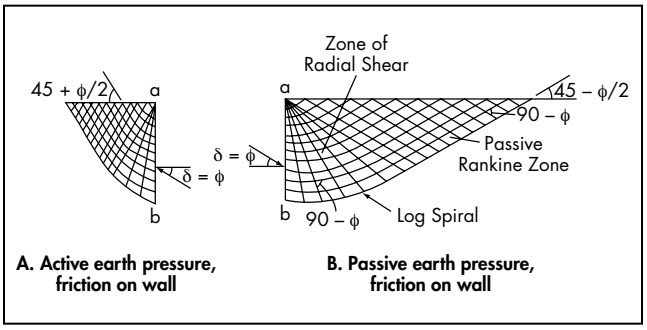

Figure 8.2-11 illustrates the procedure for determining the stability of a slope by analyzing multiple wedges or slices of the potential sliding mass. Multiple slices are treated by summing forces in the same manner as for the Coulomb wedge described previously. A slice is related to the adjacent slice by equating the force acting between the two slices.

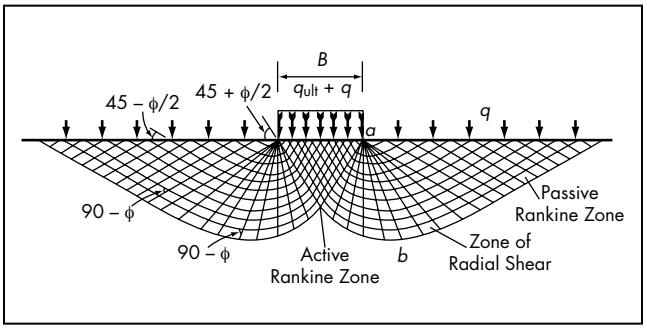
Several techniques exist for evaluating the forces between slices. In general, forces acting between vertical slices are assumed to act parallel to the slope, as is the case for an infinite slope. Where one slice or wedge has a significant vertical displacement with respect to an adjacent wedge or slice, the forces acting between the two may approach their maximum obliquity, at ϕ degrees to the normal. The mobilized or developed friction angle ϕ_D (required to produce a factor of safety of 1) is determined from trials using the graphical construction for the composite force polygon shown in Figure 8.2-11C. The factor of safety (FS) is the ratio of tan ϕ to tan ϕ_D.

In most slope-stability analyses, the slope is assumed to be 2-D. For an actual three-dimensional slope (that does not extend a large distance in the third dimension), 2-D analysis gives a conservative (lower than actual) value of FS. For analysis of a 3-D slope, back-analysis of shear-strength parameters assuming that the slope is 2-D overestimates the shear strength.



Circular Failure Surface for Stability of Cohesive Material

The maximum height of a slope or a cut in a cohesive material, in which the undrained shearing resistance s_u is assumed to apply, can be determined from the stability chart of Figure 8.2-12 (Peck et al. 1974). The factor of safety, FS, of the slope is

Source: Cording and Cepeda-Díaz 1992.

Figure 8.2-13 Active and passive earth pressures, curved failure surfaces

Source: Cording and Cepeda-Díaz 1992.

Figure 8.2-14 Bearing capacity of a shallow footing

$$FS = N_o s_u/\gamma H \tag{8.2-18}$$

Use of the undrained shear strength s_u is unconservative if the slope is excavated in overconsolidated or fissured clays or in clays containing sand and silt seams. In such cases, effective shear strength parameters should be used, which assume that the material has frictional resistance and, in some cases, a small effective cohesion.

Curved Failure Surfaces for Passive Earth Pressure

Coulomb analysis produces unconservative results for the passive case when the passive force on a wall acts at a significant angle δ to the normal. In this case, a curved failure surface should be assumed in order to determine the passive earth pressure. The failure zone consists of a zone of radial shear and a passive Rankine zone (Figure 8.2-13). For a frictional material, the shape of the failure surface in the zone of radial shear approximates a logarithmic spiral. Use of a log spiral simplifies calculations because the limiting reactions acting on the log-spiral failure surface meet at a point and can be ignored in the analysis by summing moments about that point. Figure 8.2-13 shows the pattern of slip lines for the case when the angle δ on the wall is at its maximum value, equal to the angle of friction, in which case the plane of the wall becomes a slip line for the soil mass. The active-earth-pressure case is also shown in Figure 8.2-13 for completeness.

General Bearing-Capacity Relationship

Relationships for the bearing capacity of soils loaded by foundations have been developed from the theory of plasticity. The solutions of Prandtl (1921) and Reissner (1924) were obtained for a rough, rigid strip footing on the surface of a weightless, perfectly plastic material (Figure 8.2-14). The pattern of the failure surfaces is similar to the combined active and passive zones shown in Figure 8.2-13. The ultimate bearing capacity q_{ult} is related to the undrained shear strength of the soil c and the surcharge pressure q as follows:

$$q_{ult} = cN_c + qN_q \tag{8.2-19}$$

where N_c and N_q are dimensionless bearing-capacity factors that are a function of the friction angle ϕ:

$$N_q = \exp(\pi \tan \phi) \text{ and } \tan^2(45^\circ + \phi/2) \tag{8.2-20}$$

$$N_c = (N_q - 1)\cot \phi \tag{8.2-21}$$

The general bearing-capacity relationship (Terzaghi 1943) is an approximate solution, obtained by superposing on Equation 8.2-15 an additional relationship for a frictional soil with weight but without cohesion intercept ($c = 0$) or surcharge ($q = 0$). The superposition produces an error on the safe side (≤20%) for friction angles of 30°–40°, and, of course, no error for a friction angle of zero (Vesic 1975). The additional term is proportional to the shear capacity developed from normal stresses in the weighted soil mass below the footing, and is therefore proportional to the size B of the mass and is also a function of the friction angle ϕ.

The resulting general bearing-capacity relationship for a long strip footing of width B is given by

$$q_{ult} = cN_c + qN_q + \tfrac{1}{2}B\gamma N_\gamma \tag{8.2-22}$$

where N_γ is a dimensionless bearing-capacity factor that is a function of ϕ and must be evaluated numerically. It can be approximated by the expression

$$N_\gamma = 2(N_q + 1)\tan \phi \tag{8.2-23}$$

with an error on the safe side (5%–10%) (Vesic 1975).

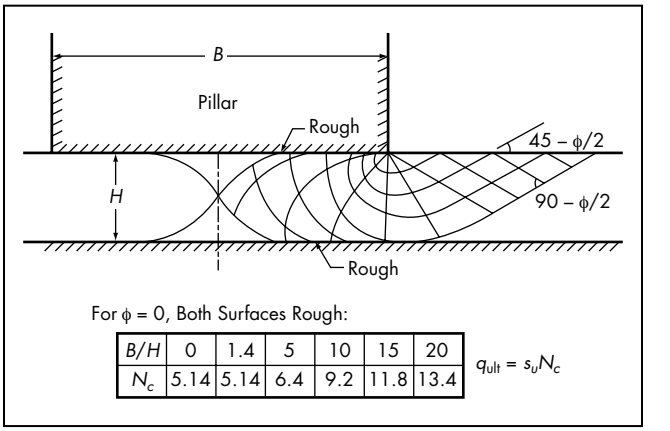
Contrary to some earlier discussions in the literature, Vesic (1975) notes that the shape of the failure zone and the magnitude of the ultimate bearing capacity are not strongly affected by the presence or lack of friction at the base of the footing. He further notes that the ultimate bearing capacity is not strongly influenced by the stress distribution at the base of the footing, which can range from a uniform pressure for a flexible foundation to a variable stress distribution created by a rigid footing (or punch) displacing a constant amount into the soil mass. However, if the base of the footing rests on a thin soft layer above a stronger layer (such as for underclays beneath a mine pillar), significant reductions in bearing capacity can result by changing from a rough to a smooth footing or from a rigid punch to a uniform pressure acting at the base of the footing.

For foundations wider than about 4 ft (1.2 m) in sands and other frictional materials, the bearing-capacity factors are quite high and bearing-capacity failures develop only for very high foundation loads. In these cases, the capacity of the foundation is controlled by the allowable settlement.

Adjustments to the general bearing-capacity relationship have been made for other footing shapes and for extension of the failure planes into the soil surcharge above the footing base.

For cohesive, frictionless materials, a linear approximation of the bearing-capacity relationship (Skempton 1951) is given by

$$q_{ult} = (1 + 0.2D_f/B)\,(1 + 0.2B/L)s_u N_c \quad (8.2\text{-}24)$$



where

D_f = depth of the surcharge above the footing base, equal to $2B$ for values of $D_f > 2B$
B = footing width
B/L = ratio of width to length for the footing
$N_c = 5.14$

The ultimate bearing capacity q_{ult} is the pressure in excess of the pressure applied by the surrounding soil surcharge γD_f.

This relationship is used to estimate the allowable bearing capacity q_a for foundations on clay. The allowable bearing capacity is computed by dividing the ultimate bearing capacity q_{ult} by FS, which is typically 3 for foundations. In addition, the foundation can accept a pressure equal to the surrounding soil surcharge pressure γD_f as follows:

$$q_a = q_{ult}/3 + \gamma D_f \quad (8.2\text{-}25)$$

Figure 8.2-15 Squeezing a layer of underclay out from beneath a mine pillar

Bearing Capacity of Mine Pillars on Underclays

In many coal mines, underclays are present beneath the coal pillar and the floor of the mine. Stresses in the pillars are often high enough to cause a bearing-capacity failure. Several types of bearing failure can occur. The pillar can punch into the underclay, or a general bearing-capacity failure can develop, with large heave occurring in the floor adjacent to the pillar. Typically, underclays are in layers that are thin compared to the pillar width, in which case the slip surfaces used to determine the general bearing-capacity relationship cannot form and the underclay must be squeezed out between the base of the pillar and the underlying stronger rock layers (Figure 8.2-15).

As a result, the ultimate bearing capacity is greater than for a deep deposit of the same material. Vesic (1975) and Mandel and Salençon (1972) show that, as the ratio of pillar width to soft-layer thickness increases, the ultimate bearing capacity for a cohesive, frictionless soil increases from 1 to approximately 2.5 times the ultimate bearing capacity for a deep deposit of the same soil.

Experience with coal pillars overlying underclay shows an interesting interaction between the pillar and the underclay. As the underclay is squeezed laterally outward from beneath the pillar, the pillar is subjected to tensile stresses, causing vertical fractures to develop in the pillar. Squeezing of the underclay not only causes closure of the opening but also can lead to collapse of the pillar and further closure of the mine opening. Formation of vertical tensile fractures in the pillar demonstrates the inability of the pillar to sustain shear stresses that tend to develop between the pillar and the underclay as the clay squeezes outward. Mandel and Salençon show that the increase in bearing-capacity factor N_c is much less significant if there is no shear resistance on one of the layers bounding the thin failing layer.

Shear stresses that develop at the base of a pillar have a much greater effect on the bearing capacity of a thin soil layer than a deep layer. Failure of a footing above a deep layer is by a general downward movement of the soil beneath the footing. In contrast, failure of a pillar above a thin weak layer is by soil squeezing out laterally between the pillar above and the stronger layer below. Vertical fractures in a pillar cause the pillar to break into what is effectively a group of narrow pillars, thus decreasing the ratio of pillar width to layer depth, possibly reducing the shear stresses along the pillar–underclay contact and decreasing the bearing capacity.

Time effects also occur in the failure of coal pillars overlying underclay. Squeezing of the underclay occurs with time as a result of clay creep under high stress and loss of strength of the underclay beneath the floor due to swelling in response to excavation unloading. Pillar settlement and floor heave may begin during active mining, but often the time-dependent effects cause continued failures, floor heave, and large settlements long after excavation has been completed. Large and relatively abrupt subsidence has taken place over abandoned room-and-pillar workings many years after the facilities were abandoned.

SETTLEMENT OF FOUNDATIONS

In engineering applications, the settlement of foundations is a major design consideration, and foundation systems are designed to keep settlement within tolerable limits. The following sections briefly discuss approaches to estimating the anticipated settlement for foundations constructed on various soil and rock materials.

Soft Clays

When load from a footing or fill is placed on a layer of soft clay, most settlement takes place with time as water is squeezed from the soil pores and the volume of the voids decreases. The settlement of a foundation on soft clay can be estimated by determining the change in effective stress on the clay layer and the effective stress existing before loading, and then determining the change in the void ratio by using an appropriate slope on a plot of void ratio versus change in effective pressure (e vs. log σ'_v). The slope to be used can be estimated from laboratory tests or other field tests. For a material loaded above its maximum previous consolidation pressure or preconsolidation pressure σ'_p, steeper slopes corresponding to C_c apply. For stress changes below σ'_p, flatter slopes corresponding to C_r apply.

Stresses resulting from a footing load tend to spread out with depth below the footing, reducing the imposed stress. In order to estimate the stresses at depth, an elastic distribution of stresses is usually assumed. Newmark charts, available in most soil-mechanics texts, provide a means of graphically

determining the stresses at any depth below a footing. An approximate estimate can also be obtained by assuming that the stresses spread on a $2V$:$1H$ slope from the edge of the footing.

Sands

The standard penetration test and its corresponding N values are generally used to predict the allowable contact pressure to which a granular soil can be subjected by a foundation in order not to exceed tolerable settlements. Compression of saturated coarse-grained soils occurs rapidly as a result of their high permeability.

For footings with widths $B > \sim 4$ ft (1.2 m), the allowable pressure q_a expected to produce a total settlement of <1 in. (25.4 mm) and corresponding differential settlements of ≤0.5 in. (12.7 mm) can be approximated by

$$q_a = 0.11\ N \tag{8.2-26}$$

where

q_a = allowable pressure, tons/ft^2
N = smallest average value of the standard penetration resistance

The value of N is within a depth interval equal to B below the foundation level after corrections are made, if necessary, to take into account the effect of overburden pressure and the position of the water table (Peck et al. 1974).

The ratio of differential settlement to total settlement is significantly less for very wide footings or raft foundations than for regular-size footings, and thus the allowable pressure for rafts is that corresponding to a total settlement of 2 in. (50.8 mm), which can be approximated by $q_a = 0.22\ N$. For very narrow footings ($B < 4$ ft [1.2 m]), a small increase in pressure may lead to sufficient settlement to consider failure to be a bearing-capacity failure. Therefore, the margin against bearing-capacity failure for these footings should also be investigated as explained previously.

Weak Rock and Stiff Soils

The compressibility of foundations in weak rock and stiff soils can be evaluated using the theory of elasticity, assuming an appropriate deformation modulus for the material. The Boussinesq equation gives the displacements and stresses in an elastic mass due to a point load applied at the ground surface. The equation is integrated to determine displacements and stresses due to loads distributed over some area at the ground surface. Newmark developed a graphical method for determining stresses or displacements for any assumed distribution of pressures at the ground surface. For the simple case of a uniform pressure p acting over a circular area of radius a on the surface of an elastic medium, the surface displacement d at the center of the circle can be estimated as

$$d = 2pa(1 - \mu^2)/E \tag{8.2-27}$$

where

μ = Poisson's ratio
E = in-situ deformation modulus

For rock containing natural fractures, the stiffness obtained in a laboratory test on an intact sample should be reduced in order to obtain the in-situ deformation modulus. Parameters that index the degree of fracturing of the rock mass, such as the rock quality designation (RQD) or the ratio of field seismic velocity to laboratory sonic velocity, can be used to estimate the amount by which the in-situ deformation modulus should be reduced from the laboratory modulus. Plate-bearing tests (typically with plate diameters of 3 ft [1 m]) can be used to determine the in-situ modulus at selected locations in the field.

TUNNELING

Tunnels are constructed in many mining and civil-engineering applications. Among the important considerations in their design are ensuring the safety of personnel and equipment and minimizing the impact of tunneling on nearby infrastructure. The following sections discuss some of these engineering considerations in tunnel design.

Tunneling Conditions

The following should be considered when constructing a tunnel in soil or weak rock (Peck 1969):

- The mining company's ability to
  - Safely excavate and support the tunnel and
  - Limit damage to third parties—in particular, to control ground movements that could affect nearby buildings and utilities;
- The tunnel's capability to perform its intended function over the life of the project—in particular, an adequate lining.

Long, circular tunnels in soil are commonly constructed by shoving circular shields through the ground, excavating the soil at the face of the shield. The shields provide initial support to the perimeter of the tunnel heading and permit the initial tunnel lining to be erected in the tail section of the shield without exposing the soil surface.

Stability of the tunnel heading and prevention of damage to ground settlements are major concerns in soft-ground tunneling.

Design of the tunneling process is more difficult when ground conditions vary across the tunnel face or along the length of the tunnel alignment. A single shield may not accommodate all conditions efficiently, and it may be necessary to change tunneling procedures or use ground-modification techniques such as dewatering or grouting to advance the tunnel.

Mixed-face conditions, in which rock and soil are encountered in a single tunnel face, create difficulties in excavating the rock while supporting the soils, which are often unstable. Bedding and layering of soils create variations in permeability that allow water to perch on top of low-permeability layers and flow into the tunnel. To minimize such flows requires placement of dewatering wells on very close spacings adjacent to the tunnel.

Soil-tunneling procedures must also be used for tunneling in rock when a mixed face of soil and rock is encountered at the contact between rock and the overlying soil overburden, or when fault zones are encountered in the rock. Commonly, water in the soil and permeable-rock fractures contributes to the instability of these zones. Although rapid and efficient tunneling may not be possible in the soil, it is desirable that the methods used to get through the soil zones allow safe, steady progress. This is more likely if the possible existence of such conditions is anticipated during tunnel design.

The initial tunnel lining must accommodate loads applied during construction as well as stresses produced by ground loads. In shielded tunnels, initial support commonly

Table 8.2-7 Tunnelman's Ground Classification System

Classification	Behavior	Typical Soil Types
Firm	Heading can be advanced without initial support, and final lining can be constructed before ground starts to move.	Loess above water table; hard clay, marl, cemented sand, and gravel when not highly overstressed.
Raveling • Fast raveling • Slow raveling	Chunks or flakes of material begin to drop out of the arch or walls sometime after the ground has been exposed, due to loosening or to overstress and "brittle" fracture (ground separates or breaks along distinct surfaces, as opposed to squeezing ground). In fast raveling ground, the process starts within a few minutes.	Residual soils or sand with small amounts of binder may be fast raveling below the water table and slow raveling above. Stiff fissured clays may be fast or slow raveling depending on the degree of overstress.
Squeezing	Ground squeezes or extrudes plastically into the tunnel, without visible fracturing or loss of continuity or perceptible increase in water content. Ductile, plastic yield, and flow occur because of overstress.	Ground with low frictional strength. The rate of squeeze depends on the degree of overstress. Occurs at shallow to medium depth in clay of very soft to medium consistency. Stiff to hard clay under high cover may move in a combination of raveling at excavation surface and squeezing at depth.
Running • Cohesive running • Running	Granular materials without cohesion are unstable at slopes greater than their angle of repose (±30°–35°). When exposed at steeper slopes, they run like granulated sugar or dune sand until the slope flattens to the angle of repose.	Clean, dry granular materials. Apparent cohesion in moist sand or weak cementation in any granular soil may allow the material to stand for a brief period of raveling before it breaks down and runs; termed *cohesive running*.
Flowing	A mixture of soil and water flows into the tunnel like a viscous fluid. The material can enter the tunnel from the invert as well as from the face, crown, and walls, and can flow for great distances, completely filling the tunnel in some cases.	Below the water table in silt, sand, or gravel without enough clay content to give significant cohesion and plasticity. May also occur in highly sensitive clay when it is disturbed.
Swelling	The ground absorbs water, increases in volume, and expands slowly into the tunnel.	Highly preconsolidated clay with plasticity index 30, generally containing significant montmorillonite.

Source: Adapted from Terzaghi 1950, Peck 1969, and Heuer 1974.

consists of steel ribs and lagging, steel-liner plate segments, or concrete segments. Significant loads can develop during erection and subsequent grouting or expansion of the segments against the ground. If the ground has been excessively loosened or if it forms an irregular perimeter in poor contact with the lining, the resultant nonuniform loadings and bending may result in significant damage to and even buckling of the lining. As the shield advances, ground loads are transferred to the installed lining. Elastic analyses and experience show that the ground and the lining interact significantly. If the lining is in full contact with the ground around its perimeter, then active ground loads applied to one portion of the lining perimeter cause a small outward deflection and buildup of a passive ground reaction on other portions of the perimeter that will support the lining and permit it to act as a stable arch. If the lining is relatively flexible with respect to the soil mass, then the bending moments that develop in the lining will be quite small.

Tunnelman's Ground Classification

Because tunneling may temporarily expose the ground overhead or on vertical surfaces, the capability of the soil to stand until support can be placed is of great concern. A major factor involved in controlling the stand-up time of soil is its short-term cohesion or cementing, as well as the amount of soil surface that is exposed ahead of the supports at any time. It is often difficult to anticipate tunnel behavior from the standard index properties obtained in the soil-exploration program. Sampling often disturbs cohesive granular soils or partially cemented soils, causing their in-situ cohesive characteristics to be lost. Another major factor involved in controlling stand-up time is groundwater flow. Flow into the tunnel creates high seepage-pressure gradients near the tunnel face that can destabilize the soil, causing it to flow into the tunnel.

The so-called Tunnelman's Ground Classification System is a qualitative description of the types of soil behavior encountered during tunneling. Table 8.2-7 presents the system as proposed by Terzaghi (1950) and modified by Peck (1969) and Heuer (1974).

The classification is more than a description of the properties of the soil because it describes behavior under some of the conditions encountered in a tunnel. Construction methods, construction equipment, and tunnel geometry all influence ground behavior.

The stand-up characteristics of soil are the primary factors that define the categories. The initial cohesion or cementing of a soil differentiates between firm, raveling, and running ground. Groundwater seepage can transform running ground into flowing ground. Swelling and squeezing ground are most likely in shales or clays of high plasticity. Protection of the shale from disturbance and access to water minimize any swelling pressures that develop. Thus, early placement of a continuous lining against potentially swelling surfaces is usually desirable. If pressures still are high, then procedures to allow the ground to displace in a controlled manner can be devised.

Squeezing Ground

The severity of squeezing ground in a tunnel can be estimated from the ratio of overburden pressure γH to the undrained shear strength s_u of the clay (Peck 1969). Ratios greater than 5 produce the equivalent of bearing-capacity failure of the clay surrounding the tunnel, with rapid squeezing into unsupported areas in the tunnel face or into voids around the shield and lining. Compressed-air pressures used in the tunnel are subtracted from the overburden pressure to reduce the ratio to acceptable levels. Although squeezing conditions are not as severe for ratios less than about 4, some time-dependent movement and loading of supports takes place for ratios between 1 and 4.

Squeezing relationships can be evaluated not just for soft clays in shallow tunnels but also for deep rock tunnels in shales and fault zones. In mine pillars or abutments where mining nearby has resulted in transfer of large stresses to the pillars, the stresses that cause failure or time-dependent movements are greater than the overburden pressure and are a function

Table 8.2-8 Strength (back-calculated and estimated) and creep parameters for various classes of shale

Ground Class	Description	ϕ, degrees	q_u, psi	λ, %	$E_s/(\sigma_1-\sigma_3)_f$	R_f	Diametral Closure, % at 3 months
CL I	Sandstone and siltstone, widely spaced joints	50	9,000	—	200–500	0.1	
CL II	Siltstone to shale, moderately jointed	45	2,000–4,000	1–2	250–300	0.1–0.2	0.2 to 0.4 (steel ribs)
CL III	Shale, closely jointed with some thin shears	35	500–1,000	5–7	250–300	0.5	1 to 2 (steel ribs)
CL IV	Shale, closely jointed and sheared, shear zones contain crushed and soft materials	25	200–300	7–10	200–250	0.8–0.9	0.8% (concrete segments)
CL IVb	Shale, wide shear zones of crushed and soft materials	25	0–100	12–15	150–200	0.9	4% (steel ribs)

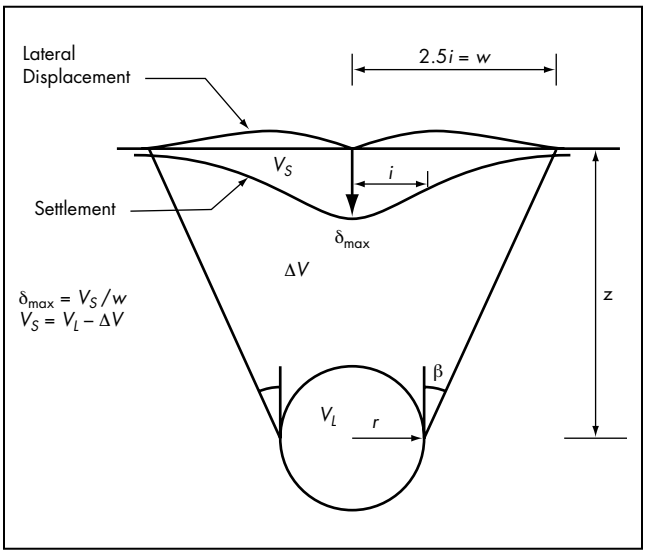
Note: Steel ribs developed yield stresses (40 psi radial pressure) in Class III–IVb ground.
Concrete segments were effectively stiffer and developed approximately 100 psi radial pressure.



of the degree to which adjacent material has been removed in addition to other factors. The time rate of closure and buildup of pressures on linings in squeezing ground can be evaluated using creep relationships such as given in Equation 8.2-12. Using this equation to describe the stress–strain–time relationships, creep closure around a circular tunnel instantly excavated in a hydrostatic stress field was analyzed and compared with the results of field measurements of the Stillwater Tunnel in Utah (United States), excavated at a depth of 2,000 ft (600 m) in shale containing fault zones and closely fractured zones subject to squeezing (Phienweja 1987). Creep parameters were estimated not only from laboratory creep tests on shale and sheared clay gouge but also from measured closure and lining pressures in various rock-mass classes. Table 8.2-8 lists the creep parameters and typical values of pressure and deformation that developed for the ground classes. The slope of the (log of tunnel closure) – (log of time) plot was initially greater than λ as the headings advanced but approached λ with time. Pressures that develop on a lining installed soon after excavation are also strongly influenced by λ.

Estimating Ground Movements Around Shallow Tunnels

In any tunnel, the ground in the heading must be controlled to prevent instability before and during installation of the tunnel lining. When advancing shallow tunnels in soil in the vicinity of structures and utilities, a further requirement is to limit ground movements to prevent unacceptable movements and damage. Ground control measures must be selected with due consideration to the stand-up time of the soil. Two types of ground loss can occur: (1) large loss of ground, often in a sudden, uncontrolled, or catastrophic manner; and (2) the regular, smaller ground movements that occur throughout the length of the tunnel drive.

Large ground losses usually occur by means of running, flowing, or squeezing of soil into the tunnel face, but can also occur by means of soil flow through the tunnel lining or collapse of an unstable lining. Tunneling procedures should be selected to minimize the risk of large ground losses for the anticipated ground conditions.

Regular ground losses occur around the shield and lining, during excavation and installation of the lining, throughout the tunnel drive. For a shielded tunnel, most regular ground losses occur when the shield cuts a perimeter that is several inches (tens of millimeters) outside the outer perimeter of the installed support. Ground losses are minimized by a shield that has minimum overcutting and is easily steered on line and grade, and by rapid and complete expansion or grouting of the lining behind the tail of the shield.

Source: Cording and Cepeda-Díaz 1992.
Figure 8.2-16 Settlement trough formed by ground loss in a tunnel

The volume of ground loss in a tunnel is distributed through the soil mass and results in a settlement trough of volume V_S that is less than the volume of ground loss V_L by the amount of volume expansion ΔV in the ground (Figure 8.2-16). The denser the soil and the larger the ratio of tunnel depth to diameter, the greater is the volume expansion, which reduces the volume of the surface settlement trough for a given volume of ground loss around the tunnel. In soft clays, V_S is approximately equal to V_L, but exceeds V_L if drainage or disturbance of the clay surrounding the tunnel results in consolidation with time.

The half-width w of the settlement trough can be estimated using procedures described by Peck (1969) and Cording and Hansmire (1975). For a settlement trough shaped like a normal distribution curve with an inflection point i, $w = 2.5\,i$. Typically, for sands, the angle β is in the range 10°–30°, and for clays, β is in the range 25°–45°. With these relationships, the magnitude and distribution of surface settlements and the damage to structures can be estimated for given volumes of ground loss.

Controlling Ground Movements

A variety of tunneling procedures and shield designs can be used to control the face as well as limit movements around the shield and lining. Open-face shields or shields using

mechanical diggers support the face with muck that is excavated and with additional breasting boards or plates positioned against the face. Wheeled excavators must control the face by rotating the wheel only sufficiently to excavate a volume of soil equivalent to the volume of the tunnel that is advanced. For both of these techniques, additional measures such as compressed air or dewatering may be used to prevent inflow of soil, and it may also be necessary to prevent running by use of techniques such as chemical grouting of the soils ahead of the face. Pressurized face shields may be used in lieu of compressed air to stabilize the face; the shields use air, water, a slurry, or excavated muck to provide positive pressures in a chamber at the face of the shield to balance the water and earth pressures in the soil ahead of the face. Even with this technique, additional ground control measures may be necessary to prevent loss of ground in the face.

Procedures used to modify ground and groundwater conditions before tunneling include dewatering, chemical or cement grouting to penetrate the ground, jet grouting to form soil–cement columns around the tunnel, and freezing. Structures that would be damaged by settlements can be directly supported by underpinning or tied to reduce lateral extension of the structure. Compaction grouting can be used as required during tunneling to redensify ground that has loosened above the tunnel before it causes surface settlement. Compaction grouting involves placing a low slump grout at high pressures above the tunnel, usually after the shield has passed, in holes drilled down from the surface or up from the tunnel (Baker et al. 1983).

CHAPTER 8.3

Slope Stability

Charles A. Kliche

INTRODUCTION

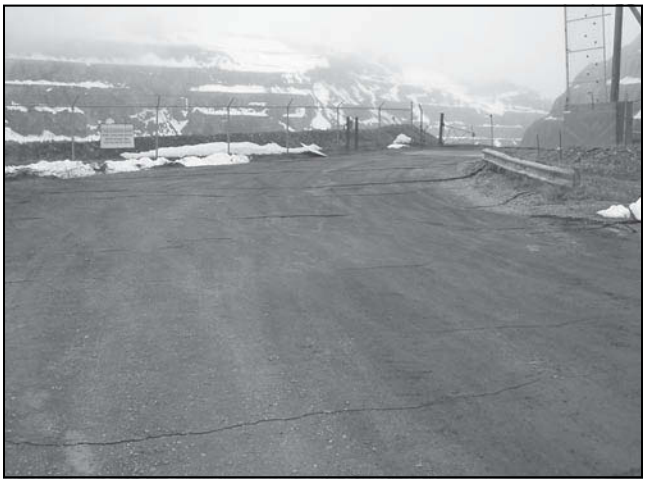
Because of the discontinuous nature of rock, the design of stable rock slopes is as much an art as it is applied engineering. Experience is as important as the proper use of the theories of soil and rock mechanics, structural geology, and hydrology.

Many computerized tools are now available to rock slope design engineers. It is important that these engineers understand the basic theory of rock slope stability (or instability) before they attempt to use many of the computerized methods—especially before they attempt to interpret and apply the results.

The civil engineering field uses mainly soil mechanics principles for slope-stability analysis. This field is mostly concerned with slopes cut in soil-like materials. The analysis is used mainly for foundations, buildings, or dam sites; road cuts; cut-and-cover tunneling; irrigation ditches and channels; tailings dams; and mine waste or lean ore repositories.

On the other hand, the mining engineering field uses mainly rock mechanics principles to analyze the stability of slopes cut in rocks. Rock mechanics is more complicated than soil mechanics for the following reasons (Brawner and Milligan 1971): rock materials are heterogeneous and usually anisotropic; strength parameters relating to rock masses are infinitely variable and difficult, if not impossible, to determine precisely; generalized models and theories of rock behavior are complex, as are the mathematics involved; field conditions are extremely difficult and often impossible to duplicate in the laboratory; field testing is usually complicated and time-consuming and is almost always very expensive.

Rock slope engineering is the application of rock mechanics principles and structural geology principles to the stability of a slope cut in rock. It is a specialized branch of geomechanical engineering. It includes not only kinetic analysis (possible modes of failure) and kinematic analysis (stability of the failure modes) but also probabilistic analysis, specialized numerical methods, slope stabilization methods, groundwater analysis, geologic data collection and interpretation, slope-monitoring methods, and specialized rock-blasting techniques.



Stability Criteria

From the standpoint of simple mechanics, the stability of a slope is the ratio of the strength of the material (resisting forces, stresses, or moments) to the stresses in the slope tending to destabilize it (driving forces, stresses, or moments). If the destabilizing stress exceeds the strength, the slope is unstable, and the factor of safety is less than unity. Conversely, if the strength exceeds the destabilizing stress, the slope is stable, and the factor of safety of the slope is greater than unity. This ratio, termed the *safety factor* or *factor of safety*, has been the basis for stability analysis in civil engineering for many years. The safety factor to which the slope should be designed is a function of the risk involved, namely, the condition of the slope and the exposure.

Because of the variability of rock properties, uncertainty in the measurement of these properties, and the influence of quasi-random events such as earthquakes and rainfall, the stresses and strengths used in stability are estimates of populations with significant distributions rather than single values. For this reason, an alternate approach to defining stability is to use the reliability (probabilistic) method, whereby the probability of whether or not a slope will be stable is calculated from the distribution of input values (i.e., the distribution of parameters such as cohesion, internal angle of friction, water pressure, transitory forces, etc.).

Slope instability does not necessarily mean slope failure from the operational standpoint. It is not uncommon for a slope to become unstable, with the resulting displacement being <1 m (3 ft). An example of this type of instability is the appearance of tension cracks along the crest of a slope without overall slope failure (Figure 8.3-1). Whether an unstable slope results in significant cost to the operation depends on the rate of movement, the type of mining operation, and the relationship of the unstable material to the mining operation. Unstable areas with displacement rates of >100 mm/d (4 in./d) have been successfully mined by truck and shovel operations. On the other hand, a few millimeters of displacement of the rock under a crusher, conveyor, or building may require extensive

Courtesy of Homestake Mining Company.
Figure 8.3-1 Tension cracks at the crest of a highwall

repair and stabilization. When the rate of displacement is such that it disrupts the operation or the movement produces damage to mining facilities, it is considered an operational slope failure. A similar economic concept was used by Varnes (1978) to distinguish between creep and landslides. He restricts the lower limit of the rate of movement of landslide material "to that actual or potential rate of movement which provokes correction or maintenance."

Safety

Many rock slopes move to varying degrees during the course of their operational lives. Such movement indicates that the slope is in a quasi-stable state, but this condition may continue for many years, or even centuries, without failure occurring. However, in other cases, initial minor slope movement may be a precursor for accelerating movement followed by collapse of the slope. Because of the unpredictability of slope behavior, movement monitoring programs can be of value in managing slope hazards, and they provide information that is useful for the design of remedial work.

Slope movement is most common in open-pit mines, and many mines continue to operate safely for years with moving slopes that are carefully monitored to warn of deteriorating stability conditions. Other slopes that undergo long-term movement are landslides that may creep for hundreds of years resulting in accumulative movement of tens of meters. Such movement may comprise an approximately uniform creep rate, on which may be superimposed short periods of more rapid movement resulting from such events as earthquakes, unusually high precipitation periods, and human activities. Creep has been defined by Varnes (1978) as "extremely slow distributed movements in both rock and soil." Human activities that can contribute to slope instability include adding a surcharge weight to the crest of the slope, excavations at the toe of the slope, transitory earth stresses (blasting and vibrating equipment), and changing the groundwater conditions by dam filling or irrigation.

When a rock or soil mass is disturbed, either by the actions of people or by natural events, it undergoes a redistribution of stresses, resulting in a change in shape. This readjustment is reflected in displacements, deflections, pressures, loads, stresses, and strains that can be detected and measured. Many of the same measurement methods and instrumentation techniques can also be used to investigate the mechanical properties of the mass, the interaction between the mass and any associated artificial structures, and the effectiveness of remedial measures proposed to correct defects in either the mass or the structures.

Monitoring is the surveillance of engineering structures either visually or with the aid of instruments (Brown 1993). The objectives of a rock slope monitoring program are (Call 1982)

- To maintain a safe operation for the protection of personnel and equipment;
- To provide advance notice of instability, thus allowing for the modification of the excavation plan to minimize the impact of the instability; and
- To provide geotechnical information in order to analyze the slope failure mechanism, design appropriate remedial measures, and/or conduct a redesign of the rock slope.

Slope Geometry

Three main components of an open-pit slope design have been defined (Wyllie and Mah 2004): (1) the overall pit-slope angle from the toe of the excavation to the crest, which incorporates all ramps and benches between; (2) the interramp angle, which is the slope, or slopes, lying between each ramp or ramp segment that depends on the number of ramps and their widths; and (3) the face angle of individual benches, which depends on the vertical spacing between benches, or combined multiple benches, and the width of any berms (or "catch benches") included therein (Figure 8.3-2). The interramp angle is the slope angle produced normally by a number of benches. Where there are haul roads, working levels, or other wide benches, the overall slope angle will be flatter than the interramp angle. And, normally, the bench face angle will be the steepest angle, often approaching vertical. It is important in slope design to consider these components. For example, in the case of bedding dipping into the pit at 40°, as shown on Figure 8.3-2, the daylighting plane shear criteria would result in a design angle of 40°. If this angle were used for the overall slope angle, haul roads cut into the slope would undercut the bedding and result in interramp instability. In addition, there would be almost no catch benches left, as the bench face angle would be steeper than the bedding.

The Detailed Slope-Stability Study

The detailed slope-stability study can be divided into two parts: field work, and office and laboratory work.

Field Work

Field work is the data collection phase of the detailed slope-stability investigation. It should include

- Compiling and editing topographic maps;
- Detailing of geologic mapping (1:1,000 to 1:500)
  - Mapping formation boundaries on about 1:1,000 scale
  - Mapping structural features within the boundaries; using a geological compass to map the structures; putting the mapped structures on the survey map;
- Ascertaining the location of groundwater discharge points in the study area. Determining discharge amounts (monitoring at least twice per year for at least 2 years);
- Collecting rock samples for laboratory testing;

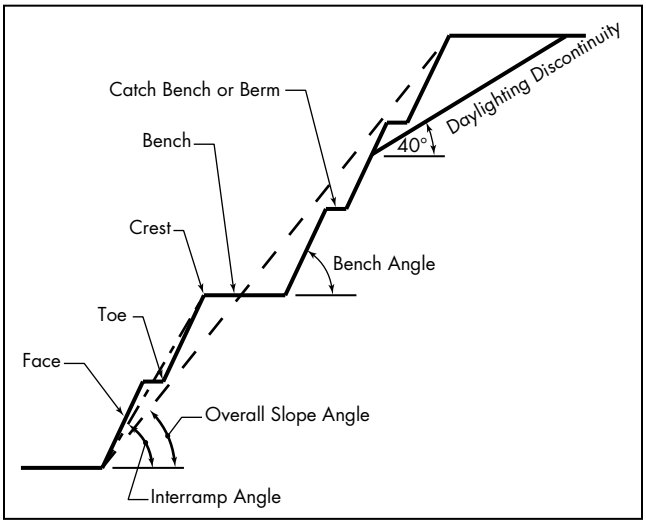

Figure 8.3-2 Highwall slope configuration with 40° daylighting discontinuity

- Conducting a core drilling program (core recovery should be at least 90%), if needed;
- Drilling, and providing instrumentation for, any needed groundwater monitoring wells; and
- Conducting any necessary geophysical studies.

Office and Laboratory Work

Office and laboratory work is the data reduction and interpretation phase of the detailed slope-stability study. This phase should include

- Development of systematic working cross sections: radial for open pits, axial for long pits or road cuts;
- Discontinuity evaluations;
- Laboratory testing of samples collected from the field
  - Testing of intact rock specimens (uniaxial, triaxial, maybe direct shear)
  - Testing of discontinuity surface samples (direct shear);
- Evaluation of the stability of proposed slopes by sector;
- Determination of the seismicity of the region; and
- Stability analysis sector-by-sector, based on available data and sound engineering judgment. If the stability (based on factor of safety, probability of failure, numerical modeling, or other acceptable technique) along a cross section is below the acceptable level, take one or more of the following steps: (1) accept the risk of failure, (2) flatten the slope, (3) use artificial support, and/or (4) drain the slope, if appropriate. Steps 2 through 4 are normally within the responsibilities of the geotechnical engineer, whereas Step 1 would be a management decision.

GENERAL MODES OF SLOPE FAILURE IN ROCK MASS

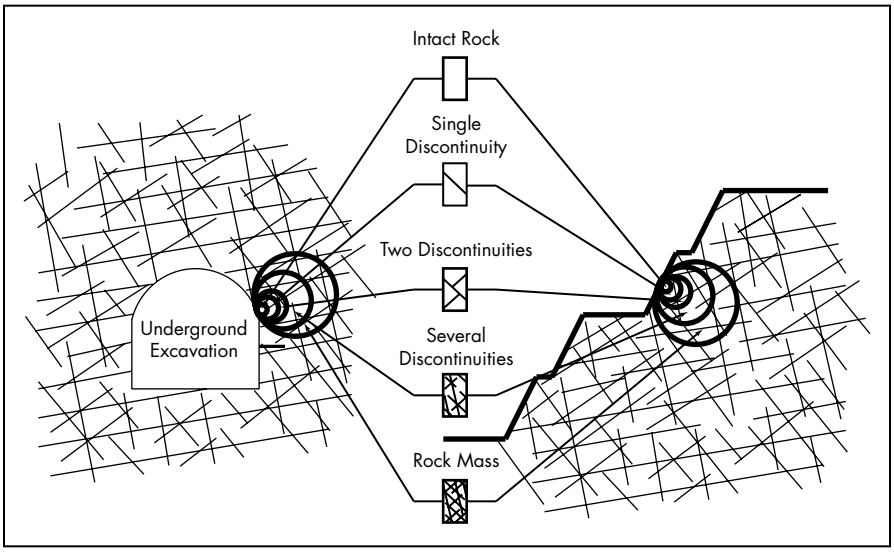
Numerous primary, and what will be called secondary, modes of slope failure in rock masses have been identified (Hoek and Bray 1981; Kliche 1999; Wyllie and Mah 2004; Call 1992). These modes include

- Plane shear (planar and wedge) failure,
- Rotational failure (including curvilinear or spiral failure surface),
- Toppling failure (including complex planar plus toppling),
- Rockfall,
- Stepped path (stepped plane and stepped wedge),
- Flexural thin-bed failure, and
- Two-block (active/passive blocks).

In order to make a quantitative estimate of the stability of a slope, analytical models amenable to mathematical solutions must be used. The requirements for stability analysis using any of these models are the slope and failure geometry; material, hydrological, rock mass and strength properties; and any assumptions regarding stress distributions and strength.

Geologic Model

The influence of rock sample size on strength has been widely discussed in geotechnical literature, and it is normally assumed that there is a significant decrease in rock strength as the sample size increases. A general discussion of this size–strength relationship can be found in Hoek (2007).



The rock of a slope can be considered to consist of the following components (Figure 8.3-3).

- **Intact rock:** The primary unbroken rock as determined from a piece of core cut for compression testing. The term *rock substance* has also been used for the unbroken rock.
- **Discontinuities:** The term *discontinuity* refers to any of a number of different types of defects in the rock fabric. Discontinuities, representing weakness planes in the mass, control the engineering properties by dividing the mass into blocks separated by fractures such as faults, joints, foliations, and bedding. Joints are the most common defect in rock masses; faults are the most serious. All discontinuities have the following physical properties: orientation, spacing, width of opening, intensity, and roughness.
- **Rock mass:** The combination of intact rock and fractures considered as a unit. Soil could be considered a special case of rock mass.
- **Major structures:** Geologic features such as faults or shear zones along which displacement has occurred and that are large enough to be mapped and located as individual structures. There is actually a continuum between fractures and major structures, but the differentiation is useful for design purposes.
- **Minor structures:** These include fractures, joints, bedding planes, foliation planes, and other defects in the rock mass, generally of lesser importance with respect to rock slope instability.

Collecting and Using Geologic Structure Data

The two most important rock mass factors that control slope stability are (1) discontinuity strength, and (2) the location and orientation of the discontinuities with respect to the slope. This is because the major source of slope instability in rock slopes is failure along preexisting discontinuities. Other important factors include the rock material type, the discontinuity type, discontinuity (joint) intensity, the discontinuity surface roughness, the amount of attachments across the discontinuity, and the type and nature of filling material (if any) between the two planes of the discontinuity.

Geologic structures, which are important for open-pit slope stability, can be divided into rock fabric, which is defined as geologic structures that are too numerous to be evaluated

Source: Adapted from Hoek 2007.

Figure 8.3-3 Transition from intact rock to rock mass

individually and are, therefore, treated statistically in slope design analysis; intermediate structures, which include only major structures that are larger than a lower-limit baseline; and regional structures, which are major structures that are of a regional scale, and are often faults with measured length >100 m (>330 ft) (Nicholas and Sims 2000).

The recording and analyzing of the orientation of discontinuities is normally the first step in the investigation of a slope for the formation of potentially unstable blocks of rock (Hoek and Bray 1981; Wyllie and Mah 2004). Since patterns of jointing are invariably preferentially developed over reasonably large areas, the degree of stability of slopes of the same pit will vary, since some slopes will be formed in rock with adversely oriented joints and others not.

Figure 8.3-4 shows a lower hemisphere stereographic plot of what is known as the Markland test for the possibility of planar-type failure, wedge-type failure, and toppling-type failure. For plane shear failure (or wedge-type failure) to be kinematically possible, the following conditions must be met (Hoek and Bray 1981; Piteau and Martin 1982):

1. The dip of the discontinuity (or plunge of the line of intersection of two discontinuities) must exceed the angle of friction, ϕ, for the rock surface.
2. The discontinuity (or line of intersection of two discontinuities) must daylight in the slope face.
3. The dip of the discontinuity (or plunge of the line of intersection of two discontinuities) must be less than the dip of the slope face, ψ.

These conditions can be expressed by the following relationship, and are also illustrated in Figure 8.3-4:

$$\psi > \beta > \phi$$

where

ψ = dip of the slope face
β = dip of the discontinuity or plunge of the line of intersection
ϕ = angle of friction for the rock surface

For toppling failure to be kinematically possible, the discontinuity set must dip steeply back into the slope face (undercutting condition) and the strike of the discontinuity set must be approximately parallel to the strike of the slope face.

The pole to a plane in space is the normal to that plane, projected to intersect the lower half reference of the stereographical projection. Pole plots, in which each plane is represented by a single point, are the most convenient means of examining the orientation of a large number of discontinuities (Wyllie and Mah 2004). The plot provides an immediate visual depiction of concentrations of poles representing the orientations of discontinuity sets and, along with the orientation of the slope face, will indicate which failure modes are possible.

Plane Shear Failure Geometries

The plane shear failure mode refers to a situation in which displacement occurs along one or more geologic structures and the failure mass is considered to be a rigid block or a number of blocks. These geometries are shown in Figure 8.3-5. A brief description of each of the plane shear modes follows.

- **Planar.** The planar mode is the simplest geometry consisting of a single plane striking nearly parallel to the slope (within 15°–20°). The structure must have a dip flatter than the slope angle, must be long enough to reach the surface or a tension crack, and the rock–rock apparent friction (incorporating rock friction, roughness, and cohesion) must be less than the dip of the discontinuity. Since the stability analysis is two dimensional, the width of the failure must be great enough that the end results are negligible, or there must exist boundary structures that define the lateral extent of the failure. Figure 8.3-6 shows a steeply-dipping discontinuity daylighting in the bench face upon which planar failure occurred.
- **Step path.** The step path geometry occurs where there is a fracture set dipping into the pit in the orientation given for the planar mode, but no individual fracture is long enough to form a single, continuous failure plane. Sliding

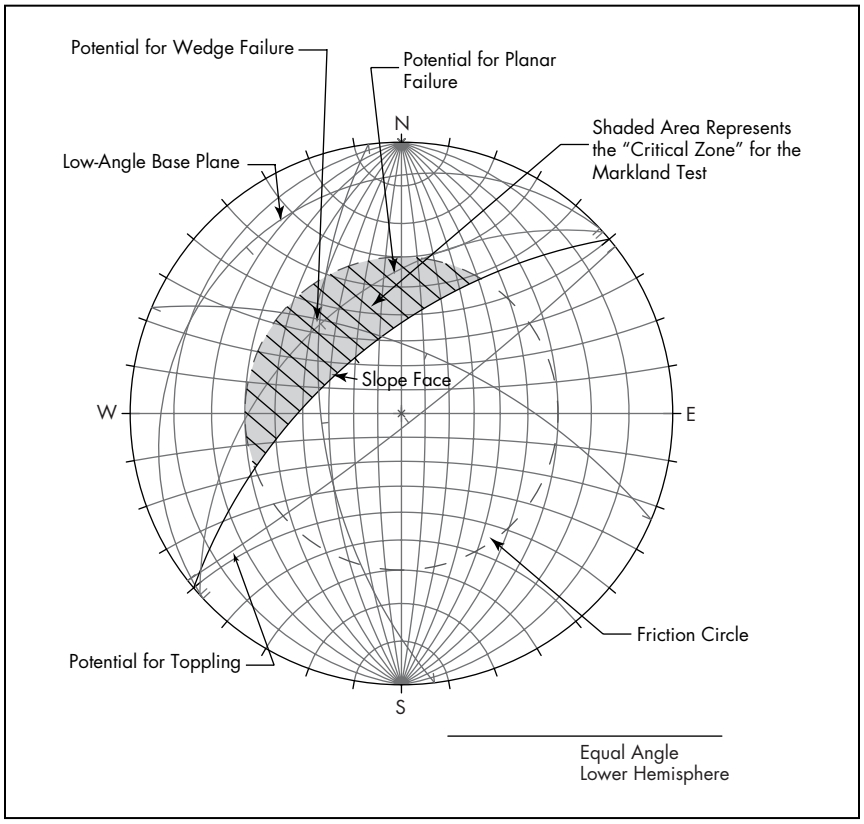


Figure 8.3-4 Stereographic projection of wedge-type failure, planar-type failure, and toppling failure modes

is assumed to occur along fractures in the master joint set, and separation along fractures approximately perpendicular to the master joint set or tensile failure of the rock between the master joints.

- **Wedge.** The wedge failure geometry is the result of two planar geologic structures intersecting to form a detached tetrahedron of material. Sliding can occur down the intersection or on one of the two planes, with separation on the other plane. In some cases the sliding on one will demonstrate elements of rotation rather than simple translation. Figure 8.3-7 shows a wedge-type failure at an open-pit mine.
- **Step wedge.** The step wedge is similar to the simple wedge except that one or both of the failure surfaces are step paths. The stepped-path follows a complex path along numerous intersecting discontinuities.
- **Two-block.** The two-block is a two-dimensional plane shear geometry where there are two plane shear structures dipping into the pit, with a third structure dipping back into the wall that divides the failure into an active and a passive block.
- **Slab.** Where there is bedding or foliation parallel to the pit, slope instability can occur even though the structures are not daylighted. The possible failure mechanisms are crushing at the toe, a two-block geometry formed by joints at the toe, and buckling.

Nonplanar Failure Surfaces

Nonplanar failure surfaces include rotational shear and general surface failures.

In a soil or weak rock mass slope where there are no geologic structures that control the failure, with rotational shear the most unstable failure surface is approximately a circular arc. The radius and location of the most unstable circle (the critical circle) depends on the material properties and must be found by iterative solutions of trial circles. The stability of the circular arc is usually analyzed by one of the many methods of slices (Bishop's method, the Ordinary Method of Slices, or Janbu's method, for example).

The general surface is a mixed mode failure in which part of the failure surface is structurally controlled and part is failure through the rock mass. An example would be a nondaylighted plane shear. Any of the many methods of slices may be used to analyze the stability of the general surface.

Other failure modes include block flow, toppling, and rockfalls and raveling.

Compared with underground rock mechanics, in block flow failure mode the stresses in a pit slope are low and do not exceed the rock mass strength. Thus, most slope instability is controlled by geologic structure. However, in deep pits there is the possibility that the stresses in the toe of the slope would be sufficient to result in the crushing failure of the rock mass, particularly if there was a high horizontal stress. This mode of instability is referred to as block flow by Coates (1981).

A conceptually possible variation of the block flow would be a situation where the rock mass under confinement in the slope wall yields plastically. The resulting deformation would be plastic flow such as occurs in a glacier. At the surface of the pit slope, where there is no confinement, secondary sliding block failure would occur similar to the calving of a glacier.

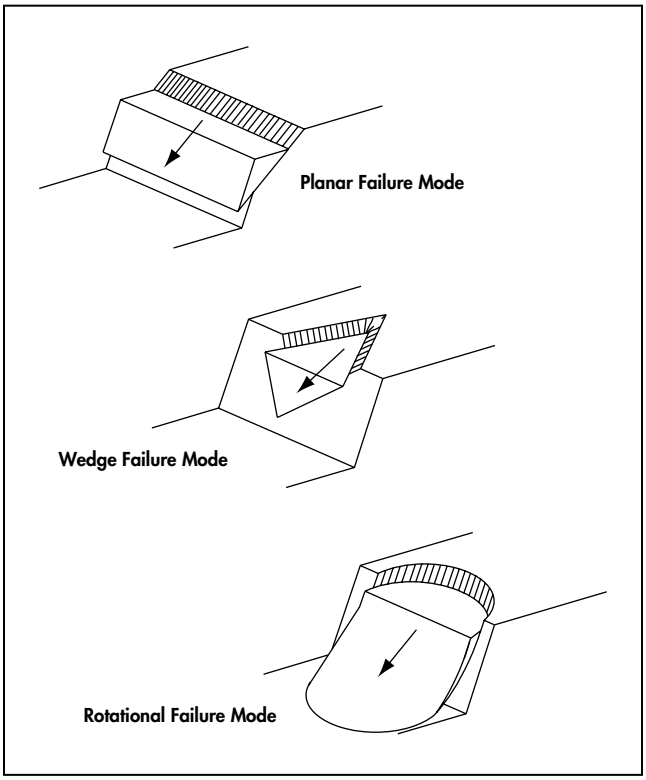

Figure 8.3-5 Typical shear failure modes (planar and rotational)

This is a possible explanation for situations where instability occurs in a relatively flat slope and the back analysis indicates unusually low shear strength.

Toppling is possible whenever a set of well-developed or throughgoing discontinuities dips steeply into the slope (Piteau and Martin 1982). In this type of failure, long, thin columns of rock formed by the steeply dipping discontinuities may rotate about a pivot point located at the lowest corner of the block. Therefore, the governing factor for toppling of a block is the location of the weight vector of the column with respect to the pivot point on the block. If the block thickness-to-height ratio is less than the tangent of the dip of the base plane ($t/h < \tan\beta$), then the resultant force due to the weight of the block will occur outside the toe of the block, and an overturning moment will develop about the pivot point. Toppling is most commonly observed as a secondary failure mechanism resulting from displacement caused by another mode of instability (Figure 8.3-8).

With rockfalls and raveling, bench faces are normally cut as steeply as the excavator being employed can dig them. As a result, individual blocks in the face are at or close to limiting equilibrium, and disturbing forces can dislodge them. The primary disturbing forces are gravity, freeze–thaw, transitory earth motion (vibrations), and water from rainfall. The action of these disturbing forces can dislodge individual blocks, producing a rockfall. The dislodging of large numbers of blocks is termed *raveling*. Weathering can also produce raveling by the deterioration of the material supporting the blocks. In principle, the stability of individual blocks could be analyzed, and there are commercial computer programs available to do so. However, there is no practical method of conducting stability analyses for raveling on a pit scale. The design approach, therefore, is to provide for adequate catch benches.

Slope-Stability Assessment Techniques

Techniques for slope-stability assessment are discussed in this section.

Limit Equilibrium Technique

Limiting equilibrium methods are the most common analysis techniques used for the solution of rock slope stability problems. At limiting equilibrium, by definition, all points along the potential failure surface are on the verge of failure. At this point in time, the driving forces (or stresses, moments) just equal the resisting forces (or stresses, moments), and the factor of safety equals unity. Where the resisting forces of a slope are greater than the driving forces, the factor of safety is greater than unity and the slope has a higher probability of remaining stable; when the resisting forces are less than the driving forces, the slope is unstable. Failure modes that can be analyzed by limiting equilibrium techniques include plane shear (planar failure, wedge failure), rotational shear, and toppling failure.

Courtesy of Mine Safety and Health Administration.

Figure 8.3-8 Toppling-type failure

The stability of rock slopes that can be modeled by plane shear at limiting equilibrium depends on the shear strength generated along the sliding surface. For all shear-type failures, the rock can be assumed to be a Mohr–Coulomb material in which shear strength is expressed in terms of cohesion, c, and friction, ϕ , by the equation

$$S = c + \sigma \times \tan$$

where

S = shear strength along the failure plane
c = cohesion generated along the failure plane
σ = normal stress across the failure plane
ϕ = angle of friction for the rock surface

Limit equilibrium analysis can apply to a wide range of conditions and can incorporate additional forces such as surcharge (W_s), horizontal water pressure (V), normal or uplift water pressure (U), vibratory forces ($k_h \times W$, where k_h is the horizontal seismic coefficient), and rock bolt forces (T) applied at some angle inclined upward from horizontal (+θ).

Figure 8.3-9A shows a slope containing a throughgoing discontinuity with area, A, and dip, β, and a vertical tension crack. The slope is partially saturated such that the tension crack is half-filled with water, and the water table daylights in the slope face at the same place as the failure surface. No surcharge weight is to be added to the slope and vibratory forces will be neglected. A tensioned rock bolt force (active case), inclined at angle +θ and anchored below the failure plane, will be added to the slope.

Figure 8.3-9B shows the free-body diagram of the rock wedge with the driving forces and resisting forces resolved. If the resisting forces are equated to the driving forces at limiting equilibrium (FS = 1.0), the following equation for factor of safety (FS) can be developed:

$$\mathrm{FS} = \frac{c \times A(W\cos\beta - U - V\sin\beta + T\sin(\theta+\beta))\tan\phi + T\cos(\theta+\beta)}{W\sin\beta + V\cos\beta}$$

where

c = cohesion generated along the failure plane
A = surface area of the failure plane
W = weight of the sliding mass
β = inclination (dip) of the throughgoing discontinuity
U = uplift water force on the sliding plane
$= \frac{1}{2}\gamma_w \times h_w$
V = horizontal water force on the tension crack
$= \frac{1}{2}\gamma_w \times h_w^2$
h_w = height of water in the tension crack
T = rock bolt force
θ = angle of inclination of rock bolt force (+ is ↑ from horizontal)
ϕ = angle of friction along the throughgoing discontinuity

For the *active* rock bolt case, the assumption is that the component of T parallel to the failure plane tends to increase the resisting forces along the potential failure plane; whereas, for the *passive* rock bolt case, the component of T acting parallel to the failure plane will be mobilized as the failure mass moves and, therefore, the horizontal force T will tend to decrease the driving forces.

This analysis is valid for the model of block sliding on an inclined plane at limiting equilibrium. If, on the other hand, the block is of such height-to-width ratio that it may tend to rotate about its lowermost corner (topple instead of slide), the FS can then be calculated as the ratio of the resisting moments to the driving moments:

$$\mathrm{FS} = \frac{\Sigma(\text{resisting moments})}{\Sigma(\text{driving moments})} = \frac{W\cos\beta \times (t/h)}{W\sin\beta \times (t/h)} = \frac{(t/h)}{\tan\beta}$$

where t/h is the block thickness-to-height ratio.

For limiting equilibrium of rotational-type failures, the model generally applied is one of many methods of slices. These models generally differ only in the assumptions needed to make the equations statically determinate.

Rotational-type ("circular") failure may occur in slopes composed of soil or soil-like material (i.e., overburden repositories, waste dumps, fills, dragline spoil piles, etc.). Much of the development of rotational failure analysis methods was carried out in the 1950s and 1960s, resulting in the development of several easy-to-use stability charts (see Hoek and Bray 1981; Perloff and Baron 1976; Naval Facilities Engineering Command 1986). Moreover, several very good commercial computer packages are available that offer deterministic, probabilistic, sensitivity, and back-analysis capabilities using one or more of a number of built-in analysis techniques.

For rotational failure to occur, the total shear stress along the failure surface must be equal to or greater than the shear strength along the surface. The stability analysis of rotational failure is carried out using the limit equilibrium procedure similar to that discussed earlier. However, the application of this procedure to rotational failure involves the division of the slope (potential failure zone) into a series of slices that are usually vertical but may be inclined to coincide with certain geological features (Wyllie and Mah 2004). The base of each slice should be wholly contained within a soil layer to make calculations a bit easier. The forces acting on each slice are the normal forces on the base, the interslice normal forces, the interslice shear forces, the weight of each slice, and the shear force along the base (Figure 8.3-10). This results in $5 \times n - 2$ total unknowns for n slices in rotational failure analysis. If the rotational failure problem is to be solved in the x–y plane (using a unit width of slice through the assumed failure), and if it is assumed that the slope is in equilibrium, then the total

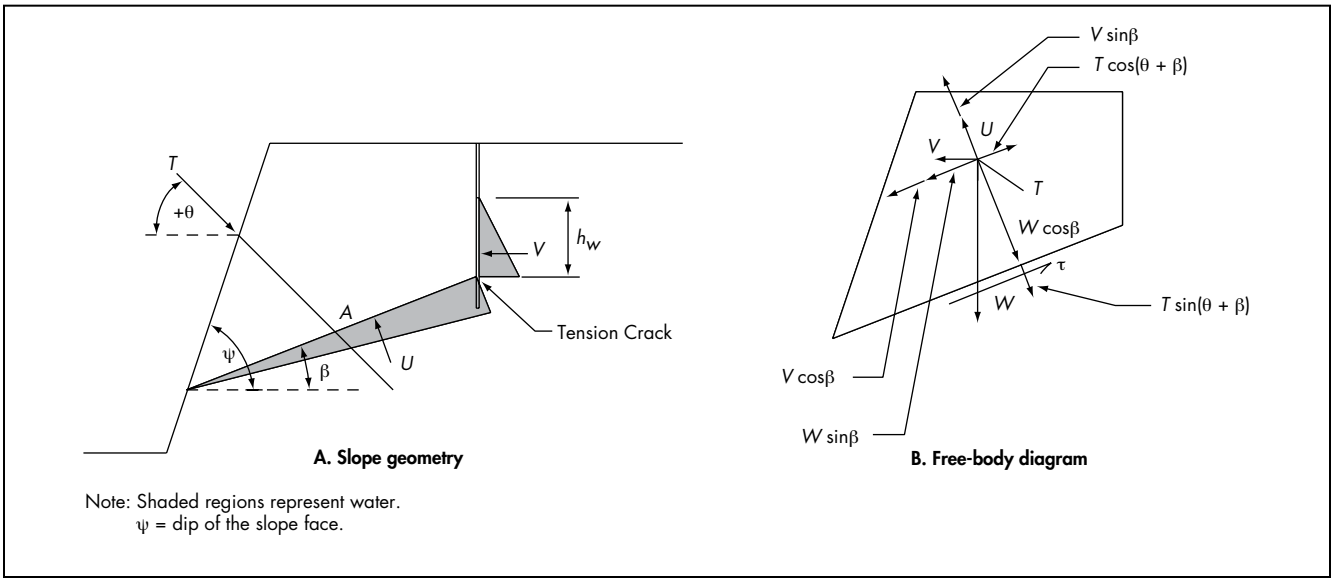

Figure 8.3-9 Plane shear failure geometry showing a slope with a throughgoing discontinuity

number of equations available is the $3 \times n$ equations of statics equilibrium. The methodologies differ mainly in the assumptions made to reduce the equations in order to allow for the solution for the FS (another unknown and assumption is that the FS does not vary slice-to-slice).

Probabilistic Method

The probabilistic method, used most commonly with the Monte Carlo technique, uses known or assumed probability distributions of critical or sensitive parameters to examine the possible effect that variations in these parameters may have on the overall design factor of safety. That is, by simulating different values of the critical parameters (random variables) within the measured distributions (friction, cohesion, dip, dip direction, water level, joint continuity, etc.), a distribution of factor of safety values can be generated for the slope. This can then be used to answer the critical question, "What is the probability that the designed slope will have a factor of safety less than, for instance, 1.3?"

Typical probability density functions (PDFs) for some of the more important variables affecting slope stability are shown in Figure 8.3-11. Plotted on the abscissa (x-axis) is the range of measured values (e.g., cohesion, friction angle, strike); plotted on the ordinate (y-axis) is a ratio representing the normalized number of occurrences within each class interval (i.e., number of occurrences of a dip measurement within the range of 28°–30° divided by the total number of dip angle measurements). This normalization procedure results in the sum of the area under the PDF equaling 1.0. Since the area under the PDF equals 1.0, it can now be used as a means to estimate the probability of occurrence of any value, x, within the range of observed data.

Some of the more important statistical terms frequently used in conjunction with this method are defined here. (See Everitt 2006, for example, for a more-detailed description of the terms.)

- **Random variables**, which include, for example, cohesion, friction angle, joint length, and joint spacing.
- **Probability distribution** describes the range of possible values that a random variable can attain and the probability that the value of the random variable is within any (measurable) subset of that range.
- **Sample mean** indicates the center of gravity of a probability distribution.
- **Sample variance** is defined as the mean of the square of the difference between the value of x_i and the mean value, $\bar{x}$.
- **Standard deviation** is given by the positive square root of the variance, s^2. In the case of the commonly used normal distribution, about 68.3% of the data will fall within ±1 standard deviation, and approximately 95.4% will fall within ±2 standard deviations (Figure 8.3-12).
- **Coefficient of variation** is a normalized measure of dispersion of a probability distribution. It is defined as the ratio of the standard deviation, s, to the mean.
- **Normal distribution** is a common type of probability density—the normal probability density (usually referred to as simply the normal distribution)—and is a mathematical function that takes the form of the familiar bell-shaped curve (Figure 8.3-12).

Since the normal probability density cannot be integrated in closed form between every pair of limits a and b, probabilities relating to normal distributions are usually obtained from a special table. The table pertains to the standard normal distribution, namely the normal distribution with a mean (μ) of 0 and a standard deviation (σ) of 1 (Miller and Freund 1985). In other words, one cannot directly solve the equation of the normal distribution for the value along the abscissa (z-value) given the corresponding accumulated area under the curve by integration, so special tables must be used that give close approximate solutions for the value of z given $F(x)$.

Therefore, if a probability between the limits of 0 and 1 is generated (by using a random number generator), then this probability can be used to generate a corresponding z value. And then the appropriate random variable value from the data set (x) can be determined from the equation

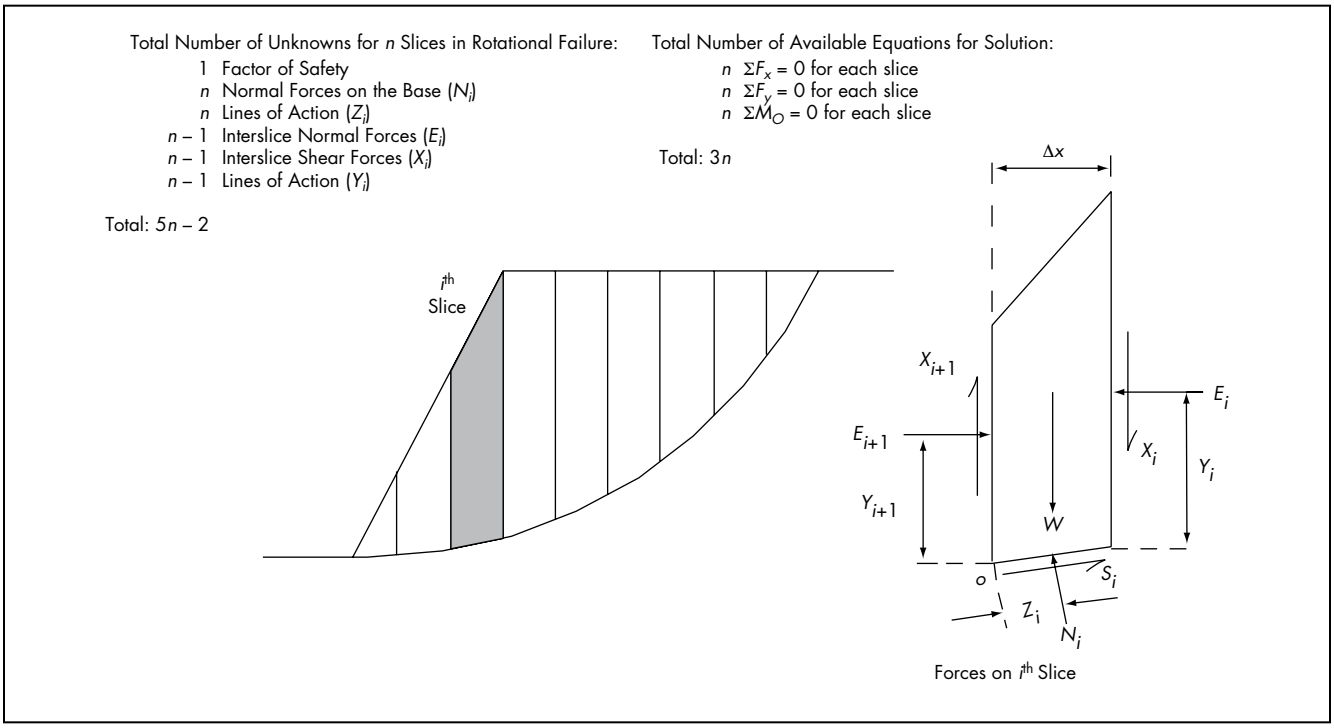

Figure 8.3-10 Statics for the methods of slices for rotational failure

$$z = \frac{x - \mu}{\sigma}, \text{ or } x = \mu + \sigma z$$

In addition to the normal distribution, other distributions commonly used in probability analysis include the lognormal distribution, the beta distribution (of which the uniform distribution is a special case), the exponential distribution, the multivariate normal distribution, and the Weibull distribution.

The Monte Carlo procedure, named for the administrative area of the same name in Monaco on the French Riviera in which Le Grand Casino is located, is a procedure, often computerized, that uses random or pseudorandom numbers to sample from probability distributions and, if a sufficiently large amount of samples are generated and used in calculations such as the factor of safety, then a distribution of values of the end product (factor of safety) can be constructed.

And finally, *numerical models* are defined as the computer programs that attempt to represent the mechanical response of a rock mass subjected to a set of initial conditions such as in-situ stresses and water levels, boundary conditions, and induced changes (e.g., slope excavations). The result of a numerical model simulation is typically either equilibrium or collapse. If the result obtained is equilibrium, the resultant stresses and displacements at any point in the rock mass can be compared to measured values. If the result obtained is collapse, the predicted mode of failure is demonstrated.

The rock mass is divided into elements (or zones) for numerical models. Each element is assigned a material model and properties. The material models are idealized stress/strain relations that describe how the material behaves. The simplest model is a linear elastic one, which uses the elastic properties—Young's modulus, Poisson's ratio—of the material. Elastic–plastic models use strength parameters to limit the shear stress that an element (or zone) may sustain.

The zones may be tied together, termed a *continuum model*, or separated by discontinuities, termed a *discontinuum model*. Discontinuum models allow slip and separation at explicitly located surfaces within the model.

For slopes, the factor of safety is often defined as the ratio of the actual shear strength to the minimum shear strength required to prevent failure. The methodology used in many of the numerical modeling techniques (finite element or finite difference) in order to compute the factor of safety is to reduce the shear strength until collapse occurs. The slope's factor of safety is then the ratio of the actual strength to the calculated reduced shear strength at failure.

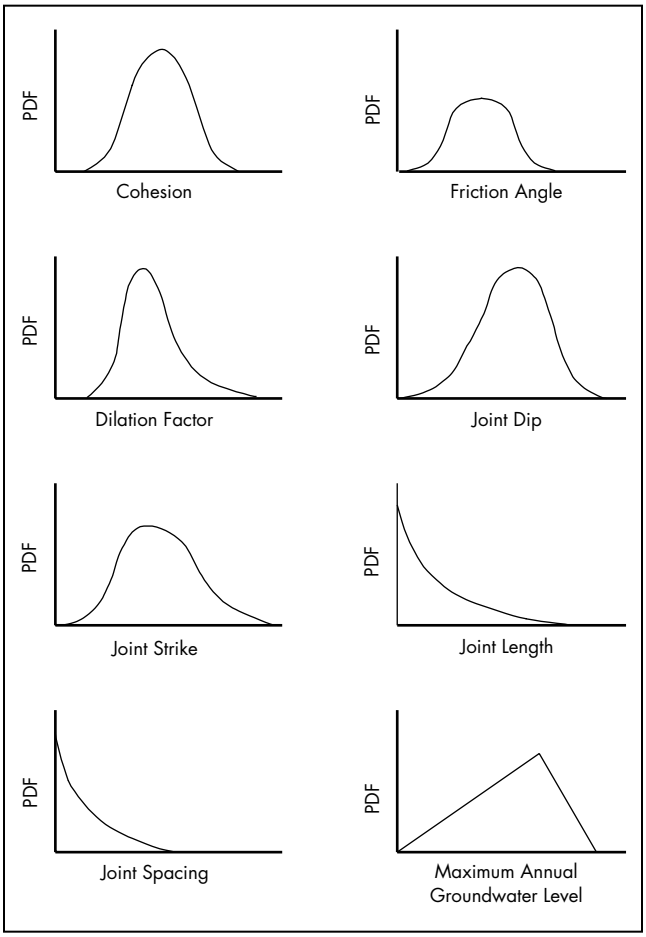
To perform slope-stability analysis with the shear strength reduction technique, simulations are run for a series of increasing trial factors of safety (F). Actual shear strength properties, material cohesion (c) and material friction angle (ϕ), are reduced for each trial according to the following equations:

$$c_{\text{trial}} = \left(\frac{1}{F}\right)c$$

$$\phi_{\text{trial}} = \arctan\left(\frac{1}{F}\right)\tan\phi$$

If multiple materials and/or joints are present, the reduction is made simultaneously for all materials. The trial factor of safety is increased incrementally until the slope fails. At failure, the factor of safety equals the trial factor of safety (i.e., $FS = F$).

According to Lorig and Verona (2004), the shear strength reduction method has two main advantages over the limit equilibrium technique for slope-stability analysis. First, the critical slide surface is found automatically, and it is therefore not necessary to specify the shape of the surface (e.g., circular,



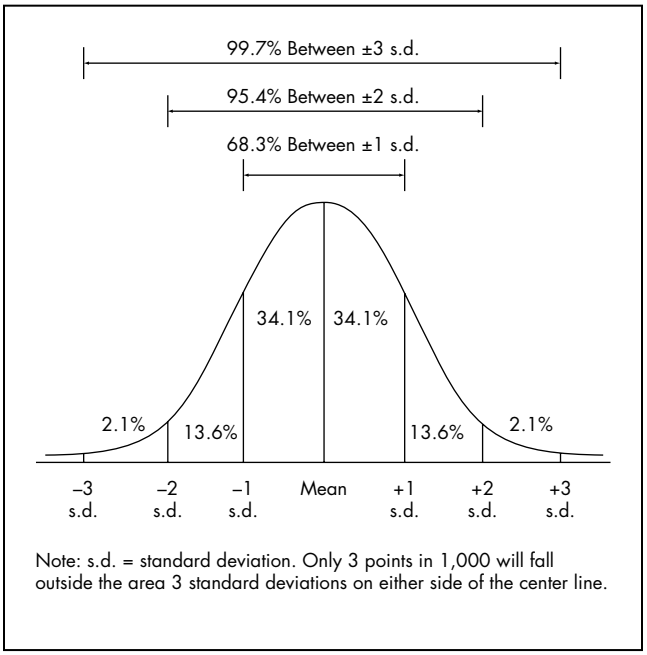


Figure 8.3-11 Typical PDFs for variables affecting slope stability

Source: Syque.com, n.d.

Figure 8.3-12 Normal probability distribution

curvilinear, spiral) in advance. Second, numerical methods automatically satisfy translational and rotational equilibrium, whereas not all limit equilibrium methods do so. Therefore, the shear strength reduction technique will normally determine a factor of safety equal to or slightly less than the limit equilibrium–obtained one.

Figure 8.3-13 illustrates a slope analyzed by the shear strength reduction method with a finite-difference computer code.

STRESSES AND STRENGTH

Numerical analysis techniques have shown that major stress concentrations can be produced where there are rocks of differing stiffness in the slope. Stiffer rock units carry more load and thus have a stress concentration. Of particular concern for slope stability is the development of high shear stresses in the vicinity of the contact between rocks of differing stiffness.

In-Situ Stress

The stability of deep excavations (i.e., very high mine-pit walls) depends on the strength of the rock mass and the stresses induced in the rock. These induced stresses are a function of the shape of the excavations and the in-situ stresses that existed before the creation of the excavations. The magnitudes of preexisting in-situ stresses vary widely, depending on the geological history of the rock mass in which they are measured (Hoek and Brown 1980a, 1980b). Theoretical predictions of these stresses are considered to be unreliable, and measurement of the actual in-situ stresses is necessary for major mine highwall excavation design (Hoek 2007).

Simple gravitational loading would produce a vertical stress equal to the weight of the overlying material as expressed in the following equation:

$$\sigma_v = \gamma \times z$$

where

σ_v = vertical induced stress, t/m^2 (st/ft^2)
γ = unit weight of rock, typically around 2.7 t/m^3 (0.0373 st/ft^3)
z = depth below the surface, m (ft)

The horizontal stresses at some depth, z, below the surface are much more difficult to estimate than the vertical stresses. According to elastic theory, the horizontal stress would be a function of the vertical stress and Poisson's ratio. For the common value of 0.25 for Poisson's ratio, the horizontal stress (σ_h) would be 0.33 ($k = \nu / 1 - \nu$) times the vertical stress (σ_v). This relationship, developed by Terzaghi and Richart (1952), was widely used in the early days of rock mechanics, but proved to be quite inaccurate and has since been supplanted with the more realistic relationship (Hoek 2007):

$$k = 0.25 + 7E_h\left(0.001 + \frac{1}{z}\right)$$

where

k = ratio of horizontal to vertical stresses
E_h = average deformation modulus of the upper part of the earth's crust measured in a horizontal direction (GPa). This direction of measurement is particularly important, especially in layered sedimentary rocks, in which the deformation

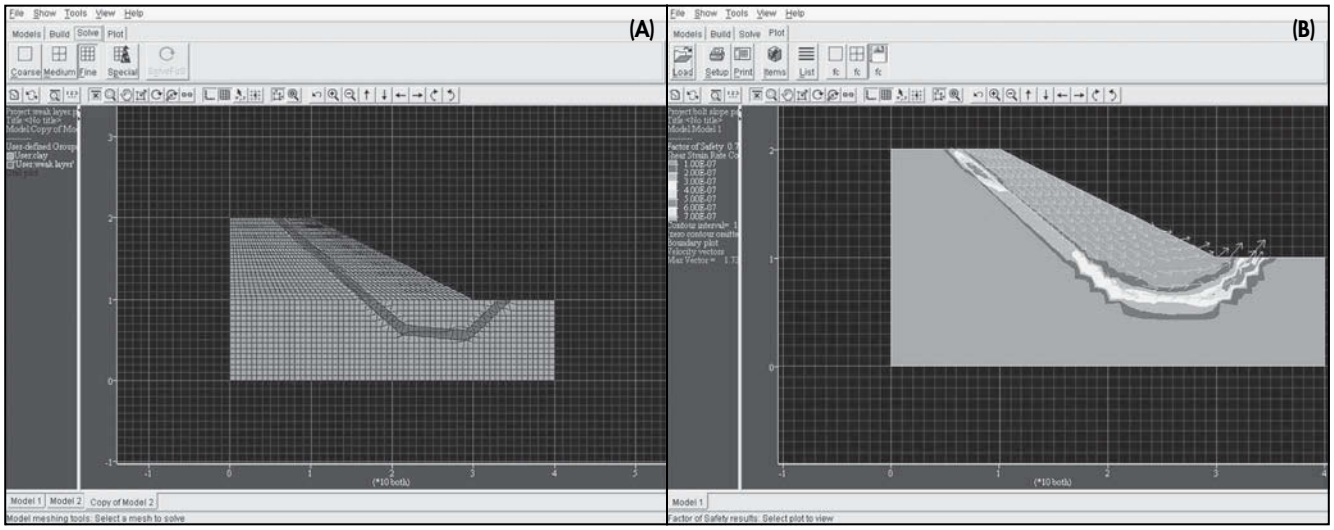

Figure 8.3-13 Shear strength reduction method: (A) grid mesh model and (B) movement vectors and failure surface

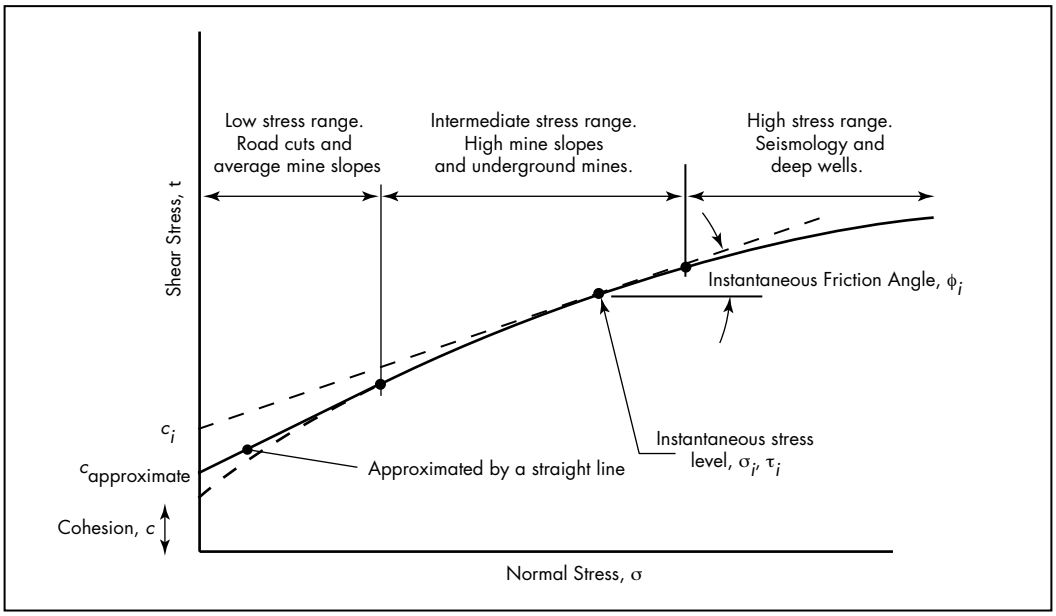

Figure 8.3-14 Hoek–Brown curvilinear failure envelope showing instantaneous friction and cohesion

modulus may be different in the different directions.

z = depth below the surface (m)

This equation, known as Sheorey's equation (Sheorey 1994), gives the ratio of horizontal to vertical stresses, k, for different deformation moduli, E_h. The model predicts a high ratio, k, at shallow depths and it decreases at depth.

Measurements of in-situ stress in underground mines have demonstrated that the horizontal stress can be greater than the vertical stress as a result of active or residual tectonic stress. Additionally, the horizontal stress is rarely equal in all directions.

In the absence of in-situ stress measurements or other indications of a high horizontal stress, the most convenient assumption is that the horizontal stress is equal to the vertical stress (Call 1992). If this assumption is made, then for normal, shallow rock slopes the Mohr–Coulomb failure envelope can be considered to be linear and the strength attributes (ϕ and cohesion, c) defined by the criteria can be considered to be relatively constant; for intermediate depths (high rock slopes) the values of ϕ and c will vary with normal stress (depth); and for great depths (deep underground excavations) the values of ϕ and c again can be considered as being relatively constant, but similar to a plastic material. This is shown on Figure 8.3-14, the Hoek–Brown curvilinear failure envelope, which is discussed later.

Shear Strength of Discontinuities

In analyzing the stability of a rock slope, the most important factor to be considered is the geometry of the rock mass behind the slope face (Hoek and Bray 1981). The next most

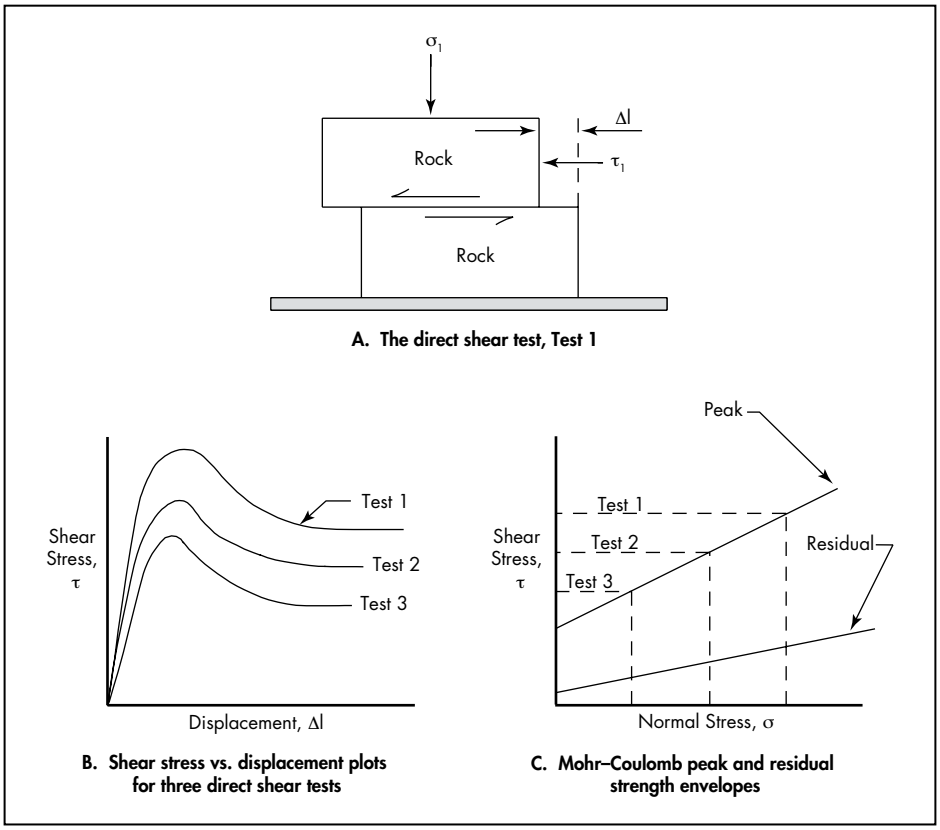

Figure 8.3-15 Peak and residual Mohr–Coulomb strength envelopes

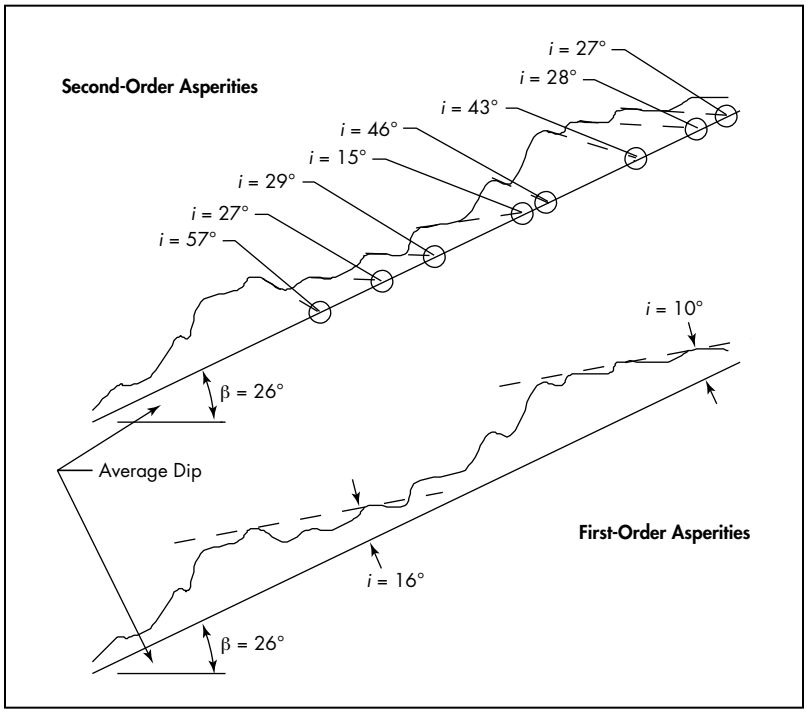
important factor is the shear strength of the potential failure surface. All rock masses contain discontinuities such as joints, bedding planes, shear zones, and faults. For rock-strength purposes, the most serious types of discontinuities are faults and shear zones—those discontinuities that have demonstrated some sort of previous movement. At shallow depth, where in-situ stresses are low, failure of the intact rock mass is minimal and the behavior of the rock mass is controlled by sliding along the discontinuities (Hoek 2007). Shear strength along the discontinuity is controlled by rock type, the surface roughness of the discontinuity, the amount of attachments across the discontinuity, normal stress across the discontinuity, and the type and nature of filling material (if any) between the two planes of the discontinuity.

Shear Strength of Smooth Discontinuities

In rock slope design, rock is assumed to be a Coulomb material in which the shear strength of the sliding surface is expressed in terms of the cohesion (c) and the friction angle (ϕ). Two general failure criteria are in common use for rock slope design: (1) the Hoek–Brown failure criterion (Figure 8.3-14), and (2) the Mohr–Coulomb failure criteria (Figure 8.3-15). For a detailed discussion of these two failure criteria and their applications, refer to Chapter 8.4.

Shear Strength of Rough Discontinuities

Rock slope engineers generally recognize two orders of joint wall roughness (Patton 1966) that affect either the movement characteristics or strength properties of the joints (some practitioners recognize three). Figure 8.3-16 is a side view of a rock surface showing first-order surface asperities on the bottom portion of the figure and second-order surface asperities on the top portion. Waviness of a mean joint surface is regarded as a major, or first-order, type of asperity. These asperities are considered to be of such dimensions that they are unlikely to shear off; for practical purposes they appear as undulations of the joint surface. Waviness is considered to modify the apparent angle of dip but not the joint frictional properties (friction angle and cohesion); and in the stability analysis, effects of waviness are considered as influencing the direction of shear movement of the sliding block.



Minor, or second-order, asperities are designated as roughness. Asperities of roughness are considered to be sufficiently small that they are likely to be sheared off during movement along the joint plane (Piteau 1970). Increased roughness of the joint walls results in an increased friction angle along the joint. However, the effects of first- or second-order asperities have been found to be greatly reduced by gouge or other infilling materials.

Using the Mohr–Coulomb failure criteria, the shear strength of rough discontinuities can be represented by

$$\tau = c + \sigma \times \tan(\phi + i)$$

where

τ = shear stress along the discontinuity
c = cohesion across the discontinuity
σ = normal stress across the discontinuity
$\tan(\phi + i)$ = friction along the discontinuity taking into account the rock–rock friction and the average asperity angle, i

Source: Kliche 1999.

Figure 8.3-16 First- and second-order discontinuity roughness

Factors Contributing to Changes in Stress and Rock Strength

Varnes (1978) grouped the factors that contribute to the initiation of slope failure in rock or soil into two main categories: (1) factors that contribute to increased shear stress, and (2) factors that contribute to low or reduced shear strength.

Factors that contribute to increased shear stress include the following:

- The removal of lateral support. This is a common cause of mine highwall failures due to equipment excavating at the toe of an unstable slope.
- The addition of surcharge to the slope. Surcharge may be added to a slope by actions such as the construction of a fill; the construction of mine waste dumps, ore stockpiles, or leach piles; the weight of buildings, other human-made structures, trains, or excavators; and the weight of water from leaking pipelines, sewers, canals, and reservoirs.
- Transitory earth stresses, which include vibrations from earthquakes, blasting, heavy machinery, traffic, pile driving, vibratory compactors, and so on. The shock wave from an earthquake exerts a temporary additional stress on a slope that can cause instability. This has been demonstrated by the number of landslides triggered by earthquakes (Glass 1982), although this record is misleading with regard to rock slopes, as saturated soil slopes are subjected to liquefaction, which would result in much greater displacement at lower seismic loading. Thus it is appropriate to include the affect)of dynamic stresses in the stability analysis of slopes. The classic method of including the effect of earthquakes in stability analysis is the pseudostatic approach whereby the maximum site acceleration that could be produced by an earthquake is input into the stability analysis as an additional horizontal driving force ($k_h \times W$, discussed previously in the "Limit Equilibrium Technique" section).
- A slow increase in the slope angle through regional tilting.
- The removal of underlying support of the slope, which may happen because of undercutting of banks by rivers, streams, or wave actions; mining, quarrying, road construction, and similar actions; loss of strength or failure in underlying material such as clays; and the squeezing out of underlying plastic material.
- Lateral pressure, most commonly from water in pore spaces, cracks, caverns, or cavities. Other sources of lateral pressure include the freezing of water in cracks, swelling of soils as a result of hydration of clay or anhydrite, and the mobilization of residual stresses.
- Volcanic processes, such as swelling or shrinking of magma chambers.
- Tectonic activities, which may alter the stress fields on a very large scale, thereby causing an increase or shift in the direction of geostatic stresses.
- Processes that created the slope. These may include creep on the slope or creep in weak strata below the foot of the slope.

Factors that contribute to low or reduced shear strength include the following:

- Factors stemming from the initial state or inherent characteristics of the material. These factors include the presence and orientation of discontinuities, slope orientation, the existence of massive beds over weak or plastic materials, and the alternation of permeable beds and weak impermeable beds.
- Changes in shear strength due to weathering and other physiochemical reactions. These changes can include

softening of fissured clays; physical disintegration of granular rocks due to the action of frost or by thermal expansion and contraction; hydration (or dehydration) of clay materials; drying of clays, which results in cracks; drying of shales, which creates cracks on bedding and shear planes; and removal of cement within discontinuities by solution.
- Changes in intergranular forces due to water content and pressure in pores and fractures, which may result from rapid drawdown of a lake or reservoir, rapid changes in the elevation of the water table, rise of the water table in a distant aquifer, or seepage from an artificial source of water. The primary affect of groundwater pressure in reducing the stability of rock slopes is the resulting decrease in effective shear strength of discontinuities.
- Changes in structure can be caused by remolding clays or clay-like materials upon disturbance, by the fissuring of shales and preconsolidated clays, and by the fracturing and loosening of rock slopes due to the release of vertical or lateral restraints upon excavation.
- Miscellaneous causes can include weakening of a slope due to progressive creep or due to the actions of roots and burrowing animals.

DATA COLLECTION

Collecting adequate and appropriate data for stability analysis is a key aspect of slope design. Obtaining incorrect results from slope-stability analysis is predominantly the result of failing to analyze the critical failure mode or not having the suitable estimates of the input parameters such as rock strength or the geometry of geologic structures. With the use of computers, our ability to construct mathematical models and perform the calculations exceeds our ability to collect adequate input data for the models. There are two aspects to the problem of data collection: sampling and measurement.

As an example, consider the specific task of determining the uniaxial compressive strength of the rock mass. This is usually measured by conducting a series of compressive strength tests on cylinders, 50–75 mm (2–3 in.) in diameter and 100–200 mm (4–8 in.) in length, cored from the rock mass. These tests should be conducted according to ASTM International standards (ASTM 2008). The population of interest (referred to as the target population by statisticians) includes all the cylinders of the given size contained within the potential slope instability mass. Because of stress considerations, the volume may very well extend some distance beyond the projected limits of the slope instability boundary. It is obvious that all of the target population could not be tested, so the strength distribution must be estimated using the test results from some small, hopefully representative, sample population.

The availability of samples for testing is determined by access, which would be the ground surface, the pit wall, underground workings, and drill holes. Where there is no preexisting pit or underground workings, and the ground surface is covered by alluvium, access to samples is restricted to drill holes. These accessible samples are referred to as the sampled population. The samples that are actually collected and tested are referred to as the sample population. To make valid statistical inferences about a population, every member of the population in question must have an equal likelihood of being sampled, and the tested samples must be an unbiased representation of the population. An example of sampling bias is the determination of rock quality designation (RQD) from rock cores from vertically drilled boreholes that do not intersect an important vertical joint set. The RQD will be biased due to underrepresentation of that important joint set.

In the case of geologic structure data collection, parameters such as orientation, length, and spacing are geometric rather than scalar, and cannot be measured at a point. This results in a window problem, particularly in the case of fracture length. If the fracture is larger than the observation window, such as a bench face, the length cannot be directly measured. This is why surface mapping is preferable to drillhole data where the core diameter is the window. There is also an orientation bias, as a linear sampling window such as a drill hole does not intersect fractures parallel to the window.

Data collection should be well organized, with specific objectives regarding the use of the data and the quantity required. Collecting data for data's sake should be avoided, as it will result not only in information that is not used, but the possible omission of information needed. Ongoing data reduction is important in order to determine whether a sufficient quantity of appropriate data is being collected.

The following general procedure is suggested for geologic data collection prior to, or during, a slope-stability investigation (Kliche 1999):

1. Determine the boundaries between geologic materials with different properties: weathering can be used as criteria (e.g., color changes, hammer impact); look for differences in sedimentation (e.g., grain size distribution); consider differences in joint intensity (e.g., high versus less).
2. Determine structural features: folds; faults and faulting systems; bedding in sedimentary rocks; schistosity and cleavage in metamorphic rocks; discontinuities (e.g., joints, shear zones, bedding planes, faults).
3. Map discontinuities (Figure 8.3-17 shows a typical discontinuity survey data sheet): location (coordinates—along a line survey, or X-Y-Z values); determine material type (i.e., host rock); note the type of discontinuity (fault, shear zone, bedding plane, etc.); determine the orientation of the discontinuity (dip and dip direction or dip and strike); determine the persistence or the continuity of the discontinuity (i.e., look at the continuity of the discontinuity and the joint length); determine joint intensity (number of joints per unit distance normal to the strike of the set) and the degree of separation between the joint faces; determine the openness or closed nature of the discontinuity. If it is open, look for the presence of filling material such as gouge or transported material. If filling is present, look at the type: clay, granular material, crystalline material, or veins. Measure the thickness of the filling material; determine the waviness and the roughness (i.e., first and second order of asperities).
4. Conduct a sampling program: obtain samples of intact rock, both weathered and unjointed; obtain samples of the discontinuity surface for shear testing (care must be taken so as to not disturb the two surfaces of the discontinuity); if filling material is present, obtain representative samples (may require soil mechanics tests for strength parameters).
5. Determine groundwater conditions: locate springs or seeps; determine the permeability of the rock and the

joints (joint conductivity is usually the most important—may need drawdown or recovery tests); measure the discharge of springs or seeps, at least twice per year.

Geology and Major Structure

Conventional geology provides the distribution of rock types and alteration, and the location of major structures. Geologic data should be in the form of a surface map, cross sections, and level maps. It is preferable to have two sets of documents: the factual sheets that show only the actual observations, and a set of interpreted maps and cross sections.

For the design of final pits, a geologic map of a trial pit design and cross sections normal to the pit wall should be constructed.

Rock Fabric

Rock fabric is the orientation, length, and spacing of fractures. These are the geometric attributes used in stability analysis and in characterizing the rock mass. On a pit scale, the number of fractures such as joints are too numerous to map. Fracture mapping, therefore, consists of measuring the attributes of a subset of the total fractures and characterizing the population with distributions of the attributes.

Detailed mapping reveals that the orientation of fracture sets (dip and dip direction or dip and strike) has a normal or bivariate normal distribution. Since the orientation is vector quantity, it is properly a spherical normal distribution. This can be seen by observing the contoured pole density clusters of Figure 8.3-18.

The measurable aspect of joint size is the trace length, which is the intersection of the joint and the mapping surface. The negative exponential appears to be the best distribution for trace lengths on the basis of fit-to-mapping data and theoretical considerations. Models such as the circular disk and the Poisson flat have been postulated to describe joints in three dimensions. These models can be used to correct for the observation window limitation.

Several common mapping methods are available (Call 1992):

- **Fracture set mapping.** This is a modification of conventional joint mapping where fracture sets are identified by eye, and the orientation, length, and spacing are recorded. If joints or other structure orientations have been recorded during regular geologic mapping, they can be compiled and used in slope design.
- **Detail line.** The detail line method is a systematic spot-sampling method in which a measuring tape is stretched along the bench face or outcrop to be measured. For all the fractures along the tape, the point of intersection with the tape, orientation, length, roughness, filling type, and thickness are recorded (Figure 8.3-17). To get an adequate representation of the fabric, at least 100 fractures should be mapped. This is the least subjective method, as individual fractures are recorded, and it provides the most detailed length and spacing data. It is relatively inefficient, however, as more observations are made on closely spaced fracture sets than are required for adequate statistical representation.
- **Cell mapping.** In this method, mapping surfaces such as a bench face are divided into cells. Normally, the width of the cells is made equal to the height of the cells. Within each cell, the fracture sets are identified by eye, and the orientation, length, and spacing characteristics are recorded. Cell mapping is a combination of fracture set mapping and detail line, with the efficiency of visual identification of fracture sets and some of the more rigorous measurements of detail line.
- **Oriented core.** Oriented core provides information on fracture orientation and spacing, but the length of fractures cannot be directly measured. This technique is used when the rock types of interest are not exposed. It

is also used to determine whether the geologic structural domains, mapped on the surface, extend back or downward for some distance (Nicholas and Sims 2000).

Rock Strength Properties

Since the spatial variability of rock properties is large, the potential for sampling error is greater than the measurement error. For this reason, it is preferable to use simple test methods for a number of samples than to use an expensive precise method on one sample.

For the shear strength of discontinuities and fault gouge, the direct shear test is recommended as it is a simulator of field conditions. Since the shear/normal failure curve may be nonlinear, it is important to use normal stress values for the test that represent the expected range of normal stresses for potential failure geometries in the slope. The tests at each normal stress should be run with sufficient displacement to obtain both the peak shear strength and the residual shear strength, as the residual shear strength usually is a better estimate of in-situ strength than the peak strength.

For intact rock, unconfined compression and Brazilian disk tension tests are recommended. In addition to obtaining the compressive and tensile strengths, the uniaxial compression tests can be gauged with strain gauges to obtain the Young's modulus and Poisson's ratio for the intact rock.

Index tests such as the point load can also be used to evaluate the spatial variability of intact rock strength.

For the rock mass where direct testing is not possible, indirect methods such as the rock structure rating, rock mass rating, or the rock tunnel quality index and back analysis must be used.

For a more complete discussion of rock strength properties, refer to Chapter 8.4.

Hydrology

The most important groundwater parameter for stability purposes is the groundwater pressure distribution within slopes. This distribution can be obtained in two ways: (1) by direct measurement of pressure using piezometers, or (2) by determining pressures from an analysis of the hydraulic properties of the rock mass (e.g., geology and permeability characteristics). The most satisfactory approach is usually to measure groundwater pressures with piezometers at representative locations, and to correlate these data with analytical studies based on a thorough understanding of the geology and on selected permeability or conductivity measurements of representative soil and rock strata.

In slope stabilization using water pressure control, the focus is on reducing groundwater pressure. Typically, any stabilization involves installing pressure control devices—dewatering pumps, drainage galleries, or drain holes—at a number of locations and reducing the water level (i.e., the pressure), in the material around and between those devices. The process focuses on obtaining a major water pressure reduction in an acceptable time period.

Standard hydrologic procedures such as piezometers and pump tests can be used to obtain the current pore pressure distribution and the permeability for predicting changes in pore pressure with time and changes in pit geometry. Simple techniques, such as measuring the water level in drill holes, can be used. Two factors need to be considered, however: (1) Water behavior in rock slopes is a fracture flow phenomenon, and porous media analysis, while useful at a regional scale, may be a poor predictor of pore pressure at pit slope scale; and (2) The critical factor in slope design is the pore pressure rather than the quantity of water. A low permeability rock mass may yield very little water and appear "dry" yet have significant pore pressure.

Stress Measurements

A number of techniques are available for measuring in-situ stress. Generally, each technique should be evaluated prior to its use at a particular mine site. During early site investigations, when no underground access is available, the only practical method for measuring in-situ stresses is by hydrofracturing (Haimson 1978), in which the hydraulic pressure required to open existing cracks is used to estimate in-situ stress levels. After underground access is available, overcoring techniques for in-situ stress measurement (Leeman and Hayes 1966; Worotnicki and Walton 1976) can be used with such techniques as the Commonwealth Scientific and Industrial Research Organization (CSIRO-) type hollow inclusion cell and, provided that sufficient care is taken in executing the measurements, the results are usually adequate for design purposes.

DESIGN

Steps in slope design include

1. Defining design sectors;
2. Conducting a bench design analysis to determine the maximum interramp slope;
3. Conducting interramp design analysis using economic criteria for the selection of interramp angles; and
4. Evaluating the resulting overall slope for potential instability and modifying the design if required.

Slope design is an interactive process because a trial pit is required to select design sectors, but the development of a trial pit requires slope angles. Frequently, the way this is handled is to generate a trial pit shell using critical parameters based on experience (bench height, bench angle, berm width, interramp angle, overall pit angle). As more geotechnical, geological, hydrological, and operating information comes in, the trial pit is refined, over and over, until the final pit design is established. Rarely, however, is there a "final pit design" until the end of mining, as the design parameters will change as additional or more current information comes in to the designer.

Design Sectors

To conduct stability analyses and develop optimum slope angles for input into pit design, the proposed pit must be divided into design sectors that are sections of the pit with similar geologic and operational characteristics (Figure 8.3-19).

The first criterion for the selection of design sectors is the structural domain, which is an area within which the rock properties and fabric are consistent. Typical structural domain boundaries are lithologic contacts and major structures that separate areas of dissimilar fabric.

The second criterion is wall orientation. Since rock is usually anisotropic, different wall orientations within the same structural domain can have significantly different modes of instability and different optimum angles. One way of handling the situation of a change in highwall orientations with the rock properties and fabric remaining constant is to divide the sector into subsectors based on the changing orientation (see Figure 8.3-19).

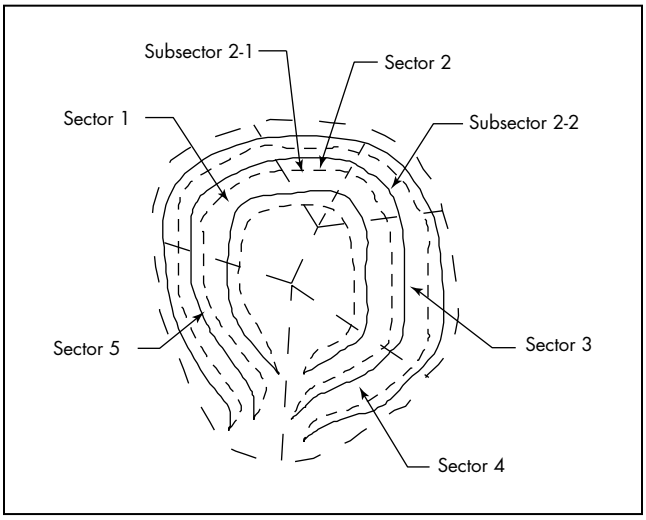

Figure 8.3-19 Pit plan with slope design sectors

A third criterion for defining design sectors is operational considerations. Sectors containing critical structures such as in-pit crushers, conveyors, and haul roads require different stability criteria than the same wall orientation in the same structural domain without the critical structures. That is, the design factor of safety may have to be modified upward based on exposure and risk considerations. For each of the design sectors or subsectors, the rock fabric, major structure orientation data, and planned highwall orientation can be plotted on a stereographic projection. This diagram is used to determine which failure modes may be kinematically possible and to select structure sets for stability analyses.

Catch Bench (Berm) Design

Bench faces are normally mined as steeply as possible so that some bench-scale rockfalls and raveling can be expected. Development of catch benches in mine slopes is necessary in areas of such rockfall since the catch benches, if designed properly, prohibit rocks from rolling from upper portions of the pit slope to the working areas where personnel and equipment are located. The bench geometry defines the steepest interramp slope that can be mined while maintaining adequate catch bench widths. The two primary factors that control bench configuration are the type of mining equipment that is used and the bench face angles that can be achieved. The type of mining equipment determines the safe operating height of the bench. The achievable bench face angles are controlled by rock strength, geologic structure characteristics, and the mining techniques used to construct the slope (e.g., the blasting and digging practices) (Ryan and Pryor 2000).

Bench design is the process of conducting stability analyses to estimate the bench face angles, selecting the bench width, and, to a limited extent, the bench height. The bench height is controlled by the height of the mining levels, but it is possible to increase the height by leaving catch benches on every other level (double benching) or every third level (triple benching).

The sole purpose of a catch bench is to "catch" rocks so that they do not continue unhindered to the toe of the slope or away from the base of the rock cut. The bench is designed with a specific width relative to its height so that rocks will come to rest before falling off the next crest. In addition, a back-break distance is often incorporated into the design as the bench crest will often fail from its (usual) vertical position. The design catch bench width is thus always wider than the bench width required for safety, as shown in Figure 8.3-20 (Zostrich Geotechnical 2009). Design catch bench width, w, can be estimated from the following equation (Bertuzzi 1999; Martin and Piteau 1977; Piteau and Martin 1982) (see Figure 8.3-21):

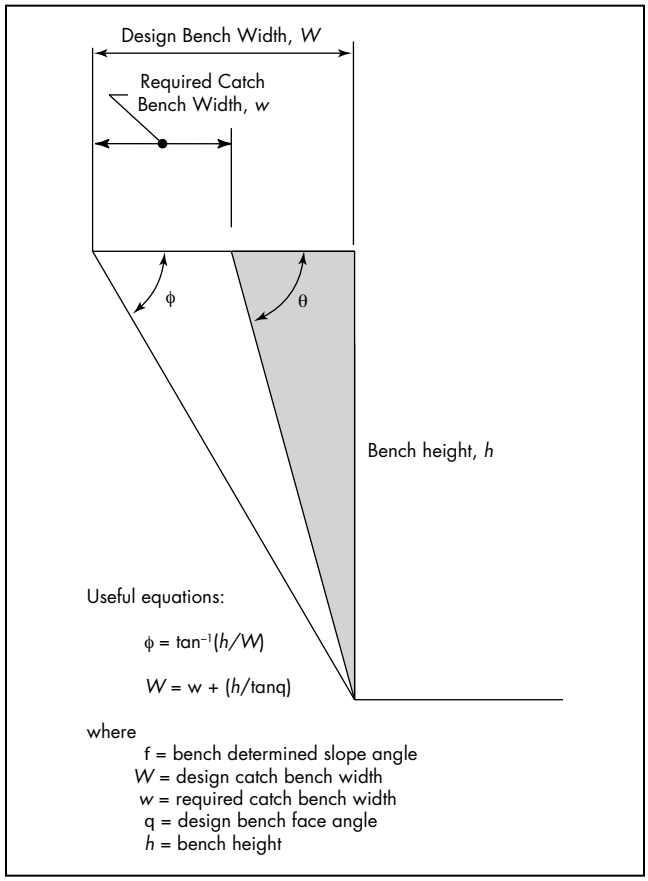

Figure 8.3-20 Required catch bench width versus design bench width

$$w = h\sqrt{x \times z \times \gamma_{bulk}}$$

where

h = bench height

$$x = \frac{1}{\tan\beta} - \frac{1}{\tan\alpha}$$

$$z = \frac{1}{\tan r} - \frac{1}{\tan\beta}$$

γ_{bulk} = 1 + [(material % swell)/100)]

and

β = dip of the discontinuity

α = bench slope angle

r = angle of repose of broken rock; typically about 37°

Where the defect is short and affects only part of the slope (Figure 8.3-22), the catch bench width, w, can be estimated from

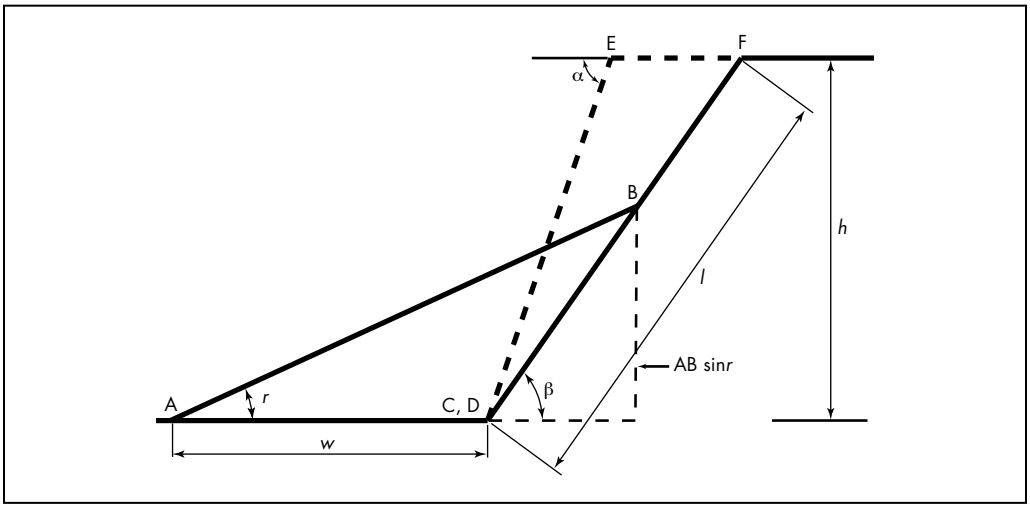

Figure 8.3-21 Geometry for catch bench design when the defect is long and affects the entire slope

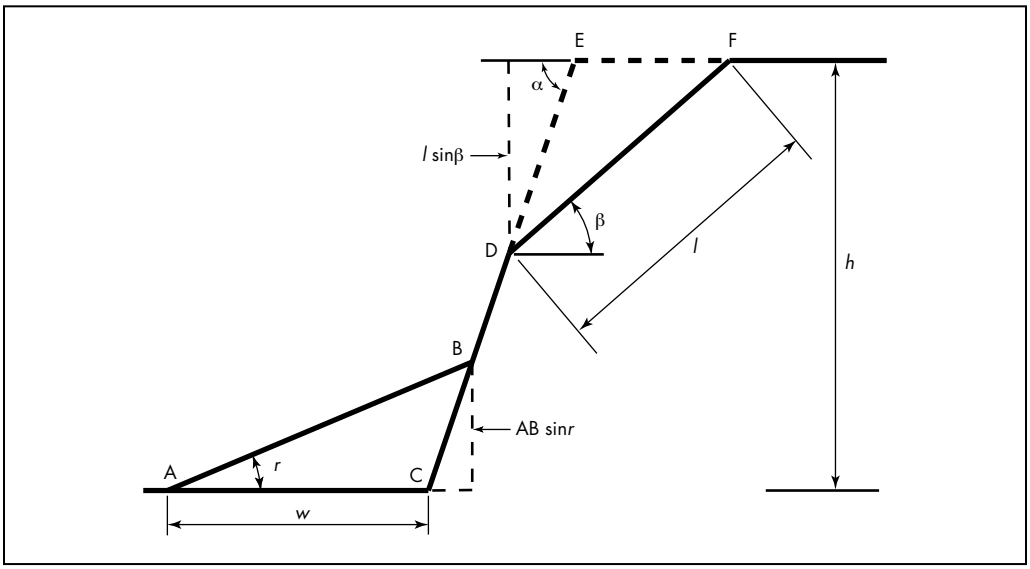

Figure 8.3-22 Geometry for catch bench design when defect is short and affects only part of slope

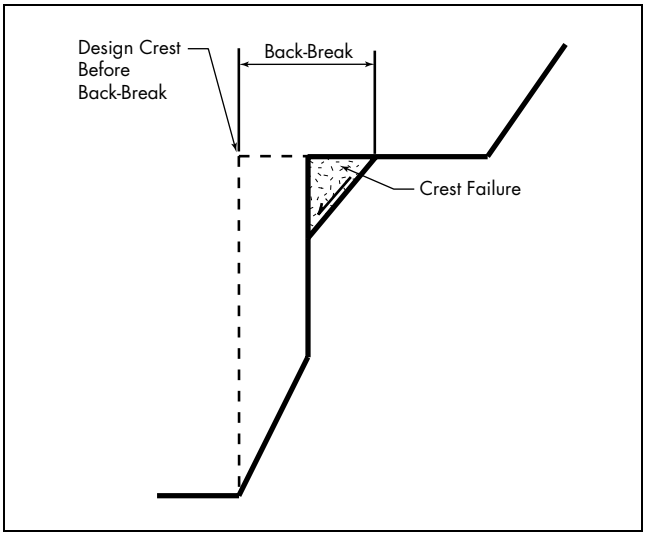
$$w = l \times \sin\beta \sqrt{x \times y \times \gamma_{\text{bulk}}}$$

where

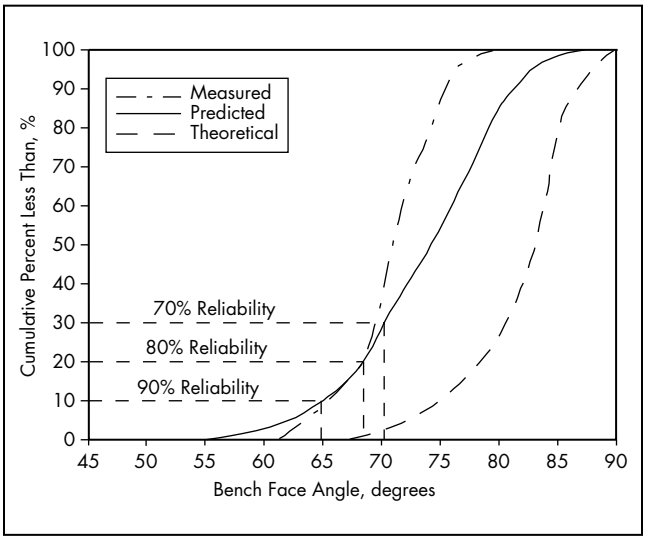
l = throughgoing discontinuity length



x = defined previously

$y = \frac{1}{\tan r} - \frac{1}{\tan \alpha}$, where r and α are defined previously

Based on an analysis of rockfall mechanics, Ritchie (1963) developed width and depth criteria for a ditch at the toe of a slope to protect highways from rockfalls. Falling rocks impact close to the toe of the slope, but, because of horizontal momentum and spin, can roll considerable distances from the toe. The concept of Ritchie's design was that the rock would impact in the ditch, and the side of the ditch would stop the horizontal roll.



A reliability approach to catch bench design, wherein the analysis is structured to evaluate the percentage of the slope area that meets or exceeds a chosen catch bench width criteria, has been recently developed (Ryan and Prior 2000). The developers have found this technique to be a more useful risk management approach for rockfall containment and for slope management. In this approach, a combination of structural modeling, bench face stability analysis, and the modified Ritchie criteria is used to determine the catch bench reliability, which refers to the percentage of benches having final widths equal to or greater than the modified Ritchie criteria. The developers state that the selection of the proper reliability for maintaining a catch bench of a certain width is dependent on such factors as

- The potential for slope raveling,
- The proximity to large slope failures,
- The decision to contain overbank from a higher pushback on the benches,
- The length of time the benches are expected to be functional,
- The climate,

Source: Ryan and Pryor 2000.

Figure 8.3-23 Crest failures often make up the majority of back break

Source: Ryan and Pryor 2000.

Figure 8.3-24 Effective bench face angle distributions: theoretical versus predicted versus measured

- The type of blast control, and
- The operator's experience.

Because the bench configuration is based on the reliability of the catch bench width, it is the amount of local back break rather than the bench face angle that is of most concern.

The percent reliability, therefore, represents the percentage of the bench along a given level that would be wider than the minimum required bench width to catch rockfalls. The reliability should be selected on the basis of the potential for rockfall and the exposure of personnel and equipment. For example, the catch bench in raveling ground above a haul road requires a greater reliability than catch benches in a stripping area with more competent ground. In practice, reliabilities from 60%–90% have been satisfactory.

Interramp Slope Angle

For a given bench height and corresponding bench width, the upper limit of the interramp angle becomes a function of the bench face angle. The bench face angle, however, is not a unique value, as variability of the rock fabric results in varying amounts of back break. Back break is defined as the distance from the design crest to the as-mined crest (Figure 8.3-23). Because of this variability, it is preferable to use a reliability approach rather than using the mean bench face angle. (Calculating an interramp slope using the minimum bench width and the mean bench face angle results in 50% of the benches being too narrow.) The procedure is to select a percentage reliability and use the cumulative frequency distribution of the bench face angle to find the angle where the percentage greater is equal to the reliability (Figure 8.3-24). This gives the design bench face angle to use, with the minimum bench width and the bench height, to calculate the interramp slope angle.

In an operating property, the actual bench faces can be measured and the measured bench face angle distribution can be used in design. Where existing bench faces are not available, a bench-face angle distribution can be obtained by running a stability analysis for a vertical face. For this analysis, the plane shear, wedge, and step path analyses are run using the fracture data. The height analysis should be incremented in steps up to the bench height, and the resulting back break composited, as short fractures that would not result in full bench failure can still cause crest back break. This bench face angle distribution is referred to as the theoretical bench face distribution, as the effect of blasting and digging is not included. If there is a strong geologic control such as bedding or foliation, the measured and theoretical bench face angles are the same. Where no strong structure exists, the theoretical bench face angles should be reduced to include the effect of blasting. Based on comparisons that have been made between measured and theoretical angles, the reduction should be between 10° and 20°, depending on the controlled blasting to be used.

Interramp Design

The stability of interramp slopes is primarily controlled by intermediate and major structure failure geometry. Where major structures can be specifically located in space, the geometry relative to the slope can be defined and a discrete stability analysis can be conducted. Commonly, however, the number of mapped structures is large and the distance between the mapping sites and the design wall is greater than the length of the structures. In this case, the structural data must be considered a statistical representation of the structures that will occur in the design slope, and a probabilistic analysis is required.

To obtain the input for stability analysis, the wall orientation can be plotted on a lower hemisphere stereographic plot of the poles of the fractures and the major structures. The fractures and major structures are sorted into design sets based on their orientation relative to the orientations for failure modes, and the distribution of orientation, length, and spacing can be computed for the design set. These design sets may not correspond to geologic sectors, although the boundaries of the sets may be adjusted to avoid splitting a geologic sector. An advantage of this approach is that it is based on kinematic tests for viable failure geometry, making it unnecessary to test all the structures for each failure mode.

Major Structures

In the case of throughgoing major structures where the geometry is known, a safety factor can be calculated for specific slope angles and slope heights using analytical models described in the references for the appropriate failure model. For a deterministic design, the slope angle with the desired factor of safety would be selected.

In the reliability method, the probability of sliding can be calculated by Monte Carlo sampling of the shear strength distribution to obtain a distribution of safety factors and computing the area of the safety factor distribution <1. Other techniques can be used, such as the point estimate method (Harr 1984) or calculating the probability that the shear strength is less than the strength required for a safety factor of 1.

Because of the variability of the shear strength, a safety factor >1 is used to reduce the risk of instability to an acceptable level. One problem with this is that a given safety factor will have a different level of risk depending on the dispersion of the input parameters. The advantage of the reliability approach is that it deals directly with the risk.

Failure Volume Estimation

Where the geologic structures compose a statistical population, the probability of failure for the single occurrence of a specified failure mode is a function of the probability that the structures exist and form a viable failure geometry, as well as the probability of sliding (Marek and Savely 1978). The probability of existence is calculated from the orientation, length, and spacing of the structures.

To calculate the expected number of failures and the expected failure volume for input to a cost–benefit analysis, the probability of failure for the possible failure modes must be calculated for a range of heights and angles and then composited.

Cost of Failure

Given the expected number of failures and the expected failure tonnage, the cost of slope failure can be estimated. Failure costs consist of cleaning up failure material, repairing haul roads, repair of facilities, lost production due to disruption of operations, the value of lost ore buried by a failure, and engineering costs. The method used to estimate failure cost is a "what if" mine planning procedure. A failure is postulated for a design sector, a plan for responding to the failure is made, and the cost of the plan is estimated. These exercises are useful whether or not a full cost–benefit optimization is done, as they can lead to modifications of the mine plan that will reduce the impact of slope instability.

Overall Slope

The overall slope is usually flatter than the interramp slope because of catch benches or other step-outs. Thus the overall slope normally will be more stable than the interramp except for stress-induced failure or failure modes not analyzed for the interramp.

Numerical modeling techniques can be used, in addition to deterministic techniques, to analyze the potential for the various modes of failure including block flow, multibench wedge, planar type, and rotational. Numerical techniques have been time-consuming and expensive in the past; however, with the faster computers and better software currently available, it has become very feasible and routine. A quick check can be made for block flow potential using the charts developed by Coates (1981). If the charts do not indicate block flow potential with any regional stress assumption, numerical modeling is not needed unless there is a high contrast in stiffness between adjacent materials in the slope. The charts assume a homogeneous material and would therefore not indicate stress concentrations produced by stiffness contrasts.

Changes in the overall slope angle have relatively little effect on the stress concentration at the toe of the slope, where a greater concentration could produce block flow. Therefore, block flow potential would not be a suitable method for selecting overall slope angles. A more effective design approach would be to design the slope based on other criteria, and to make provision in the mine plan for step-outs, if needed, in the toe area of the pit to reduce the stress concentration produced by the notch effect of the bottom of the slope. The loss of ore from step-outs at the toe would have less economic impact than the amount of stripping required to have the same effect on block flow potential.

Rotational shear analysis should be run for the overall slope, even on rock slopes, to verify that it would not be a critical failure mode. Rotational shear would be a primary method of analysis for both interramp and overall slopes in alluvium and low rock mass-strength slopes such as soft coal measures.

The general surface analysis should be used for the overall slope to evaluate mixed mode failure types where part of the failure is structurally controlled and part is failure of low rock mass strength. Nondaylighted wedge and plane shear failures in which the weak rock at the toe fails are becoming recognized as a more significant failure mode. This is in part because pits are becoming steeper and deeper, and partly because more pits have been designed for the simpler sliding block failure modes.

Slope Support and Stabilization

Slope stabilization techniques can be divided into six general categories:

1. Grading
2. Controlled blasting
3. Mechanical stabilization
4. Structural stabilization
5. Vegetative stabilization
6. Water control

Grading

Grading involves the shaping of the rock slope into a more stable configuration. It may include flattening the slope, leaving benches in the slope face, or sculpting the slope face to a more natural appearance. Catch bench design and application are as discussed previously.

Controlled Blasting

Specialized blasting techniques are used to control overbreak and produce a competent final excavation wall by minimizing damage to the final pit walls from production blasts.

The purpose of overbreak control is to achieve a stable highwall by limiting the damage from production blasting beyond the cut limit. Often, a secondary purpose is to achieve an aesthetically appealing wall. Several drilling and blasting techniques have been developed for overbreak control to accomplish this purpose (McKown 1984; Floyd 1998), including the following.

Source: Kliche 1999.

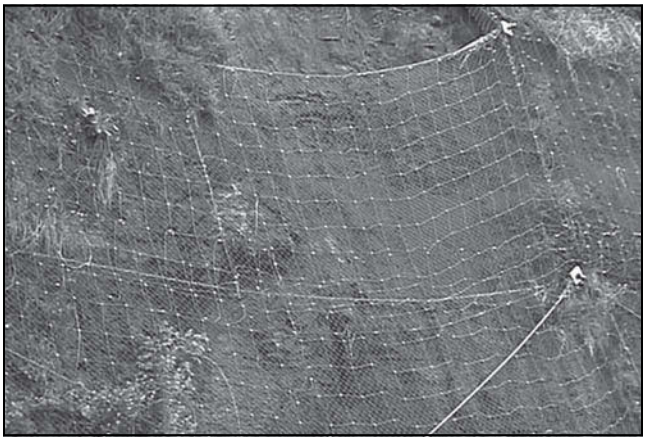
Figure 8.3-25 Mine highwall where presplit blasting has been utilized to control overbreak and produce a stable final wall

Modified production blasts. In modified production blasting, the energy level is decreased adjacent to the wall to reduce overbreak. This decrease in energy level is often achieved for competent rock simply by reducing the charge weight in the row nearest the slope by about 30%–60% (Floyd 1998). For less-competent rock masses, additional modifications to the blast design may be required to minimize overbreak damage. These modifications can include using decked charges, reducing the burden (i.e., the distance to the nearest free face) and spacing of the last row, minimizing subdrilling, and increasing the delay interval between the last two rows of blastholes. The primary advantage of the modified production blasting technique is that it requires few design changes. The primary disadvantage is that the wall rock is not protected from crack dilation, gas penetration, and block heaving (Floyd 1998). Reducing the number of holes per delay will reduce the peak particle velocity, but for the perimeter row of holes and the buffer row, a production-hole charge is usually too large and must be reduced. To maintain the same powder factor, the hole spacing must be reduced concurrently with the reduction in hole charge. In practice, this method of controlled blasting increases the measured bench face angle by 5° (Savely 1986).

Presplit blasting. Presplitting uses lightly loaded, closely spaced drill holes that are fired before the production blast to form a fracture plane across which the radial cracking from the production blast cannot travel (Konya 1995). As a secondary benefit, the fracture plane formed may be aesthetically appealing. Figure 8.3-25 shows a mine highwall where presplit blasting has been utilized to control overbreak and produce a stable final wall. The presplit blast may be fired a considerable amount of time before the production blast (hours, days, weeks, or longer) or shortly before, as on a prior delay. Delayed blasting techniques are frequently used to separate the detonation times of explosive charges (i.e., individual holes or series of holes, as in a row of holes).

Trim (cushion) blasting. Trim blasting is a control blasting technique that is used to clean up a final wall after the production blast has taken place (Konya 1995). The trim blast may be on a later delay of the production blast or at a much later date, possibly years after blasting. The purpose of the trim blast is twofold: to create an aesthetically appealing final wall and to enhance the stability of the final wall by removing overbreak from the production blasting. Because the trim row is shot after the final production row, the trim blast does little to protect the stability of the final wall from production blasting. It does, however, provide enhanced stability by removing the loose material caused by overbreak from the production blasting. In trim blasting, cost is incurred from extra drilling, longer blasthole-loading time, and some reduced mine production, but these short-term costs are often offset by decreased future costs in terms of stripping and slope failure. Both of these potential future costs—stripping and slope failure—can be incurred as a result of overbreak into the final highwall from the production blasting.

Line drilling. Line drilling is often included as one of the controlled blasting techniques. However, it is not a blasting technique per se. Line drilling uses a single row of unloaded, closely spaced drill holes at the perimeter of the excavation. When a production blast adjacent to a series of line-drilled holes is detonated, the shock wave from the detonating holes will cause a stress concentration around the unloaded, line-drilled holes. If the stress exceeds the rock strength, failure will occur in the form of a crack extending from one line-drilled hole to the adjacent line-drilled hole. Line drilling is an expensive perimeter control technique because of the number of holes required for the technique to work properly.



Two aspects of final wall design should be considered in selecting the appropriate controlled blasting technique, or combination of techniques, for a particular job: defining rock damage criteria and developing a procedure to design blasts that will minimize rock damage without seriously affecting production.

Mechanical Stabilization

Mechanical methods of slope stabilization are those that alter or protect the slope face to reduce erosion, prevent rockfall, or to reduce raveling. Common methods include protective blankets, geotextiles, and wire net or mesh.

Protective blankets. Protective blankets made from jute, excelsior, burlap, cotton, or other natural or manufactured materials have been used for many years for erosion control and to prevent or reduce raveling on cut slopes. The blankets are usually pinned to the slopes and combined with seed and fertilizer. The purpose of pinning the blanket is to hold it in place until the vegetation takes root. The blankets are often expected to deteriorate and thus biodegrade over time as the vegetation takes hold.

Geotextiles. A geotextile is defined by ASTM as "any permeable textile material used with foundation, soil, rock, earth, or any other geotechnical engineering-related material, as an integral part of a man-made project, structure, or system" (Christopher and Holtz 1985). Geotextile applications can be divided into four primary functions: separation, drainage, reinforcement, and filtration (Christopher and Holtz 1985). In separation, layers of different sizes of solid particles are separated from one another by the geotextile (e.g., landfill covers). In drainage, the geotextile allows water to pass; in the special case of "drainage transmission," the geotextile itself acts as a drain to transmit water through soils of low permeability (e.g., horizontal drains below heap leach pads). In the case of reinforcement, the geotextile acts as a reinforcing element in the earth through either stress distribution or an increase in soil modulus (e.g., a net against rockfalls). For filtration, the fabric acts in a similar fashion to a two-dimensional sand

Courtesy of Mine Safety and Health Administration.

Figure 8.3-26 Combination of Geobrugg-type rockfall net with chain link fence pinned to the highwall utilizing rock dowels and cable lashing

filter, allowing water to move from the soil while retaining the soil (e.g., silt screens).

Wire net or mesh. Another method of slope stabilization involves draping or pinning wire netting over the slope face to prevent rockfalls from bouncing outward from the toe region. Three types of wire mesh are commonly used for this purpose: (1) welded wire fabric, such as that used in concrete reinforcement; or (2) chain-link mesh, as is commonly used for fencing; and (3) flexible wire rope nets with or without underlaid wire netting (Geobrugg-type netting). A typical welded wire mesh application would be to use mesh with a 100 × 100 mm (4 × 4 in.) or 150 × 150 mm (6 × 6 in.) opening and a wire size from 9 to 4 gauge (Seegmiller 1982). Chain-link fence is often coated with a galvanizing agent and will therefore better withstand adverse environmental conditions. Also, because of the nature of its construction, chain-link fence tends to be more flexible and stronger.

Pinning the net or wire mesh to the face holds the rock in place and reduces rock removal at the toe (see Figure 8.3-26). The pins (typically rock bolts, rock dowels, thread bars, or rebar) must be strong enough and spaced close enough to hold large, loose rocks and prevent them from dislodging and tearing the mesh.

Structural Stabilization

Structural stabilization includes those methods that reinforce the structure of the rock at the slope face or provide a structure that supports the slope. Methods available include the use of gunite or shotcrete, rock bolting, and construction of rock buttresses or retaining walls.

Shotcrete. One common method of mechanical stabilization uses pneumatically applied mortar and concrete (generally known as gunite or shotcrete) sprayed or pumped onto the slope face to seal the face and bind together small fragments on the face. This approach is used primarily to prevent weathering and spalling of a rock surface, as well as to knit together the surface of a slope. Generally, for rock slope stabilization, the material is applied in one 50–75-mm (2–3-in.) layer (Brawner 1994). One disadvantage of shotcrete is its low tensile strength. For this reason, welded wire mesh, anchored to the rock, is often used to reinforce the shotcrete. A problem with using wire mesh as reinforcement for shotcrete is the difficulty of molding the mesh to a rough surface. Where the surface is irregular, large gaps may develop between the mesh and the rock, making bonding of the shotcrete to the rock difficult. Additives can be added to either the wet or dry mix to provide additional strength and durability. Steel fibers, when added to the mix, increase the tensile strength of the shotcrete by providing numerous bonding surfaces within a small area. The fiber reinforcement also reduces the risk that shrinkage cracks will develop during curing. In many cases, the addition of fibers can replace wire mesh as reinforcement, thus reducing the overall cost.

Steel reinforcement members. Steel reinforcement in the form of rock bolts, cable bolts, resin-grouted thread bars, or rock dowels are used to tie together the rock mass so that the stability of a rock cut or slope is maintained. Rock bolts are commonly used to reinforce the surface or near-surface rock of the excavation, and rock anchors are used for supporting deep-seated instability modes in which sliding or separation on a discontinuity is possible.

A rock anchor generally consists of a bar or cable of high-strength steel tensioned inside a borehole to about 60%–70% of its yield strength. Tension in the member is transmitted to the surrounding rock mass by anchorage points at the ends. The length of the rock anchor can be from 3 m (10 ft) to >100 m (330 ft) (Sage 1977).

Resin-grouted, tensioned thread bar and grouted cables provide a means to control large failure blocks. Lengths of the units may be as short as 3 m (10 ft) or as long as 100 m (330 ft), depending on the specific application. Holes for installation of the anchors are normally drilled well past the potential failure plane; then the anchors are inserted and grouted in place with or without tensioning.

Grade 60 (423.7 MPa or 60,000 psi), resin-grouted, tensioned thread bar comes in diameters ranging from 19.1 mm (0.750 in.) to 57.3 mm (2.26 in.) and in nominal lengths of 12.2 m (40 ft). Such thread bar can be cut to lengths shorter than 12.2 m (40 ft) or made longer by coupling two or more units together.

Grouted cables were introduced to mining for reinforcement of the backs of cut-and-fill stopes. Cable bolting, whether tensioned or untensioned, is widely used in mining applications. The cable bolts should be made from high-strength steel (about 1,380 MPa or 200,000 psi yield strength, typically) because the steel will creep in tension; as a result, a gradual decrease in anchor load will occur over time. This loss in strength is approximately the same for all types of steel (Sage 1977). A special prestressing jack (Figure 8.3-27) is required for tensioning the bolt. Also, for the tensioned cable bolt, a special bearing plate, an anchor block, and cable-gripping cones are required.

For a more complete discussion of steel reinforcement members that may be used in slope reinforcement, refer to Chapter 8.8.

Vegetative Stabilization

Vegetative techniques are most frequently used for aesthetic purposes, such as slope reclamation. However, there are many treatment methods that use vegetation to improve the stability of a slope. Generally, these methods are most successful when minor or shallow instability (such as raveling or erosion) is involved, as is usually the case for soil slopes or highly fractured rock slopes (Buss et al. 1995). The establishment of vegetation on steep-soil slopes or loose-rock slopes is often

Figure 8.3-27 Hydraulic prestressing jack

enhanced by the construction of benches or stair-step terraces in the slope face. These arrangements act to hold the seed mix in place, to encourage infiltration, and to impede water flow in order to minimize erosion and sedimentation. Natural or manufactured mats, webs, or fabrics can also be used for erosion control and to hold seeds in place, though their cost and effectiveness often limit their use. They require high labor inputs for installation and cost much more than tacked or hydromulched straw; in addition, some are not well adapted to fitting to rough surfaces. They must also be heavy enough or anchored in enough spots to prevent wind whipping.

The planting of trees or other large woody plants on rock slopes is beneficial in "softening" the appearance of the cut slope to make it appear more natural (Buss et al. 1995). In order to make access easier for planting trees or shrubs, benches, berms, or furrows must be constructed in the slope face. If access allows, the use of a tree spade enables the transplanting of large, mature trees. The plants are placed in holes that have been previously excavated on the reclamation site. (A single hole drilled and blasted in rock will provide an excellent site for a transported tree or shrub.) The plants are transplanted with a minimum of root disturbance. Tree spades, however, are expensive to use, and their use should be reserved to transporting hard-to-establish trees or to achieve an objective of immediate stocking with mature trees.

Water Control

The presence of groundwater in a rock slope can have a detrimental effect on stability for the following reasons:

- Water pressure reduces the stability of the slopes by diminishing the shear strength of potential failure surfaces. Water pressure in tension cracks reduces stability by increasing the driving forces.
- Changes in moisture content of some rock, particularly shales, can cause accelerated weathering and decreases in shear strength.
- Freezing of groundwater can cause wedging in water-filled fissures due to temperature-dependent volume changes in the ice. This can result in expansion of an opening, such as a tension crack upon freezing, which does not contract upon thawing of the water.
- Erosion of weathered rock by surface water and of low-strength infillings by groundwater can result in local instability where the toe of the slope is undermined or a block of rock is loosened.
- Excavation costs can be increased when working below the water table.

By far the most important effect of groundwater in a rock mass is the reduction in stability resulting from the water pressures within the discontinuities.

Grading and shaping are major considerations in the control of surface water. Surface water can be controlled through a combination of topographic shaping and runoff control structures (Glover et al. 1978). Surface water allowed to flow down a slope, or to pond on benches of a slope, can infiltrate into the ground along discontinuities and thereby cause an increase in the driving forces on an unstable area through a buildup in pore pressure. Runoff control structures include dikes, waterways, diversion ditches, diversion swales, and chutes or flumes (Glover et al. 1978). The purpose of these structures is to intercept surface water flow before it reaches a critical area and to divert it to a disposal area.

The purpose of subsurface drainage (i.e., groundwater control) is to lower the water table and, therefore, the water pressure to a level below that of the potential failure surfaces. Methods of subsurface drainage include drain holes, pumped wells, and drainage galleries or adits.

Drain holes. Horizontal drain holes drilled into the face of the slope from the toe region offer an effective method of slope drainage. Normally, the holes are 50–150 mm (2–6 in.) in diameter and are drilled at an inclination of +3° to +5° from the horizontal. The length of the holes should extend beyond the critical failure surface. The direction of the drain holes depends on the orientation of the critical discontinuities; the optimum design is to intersect the maximum number of significant discontinuities for each unit length. Spacing of the drain holes can range from about 7 to 30 m (20 to 100 ft), and lengths into the slope should not exceed one-half the slope height, with a minimum length of 15 m (49 ft) and a maximum length of 100–125 m (330–410 ft) (Brawner 1982). For high rock cuts, installation of drain holes at different levels is recommended. Where rock is taken out in several lifts, drain holes should be drilled at the toe of every lift (Brawner 1994).

Dewatering wells. Dewatering wells are designed primarily to lower the groundwater level to a predetermined depth and to maintain that depth until all below-ground activities have been completed. The main purposes for construction dewatering include the following (Driscoll 1986):

- Intercepting seepage that would enter an excavation site and interfere with construction activities
- Improving the stability of slopes, thus preventing sloughing or slope failures
- Preventing the bottoms of excavations from heaving because of excessive hydrostatic pressure
- Improving the compaction characteristics of soils in the bottoms of excavations
- Drying up borrow pits so that excavated materials can be properly compacted in embankments
- Reducing earth pressures on temporary supports and sheeting

Drainage galleries or adits. Drainage adits or galleries driven under a pit—or into a slope or highwall to intercept the groundwater—can provide an effective method of drainage. Where employed, drain holes should be drilled from the adit

upward in a fan pattern to increase drainage effectiveness. An adit can be used not only for drainage, but also as a means of obtaining detailed discontinuity information. This type of data is useful for future slope-stability predictions. Additional information, such as water quality and the variations in permeability along the length of the adit, can also be gathered. The cost of driving an adit is high. However, it need only be large enough to allow efficient excavation and to properly drain the problem area, generally 1.0–1.5 × 2.0–2.2 m (3.3–4.9 × 6.5–7.2 ft).

SLOPE MANAGEMENT

Three general principles of slope mechanics should be kept in mind in cases of slope instability (Call and Savely 1990):

1. Slope failures do not occur spontaneously. One or more of the forces acting on a potentially unstable rock mass must change in order for the mass to become unstable.
2. Most slope failures tend toward equilibrium. A slope fails because it is unstable under the existing conditions. Failure tends to bring the slope to some sort of equilibrium. It normally involves a reduction in the driving forces and/or an increase in the resisting forces of the failed zone.
3. A slope failure does not occur without warning. Prior to failure, measurable movement and/or the development of tension cracks will occur. These indications of failure can develop, indicating imminent slope failure, then subside for a long period of time, indicating apparent stability.

In the evaluation of the necessity and type of stabilization technique to be used, the first issue to be considered is the degree of urgency. If the slope has started to move, immediate remedial actions should be taken. These actions may include evacuating structures, closing roadways, or cordoning off a section of a mine.

After the situation has become less urgent, determining the cause of the instability is necessary by the following means: visual observation based on experience, water level measurements, slope instrumentation, tests on the materials, and a survey of the discontinuity patterns (Golder 1971). Laboratory tests may be required on the rock and discontinuities to determine appropriate strength parameters.

Detection and Monitoring of Instability

When a rock or soil mass is disturbed, either by the actions of people or by natural events, it undergoes a redistribution of stresses, resulting in a change in shape. This readjustment is reflected in displacements, deflections, pressures, loads, stresses, and strains, which can be detected and measured. Many of the same measurement methods and instrumentation techniques can also be used to investigate the mechanical properties of the mass, the interaction between the mass and any associated artificial structures, and the effectiveness of remedial measures proposed to correct defects in either the mass or the structures.

Monitoring is the surveillance of engineering structures either visually or with the aid of instruments (Brown 1993). The objectives of a rock slope monitoring program are as follows (Call 1982):

- To maintain a safe operation for the protection of personnel and equipment
- To provide advance notice of instability, thus allowing for the modification of the excavation plan to minimize the impact of the instability
- To provide geotechnical information in order to analyze the slope failure mechanism, design appropriate remedial measures, and/or conduct a redesign of the rock slope

Monitoring can be done from within the rock mass and/or on the excavation boundary. The techniques available to measure the various components of rock deformation may be placed in two general categories: observational and instrumentation (Windsor 1993). Observational techniques include simple visual observations, photographic recording, and electronic and optical surveying. Instrumentation techniques include the application of mechanical and electronic instruments such as extensometers, inclinometers, strain gauges, and crack gauges.

An overview of both observational and instrumental techniques, as well as the types of instruments for monitoring deformation, is given in Table 8.3-1.

An effective slope monitoring program consists of the systematic detection, measurement, interpretation, and reporting of evidences of slope instability. Measurements are normally made of both surface and subsurface displacement in order to provide an accurate assessment of slope instability.

Surface Displacement

Surface displacement measurement by means of observational techniques (surveying by conventional methods, automatic surveillance, and/or Global Positioning System) and/or instrumentation techniques (movement indicators, extensometers, inclinometers, convergence indicators) is the preferred monitoring method. A combination of the methods and instruments should be used, as no one method would give the entire picture.

Tension crack mapping. Tension cracks are an early, obvious indication of instability. By systematically mapping the cracks, the geometry of a failure can be better defined. All cracks should be mapped regardless of apparent cause. Often cracks that appear to be the result of local bench failure or blasting form a pattern showing an impending larger failure when plotted on a pit map.

The ends of the cracks should be flagged or marked so that on subsequent visits new cracks or extensions of existing cracks can be identified.

Wireline extensometers. Portable automated wireline extensometers can be used to provide monitoring in areas of active instability across tension cracks. These monitors can be quickly positioned and easily moved. The extensometer should be positioned on stable ground behind the last visible tension crack, and the wire should extend out to the unstable area. For warning devices, or for information on deformation within a sliding mass, wire extensometers can be placed at any strategic location. Anyone working in the area can make an immediate check on slope movement by inspecting the instruments.

The automated slope monitoring system has the ability to record data automatically and then transmit the data to a central computer system for analysis. The system is used for real-time displays of slope movement, as well as for long-term analysis of all recorded information (Martin 1996). The automated system is composed of two main components: the slope monitor unit, which is located in the field, and the central computer and radio, which may be located in the mine office. The system may be programmed to transmit alarms if certain conditions occur, such as broken wire, excessive movement or velocity, or communication failures. For instance, if the wire breaks or the slope anchor probe pulls loose, the wire spool falls to the base

Table 8.3-1 Classification of instruments for measuring the various components of rock deformation

Deformation Measurement Technique	Measurement Access	Measurement Method	Measurement Sensitivity
Observational Techniques			
Global Positioning System	Exposure	Manual	Manual
Terrestrial surveying	Exposure	Manual	Manual
Electronic distance meter and automatic surveillance	Exposure	Automatic	Manual
Slope-stability radar	Rock face	Automatic	High

of the mounting tripod; the falling spool pulls a magnet off the electronics box, which immediately radios a warning to the central computer (Martin 1996). The central computer system collects and processes the data and generates screen displays and/or reports on slope movement status. A solar panel can be attached and used to recharge the battery power supply.

Survey monitoring. The most widely used method of monitoring for movement employs the theodolite/EDM (electronic distance meter), total station or programmable robotic theodolite in conjunction with an array of monitoring prism targets. This continues to provide the most detailed movement history in terms of displacement directions and rates in the unstable areas. Locations of the targets should be chosen so that relative movement of the unstable area can be monitored. Additionally, the permanent control point(s) from which the targets are shot (i.e., observed) must be located on stable ground outside the slide area and within view of the targets. The network should be a set of well-conditioned triangles, with each vertex point being visible from two other points and the length of each line of sight within the measuring range of the equipment (Windsor 1993).

The instrument, as well as any backsights used, should be located on stable ground away from the slide area(s). Computerized, automatic theodolites are gaining popularity to monitor movement at 100 or more survey prism stations. The robotic theodolite may be housed in a small shed or dispatch building at a vantage point in direct line of sight with all prism stations. A computer system may also be housed in the robotic slope-monitoring shed. This system uses a specialized software package to control the theodolite, which, after preprogramming, shoots the array of prisms automatically on a programmed cycle. After completion of a cycle, the system may be set to shoot one or more subcycles or may start another cycle of shooting the set of prisms. Readings can be trans-

ferred via hard wire, Internet, modem, or radio telemetry link to a base computer located elsewhere for further processing.

Slope-stability radar. The slope-stability radar (Figure 8.3-28) is a state-of-the-art technology used for slope-stability monitoring of open-cut mine walls. It provides continuous, precise, and real-time on-line measurement of rock wall movements across the entire face of a wall. It remotely scans a rock slope to continuously monitor the spatial deformation of the face. Using differential radar interferometry, the system is used to detect deformation movements of a rough wall with submillimeter accuracy, and with high spatial and temporal resolution. The effects of atmospheric variations and spurious signals can be reduced via signal processing means. The advantage of the slope-stability radar over other monitoring techniques is that it provides full area coverage without the need for mounted reflectors or equipment on the wall. In addition, the radar waves adequately penetrate through rain, dust, and smoke to give reliable measurements, in real time and 24 hours a day (GroundProbe 2009).

Subsurface Displacement

Surface displacement measurements do not determine the subsurface extent of instability, although it is possible to make inferences from displacement vectors. There are many situations where measurement of subsurface displacement is needed. These measurements are commonly made using borehole inclinometers or borehole extensometers.

Borehole inclinometers. An inclinometer measures the change in inclination (or tilt) of a borehole and thus allows the distribution of lateral movements to be determined versus depth below the collar of the borehole as a function of time (Wilson and Mikkelsen 1978). Therefore, the application of inclinometers to slope-stability studies is important for the following reasons:

- To locate shear zone(s)
- To determine whether the shear along the zone(s) is planar or rotational
- To measure the movement along the shear zone(s) and determine whether the movement is constant, accelerating, or decelerating

Two types of inclinometer are in common use: the in-place inclinometer and the traversing probe type of inclinometer.

The in-place inclinometer was developed for automated monitoring. It is composed of a string of inclinometer sensors permanently mounted in the casing. The sensors are normally positioned within the casing to span the zone where movement is anticipated. The string of sensors is usually attached to a data acquisition system that is programmed to trigger an alarm if certain boundary conditions are exceeded. The in-place inclinometer is expensive; its use is generally limited to only the most critical applications (Boisen and Monroe 1993).

The traversing probe type of inclinometer was developed to address the problem of expense. It employs a single sensor that can be used to monitor any number of inclinometer casings. Tilt readings are typically obtained at 2-m intervals (2-ft intervals are used with probes that use the U.S. customary system of measure) as the probe is drawn from the bottom to the top of the casing. The main drawback to the system is that it is slow and requires an on-site operator (Boisen and Monroe 1993).

Borehole extensometers. The fixed borehole extensometer measures only axial displacement between a fixed number of reference points on the same measurement axis. When more than two reference points are used, the instruments are referred to as multiple-position or multipoint extensometers. Multipoint extensometer data can reveal the relative movement between anchor points and the distribution of displacement, in addition to the magnitude, rate, and acceleration of displacement (Slope Indicator Company 1994).

The basic components of a fixed borehole extensometer are an anchor, a linkage, and a reference head. The reference head is installed at the borehole collar. The linkage system may be composed of wires or of solid rods; it spans the distance between the reference head and the anchor. A change in this distance indicates that ground movement has occurred. Measurements are taken at the reference head with a depth micrometer or an electronic sensor and are used to determine the displacement.

Precision, Reliability, and Cost

The number of different devices that can be used for monitoring, as well as the precision and sophistication of the devices, are a function of the ingenuity, time, and budget of the engineer in charge of monitoring. Since none of these factors is infinite, hard choices must be made. Some general guidelines for decision making follow.

Measure the obvious things first. Surface displacement is the most direct and most critical aspect of slope instability. Tension cracks can easily be mapped or photographed; the surveyor can set survey points and log movement on a regular basis.

Simpler is better. The reliability of a series system is the product of the reliability of the individual components. A complex electronic or mechanical device with a telemetered output to a computer has significantly less chance of being in operation when needed than do two stakes and a tape measure.

Precision costs money. The cost of a measuring device is often a power function of the level of precision. Measuring to 10 mm (0.4 in.) is inexpensive compared to measuring to 0.001 mm (0.0004 in.).

Redundancy is required. No single device or technique tells the complete story. A single extensometer or survey point will not indicate the area involved in the instability, and, if it is destroyed, the continuity of the record is lost.

Multiple survey prisms should be placed in and around a slide area that is being monitored using optical or robotic surveying techniques.

Timely reporting is essential. Data collection and analysis must be rapid enough to provide information in time to make decisions. Modern computerized data acquisition systems are not always available, therefore persons doing the monitoring and reporting should submit promptly. Any indication of movement acceleration requires attention.

Establish a monitoring schedule. A definite monitoring schedule should be established. The frequency of monitoring is a function of the precision of the system, the rate of movement, and how critical the area is. If there is heavy rain or a large blast in the area, additional measurements should be made.

Cooperation between operations and engineering is important. Equipment operators often have an intuitive feel for ground conditions. Any changes in the condition of an area observed by operators (e.g., an observation of the development of tension cracks) should be reported to engineering for follow-up.

Data reduction and reporting should be conducted. The following measurements or calculations should be made for each survey reading:

- Date of reading, incremental days between readings, and total number of days the survey point has been established
- Coordinates and elevation
- Magnitude and direction of horizontal displacement
- Magnitude and plunge of vertical displacement
- Magnitude, bearing, and plunge of resultant (total) displacements
- Velocity and any change in velocity (acceleration/deceleration) of the movement vector

Both incremental and cumulative displacement values should be determined. Calculating the cumulative displacement from initial values rather than from summing incremental displacements minimizes the effects of occasional survey aberrations.

Slope displacements are best understood and analyzed when the monitoring data are graphically displayed. For engineering purposes, the most useful plots are

- Horizontal position,
- Vertical position (elevation versus change in horizontal position, plotted on a section oriented in the mean direction of horizontal displacement),
- Displacement vectors,
- Cumulative total displacement versus time, and
- Incremental total displacement rate (velocity, usually in feet or meters per day) versus time.

All graphics should be kept up-to-date and should be easily reproducible for ease of distribution. By studying several graphs simultaneously, the movement history of a particular slope can be determined.

Precipitation data should also be recorded in order to evaluate possible correlations with slope displacement. A rain gauge or system of rain gauges located at the mine site can be used to measure occurrences and amounts of precipitation. In addition, measurement of the average daily temperatures will provide some indication of freeze and thaw periods.

The location of mining areas and the number of tons mined should also be recorded on a regular basis, because slope displacements are often associated with specific mining activity. Blasting records, including seismic records, should be kept and referenced to the unstable areas. A histogram can be made of tons mined versus time, and this plot can then be compared to the total displacement graphs.

A formal monthly slope-stability report should be prepared, containing at least the following data:

- Maps (plan view showing the unstable areas and locations of monitoring devices, displacement vectors, blast locations, tension crack map, piezometric surface)
- Plots and graphs (cumulative displacement versus time, displacement rate versus time, precipitation versus time, mining versus time)
- Prediction of time to failure for critical unstable areas
- An "action plan" for each critical unstable area

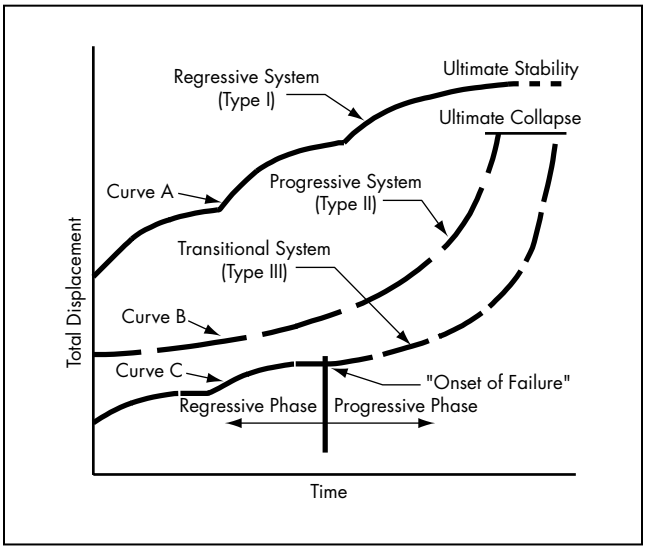
Time-Dependent Slope Movement Characteristics

All excavations, whether natural or human-made, deform with time in response to excavation. According to Zavodni (2000), the most commonly observed evidence of time-dependent deformation of cut slopes is the development of tension cracks behind the slope crest, formation of cracks on the slope, and toe heave.

Zavodni further states that mining operations can proceed safely with minimum interruption if failure mechanisms are understood and slopes are properly monitored. A serious slope instability condition is usually accompanied by gradual development of one or more tension cracks behind the slope crest. This situation then normally allows for time-displacement monitoring. Surface-displacement measurements employing prism targets are usually adequate for monitoring slope movement. The prisms may be accompanied by extensometers closely monitored to determine slope-movement velocities in order to predict slope behavior. Recent advances in survey equipment—robotic theodolites and real-time transmission of data—allow increasingly precise monitoring of movement accompanied by immediate data display and analysis.

Initial Response

Upon excavation of a rock mass, thereby creating a rock slope, the slope experiences a period of initial response as a result of elastic rebound, relaxation, and/or dilation of the rock mass due to changes in stress induced by the excavation. This initial deformation or rebound normally occurs without the development of a defined failure surface or failure mechanism. The slope rebound and extension can develop by spreading along joints in the rock mass or along low-strength discontinuities.



Zavodni (2000) reported that initial response movements ranged from 0.10 to 4 mm/d (0.004 to 0.16 in./d), although much higher instantaneous velocities could be encountered at the exact time of excavation. The rates of movement during initial response periods decreased with time and eventually dropped to zero. Results from numerous case histories indicate this decrease in movement rate can best be fit by a negative exponential relationship of the form:

$$R = A \times e^{-bt}$$

where

R = movement rate

A and b = constants that are a function of the rock mass properties, slope geometry (height and angle), mining rate, external influences, and ultimate failure mechanism. Zavodni's reported values

Source: Zavodni and Broadbent 1982.

Figure 8.3-29 Typical regressive/progressive state displacement curves

of A range from 0.113 to 2.449, while values for b range from 0.0004 to 0.00294.

t = time (days)

Zavodni reported that during a slope steepening project in Nevada (United States), documented rebound was noted 120 m (400 ft) into the slope (near the pit toe) without evidence of surface cracking. Finite element modeling confirmed these deep-seated and near-surface slope dilations.

Regressive and Progressive Movement

If it is to occur, a conventional open-pit "slope failure" begins after the initial response of the excavation and is normally associated with the creation of one or more tension crack(s) at or near the crest of the slope. The development of such cracks is evidence that the slope is at limiting equilibrium and the driving forces (stress) just equals or exceeds the resisting forces (stress). In the case of the slope at limiting equilibrium, stability is decreased by increasing the driving forces (stresses), decreasing the resisting forces (stresses), or by changing both the driving and resisting forces (stresses).

Whether the failure is regressive or progressive depends on whether a potential or active rock slope failure tends to become more stable or less stable. A regressive failure is one that shows short-term decelerating displacement cycles if disturbing events external to the rock are removed from the slope environment. A progressive failure, on the other hand, is one that will displace at an accelerating rate, usually an algebraically predictable rate, to the point of collapse unless active and effective control measures are taken (Zavodni and Broadbent 1982). A third type defined by Zavodni and Broadbent is what is known as the regressive/progressive condition (or "transitional system"). These curves are shown on Figure 8.3-29.

Type I: Regressive condition. The regressive failure type is shown as Curve A on Figure 8.3-29. This failure type is characterized by a series of either accelerating or decelerating displacement trends, as revealed from continuous monitoring programs. The characteristic that qualifies this curve as regressive is the deceleration of each cycle between external stimuli. The cycles are believed to be initiated when the driving force (stress) temporarily exceeds the resisting force (stress), thereby causing the rock slope condition to drop slightly below a safety factor of 1. The velocity of movement will decay if the external disturbance is eliminated. The excess driving force is usually related to an external event such as a mine blast, earthquake, precipitation event, temperature change groundwater pressure change, or excavation of buttressing rock.

Characteristics of regressive type failures are when the

- Ratio of driving stress to resisting stress decreases with displacement, and
- Slope will tend to become more stable with time and show decelerating or stick–slip behavior.

Type II: Progressive condition. The progressive failure demonstrates an increase in the rate of displacement over time until collapse, as shown by Curve B in Figure 8.3-29. Decelerating cycles may be present but would be subtle and nearly indistinguishable from the long-term trend. The time period over which progressive displacement of a large-scale failure takes place is usually short, 4 to 45 days (Zavodni 2000).

Type III: Regressive/progressive condition. As shown by Curve C in Figure 8.3-29, a regressive type failure may transition into a progressive type failure and rapidly lead to collapse. Causes of this change in behavior can include a situation where mining daylights a sliding surface, breakup, or excavation of rock at the toe of a slope, or an increase in water pressure.

Slide Management

Some degree of slope instability can be expected with virtually any slope cut in rock, whether the slope is a mine highwall, is for a road cut, or is a part of some other construction project. When slope-stability investigations indicate that the possibility of slope failure exists, there are a number of response options available (Call and Savely 1990):

- Leave the unstable area alone.
- Continue mining without changing the mine plan.
- Unload the slide through additional stripping.
- Leave a step-out (i.e., a bench or berm of unexcavated rock at the toe of the slope to increase the resisting forces of the slope).
- Conduct a partial cleanup.
- Mine out the failure.
- Support the unstable ground.
- Dewater the unstable area.

The option, or combination of options, that is chosen depends primarily on the nature of the instability and its operational impact. Each situation should be evaluated separately, with safety aspects carefully considered, and with the cost of any remedial action and benefit included.

Contingency Planning

Mine planning should have the flexibility to respond to slope instability. Rather than an after-the-fact crisis response to forced deviation from a rigid mine plan, contingency plans should be prepared in advance so that the response to slope instability is well thought out. A management philosophy of "Do something, even if it's wrong!" will frequently result in more problems than the original event (i.e., slope instability) precipitated. Also, the

lack of adequately trained personnel for the geotechnical group will result in significant scheduling problems and production delays when a slope failure event occurs.

Operational flexibility should be built into the mining plan. For example,

- Adequate ore should be uncovered and available so that production is not dependent on a single location;
- There should be more than one access road into the pit for service and haulage vehicles. The loss of the haul road, when it is the only access into the mine or a portion of the mine, will shut down production for an extended period of time;
- Whenever possible, more than one access to working benches should be maintained; and
- Labor and equipment should be available for slide cleanup when necessary.

CHAPTER 8.4

Rock Mechanics

Ross Seedsman

INTRODUCTION

Rock mechanics is the applied science of the mechanical behavior of rock and rock masses in a stress field. In mining, knowledge of rock mechanics is combined with empirical reasoning to make predictions of performance of excavations so that safety, environmental impact, and economic value can be optimized.

This chapter focuses on the "applied" part of the definition and particularly how the science can be applied to the practicalities of mining. It provides a ready reference for some of the key definitions and methods in current use. The opportunity is taken to provide some guidelines on the use of various concepts, highlighting where major uncertainties are still present. The coverage of the subject is not detailed or complete but is presented to introduce the subject to nonspecialist mining engineers. Numerous publications provide the detail, the theoretical basis, and recent case studies to which the specialist geotechnical engineer is referred (e.g., Hoek et al. 1998; Brady and Brown 2004).

There continue to be major advances in both mining rock mechanics and mining engineering. Mining practices have evolved in the face of increasing expectations of workplace safety and environmental impact. Zero harm is now the stated goal of most mining companies. Greater reliance is now placed on bulk mining systems, such as sublevel and block caving in metal mines, and draglines and longwalls in the coal sector. The costs of delays in bulk mining systems can be very high. There are now greater demands that the operations perform rigorously to both plan and budget. In this environment, monitoring of mining systems is an essential part of ensuring workplace safety, but it is not adequate to ensure continued production or appropriate environmental impact. Better forecasts of mining conditions are required, and these demand a much better understanding and application of rock mechanics.

In the science of rock mechanics there have been major developments in computer-based stress analysis, such that two- and three-dimensional (2-D and 3-D) stress analyses of openings in rock masses are now routine. The ease at which these can be conducted, together with the associated graphics, may give an unjustifiable level of confidence in the predicted performance of the excavations. Although knowledge of the stresses around a mine opening is essential, it is not sufficient to ensure adequate performance. One key objective of the mining process is the control of displacements into and around the openings. Failure of rock and rock masses is readily induced around mining openings, so the prediction of displacements requires knowledge of the strength of rock masses. Unfortunately, knowledge of rock strength is comparatively poor, with fundamental revisions being made within the last decade.

Much of rock mechanics depends on the appreciation of engineering geology. It is only by understanding the distribution and characteristics of rock types, the associated discontinuities, and the size of the blocks defined by them that rock mechanics can be applied.

Nature of Rock

Rock and rock masses are inherently complex (Brady and Brown 2004). The complexities relate to the following:

- Fractures are developed in a compressive stress field. This limits the ability to transfer knowledge from other branches of engineering where failures are induced in a tensile stress regime.
- Mine openings can vary in scale from the order of meters to hundreds of meters. Over this scale there is a need to consider both intact rock and the rock mass with all its discontinuities.
- As a result of the discontinuities, the tensile strength of a rock mass must be considered to be zero.
- In most cases, mining takes place below the original water table. Water may have an impact in terms of both effective stress and in terms of reducing the strength of certain rocks.
- Weathering of the rock around mine openings can lead to chemical and/or physical alteration of the mineral components and hence rock strength.

The importance of the concept of scale is illustrated in Figure 8.4-1. At the scale of a roadway or a bench, the behavior of the excavation may be controlled by the strength of the intact portions or by the presence of one or two joints or

Ross Seedsman, Director, Seedsman Geotechnics, Wollongong, New South Wales, Australia

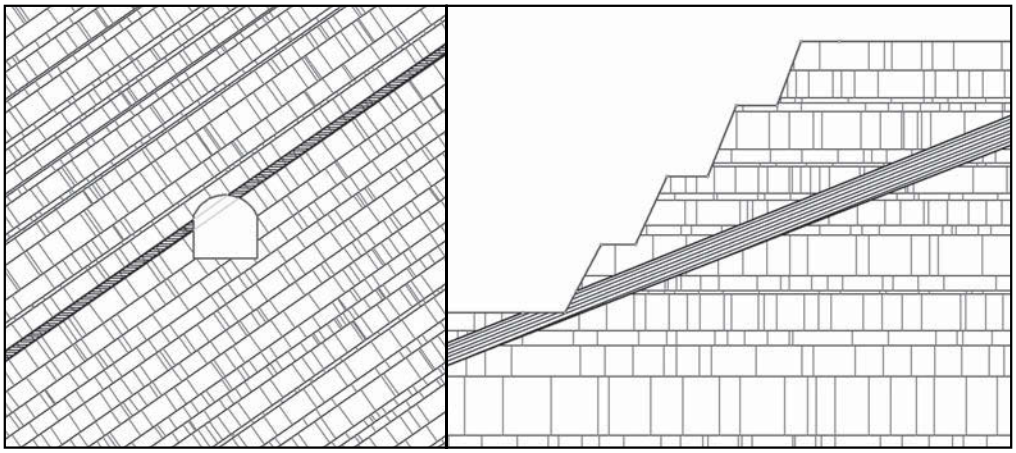

Figure 8.4-1 Different features of the rock mass control its behavior at different scales

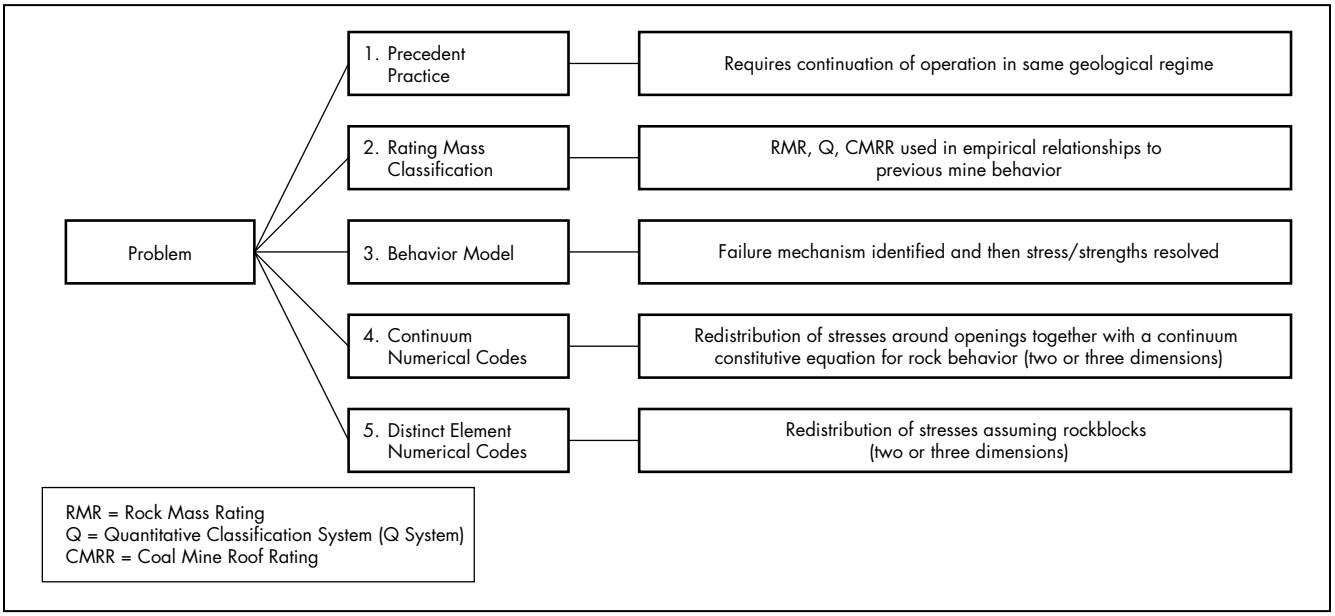

Figure 8.4-2 Different pathways for concept formulation and analysis

beds. At a large scale—for example, the wall of a deep surface mine—the behavior of the rock mass may be controlled by the overall joint and bedding structure. Should the excavation intersect a major fault zone, then the behavior will be controlled by that single feature.

For analytical convenience, rock masses are often considered to be continuous, homogeneous, isotropic, and linear elastic (CHILE) according to the following definitions:

- **Continuous:** Intact rock with no breaks
- **Homogeneous:** All the same rock
- **Isotropic:** Rock properties are the same in all directions.
- **Linear elastic:** An increment or decrement in stress produces the same increment or decrement of strain (there is no permanent deformation and no failure)

In reality, rock masses are discontinuous, inhomogeneous, anisotropic, and nonlinear elastic (DIANE). The assumption of CHILE continuum behavior introduces major risks. Many of the operational mining problems relate to the rock mass not behaving as a continuum. For example, in many applications ground support is best addressed through the consideration of blocky rock, as is bench design in surface mines, though there are notable exceptions.

Rock Mechanics and Mine Design

Rock mechanics design fits within an engineering design methodology (Bieniawski 1993). Steps in the methodology emphasize the need to characterize the site geology as well as the strength of the materials. There is a need to simplify the complex conditions into geotechnical models (concept formulation) that can be subsequently analyzed. There are five pathways through the concept formulation and analysis steps, four of which rely on aspects of the science of rock mechanics (Figure 8.4-2). Precedent practice is the exception—this is still an important pathway, so long as there is confidence that the ground conditions are the same.

Rock mass classification schemes seek to transfer knowledge gained from previous mining experiences to other sites.

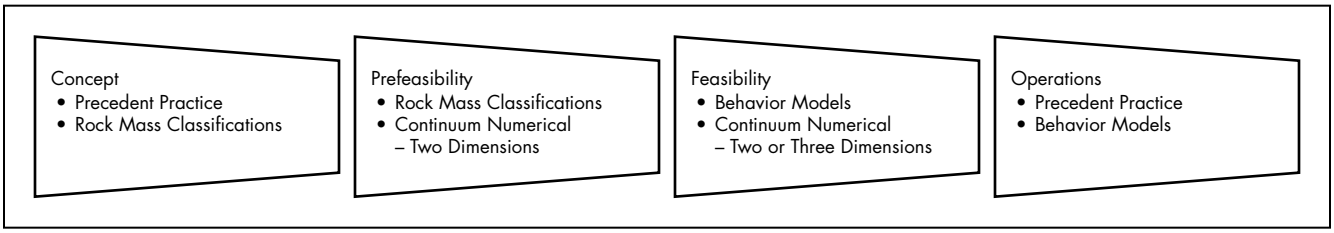

Figure 8.4-3 Suggested minimum application of design pathways for different project stages

The schemes allocate numerical values to features of the rock mass considered likely to influence overall behavior and then combine them into a single rating value. Although useful for translating experience within a single mine site or mining district, caution is required in their use in the absence of analysis of the mechanics of the problem being considered (Brady and Brown 2004). The schemes are useful for planning purposes, but they are not necessarily useful for the prescription of rock support during actual construction (Palmstrom and Broch 2006).

The term *behavior model* is used here to mean the identification of failure or collapse modes separate from the calculation of stresses. Wedge, planar, and toppling failures in the benches of surface mines are examples. The limit equilibrium methods characteristic of soils engineering are also examples of how the failure mechanism is identified prior to the analysis. Kaiser and Kim (2008) argued that by concentrating on the behavior of the excavation boundary, the significance of brittle tensile failure was identified and a new failure criterion was developed. Numerical codes may be used to assist in the calculation of stresses.

In the numerical approaches, the failure zones are identified after the stresses are calculated. Therefore, they depend on the failure criterion input to the model. Field stresses, constitutive equations (stress–strain relationships), and failure criteria are required, and these require assumptions/simplifications of equal or greater magnitude as the formulation of behavior models. Some continuum numerical codes (e.g., Phase 2, FLAC [Fast Lagrangian Analysis of Continua]) determine stresses about openings, assuming the rock mass behaves as a continuum. In some codes, discontinuities can also be modeled. In distinct element codes (e.g., UDEC [Universal Distinct Element Code]), the rock mass is treated as quasi-rigid blocks that interact through movement along the discontinuities. Codes for both 2- and 3-D analyses are now in widespread use.

Which pathway to use depends on the stage of the mining project. It is good practice to use at least two pathways to provide an internal check on the design. Figure 8.4-3 provides general guidelines for each stage; there will be situations where different levels of geotechnical knowledge will require different strategies. Precedent practice is the strongest pathway for operations, but this should be accompanied by a way of confirming that the same geotechnical regime is present. Historically, the latter has been done through the rock mass classification pathway, and the limitations of this were mentioned earlier. The classification schemes were developed before the advent of personal computers that make stress analyses readily available. Since 1990, the focus has been on the numerical code pathways, and there is now a realization that knowledge of the constitutive equations and failure criteria is limited. The behavior model pathway may be more appropriate as it demands good observation of how the rock actually behaves, and this not only identifies immediate hazards but also identifies the need for new scientific knowledge. Figure 8.4-3 suggests that the rock mass classification pathway is particularly suitable at early stages of a mining project when there is little data available. At the prefeasibility level, numerical codes can be used to determine stress redistributions around openings, and they allow for optimization of the overall layout while, at the same time, work is done to characterize the discontinuity fields. As the mine moves to the operational phase, the focus needs to move to the performance of the excavation boundaries (roadway or bench), and the behavior of relatively small blocks of rock may be best addressed by the behavior model pathway.

Sophisticated analytical and prediction tools do not ensure adequate or appropriate predictions. Using concepts from soils engineering, there is a need to be aware that for a given quantum of data there is an appropriate degree of sophistication in the analysis, beyond which the accuracy of the prediction may decline (Lambe 1973). In referring to Lambe, it is not suggested that accurate Class A predictions are essential or even possible in mining ventures; although the better the Class A predictions, the lower the risk to capital. The message is that the mining engineer must "maintain an ongoing awareness of factors that contribute to unsuccessful performance and introduce this awareness into comprehensive risk management tools" (Morgenstern 2000).

Scope

The application of four of the pathways requires knowledge of rock mechanics, either of rock mass classification systems or of the combination of the strengths of rock and rock masses as well as the stresses around excavations. This chapter is a general introduction to the subject of rock mechanics so as to provide a broad understanding of the issues and the associated uncertainties. It is anticipated that the scope will be of value to mine planners seeking to understand the constraints that need to be applied, to mining engineers who are using the readily available stress analysis codes and require an understanding of the input parameters, and to engineering geologists that are looking for an introduction to the engineering concepts.

Specialist geotechnical engineers are referred to many of the standard texts for detailed treatment of the subject.

ROCK PROPERTIES

There are two fundamental sets of rock properties: the discontinuities and the substance itself. This section describes how rocks can be characterized at the laboratory and outcrop scale. The rock properties in the following discussion are used to different degrees in the four analytical pathways discussed earlier, so they must be determined as accurately as possible.

Table 8.4-1 Definitions of terms for spacing and persistence

Spacing Descriptions	Spacing, mm
Extremely close	<20
Very close	20–60
Close	60–200
Moderate	200–600
Wide	600–2,000
Very wide	2,000–6,000
Extremely wide	>6,000
Persistence Descriptions	**Modal Trace Length, m**
Very low	<1
Low	1–3
Medium	3–10
High	10–20
Very high	>20

Source: ISRM 1978.

Discontinuities

The distinctive feature of rock masses is the presence of discontinuities. In this context, discontinuities are defined as features of a rock mass that have zero or negligible tensile strength. This terminology allows a differentiation from textural features within intact rock. From a geological perspective, discontinuities can include joints, bedding, partings, faults, veins, shear zones, cleavage, and schistosity. The term *defect* can also be used interchangeably with discontinuity. A corollary of this definition is that the tensile strength of a rock mass should be assumed to be zero.

The International Society for Rock Mechanics (ISRM) provides the framework for the description of discontinuities.

Spacing and Persistence

Table 8.4-1 presents the ISRM definitions of terms for spacing and persistence. Although this table may be satisfactory for igneous and metamorphic regimes, it does not adequately address the range of conditions that can be encountered in sedimentary sequences, such as found in coal mining. Bedding partings can have persistence values very much greater than 20 m, and there are situations in some of the coal mass-mining regimes (longwalls) where it is necessary to describe bedding parting spacings in the order of 30 to 50 m.

In most rocks, it appears that discontinuity spacing tends to follow a negative exponential function, although in some cases a lognormal distribution better applies (Brady and Brown 2004). In relatively undisturbed sedimentary rocks, a valid first-order assumption is that the mean joint spacing is equal to the mean spacing of bedding partings (Ji et al. 1998); the rock mass is composed of cubes, though this simplification should be applied with caution.

The rock quality designation (RQD) is a simple measure of discontinuity spacing and rock mass quality. The RQD is the percentage of core that reports in lengths greater than 100 mm. The core lengths should be measured along the center line, and only double- or triple-tube drilling should be used.

Reduced discontinuity spacing and greater persistence should be anticipated near faults. Many ground control problems that are reported in the vicinity of faults are related more to the smaller block size defined by the closer-spaced discontinuities than to higher stresses that are often presumed to be present. In fact, the deviatoric stresses near faults are likely to be lower than in the adjacent rock mass.

Table 8.4-2 Typical JRC values as a function of shape and roughness of discontinuities

Description	Planar (continuous without change in orientation)	Stepped (well-defined sharp changes in orientation)	Undulating (wavy shape)
Rough: Like sandpaper; many small irregularities associated with the grain size	2.5	20	14
Smooth: Roughness not detected with finger	1.5	14	11
Polished/slickensided: Reflects light; striated	0.5	11	7

Orientation

The onset of planar, wedge, and toppling failures in surface mines, and also around underground openings, is related to the relative orientation of the excavation to the dominant discontinuities. The determination of the dip and dip direction/strike of the discontinuities is therefore a critical step in any mine design. Mapping of any exposures should be conducted and supplemented with information from drill holes. Modern borehole imaging tools are to be preferred over core orientation to obtain orientation data from drilling programs.

In some situations, knowledge of the regional geology can assist in forecasting orientations. For example, in gently deformed sedimentary regimes it may be possible to infer joint orientations from knowledge of the orientation of fold axes (Fookes et al. 2000).

Surface Conditions—Joint Roughness, Aperture, and Fill

Discontinuities in rock are rarely perfectly smooth and planar. The undulations and roughness of natural discontinuity surfaces have a significant influence on their shear-strength properties, particularly at the low stresses around the immediate excavation boundary (Barton 1973). One set of definitions for surface conditions is presented in Table 8.4-2, along with corresponding joint roughness coefficients (JRCs).

The adjacent rock walls of a discontinuity may be separated by infill such as clay, calcite, and fault gouge. The aperture of a discontinuity is the perpendicular distance between the adjacent rock walls when the intervening space is filled with air or water. In most cases the aperture will be small unless there has been recent movement along irregular surfaces, dilatant stress conditions, or erosion of fill materials. Hydraulic conductivity with laminar flow is proportional to the cube of the aperture.

Shear Strength

If a rough irregular discontinuity is considered between two blocks of rock held together by a stress normal to the surface and exposed to a shear stress, as the shear stress increases, shear displacement will increase. Eventually, a peak shear stress will be reached (peak strength) and continuing shear displacement will require a lesser shear force (residual strength). Repeating this test for different normal loads allows for the construction of two sets of envelopes for the normal stress/shear stress pairs. Shear testing is normally done using a direct shear test (analogous to the left-hand diagram in Figure 8.4-4).

With a restricted number of laboratory tests (e.g., three to five), the peak strength envelope is typically found to be bi-linear. The angle of the second linear segment is called the basic friction angle (φb), and the gradient of the initial

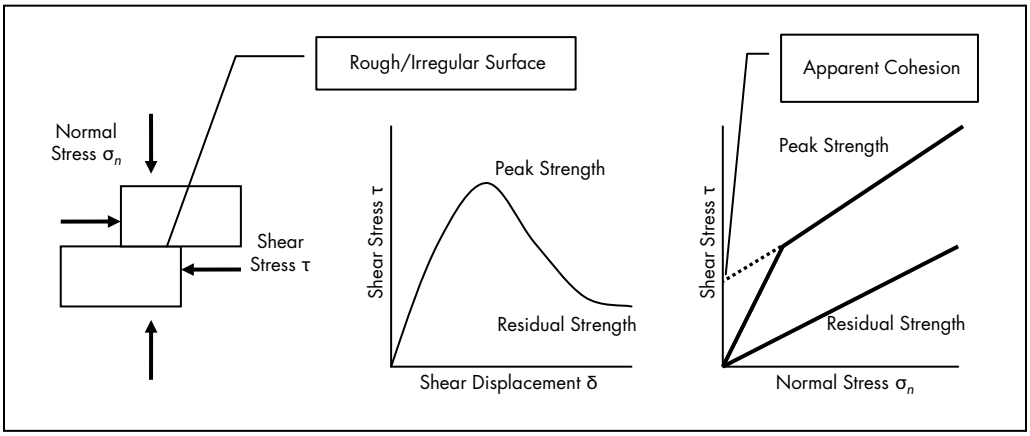

Figure 8.4-4 Terminology for shear-strength testing

Table 8.4-3 Typical basic friction angles, modular ratios, and Hoek–Brown *m* values

Rock Type	Basic Friction Angle, degrees	Modular Ratio	Hoek–Brown *m* Parameter
Amphibolite	32	400–500	26 ± 6
Basalt	35–38	250–450	25 ± 5
Bentonite	9–17	—	—
Chalk	30	>1,000	7 ± 2
Clays	12–19	—	—
Conglomerate	35	300–400	21 ± 3
Dolomite	31–37	350–500	9 ± 3
Granite	31–35	300–550	32 ± 3
Limestone	33–39	400–1,000	8 ± 3
Quartzite	—	—	20 ± 3
Sandstone	26–35	200–350	17 ± 4
Schists	31–4	250–450	10 ± 3
Shale	27–32	150–250	6 ± 2
Siltstone	31–33	350–400	7 ± 2
Slate	25–30	400–600	7 ± 4
Tuff	—	—	13 ± 5

Source: Adapted from Barton 1973, Hoek et al. 1998, and Hoek and Diederichs 2006.

linear segment is related to both the basic friction angle and the roughness of the discontinuity. Typical values for the basic friction angle for different rock types are given in Table 8.4-3.

The shear strength of natural discontinuities (Barton 1973) can be expressed as follows:

$$\tau = \sigma_n \times \tan(\text{JRC} \log10(\text{JCS}/\sigma_n) + \varphi b)$$

where

JRC = joint roughness coefficient (Table 8.4-2)
JCS = joint compressive strength (typically equal to the uniaxial compressive strength unless thick infill)

The JRC for the residual envelope is taken as zero.

At low normal stresses or high joint compressive strengths, the roughness factor results in a high equivalent friction angle and, hence, a high shear resistance. For low values of the JCS/σ_n ratio, the equivalent friction angle is lower and the shear resistance is also lower.

An alternative interpretation of the peak strength could be a single straight line that would give the finite shear strength value at zero normal load (referred to as apparent cohesion). This interpretation would overestimate the shear strength at low normal loads.

In numerical models, there is often a requirement for the joint normal stiffness, *Kn*, and the joint shear stiffness, *Ks*. Values for these two parameters are neither well documented nor easy to measure.

One analytical approach is to estimate *Kn* from the rock mass modulus, the intact rock modulus, and the joint spacing (Brady and Brown 2004). If it is assumed that the deformability of a rock mass is due to the deformability of the intact rock and the deformability of the joints in the rock mass, then

$$\frac{1}{Erm} = \frac{1}{Ei} + \frac{1}{KnL} \text{ or } Kn = \frac{EiErm}{L(Ei - Erm)}$$

where

Erm = rock mass modulus
Ei = intact rock modulus
L = mean joint spacing

The same reasoning can be used to derive the following expression for the joint shear stiffness:

$$Ks = \frac{GiGm}{L(Gi - Gm)}$$

where

Ks = joint shear stiffness
Gi = intact rock shear modulus
Gm = rock mass shear modulus
L = mean joint spacing

Another approach to estimating joint stiffness assumes that a joint has an infill material with known elastic properties. The stiffness of a joint can be estimated from the thickness and modulus of the infilling material by the following equation:

$$Kn = \frac{Eo}{H} \text{ and } Ks = \frac{Go}{H}$$

where

Eo = Young's modulus of infill material
H = joint thickness or aperture
Go = shear modulus of infill material

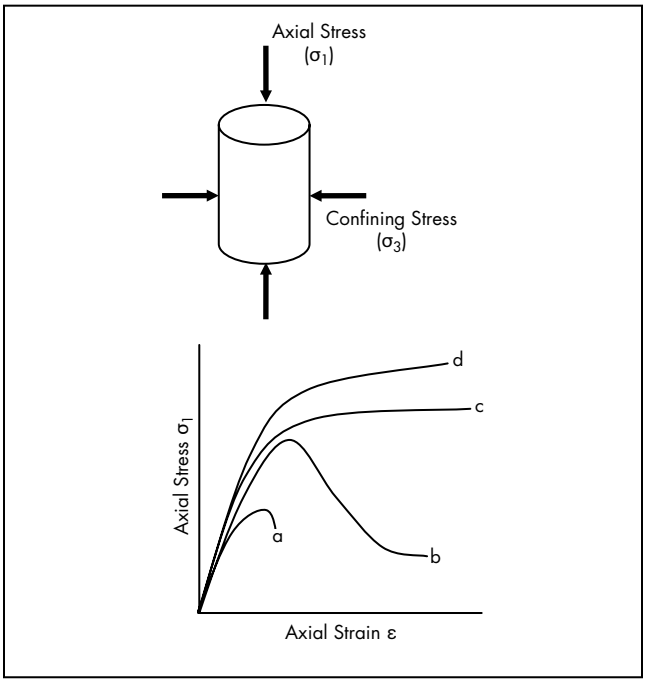

Figure 8.4-5 Terminology used for compressive strength testing

This equation may also be applied to clean joints if the value of H is assumed to be very small (e.g., <1 mm).

Intact Rock

The strength of intact rock is determined in the laboratory by a series of tests on rock cores. The cores are installed in a purpose-designed pressure vessel and exposed to a number of different confining pressures. An axial stress is applied, and as it increases, the rock compresses axially, and it initially may contract slightly laterally. Later in the test, the rock will dilate laterally. The relationship between stress and strain is not linear over the full range of applied stress; sometimes a yield point can be defined where the stress–strain curve deviates significantly from being linear. The peak strength is measured for each confining stress, and this increases with the magnitude of the confinement (Figure 8.4-5). At the same time, the shape of the post-peak part of the curve may change from brittle (Curve a) through strain softening (Curve b) to plastic (Curve c) and strain hardening (Curve d) as the confinement increases, depending on the nature of the rock material.

Uniaxial Testing

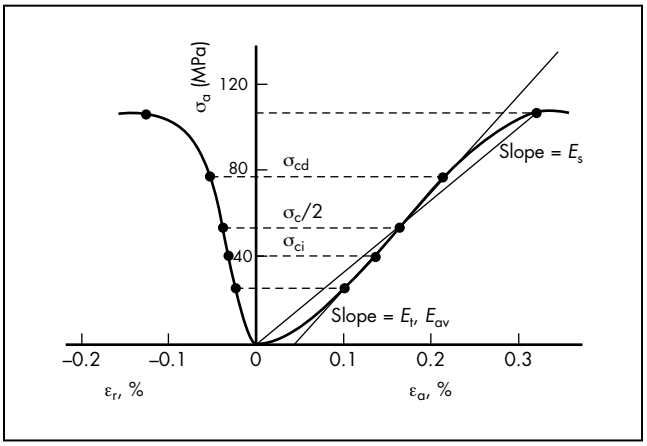
Strength. Laboratory unconfined or uniaxial compressive strength (UCS) is the key index to rock strength. The UCS is the strength measured in the laboratory on samples with the length/diameter ratio greater than 2 and typically on 50- to 65-mm-diameter samples. Testing should be conducted on fresh core and at a moisture content as close as possible to the in-situ value. Control of moisture content is important, especially for the lower-strength rocks (e.g., <20 MPa), as it is these that may be easily overstressed in some mining conditions. Testing conducted at lesser aspect ratios will result in higher indicated strengths, and testing of larger samples will result in lower strengths.

Table 8.4-4 Simple ways of estimating UCS

Term	UCS, MPa	Field Attribute
Extremely strong	>250	Chipped with a geological hammer
Very strong	100–250	Many blows with geological hammer to break core
Strong	50–100	More than one blow with geological hammer to break core
Medium strong	25–50	Cannot be scraped or peeled with pocket knife; core can be broken with single blow from hammer
Weak	5–25	Can be peeled with pocket knife; shallow indentation made by firm blow with point of geological hammer
Very weak	1–5	Crumbles under firm blow with point of hammer; can be peeled with a pocket knife
Extremely weak	0.25–1	Indented by fingernail

Source: Adapted from Hoek and Brown 1997.

Field estimates (Table 8.4-4) have been found to be very useful for the lower-strength rocks that can be readily overstressed around openings and yet may be difficult to sample and test in the laboratory. When using this table, one should be careful not to include core breaks along incipient discontinuities or textures.



The UCS is a fundamental parameter in most strength criteria and should be measured directly whenever possible. The engineering literature suggests that the UCS can be determined from the point-load strength index (UCS = 24 I_{s50} value, which is the point-load strength corrected to a 50-mm-diameter equivalent). Unfortunately, the constant has been found to vary massively between various rock types, and the default value of 24 should be used with extreme care. The testing standards require a large number of tests—at least twice as many as the UCS. A high degree of scatter in the results is common. Point-load testing should not be relied on for rocks with UCS values of less than about 25 MPa.

In the coal sector, sonic velocity obtained from slim-line borehole tools is often used as an index to UCS. Similar to the point-load test, the relationship is empirically derived for each site. Any extrapolation to other sites needs to be applied carefully, and care needs to be taken to ensure that the lower-strength rocks are adequately tested. An exponential relationship to the inverse of the sonic velocity has been found to fit the data reasonably well.

$$\text{UCS} = 5{,}800e^{-17{,}400/vel}$$

where vel is the sonic velocity in m/s (between 2,000 and 4,500 m/s). The indirect tensile strength of rock core can be measured by the so-called Brazilian test on core discs. The tensile strength is typically 1/10 to 1/20 of the UCS.

Deformation parameters. In mining rock mechanics, a common assumption is made that, prior to failure, rock can be considered to be linear elastic. In elasticity theory, there are 21 constants in the constitutive equations that relate deformation to stress. With increasing material symmetry, the number of elastic constants is reduced. An orthotropic material has three material axes and nine independent elastic constants. A gneiss or granite may be orthotropic. Many sedimentary rocks show pronounced differences in properties of samples parallel and perpendicular to the bedding and can be considered

Source: Brady and Brown 2004, reprinted with permission from Springer Science and Business Media.

Figure 8.4-6 Typical stress–strain curves during uniaxial loading

to be transversely isotropic. Five elastic constants are needed for the description of transversely isotropic rock. Only two independent elastic constants are needed for the description of isotropic rock that, by definition, lacks directional mechanical properties.

The prefailure shape of typical stress–strain curves for rock is not perfectly linear (Figure 8.4-6). Assuming linear-elastic and isotropic behavior, the elastic deformation parameters of Young's modulus and Poisson's ratio can be calculated from laboratory data. The Young's modulus is calculated as the ratio of change in axial stress to the corresponding change in axial strain, and the Poisson's ratio is the ratio of the change in the radial strain to axial strain. Typically, tangent values are determined at 50% of the peak strength, and average values are determined to be between one-third and two-thirds of peak strength. Young's modulus and Poisson's ratio are assumed not to vary with confining stress. Secant values to peak strength may also be quoted.

The interrelationships between other elastic parameters are

$$G = E/2(1 + \nu)$$
$$\lambda = 2\nu G/(1 - 2\nu)$$

where

G = shear modulus (also known as the modulus of rigidity)
E = Young's modulus
ν = Poisson's ratio
λ = Lame's constant

It has been determined empirically that the ratio of the Young's modulus to UCS (the modular ratio) varies within relatively narrow limits depending on rock type (Table 8.4-3).

The layering in sedimentary rocks introduces a degree of transverse isotropy. Implementation of transverse isotropy requires two deformation moduli and two Poisson's ratios as well as an independent shear modulus. There is very little guidance on the choice of values of the independent shear modulus. For continuum analyses of layered rock masses, the author has found that values in the order of 100 to 250 MPa may be necessary to account for both textural impacts and bedding partings.

Confined Strength

In the last 20 years, and especially since 2000, there have been major changes in the models for the confined strength of rock. As of 2009, there is no single failure criterion for the full range of stresses, and separate analyses are needed for the excavation boundary and the far field.

The envelope of confining stress/axial stress points for peak strength is nonlinear. The more sample points that are collected, the more the nonlinearity of the relationship becomes apparent. The three common approaches to fitting a relationship are

- **Straight line:** The Mohr–Coulomb criterion that is often used in software codes
- **Power:** Hoek–Brown criterion (Hoek and Brown 1980)
- **Multilinear:** The brittle criterion (Kaiser et al. 2000)

The testing cells used in standard laboratory tests mean that one confining stress is applied. The test is conventionally referred to as a triaxial test, with the understanding that the magnitudes of two of the stress axes are identical. A consequence of this is that the failure criteria refer to only two stresses, σ_1 and σ_3, because $\sigma_2 = \sigma_3$ (discussed later). A true triaxial failure criterion is the subject of ongoing research.

Mohr–Coulomb criterion. The linear fit has the following relationship:

$$\sigma_1 = \sigma_c + \sigma_3 \tan\psi$$

where

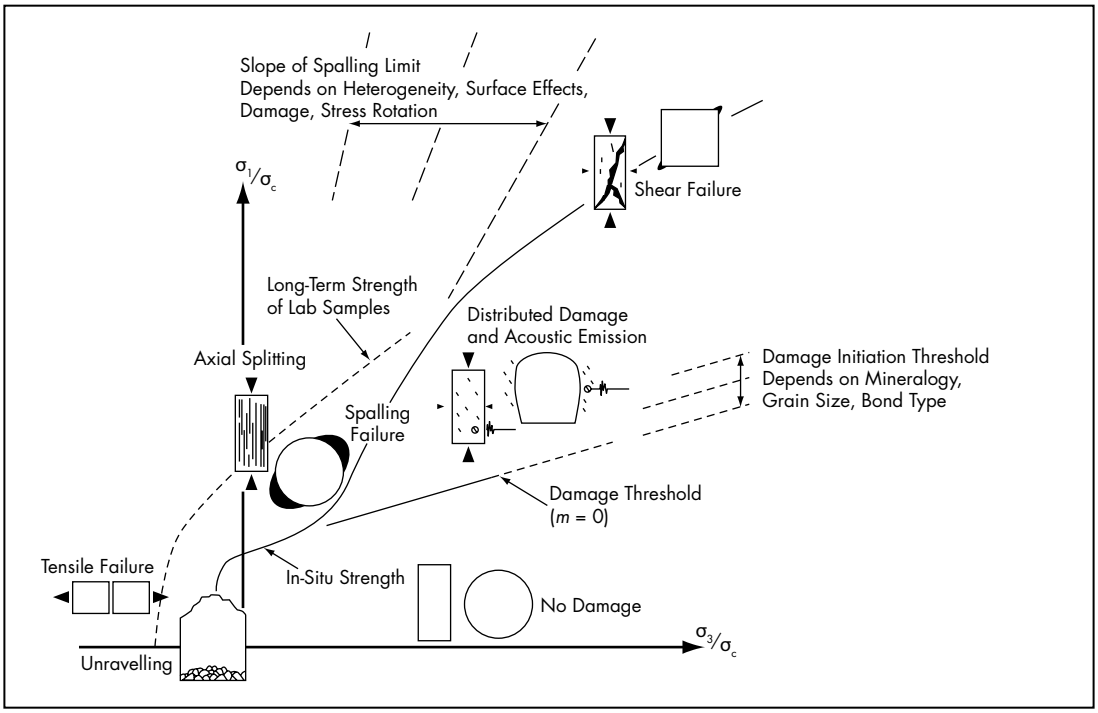
σ_c = intercept for zero confining stress and should be the same value as the UCS
ψ = slope in σ_1/σ_3 space

These parameters can be manipulated to give the cohesion, c, and friction angle, Φ, such that the following conditions are met:

$$\tan\psi = (1 + \sin\varphi)/(1 - \sin\varphi)$$
$$\sigma_c = 2c\cos\varphi/(1 - \sin\varphi)$$
$$\sin\varphi = (\tan\psi - 1)/(\tan\psi + 1)$$
$$c = \sigma_c(1 - \sin\varphi)/2\cos\varphi$$

The value of σ_c may not be the same as the UCS value. This is because the confined samples typically fail by shear, whereas the unconfined samples may fail by axial splitting.

The tensile intercept, σ_T, equals $2c\cos\phi/(1 + \sin\phi)$. When measured in the laboratory, the tensile strength is often lower than this, and it is common practice to specify a tensile cutoff T_0. Recognizing the presence of discontinuities, it is prudent to set T_0 to zero for rock masses.



The empirical basis for a straight-line fit is not strong, but there is a legacy of widespread use because of the simplicity of the parameters and the ability to make an analogy with soil strengths. The Mohr–Coulomb criterion is often implemented by a line of best fit over an appropriate stress range—this is a valid response to the nonlinearity, provided the stress range is adequately assessed.

Hoek–Brown criterion. The empirical Hoek–Brown failure criterion was developed in response to observations that the failure envelope of rock is not linear. It states that

$$\sigma_1 = \sigma_3 + (m\sigma_c\sigma_1 + s\sigma_c^2)^a$$

where

m = a value that reflects lithology (Table 8.4-3)
s = 1.0

Source: Diederichs et al. 2004, with permission from Elsevier.

Figure 8.4-7 A failure criterion incorporating brittle failure, spalling limits, and Hoek–Brown components

$a = 0.5$ for intact rock

This criterion has been subsequently extended to rock masses.

For intact rock, the implication is that $\sigma_T = \sigma_c/m$. There is typically no provision in computer software to override this with T_0 = zero.

This criterion has been widely adopted, perhaps in part because of the absence of an alternative. It has been refined several times and now forms the basis of the generalized Hoek–Brown criterion for rock masses (discussed later). Recent work suggests that this criterion should not be applied in the immediate vicinity of excavations.

Brittle failure criterion. The onset of damage around an excavation is poorly predicted with the standard Hoek–Brown criterion, and it is better modeled with a set of revised parameters such as $m = 0.0$ and $s = 0.11$ (Martin et al. 1991). This is equivalent to a cohesion value of UCS/6 to UCS/4 and a friction angle of zero degrees if the Mohr–Coulomb criterion is used.

Subsequently, the following tri-linear envelope (Figure 8.4-7) has been proposed (Kaiser et al. 2000):

- $\sigma_1 - \sigma_3$ = deviatoric stress = $\sqrt{s}\ \sigma_c$, where s is in the range of 0.11 to 0.25
- σ_1/σ_3 = spalling limit = 20:1 to less than 3.4:1
- Hoek–Brown line at higher stresses

This failure criterion has been found to predict the onset and depth of failure in the vicinity of excavation boundaries in metaliferous mines, tunnels, and underground coal mines. One advantage of the criterion is that the onset of failure is a function of the ratio of one strength parameter (the UCS) to the major principal stress, and this allows ready normalization.

The full criterion is not yet implemented in numerical codes, so the current advice is to run two sets of analyses (Kaiser and Kim 2008)—one for the excavation boundary using the $m = 0$ relationship and a second for the far field (greater than, for instance, 10 m from the boundary) using the standard Hoek–Brown rock-mass criterion (discussed later). Particularly in coal measures, there is a need to run a third analysis using the spalling limit portion of the criterion, and it may be that spalling limits as low as 3.4 need to be assessed. The $m = 0$, $s = 0.11$ form of the criterion infers artificially large tensile strengths. Until the full implementation of the criterion is available in numerical codes, it may be preferable to use the Mohr–Coulomb form, as software codes usually allow a tensile strength cutoff that can be set to zero.

Post-Peak or Yielding Behavior

Referring to Figure 8.4-7, a stress state cannot exist in a rock or rock mass above any of the failure criteria. In elastic models, the separation of the stress field from the failure criterion is expressed as some sort of strength factor. Alternatively, the post-peak or post-failure behavior can be considered in nonlinear models. This is an advanced area of rock mechanics and outside the scope of this chapter. The term *yield* is often used in this context—this is not strictly correct unless the assumption of perfect linear-elastic behavior is valid, but it is a convenient and common usage. Some very general guidance is available.

Figure 8.4-5 illustrates the following four post-peak behaviors: brittle, strain softening, plastic, and strain hardening.

Implementation in numerical codes requires failure parameters, a dilation angle, and strength parameters in the post-peak range, and there is very little experimental data to support the selection of the latter two parameters (Table 8.4-5). There are precedents in using the elastic-plastic assumption. Post-peak behavior can only be implemented in continuum numerical codes if the rock is assumed to be isotropic. Post-peak behavior is explicitly considered if slip along joints is implemented in a numerical model. Calibration of any

Table 8.4-5 Possible post-peak parameters

	Brittle	Strain Softening	Elastic Plastic
Dilation angle	φ/4	φ/8	0
Cohesive strength	0	UCS/2	UCS
Deformation modulus	E/4	E/2	E

Source: Adapted from Hoek and Brown 1997.

models that consider post-peak behavior is strongly advised. Application of any models outside conditions against which they have been calibrated should be done with great caution.

ROCK MASSES

Some mining problems are at such a scale that a large volume of the rock mass must be considered. There are two approaches to assess the performance of rock masses. One approach is the classical rock mass classification route that bypasses the need for any analysis of modes of behavior. A more recent approach has been to assume that the rock mass is so impacted by discontinuities that it can be considered to be a continuum and to then use a rock mass classification to generate equivalent strength and deformation parameters.

RMR and Q System

Rock mass classification systems seek to apply a single numerical value to describe the condition of rock masses based on a consideration of what are believed to be key parameters controlling behavior. Two of the most popular systems are the rock mass rating (RMR) of Bieniawski (1973, 1976, 1989), which has been revised several times, and the Q system (Barton et al. 1974). In both systems, the UCS of the rock plays a relatively minor part in the characterization reflecting the origin of the systems in what have been referred to as "hard" rock. Commentaries on the application of both systems often state that they are suitable for hard rock—unfortunately, *hard* is not defined. It is quite possible that *hard* may refer to intact rock strengths in excess of about 50 to 75 MPa. The rock mass classification approach is ideally suited for situations where the failure process is controlled by sliding and rotation of intact rock pieces; this approach is less reliable for squeezing, swelling, spalling, or slabbing ground or for rock bursting under very high stresses (Marinos et al. 2005). The RMR adds together scores for UCS, RQD, joint spacing and condition, and groundwater to get a value out of 100 (Table 8.4-6). The precision of the system is in the order of ±10 units, as reflected in the definition of five grades of rock. The most common application is in the identification of stand-up times. A related system has been developed for coal measures (Molinda and Mark 1994). There is also an application of RMR to slope stability (Romana 1993).

The Q system is based on multiplying three ratios that are considered to reflect block size, inter-block frictional strength, and the active stress.

$$Q = \left(\frac{\text{RQD}}{J_n}\right)\left(\frac{J_r}{J_a}\right)\left(\frac{J_w}{\text{SRF}}\right)$$

where

RQD = percentage of the core of a rock mass unit in lengths greater than 100 mm
J_n = joint set number (varies between 0.5 and 20)
J_r = joint roughness number (varies between 0.5 for slickensided and 5 for nonpersistent widely spaced)
J_a = joint alteration number (varies between 0.75 and 20)
J_w = joint water reduction factor (varies between 0.05 and 1.0)
SRF = stress reduction factor (varies from 0.5 for high stress and 20 for heavy squeezing)

The quantification of these parameters is listed in Table 8.4-7.

The resulting Q score can vary from 0.001 to 1,000, and with each of the three ratios varying over two to three orders of magnitude. The Q system is in common use for the specification of ground support in tunnels, assessments of the stability of raise-bored shafts, and in stope designs in underground metal mines. It has not been used extensively in underground coal mines.

Given the simplicity of the methods, both classifications should be used separately. The two methods are fundamentally different in that RMR considers only strength, whereas Q seeks to classify performance as it includes a stress term. In some applications the J_w/SRF term is set to unity, so as to reflect only rock mass strength—the resulting parameter is referred to as Q'. There have been numerous papers that seek to relate RMR values to Q values, but this is considered poor practice.

Any use of rock classification schemes should note the following warning issued by Brady and Brown (2004): "Although the use of this approach is superficially attractive, it has a number of serious shortcomings and must be used only with extreme care. The classification scheme does not always fully evaluate important aspects of a problem, so that if blindly applied without supporting analysis of the mechanics of the problem, it can lead to disastrous results."

Rock mass classification schemes are a valuable aid for assessing the likely impact of rock behavior on other aspects of a mining venture—they are particularly useful for initial scoping studies. They should not be relied on in the operational phase and can be misleading in the feasibility stage if not used in combination with other analytical techniques. As implied by Brady and Brown (2004) and many other workers, the key to good implementation is to first obtain site-specific data on the nature and behavior of the particular rock mass as soon as possible and then start analyzing the candidate behavior mechanisms.

Geological Strength Index

A relatively recent use of the rock mass classification systems, particularly the RMR, has been to use it to quantify the parameters required by a CHILE assumption for a rock mass (Hoek and Brown 1997). Since its introduction, this approach has become very popular and tends to be used without adequate consideration of its limitations. First, the scale of the excavation must be such that the consideration is either of the intact rock itself or of a very large volume with sufficient discontinuities such that an equivalent continuum is present. The implication of the intact rock scale is that one is dealing with a situation near the excavation boundary, where the brittle parameters ($m = 0.0$, $s = 0.11$) are more valid. At the other end of the scale, there is a need to ensure that throughgoing geological structures (Figure 8.4-1) are not present so as not to dominate behavior and make the continuum assumption invalid.

The method of determining the geological strength index (GSI) has been summarized in a number of cross plots (e.g., Figure 8.4-8) where consideration of the discontinuities is

Table 8.4-6 RMR classification system*

A. Classification Parameters and Their Ratings

	Parameter		Range of Values						
1	Strength of intact rock material	Point-load strength index	>10 MPa	4–10 MPa	2–4 MPa	1–2 MPa	For this low range, uniaxial compressive tests are preferred		
		Uniaxial compressive strength	>250 MPa	100–250 MPa	50–100 MPa	25–50 MPa	5–25 MPa	1–5 MPa	<1 MPa
	Rating		15	12	7	4	2	1	0
2	Drill core quality RQD		90%–100%	75%–90%	50%–75%	25%–50%	<25%		
	Rating		20	17	13	8	3		
3	Spacing of discontinuities		>2 m	0.6–2 m	200–600 mm	60–200 mm	<60 mm		
	Rating		20	15	10	8	5		
4	Condition of discontinuities (see E)		Very rough surfaces; not continuous, no separation; unweathered wall rock	Slightly rough surfaces; separation <1 mm; slightly weathered walls	Slightly rough surfaces; separation <1 mm, highly weathered walls	Slickensided surfaces or gouge <5 mm, thick or separation 1–5 mm; continuous	Soft gouge >5 mm thick or separation >5 mm; continuous		
	Rating		30	25	20	10	0		
5	Groundwater	Inflow per 10-m tunnel length, L/min	None	<10	10–25	25–125	>125		
		(joint water press)/ (major principle σ)	0	<0.1	0.1–0.2	0.2–0.5	>0.5		
		General conditions	Completely dry	Damp	Wet	Dripping	Flowing		
	Rating		15	10	7	4	0		

B. Rating Adjustment for Discontinuity Orientations (See F)

Strike and dip orientations		Very favorable	Favorable	Fair	Unfavorable	Very unfavorable
Ratings	Tunnels and mines	0	–2	–5	–10	–12
	Foundations	0	–2	–7	–15	–25
	Slopes	0	–5	–25	–50	–

C. Rock Mass Classes Determined from Total Ratings

Rating	100 ← 81	80 ← 61	60 ← 41	40 ← 21	<21
Class number	I	II	III	IV	V
Description	Very good rock	Good rock	Fair rock	Poor rock	Very poor rock

D. Meaning of Rock Classes

Class number	I	II	III	IV	V
Average stand-up time	20 years for 15-m span	1 year for 10-m span	1 week for 5-m span	10 hours for 2.5-m span	30 minutes for 1-m span
Cohesion of rock mass, kPa	>400	300–400	200–300	100–200	<100
Friction angle of rock mass, degrees	>45	35–45	25–35	15–25	<15

E. Guidelines for Classification of Discontinuity Conditions

Discontinuity length (persistence) Rating	<1 m 6	1–3 m 4	3–10 m 2	10–20 m 1	>20 m 0
Separation (aperture) Rating	None 6	<0.1 mm 5	0.1–1.0 mm 4	1–5 mm 1	>5 mm 0
Roughness Rating	Very rough 6	Rough 5	Slightly rough 3	Smooth 1	Slickensided 0
Infilling (gouge) Rating	None 6	Hard filling <5 mm 4	Hard filling >5 mm 2	Soft filling <5mm 2	Soft filling >5 mm 0
Weathering Rating	Unweathered 6	Slightly weathered 5	Moderately weathered 3	Highly weathered 1	Decomposed 0

F. Effect of Discontinuity Strike and Dip Orientation In Tunneling

Strike Perpendicular to Tunnel Axis		Strike Parallel to Tunnel Axis	
Drive with dip: Dip 45°–90°	Drive with dip: Dip 20°–45°	Dip 45°–90°	Dip 20°–45°
Very favorable	Favorable	Very favorable	Fair
Drive against dip: Dip 45°–90°	Drive against dip: Dip 20°–45°	Dip 0°–20°, irrespective of strike	
Fair	Unfavorable	Fair	

Source: Hoek et al. 1998.

*Some conditions are mutually exclusive. For example, if infilling is present, the roughness of the surface will be overshadowed by the influence of the gouge. In such cases, use A.4 directly.

Table 8.4-7 Q-system parameter values

Description	Value	ϕr degrees (approx.)	Notes
1. Rock Quality Designation	***RQD***		
A. Very poor	0–25		1. Where RQD is reported or measured as ≤10 (including 0), a nominal value of 10 is used to evaluate Q.
B. Poor	25–50		2. RQD intervals of 5 (i.e., 100, 95, 90, etc.) are sufficiently accurate.
C. Fair	50–75		
D. Good	75–90		
E. Excellent	90–100		
2. Joint Set Number	J_n		
A. Massive, no or few joints	0.5–1.0		1. For intersections, use ($3.0 \times J_n$).
B. One joint set	2		2. For portals, use ($2.0 \times J_n$).
C. One joint set plus random	3		
D. Two joint sets	4		
E. Two joint sets plus random	6		
F. Three joint sets	9		
G. Three joint sets plus random	12		
H. Four or more joint sets, random, heavily jointed, "sugar cube," etc.	15		
I. Crushed rock, earthlike	20		
3. Joint Roughness Number	J_r		
a. Rock wall contact			1. Add 1.0 if the mean spacing of the relevant joint set is greater than 3 m.
b. Rock wall contact before 10-cm shear			2. $J_r = 0.5$ can be used for planar, slickensided joints having lineations, provided that the lineations are oriented for minimum strength.
A. Discontinuous joints	4		
B. Rough and irregular, undulating	3		
C. Smooth undulating	2		
D. Slickensided undulating	1.5		
E. Rough or irregular, planar	1.5		
F. Smooth, planar	1		
G. Slickensided, planar	0.5		
c. No rock wall contact when sheared			
H. Zones containing clay minerals thick enough to prevent rock wall contact	1.0 (nominal)		
I. Sandy, gravely, or crushed zone thick enough to prevent rock wall contact	1.0 (nominal)		
4. Joint Alteration Number	J_a	ϕr degrees (approx.)	
a. Rock wall contact			1. Values of ϕr, the residual friction angle, are not intended as an approximate guide to the mineralogical properties of the alteration products, if present.
A. Tightly healed, hard, nonsoftening, impermeable filling	0.75		
B. Unaltered joint walls, surface staining only	1.0	25–35	
C. Slightly altered joint walls, nonsoftening mineral coatings, sandy particles, clay-free disintegrated rock, etc.	2.0	25–30	
D. Silty- or sandy-clay coatings, small clay fraction (nonsoftening)	3.0	20–25	
E. Softening or low-friction clay mineral coatings (i.e., kaolinite, mica). Also chlorite, talc, gypsum, graphite, etc., and small quantities of swelling clays (discontinuous coatings, 1–2 mm or less).	4.0	8–16	
b. Rock wall contact before 10-cm shear			
F. Sandy particles, clay-free, disintegrating rock, etc.	4.0	25–30	
G. Strongly over-consolidated, nonsoftening clay mineral fillings (continuous <5 mm thick)	6.0	16–24	
H. Medium or low over-consolidation, softening clay mineral fillings (continuous <5 mm thick)	8.0	12–16	
I. Swelling clay fillings (i.e., montmorillonite; continuous <5 mm thick). Values of J_a depend on percentage of swelling clay-size particles and access to water.	8.0–12.0	6–12	

(continues)

Table 8.4-7 Q-system parameter values (continued)

Description	Value		Notes
4. Joint Alteration Number (continued)	J_a	ϕr degrees (approx.)	
c. No rock wall contact when sheared			
J. Strongly over-consolidated, nonsoftening clay mineral fillings (continuous <5 mm thick)	6.0		
K. Medium or low over-consolidation, softening clay mineral fillings (continuous <5 mm thick)	8.0		
L. Swelling clay fillings (i.e., montmorillonite; continuous <5 mm thick). Values of J_a depend on percentage of swelling clay-size particles and access to water.	8.0–12.0	6–24	
M. Zones or bands of silty- or sandy-clay, small clay fraction, nonsoftening	5.0		
N. Thick continuous zones or bands of clay	10.0–13.0		
O. and P. (see G, H, and I for clay conditions)	6.0–24.0		
5. Joint Water Reduction	J_W	**Approx. Water Pressure (kgf/cm²)**	
A. Dry excavation or minor inflow (i.e., <5 L/m locally)	1.0	<1.0	1. Factors C to F are crude estimates: increase JW if drainage installed.
B. Medium inflow or pressure, occasional outwash of joint fillings	0.66	1.0–2.5	2. Special problems caused by ice formation are not considered.
C. Large inflow or high pressure in competent rock with unfilled joints	0.5	2.5–10.0	
D. Large inflow or high pressure	0.33	2.5–10.0	
E. Exceptionally high inflow or pressure at blasting, decaying with time	0.2–0.1	>10	
F. Exceptionally high inflow or pressure	0.1–0.05	>10	
6. Stress Reduction Factor	***SRF***		
a. Weakness zones intersecting excavation, which may cause loosening of rock mass when tunnel is excavated			1. Reduce these values of SRF by 25%–50%, but only if the relevant shear zone influences do not intersect the excavation.
A. Multiple occurrences of weakness zones containing clay or chemically disintegrated rock, very loose surrounding rock (any depth)	10.0		2. For strongly anisotropic virgin stress field (if measured): when $5 \le \sigma_1/\sigma_3 \le 10$, reduce σ_c to 0.8 σ_c and σ_t to 0.8 σ_t. When $\sigma_1/\sigma_3 > 10$, reduce σ_c and σ_t to 0.6 σ_c and 0.6 σ_t, where σ_c = unconfined compressive strength, and σ_t = tensile strength (point load), and σ_1 and σ_3 are the major and minor principal stresses.
B. Single weakness zones containing clay, or chemically disintegrated rock (excavation depth <50 m)	5.0		
C. Single weakness zones containing clay, or chemically disintegrated rock (excavation depth >50 m)	2.5		3. Few case records available where depth of crown below surface is less than span width. Suggest SRF increase from 2.5 to 5 for such cases (see H).
D. Multiple shear zones in competent rock (clay free) loose surrounding rock (any depth)	7.5		
E. Single shear zone in competent rock (clay free) (depth of excavation <50 m)	5.0		
F. Single shear zone in competent rock (clay free) (depth of excavation >50 m)	2.5		
G. Loose open joints, heavily jointed or "sugar cube" (any depth)	5.0		
b. Competent rock, rock stress problems	σ_c/σ_1	σ_t/σ_1	***SRF***
H. Low stress, near surface	>200	>13	2.5
I. Medium stress	200–10	13–0.66	1.0
J. High stress, very tight structure (usually favorable to stability, may be unfavorable to wall stability)	10–5	0.66–0.33	0.5–2

Notes: When making estimates of the rock mass quality (Q), the following guidelines should be followed in addition to the notes listed in the tables:

1. When borehole core is unavailable, RQD can be estimated from the number of joints per unit volume, in which the number of joints per meter for each joint set are added. A simple relationship can be used to convert this number to RQD for the case of clay-free rock masses: RQD = 115 – 3.3J_V (approx.), where J_V = total number of joints per cubic meter (0 < RQD < 100 for 35 > J_V > 4.5).
2. The parameter J_n, representing the number of joint sets, will often be affected by foliation, schistosity, slaty cleavage or bedding, etc. If strongly developed, these parallel "joints" should obviously be counted as a complete joint set. However, if there are few "joints" visible, or if only occasional breaks in the core are due to these features, then it will be more appropriate to count them as "random" joints when evaluating J_n.
3. The parameters J_r and J_a (representing shear strength) should be relevant to the weakest significant joint set or clay-filled discontinuity in the given zone. However, if the joint set or discontinuity with the minimum value of J_r/J_a is favorably oriented for stability, then a second, less favorably oriented joint set or discontinuity may sometimes be more significant, and its higher value of J_r/J_a should be used when evaluating Q. The value of J_r/J_a should in fact relate to the surface most likely to allow failure to initiate.
4. When a rock mass contains clay, the factor SRF appropriate to loosening loads should be evaluated. In such cases the strength of the intact rock is of little interest. However, when jointing is minimal and clay is completely absent, the strength of the intact rock may become the weakest link, and the stability will then depend on the ratio rock-stress/rock-strength. A strongly anisotropic stress field is unfavorable for stability and is roughly accounted for as in the second note in the table for stress reduction factor evaluation.
5. The compressive and tensile strengths (σ_c and σ_t) of the intact rock should be evaluated in the saturated condition if this is appropriate to the present and future in-situ conditions. A very conservative estimate of the strength should be made for those rocks that deteriorate when exposed to moist or saturated conditions.

reduced to one factor referred to as the surface condition. The various plots suggest that a precision of ±2.5 points may be the best possible (this is assessed to be highly optimistic), a precision of ±5 is likely to be the best, and a precision of ±10 is a more typical result. For RMR values in excess of 18 and 23, respectively, the GSI is numerically equal to the RMR value if the latter is calculated with the 1976 version or equal to the 1989 version less 5 points. When lower values of the GSI are indicated, the GSI can be estimated from Q' as follows:

$$\text{GSI} = 9\ \text{Ln}Q' + 44$$

The GSI is input to the generalized Hoek–Brown criterion, whereby the values of the m, s, and a parameters are given by the following equations, respectively:

$$m_b = m_i e^{\left(\text{GSI} - \frac{100}{28} - 14D\right)}$$

$$s = e^{\left(\text{GSI} - \frac{100}{9} - 3D\right)}$$

$$a = 0.5 + \left(e^{-\frac{\text{GSI}}{15}} - e^{-\frac{20}{3}}\right)/6$$

where

m_b = rock mass
m_i = intact laboratory-scale rock
D = disturbance factor, ranging from 0.0 for mechanical excavation to 1.0 for large-scale surface blasts

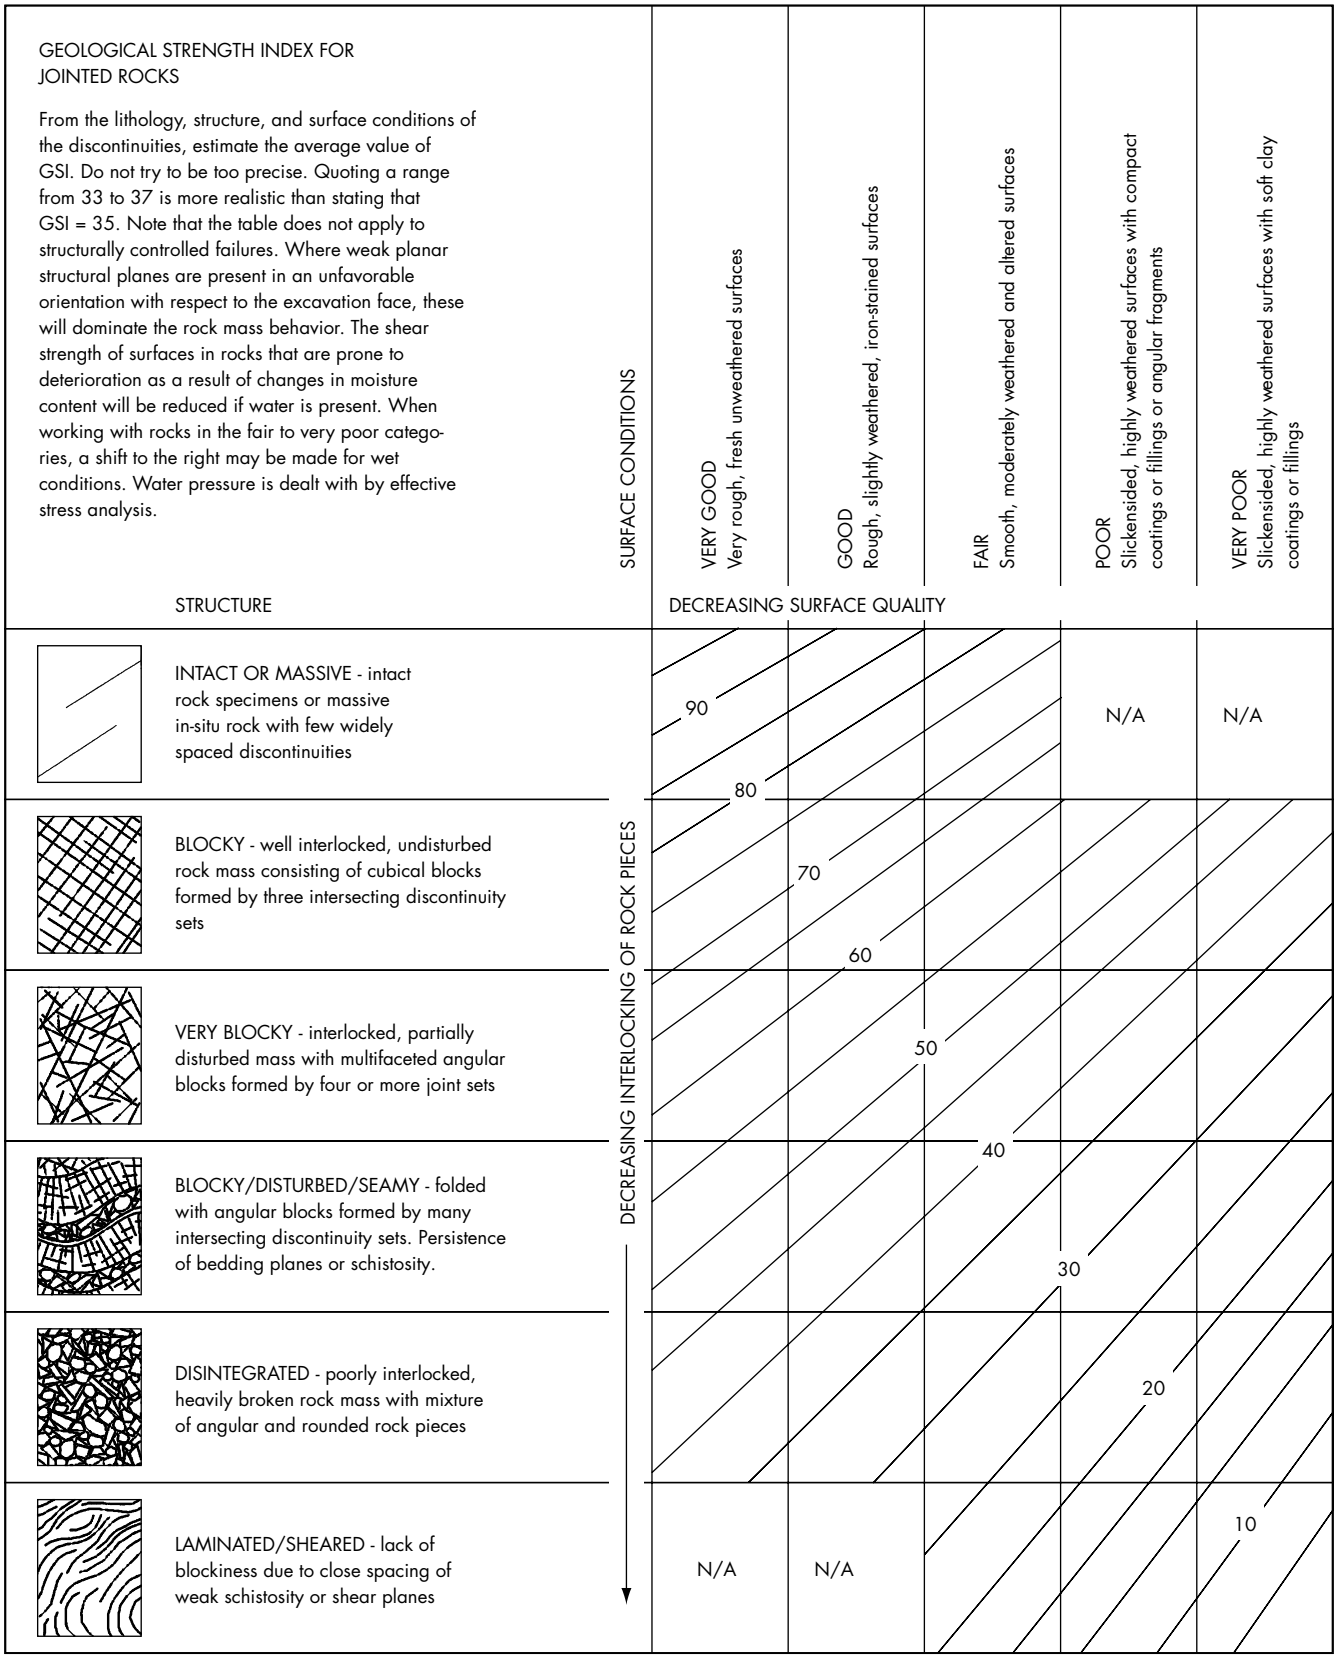
An indication of the sensitivity of the key strength and deformation parameters to the GSI value is given in Figure 8.4-9. The cohesion and tensile and unconfined compressive strengths drop rapidly with GSIs between 100 and 70. Depending on the GSI value, the precision of the estimates of the various parameters is in the range of 10% to 50%.

A number of cautions apply (Marinos et al. 2005). Firstly, there is the question of scale and the applicability of the mass criterion as discussed earlier. Secondly, the method gives a non-zero tensile strength that may not be justifiable in the case of discontinuous rock masses. Thirdly, the surface condition is independent of the UCS of the rock, which is counter to the JRC concepts for shear strength. It is possible that this is implicit in some of the other cross plots, for example, the one for flysch that is included in RocLab (a software program from Rocscience, Inc., for determining rock mass strength parameters based on the generalized Hoek–Brown failure criteria). Flysch is a sedimentary rock deposited in the marine environment; it is possibly a "soft" rock. It may be necessary to reduce the GSI by about 15 units if it is being applied to soft rock. And finally, there are concerns about the disturbance factor. The depth of blasting damage may be in the order of a few meters for most blasts. At this scale, which is that of a roadway or a bench, the Hoek–Brown criterion probably should not be applied.

Deformation Parameters

A number of analyses require values for the deformation modulus of rock masses as well as their strength.

Before the GSI system, the rock mass modulus (Erm) was determined directly from the RMR without reference to values measured in the laboratory. Such relationships could produce a modulus value that exceeds that measured in the laboratory for rocks with UCS values less than around 100 MPa. This problem is perhaps another reflection of the RMR system being applicable to hard rocks and not necessarily to soft rocks.



The GSI provides a system for estimating the rock mass modulus that is based on factoring down the laboratory value (Hoek and Diederichs 2006), as in the following equation:

$$\text{Erm} = \text{Ei}\left(0.02 + \frac{1 - D/2}{1 + \text{e}^{((60 + 15D - GSI)/11)}}\right)$$

There is no guidance on the Poisson's ratio for rock masses.

Interaction with Water

There are both chemical and physical deteriorations of rock mass strength with the presence of water. The presence of water, especially when combined with oxygen introduced by

Source: Brady and Brown 2004, reprinted with permission from Springer Science and Business Media.

Figure 8.4-8 Estimating the geological strength index

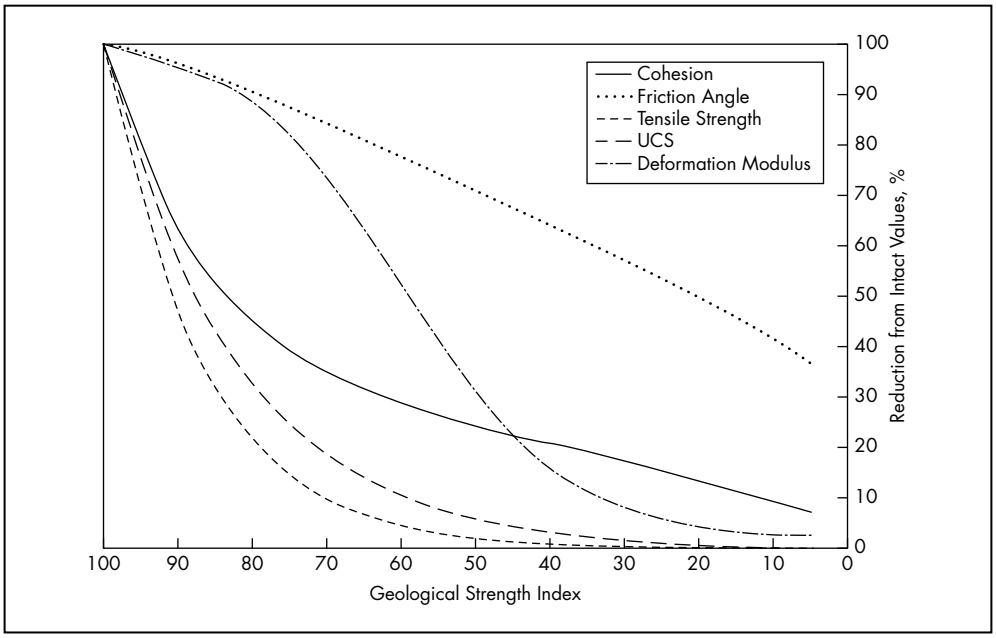


Figure 8.4-9 Sensitivity of rock mass parameters to changes in the GSI value (m_i = 10, D = 0.0)

exposure to the atmosphere, can lead to major changes in rock strength—and usually strength reductions.

Water pressures in the immediate vicinity of mine excavations are often (but not always) reduced to zero, either because free-flowing water is a nuisance underground or because drainage is critical to slope stability in the surface mines. Because of this, it is conventional in mining rock mechanics to consider stresses in terms of total (applied) stresses.

There are some applications where the principle of effective stress needs to be considered. Effective stress equals the total stress minus the pore pressure. In the context of shear along discontinuities, the pore pressure can reduce the normal stress, and hence, it can reduce the shear resistance; this is important behavior in rock slope stability. In addition, low modulus rocks that are also aquifers may undergo significant deformations during depressurization, such that the stress field is altered immediately ahead of the excavation compared to that of the far-field condition. This effect has been identified in porous sandstones and possibly in coal (Seedsman 2004).

STRESSES

Rock and rock masses deform and collapse in response to self-weight and applied stresses. Self-weight is the stress driver for planar and wedge failures and is ultimately the driver for most collapse modes. There are some closed-form solutions for the redistribution of applied stress around simple excavations. Since the 1980s and building on the availability of personal computers, there have been huge advances in the scope and capability of computational methods to study the distribution of stresses around excavations in both two and three dimensions, with the important proviso that the material can be considered to be linear elastic. Boundary element, finite element, distinct element, and finite difference are merely different computational methods to solve the same complex equations, and each has strengths and weaknesses.

In contrast to civil excavations, mining ventures seek to operate at the limit of elastic behavior, if not beyond, so long as the workplace is safe and the business risks are acceptable. Because of the inability to adequately characterize the post-peak behavior of rock, many mining problems are beyond the capacity of even the most complex numerical codes.

Computational methods require knowledge of the stress field that was acting prior to mining. There are now several tools to measure or estimate this stress field. The stress field that is measured is itself a function of the properties of the rock mass in the immediate vicinity to which it is measured. It is unlikely that the stress field can be adequately characterized prior to mining. Close observations of early excavations are still required, and it is essential that the interpretation of the stress field does not become distorted by the models that are applied. Most observations are of deformations, and this means that any calibration of the stress models includes assumptions not only on the deformation properties of the rock but also the stress redistribution about the excavation.

Nature of Stresses and Stress Equations

The rock in which mining is conducted is stressed by forces associated with the gravitational weight of the overlying rock, tectonic stresses, and residual stresses related to earlier changes in depth of burial and rock temperature. In mining rock mechanics it is conventional practice to assume that pore pressures are zero close to the excavation. Soil mechanics is the field of engineering that concentrates on the implications of non-zero pore pressures, and while this subdivision is convenient, there are still many mining circumstances, such as with very weak and extremely weak rock, where the concepts of effective stress need to be invoked.

Any stress field is 3-D, and it is conventional to resolve the field into the three principal planes and their associated principal stresses. Principal planes are those planes on which there are no shear stresses acting, and by definition the principal stresses act normal to these planes. The faces of excavations and the earth's surface are free of shear stresses, and hence they are locally principal planes.

The terminology for stresses includes the following:

- σ_1, σ_2, and σ_3 are the major, intermediate, and minor principal stresses, respectively.
- Compressive stresses are taken as positive.
- σ_{xx}, σ_{yy}, and σ_{zz} are the magnitude of the stresses acting parallel to a local coordinate system.
- σ_p is the stress acting normal to a plane at an angle α to the coordinate system.
- σ_{ll} and σ_{mm} are the stresses acting in a plane.

In two dimensions, the following relationships can be of use:

$$\sigma_{ll} = 0.5(\sigma_{xx} + \sigma_{yy}) + 0.5(\sigma_{xx} - \sigma_{yy})\cos 2\alpha + \sigma_{xy}\sin 2\alpha$$
$$\sigma_{mm} = 0.5(\sigma_{xx} + \sigma_{yy}) - 0.5(\sigma_{xx} - \sigma_{yy})\cos 2\alpha - \sigma_{xy}\sin 2\alpha$$
$$\sigma_{lm} = \sigma_{xy}\cos 2\alpha - 0.5(\sigma_{xx} - \sigma_{yy})\sin 2\alpha$$
$$\alpha = \tan^{-1}\left(\frac{\sigma_p - \sigma_{xx}}{\sigma_{xy}}\right)$$

When considering the performance of rock, the concepts of mean stress, σ_m, and deviatoric stress are also useful. These are defined by the following equations:

$$\text{mean stress} = (\sigma_1 + \sigma_3)/2$$
$$\text{deviatoric stress} = \sigma_1 - \sigma_3$$

In-Situ Stresses

The World Stress Map (Heidbach et al. 2008) can be used to obtain an initial assessment of the direction of the major principal stress in a horizontal direction. A better estimate may be obtained if the structural geology of the deposit is known—the local stress field is highly likely to be aligned with one of the axes normal to any dominant throughgoing discontinuity. In fact with knowledge of the fault orientations and the associated fiction angles, it is possible to constrain the estimate of the stress field. In layered materials close to the surface (e.g., within 200 m), one of the horizontal stress axes must be parallel to the strike of the layers. If it develops, borehole breakout is a reliable indicator of stress directions that can now be readily determined using downhole tools.

Many researchers have made compilations of stress magnitudes with depth. Until more site-specific information is available, it is reasonable to assume as a first approximation that the vertical stress can be calculated from the depth of cover, and the major principal stress has a magnitude of between 0.3 and 2.5 times this vertical stress to a depth of 1,000 m and a magnitude of between 0.3 and 1.0 times this vertical stress below 1,000 m. It is emphasized that the stress magnitudes are not the result of the so-called Poisson's ratio effect. If stresses were considered to be applied in plane strain, then higher stress magnitudes would be found in the stiffer units. The stress field in coal is different to the stress field in the adjacent rock—part of this may be due to the stiffness contrast, but there is also a component that may be related to stress redistributions associated with volume changes as the coal is depressurized by mining. Stress magnitudes near faults will be less than at distant locations.

It is apparent that predicting the stress field before mining is difficult. There are several techniques for measuring the stresses prior to mining, but they are relatively expensive; and because of the same geological controls that make the stress field variable, it is possible that they will not be representative of the whole mine. Until in-mine observations are possible, the approach should be to combine any site data with inference of stress directions from an interpretation of the structural geology and to consider a range of stress ratios between 0.3 and 2.5. It is important not to ignore the possibility of low ratios, such as, for example, in coal mining.

Elastic Redistributions

The ready availability of numerical codes makes the calculation of stresses around excavations in two and three dimensions a relatively trivial exercise, providing that the material can be considered linear elastic. As the graphics are improved, the interpretation and understanding of the stress field in three dimensions is improving.

For metaliferous mines and tunnels excavated by drill-and-blast or by roadheaders, the mining methods tend to produce rounded corners, and the simplifying assumptions of circular and ellipsoidal holes are valuable simplifications.

For circular and elliptical holes, the stresses on the boundary are as follows:

$$\sigma_{\text{side}} = p(1 - K + 2q)$$
$$\sigma_{\text{crown}} = p(K - 1 + 2K/q)$$

where

K = ratio of stresses
$q = W/H$ (Figure 8.4-10)

Importantly, in linear-elastic theory, the redistribution of stresses is a function of the stress ratio and the aspect ratio and independent of the deformation properties, and this applies to all excavation shapes. Large excavations are less stable as a result of the greater likelihood of encountering discontinuities.

For circular openings, K values less than 0.33 induce tensile stresses in the crown, and for a W/H value of 2, a K value of 0.5 induces tensile stress in the crown. Recalling that a rock mass with discontinuities should be assumed to have zero tensile strength, the importance of induced tensile stresses cannot be overestimated. The onset of tensile stress should be considered to be the precursor to possible collapse that may develop rapidly and without warning.

The two equations suggest that there is an ability to modify the induced stresses by modifying the aspect ratio of an excavation—the maximum boundary stress can be reduced by having an aspect ratio similar to the stress ratio. It is unlikely that a mining operation will have such flexibility.

In coal mines, continuous miners result in rectangular roadways and if the seam is flat lying, two of the stress axes will be co-planar with the bedding. Typical elastic stress patterns in isotropic materials are shown in Figure 8.4-11 for a 6- × 1.5-m rectangular opening and for a circular opening for a 2:1 stress ratio. The following three stress components are of interest:

1. **Vertical stress, σ_{yy}:** Elevated stress can cause failure in the rib.
2. **Horizontal stress, σ_{xx}:** Low values could allow mobilization of vertical joints.
3. **Deviatoric stress, $\sigma_1 - \sigma_3$:** High values could cause compressive failure of the rock.

For the case where $K = 2.0$, the vertical stress at the upper corner of the excavation is increased by about 14%, and at the midpoint of the sides the vertical stress is reduced to about 60% of the initial value. The horizontal stress is increased by about 60% at the corner and reduced to 80% at the centerline of the roof. The deviatoric stress increases fourfold at

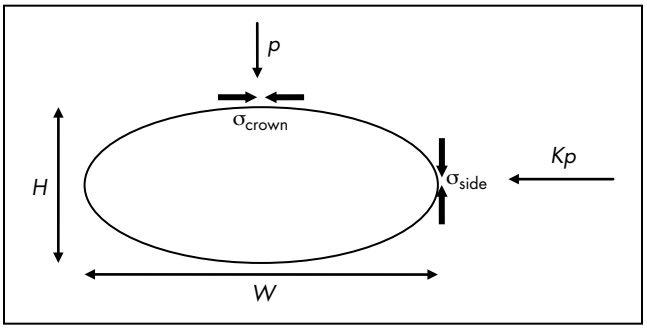

Figure 8.4-10 Definition of symbols used for the equations for stress around an elliptical hole

the corners and doubles at the centerline of the roof. Another characteristic is the tendency for the deviatoric stresses to arch over rectangular excavations, whereas they concentrate in the crown of a circular excavation.

Figure 8.4-11A and 8.4-11B shows the location of three points that are located 250 mm in from the boundary at the spring line and the crown and also 250 mm in the roof directly above the rib line. The relationships between the stress magnitudes at these three points with variations in the stress ratio and the aspect ratio of the roadway are shown in Figure 8.4-12. The following key observations can be made:

- The horizontal stresses in the roof become tensile at *K* values of about 0.6.
- The vertical stresses are higher and the horizontal stresses are lower for the excavation with the flatter aspect ratio.
- The deviatoric stresses for the rectangular roadways are between 2 to 3.5 times the vertical stress.
- The horizontal stresses at the crown of the circle are greater than at the roof centerline of the rectangular excavations.

For layered materials, the isotropic assumption can result in the anticipation of lower stresses than actually develop. For a condition where the value of independent shear modulus (G) is 1/100 of the isotropic value, the induced deviatoric stress within 0.5 m of the excavation boundary may be higher by approximately 50% for a rectangular excavation and 100% for a circular excavation.

The magnitude of the induced stresses decrease with the square of the distance from the excavation, so that at two diameters away the stress change is less than 5%. These simple elastic models readily demonstrate that large excavations can induce major changes in the stress field around adjacent smaller excavations. This is well recognized in metaliferous mining and is also a feature of longwall and pillar extraction in coal mines. The extraction of a cut-and-fill stope can result in temporary increases in stresses as the excavation approaches the level of access drives and then a relaxation of stresses as the extraction level rises (Figure 8.4-13). In a longwall, both the horizontal and vertical stresses increase at the face corner against unmined coal; in the tailgate adjacent to previously extracted coal, the horizontal stresses decrease and the vertical stresses increase.

An example of parametric analyses of the deviatoric stresses that can develop at the base of surface excavations is summarized in Figure 8.4-14. In these analyses, the stresses are generated by self-weight only, and the figure presents the

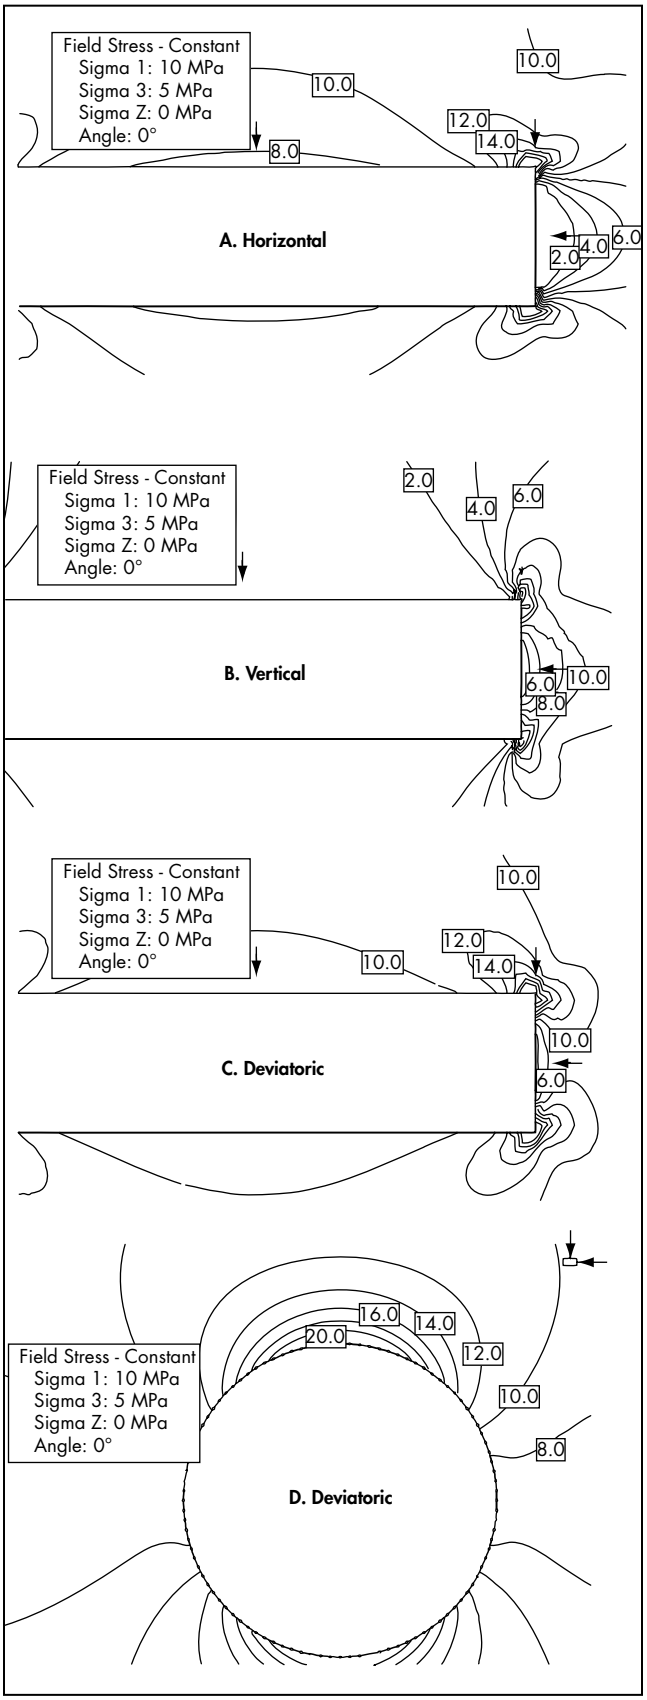

Figure 8.4-11 Distribution of stresses with rectangular roadways (A, B, and C) and with a circular excavation (D)

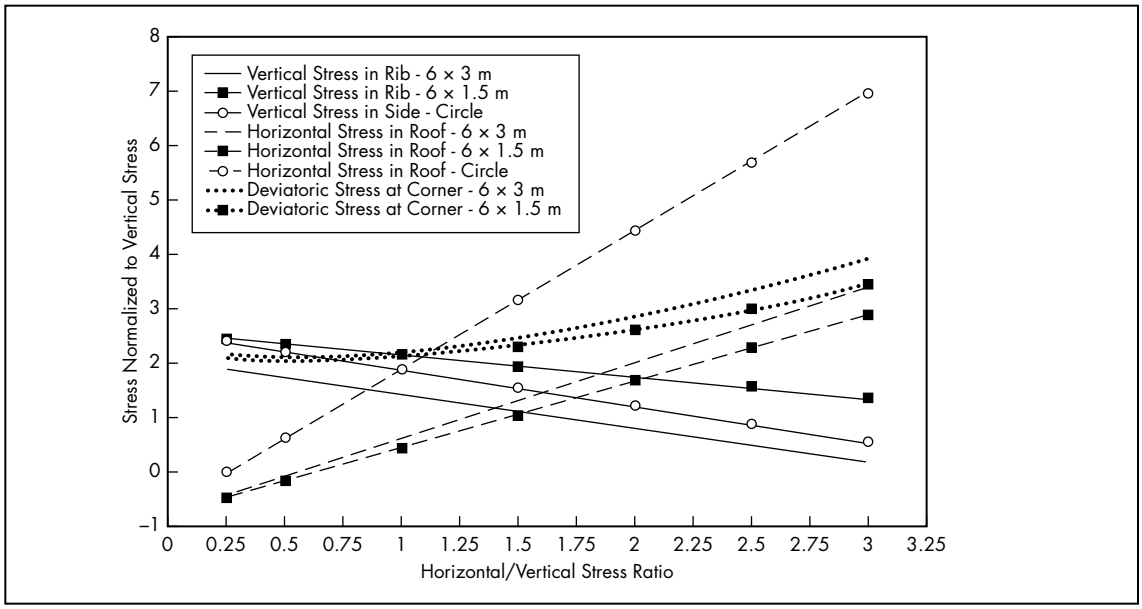

Figure 8.4-12 Variation in stress concentration factors with *K* ratio and aspect ratio of rectangular roadways

normalized stress magnitude along a line drawn vertically down at the toe. The normalization is based on the deviatoric stress that was present at the toe horizon prior to excavation. Depending on the face angle, the deviatoric stress can be concentrated two to three times, and the zone of influence is restricted to about 30% of the excavation height.

Nonelastic Behavior Around Excavations

Yielding

Yielding can result from either the peak strength of the rock being exceeded or shear along discontinuities being induced. Either way, movement is induced. In most mining situations, the applied stresses can be considered to be "stiff," such that they are redistributed elsewhere if the rock about the excavation moves beyond the elastic limit (Figure 8.4-15). The limit of elastic deformation is in the order of 10 mm. The implication is that after initial roadway formation, the stresses in the immediate roof should be assumed to be very low. This behavior, and the limitation of many computational methods to adequately manage it, is particularly important when roadways experience changes in stress conditions during their lifetime.

Stress relaxation can also occur in the roof if there is yielding or failure in the sides or floor of an excavation (Figure 8.4-15). In this case, the relaxation may be sufficient to induce the onset of tensile horizontal stresses and the mobilization of steep or vertically oriented joints. The amount of deformation that is required for relaxation of roof will be partly a function of the relaxation that has already developed in the roof. The hazard should be anticipated if the roadway defines a pillar that is designed to yield or if there is a low-strength floor horizon that may compress or fail.

Body Stresses

Recalling that rock masses are assemblages of blocks, if the blocks begin to rotate, they can interact and generate areas of high compressive stress, while in immediately adjacent areas there can be an opening of joints in response to localized tensile stress. An example of this is the voussoir beam mechanism (Sofianos and Kapenis 1998) that develops in a roof with no applied compressive stresses and yet failure can be via compression (Figure 8.4-16). Cantilevering behavior can also be anticipated in some layered materials. Both these two behaviors may generate compressive failure in the roof/rib corner at the same location as stress concentrations develop in linear-elastic codes. An implication of this is the need for an underground observer to be careful about inferring the nature of the applied stress field from simple observations—an analysis of likely stress magnitudes and rock strength is needed before the stress field can be inferred.

PRACTICAL IMPLEMENTATION OF ROCK MECHANICS

In many respects, this chapter highlights the many uncertainties that are inherent in the application of rock mechanics to mining. The general nature of these uncertainties is no different to those that face any engineering venture in soil or rock. Absolute guarantees of acceptable performance are not possible. The rock mechanics engineering profession has developed a number of strategies to manage the hazards and risks that are generated by the uncertainties of rock.

Observations and monitoring are recognized as an essential part of developing and applying empirical reasoning to any mine design. Recognizing the uncertainties of soil and rock, the observational method (Peck 1969) was introduced as a formalized process to manage contractual risks and to avoid latent condition claims. It requires full characterization of rock mass and prior assessment of likely and extreme conditions that may be encountered, such that pre-agreed responses are available. It is stressed that monitoring is not an alternative to fundamental design.

Because it requires detailed knowledge of conditions, the observational method should only be considered for specific well-constrained projects (both in time and geographically). It is obvious that the method cannot be applied to decisions of major capital expenditures prior to the operational phase. Bulk mining systems require very large daily production, and any unscheduled delays can have major cost impacts. It is possible

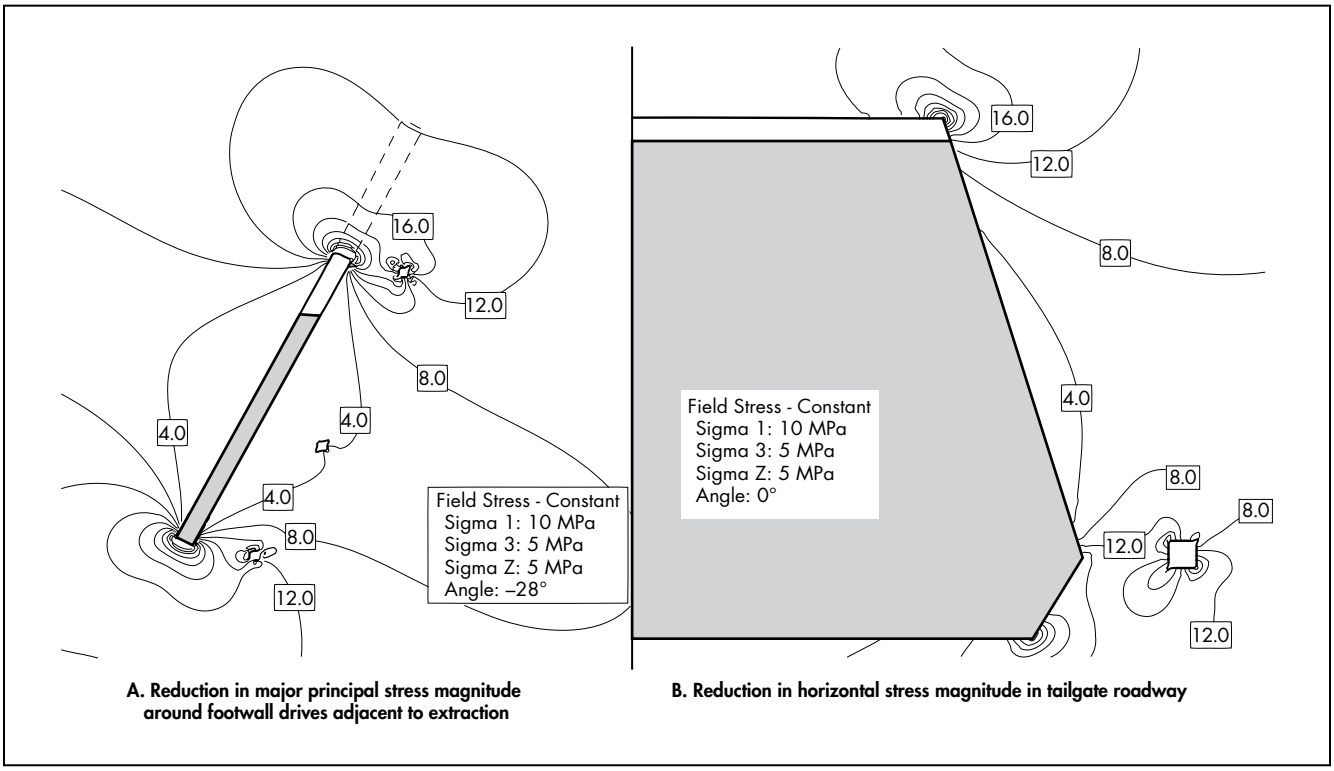

Figure 8.4-13 Large excavations result in large changes in stress regime at adjacent smaller excavation

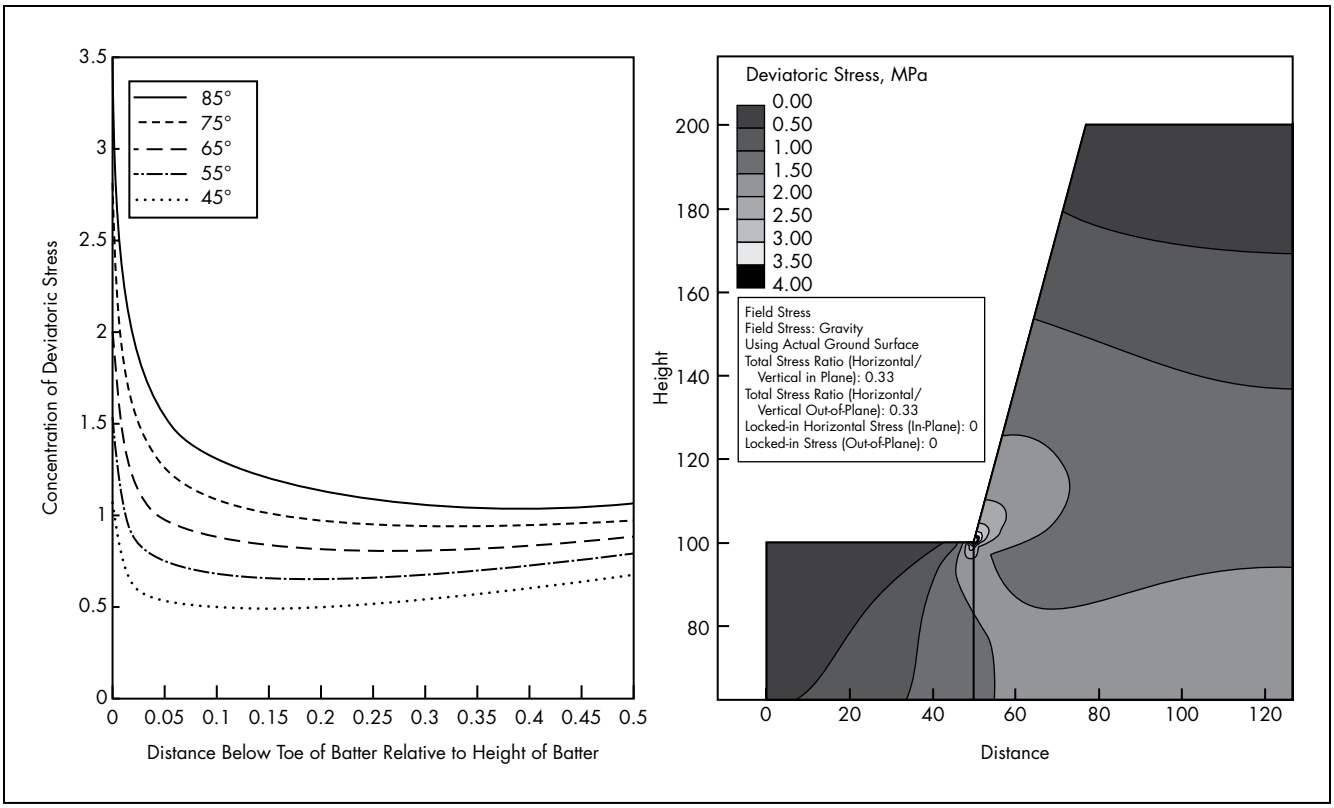

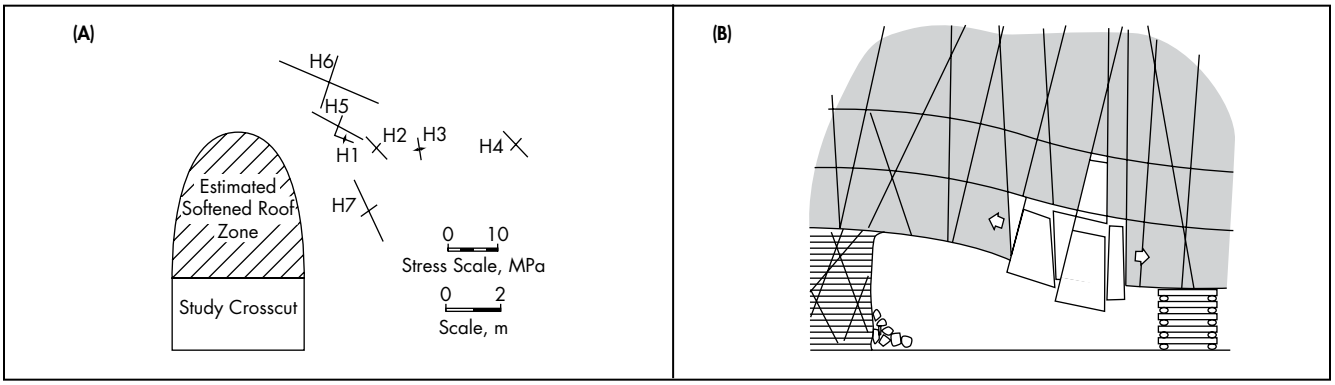

Figure 8.4-14 Elastic stresses around a surface excavation

Source: (A) Mark et al. 2007; (B) Diederichs and Kaiser 1999.

Figure 8.4-15 Redistribution of stresses if yield develops in roof or sides of roadway

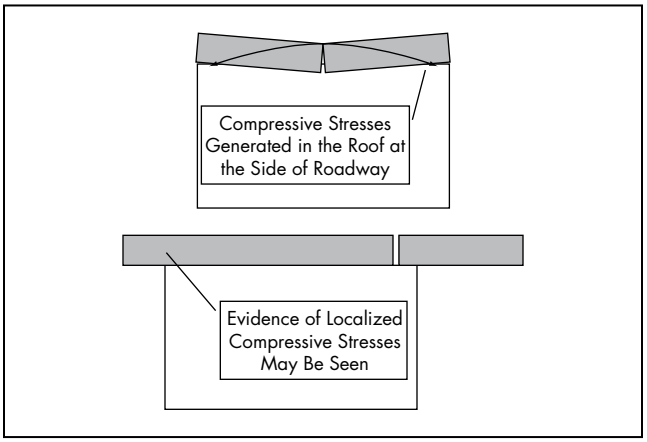

Figure 8.4-16 Roof deformations produce localized areas of compressive stress

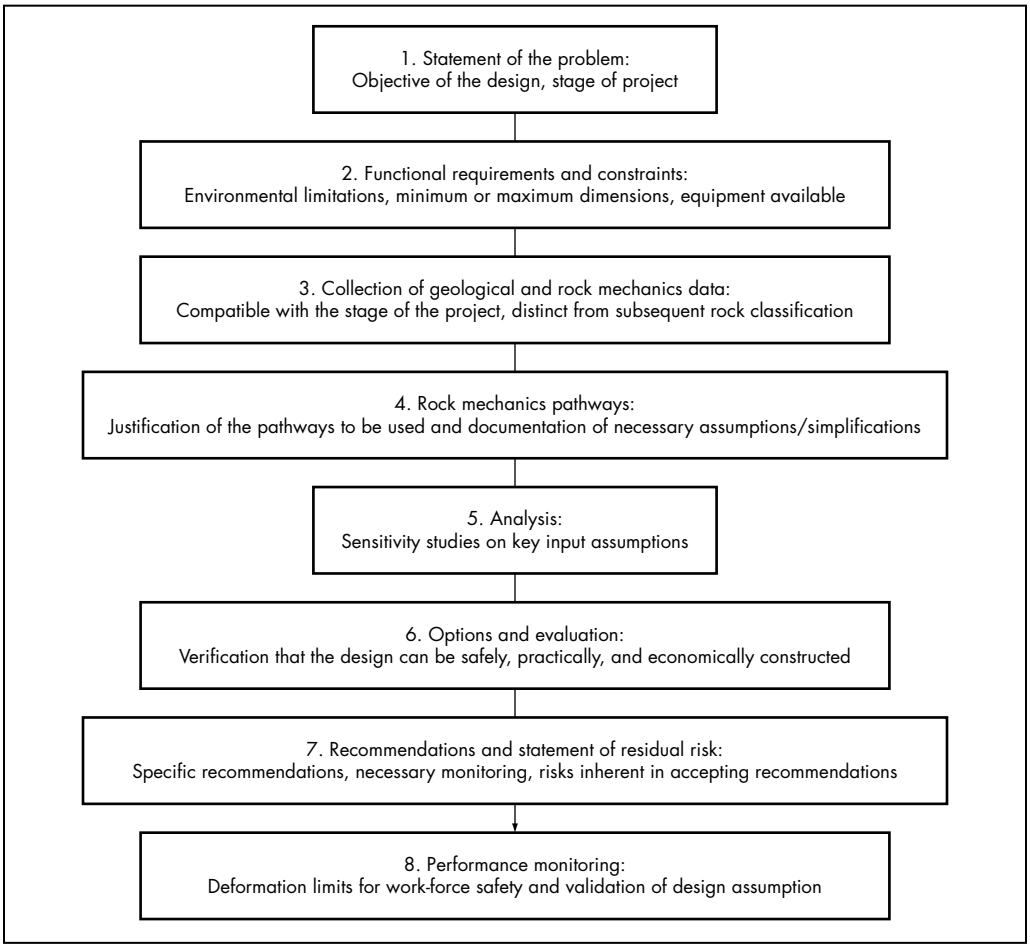
that bulk-mining systems should not consider the observational method as they can afford/demand greater geotechnical certainty that can be delivered by a worst-case design.

Monitoring to calibrate a complex numerical model may mean that in the initial stage of operations there is no "acceptable" design in place. Careful consideration of the safety and business implications of this is needed. Monitoring may also be required for triggered action response plans (TARPs), but these plans are principally about personnel safety with a secondary application of stepping between agreed support strategies as in the observational method. TARPs are an essential part of modern mining as they provide the rationale to evacuate a place, but they are not sufficient to ensure an adequate mining outcome if there is inadequate time to stabilize the ground.

An overreliance on the observational method and/or in-mine monitoring to validate designs can lead to poor business performance. What is needed is a rigorous design process for rock (Bieniawski 1993). The following are key aspects of the design methodology (Figure 8.4-17):

- Safety of the work force is the key requirement.
- There may be practical constraints to the ideal solution.
- As much geological data as possible should be collected and interrogated.
- Numerous pathways are available (Figure 8.4-2), and the choice of pathway must be justified.
- Uncertainties in the geological input requires sensitivity studies on the outcomes.
- A number of options with different levels of business risk may be identified.
- The final recommendations may carry residual business risk, which needs to be highlighted.
- Monitoring to confirm design assumptions may be additional and to separate from that required for TARPs.



The general methodology can be applied at all stages of a mining project with different pathways more applicable at different stages (Figure 8.4-3). Even within a single pathway there may be differences in how the analyses are conducted and what behavior models are used. The underlying principle is to maintain flexibility and be prepared to apply judgment if the analyses do not appear sensible—the state of the art is still not perfect.

Overall Mine Design

Because modern mining requires large capital investments, it is not valid to advocate the observational method for overall mine design. There must be a high level of confidence that the capital can be recovered within the indicated time line. A more conservative mine plan may be required initially until the uncertainties are understood; once the capital is recovered, the focus can then move to maximizing long-term revenue.

There are adequate tools to design the general size and shape of excavations in a mine. Computational methods in two and three dimensions using equivalent continuum assumptions and the generalized Hoek–Brown criterion are appropriate for underground metal mines. The simpler block geometry of many underground coal mines and bench-scale designs in surface mines allow for the application of simple behavior models and limit equilibrium analyses. Specific analyses of major throughgoing geological structures need to be considered as early as possible.

The stress-field assumptions that may be necessary prior to mining need to recognize the uncertainties in their measurement and how well they represent the entire deposit. A check of the stress field against static equilibrium on pervasive weakness planes should be conducted. If possible, decisions on the orientation of the excavations should be deferred as long as possible so that in-mine knowledge can be obtained.

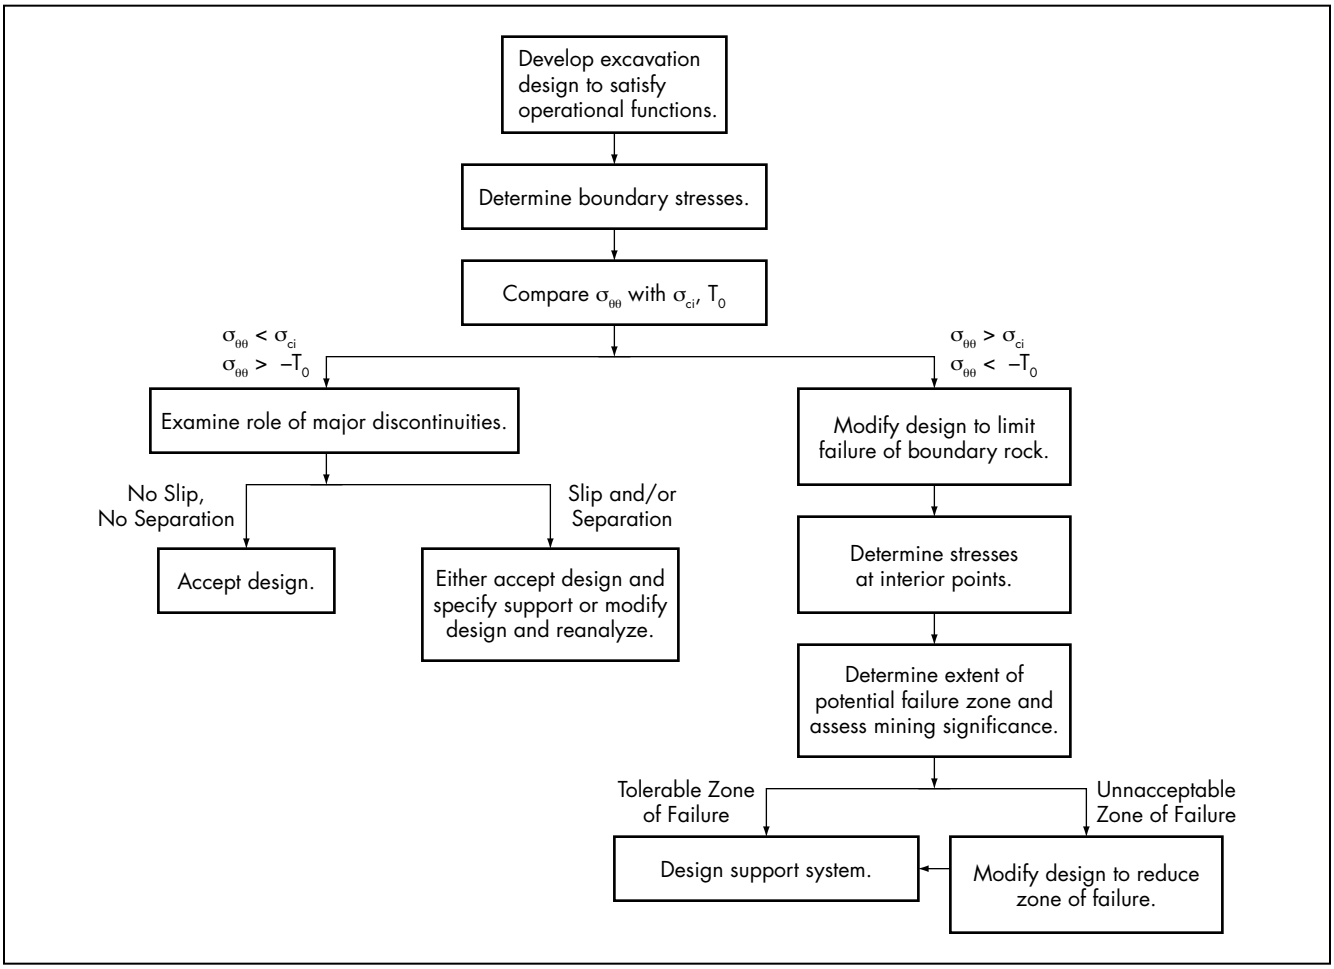
Figure 8.4-17 Design methodology for rock engineering

Failure and Collapse Modes Around Excavations

The serviceability of individual benches in surface mines and access roadways in underground mines is just as important as the performance of the larger extraction volumes. This serviceability can be adversely impacted by failure of a component of the overall mine design (such as a pillar) or by the localized collapse of the side or roof of the roadway or an individual bench. A logical framework for the design of specific excavations (Step 5 in Figure 8.4-17) is presented in Figure 8.4-18 and is equally applicable to surface and underground excavations with slight changes in emphasis. The rock mass classification pathway using the RMR or Q systems is an alternative to the use of this flow chart.



In underground excavations, the first step is to determine the boundary stresses. This is now a relatively trivial task with a range of software programs available for CHILE materials. If the lithologies are layered, there may be a need to consider the sensitivity of the stresses to the assumption of isotropic behavior. Determining the stresses at the excavation boundary induced by subsequent stress changes is still a challenge.

For surface mines, the assumption of body forces only is valid for routine analyses. Any consideration of the applied stresses in a surface mining application is best left to specialist geotechnical analyses in which the progressive excavation is modeled.

Roof

When selecting the discontinuity branch in Figure 8.4-18, there are readily available limit equilibrium methods to assess the stability of joint-bounded blocks and to specify support strategies. Accepting the concept that bedding partings define beams, there are also a number of simple elastic beam and voussoir beam models that can be applied. The proximity of the roof bolting to the mining face will determine if the determination of the forces of slip and separation need to be estimated with 2- or 3-D stress models. If bolting is conducted close to the advancing mining face (within a distance equal to the span), a 3-D model will give a better estimate of the forces developed after the support is installed.

There are many situations where the elastic boundary stress may be tensile. It is good practice to assume that the rock mass will have a tensile strength of zero, so the possibility of tensile elastic boundary stresses should be carefully reviewed as failure is indicated. Depending on the shape of the excavation, tensile conditions will be encountered if the K ratio is less than about 0.5 (i.e., when the vertical stresses are significantly higher than the horizontal stresses). Low K ratios should be anticipated in roadways close to the sides of valleys or surface excavations, when large excavations are in close proximity, and in coal roofs. Because there is no new rock breakage (just relaxation across joints), tensile failures

Source: Brady and Brown 2004, reprinted with permission from Springer Science and Business Media.
Figure 8.4-18 Logical framework for excavation design

in rock and coal masses can occur without audible or visual warning.

The onset of compressive failure can be readily assessed if the brittle failure criteria are considered, as the procedure is to compare the deviatoric stress with one strength parameter (UCS). A particularly useful step is to normalize the UCS to the estimated in-situ vertical stress based on the depth of cover and the average density. Depending on the *K* ratio and the shape of the excavation, values less than about 4 can be interpreted to indicate a greater likelihood of compressive failure at the excavation boundary.

Sides—Pit Walls and Underground

On the bench- and access-roadway scale, the discontinuity branch in Figure 8.4-18 leads to the analysis of planar slides, wedges, and topples. Rotational slips should also be considered. Numerous solutions and associated software are available.

The brittle-failure criterion is also applicable to the sides of underground excavations; in fact, the identification of this failure criterion was based on extensive work on the spalling of the sides of roadways in massive rock.

Floors

Adverse behavior of the floor should also be considered. Assuming the same deformation properties, the elastic deformation of the floor should be of a similar magnitude as for the roof—in the order of 10 mm. Because of the highly likely presence of water in mine floor, there may be some swelling of the contained minerals and some additional floor movements. Buckling of thin floor beams may also need to be considered. Floor heave is a relatively common occurrence, even in hard-rock mines under conditions of high stress.

In the underground coal sector, the possibility of a bearing capacity failure along thin layers of low-strength clayey materials needs to be considered. This is better considered in the context of soil mechanics.

CONCLUSIONS

Rock mechanics knowledge continues to evolve rapidly. The basic science is well established, and advances in computer analyses provide much greater insight into the complex stresses that develop around and between mining openings. Rock masses are complex, and their reaction to changing stress conditions is controlled by the inherent strength of the rock material, movement along large- or small-scale discontinuities, and the presence of water. The application of rock mechanics continues to drive improvements in safety and mine productivity, and even greater success will be achieved as the ability to characterize and quantify rock mass strength improves.

Currently, a wide range of design tools is available, ranging from rock mass classification schemes and closed-form solutions to 2- and 3-D stress codes. The practicing mining engineer should always carefully consider the design problem at hand and should particularly consider the scale of the opening relative to the spacing of the discontinuities in the rock mass. All the design tools have strengths and weaknesses; it is good practice to use multiple approaches. The most important part of the design problem is conceptualizing how the rock mass is likely to behave, as this will determine how it can be best analyzed. Completely different design approaches with different sets of assumptions may be needed to deal with a borehole, an excavation boundary, the interaction between drives or roadways, and the interaction between the mine and the surrounding rock mass.

CHAPTER 8.5

Geotechnical Instrumentation

Erik Eberhardt and Doug Stead

INTRODUCTION

Geotechnical instrumentation is a fundamental component of surface and underground mining engineering. Its use extends from prefeasibility studies to mine closure. Its purpose is multifold, serving both investigative and monitoring functions that are in part a necessity to ensure the economic feasibility of the mine operations and in part due diligence to ensure safe operations.

Investigative functions include

- Providing an understanding of the ground conditions for prefeasibility and design purposes,
- Providing input values for design calculations, and
- Checking for changing ground conditions as the operations expand or as workings progress to greater depths.

Monitoring functions include

- Assessing and verifying the performance of the design;
- Calibrating models and constraining design calculations; and
- Providing a warning of a change in ground behavior, thus, enabling intervention to improve safety or to limit damage through a design change or remediation measure.

The required versatility in how instruments can be deployed (on surface, from boreholes, etc.) and what they are meant to measure (rock properties, ground movements, water pressures, etc.) has led to the development of a wide variety of devices. Instrument selection, however, is only one aspect of a comprehensive step-by-step engineering process that begins with defining the objectives of their use and ends with implementation of the data (Dunnicliff 1993). It is therefore important to ask the following series of questions prior to undertaking any mine instrumentation project: What are the objectives of the monitoring project? (If the objectives are not known, then the project should not proceed.) What parameters need to be measured, and how will these aid mine excavation, ground support measures, and assessing design performance? How might these parameters vary spatially? What are the risks due to variable or poor ground conditions? What are the magnitudes of expected movement or stress increase? What are the optimal locations for instrument installation?

Only after such a reasoning exercise has been undertaken should the project proceed. The following advice of Dunnicliff and Powderham (2001) is pertinent: "The purpose of geotechnical instrumentation is to assist with answering specific questions about ground/structure interaction. If there are no questions, there should be no instrumentation."

When choosing instruments for a particular project, the engineer must consider and balance the job-related requirements of the following:

- **Range:** Range is the maximum distance over which the measurement can be performed, with greater range usually being obtained at the expense of resolution.
- **Resolution:** The resolution is the smallest numerical change an instrument can measure.
- **Accuracy:** The degree of correctness with respect to the true value is the accuracy, and it is usually expressed as a plus-or-minus number or as a percentage.
- **Precision:** Precision is the repeatability of similar measurements with respect to a mean, usually reflected in the number of significant figures quoted for a value.
- **Conformance:** Conformance is whether the presence of the instrument affects the value being measured.
- **Robustness:** This is the ability of an instrument to function properly under harsh conditions to ensure that data accuracy and continuity are maintained.
- **Reliability:** Reliability is synonymous with confidence in the data; poor quality or inaccurate data can be misleading and is worse than no data.

Dunnicliff (1993) is an excellent text on geotechnical instrumentation for monitoring field performance. The text provides a very useful discussion on these issues. Sellers (2005) eloquently discusses the concept of accuracy and puts it into perspective in relation to instrument resolution, linearity, precision, and most importantly real-world issues such as economics, reliability, and the uncertainty and natural

Table 8.5-1 Common borehole core orientation tools

Technique	Advantages	Disadvantages
Physical Techniques		
Weighted core barrel (clay imprint, spears, etc.)	Low cost; simple to use	Impression may require interpretation; unsuitable in boreholes inclined at shallow angles (<30°)
Ballmark	Simple to use; minimal drilling delays	Triggering mechanism may not operate in weak and fractured rock
Scribe system	Continuous scribing of core referenced to borehole orientation	Moderate to highly complex to use; difficult to interpret in weak and fractured rock
Ezy-Mark	Works in soft and broken rock; operates in most borehole orientations (uphole and downhole)	Requires an inclined borehole
Digital Techniques		
Reflex ACT electronic tool	Eliminates reliance on mechanical movement; highly accurate and consistent core orientations	Requires training in operation
Acoustic televiewer	Provides a continuous record of borehole wall (three-dimensional [3-D] virtual core); provides high accuracy and confidence in data; can be used in highly fractured rock	Requires a stable borehole; requires water or mud in borehole to operate
Optical televiewer	Provides a continuous record of borehole wall (3-D virtual core); provides high accuracy and confidence in data; can be used in highly fractured rock	Requires a stable borehole; requires air or clear water to operate

Source: Adapted from Read et al. 2009.

variability in most geotechnical projects. An important, but rarely discussed issue, is the true cost of geotechnical instrumentation, which according to McKenna (2006) should be considered with regard to the "life-cycle of the instrument—from its initial geotechnical design and procurement through drilling and installation, including reading and maintenance and data management and geotechnical analysis back in the office." This is in addition to decommissioning.

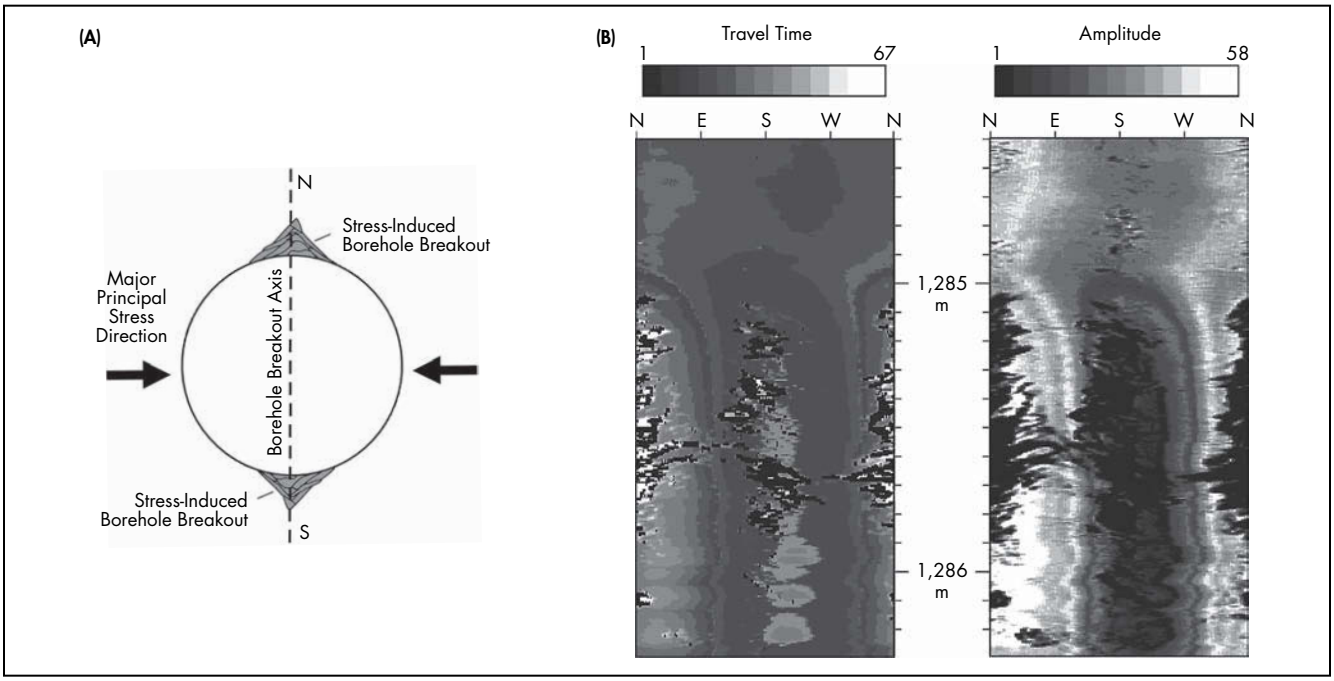
In addition to providing typical guideline costs associated with instrumentation, McKenna (2006) outlines good practices and emphasizes the care required in "all aspects of design, procurement, installation, reading, maintenance, data management, and quality assurance/quality control and analysis."

INSTRUMENTATION FOR INVESTIGATION

Geotechnical instrumentation plays an important role in the investigation of mine-site geology, geological structures (faults, jointing, etc.), rock mass properties, groundwater conditions, and in-situ stress fields. These are necessary inputs for carrying out prefeasibility studies and mine design, optimizing existing operations, and mitigating uncertainty in the mine design (but unfortunately not eliminating it). It must be recognized that rock and soil are natural earth materials, the products of many geological processes and complex interactions, and as such they are inherently variable.

Data should therefore be measured and recorded in systematic ways using standardized procedures. Furthermore, specific data may be required to make a decision on a particular aspect of mine design. Much time and effort can be wasted by collecting data that may be irrelevant or inadequate. Accordingly, the type and quality of the geotechnical data required will vary as a mine project matures. Parallels can be drawn with the Joint Ore Reserves Committee's (JORC's) code for reporting ore reserves—*inferred, probable, and proven* reserves (AusIMM 2004).

As a mining project moves from prefeasibility through to detailed mine design, the amount of data collected will increase as efforts are made to minimize uncertainty and reduce risk. The nature of the data will also become more specialized and measurement will transition from surface boreholes to the development and production levels.



Ground Characterization: Borehole Techniques

Prefeasibility assessments and subsequent mine designs are often required to be completed prior to underground development. As a result, borehole information from drill cores and downhole geotechnical instrumentation often provide the only direct observation of the rock mass that hosts the mine in design. Core drilling is typically the most expensive phase of a mine geotechnical investigation, and therefore, every effort should be made to maximize the quality and quantity of the data collected.

Core Orientation

Discontinuities represent planes of weakness along which failure may occur. Their orientations and inclinations are key factors influencing mine design, as they may intersect each other to form potentially unstable wedges or blocks. In open-pit design, kinematic analyses using discontinuity data often controls how steep the bench, inter-ramp, and overall slope angles can be, all of which have a significant impact on the mining economics. Logging of oriented cores and borehole surveys provide a means to determine the dip and the dip direction of discontinuities intersecting the borehole. Read et al. (2009) summarizes several common core orientation tools. These may be divided into physical marking and digital imaging techniques, as shown in Table 8.5-1.

Physical marking typically involves using an orienting device during drilling to identify the top or bottom edge of the core before it is removed from the borehole. This is done by lowering the orientation device down the borehole between drill runs until it reaches the bottom, producing a mark on the top of the next piece of rock to be cored. This process is repeated so that the marks on the core from each drill run can be aligned using a reference line drawn from mark to mark. Techniques such as the downhole spear and Ezy-Mark (Table 8.5-1) are often favored for being inexpensive, quick,

Source: Adapted from Maybee et al. 2002.

Figure 8.5-1 (A) Stress-induced borehole breakout and its orientation relative to the direction of the major principal stress; (B) breakout observed in an ATV log at INCO's Totten mine. The north–south breakout is persistent for approximately 1 m along the length of the borehole.

simple, and robust. Alternatively, scribe systems (Table 8.5-1) use tungsten carbide knives differentially spaced around the core barrel to continuously mark the core as it enters the barrel. Scribe systems help to insure orientation of the core in formations with extensive fracturing.

Digital imaging techniques (e.g., acoustic and optical borehole televiewers) provide a direct, oriented, permanent, and unwrapped 360° continuous record of the borehole wall. They are used principally to map the orientation of discontinuities intersecting a borehole, detect thin beds, characterize lithology, and inspect well casings. They can also be used to provide indirect information on in-situ stress orientations through borehole breakout mapping (Figure 8.5-1A). This enhanced data output has meant that borehole televiewers are increasingly replacing conventional methods of core orientation.

Borehole Televiewers

Acoustic televiewers (ATVs) work by emitting an ultrasonic pulse-echo and measuring the return time and amplitude of the acoustic signal that is reflected back from the lithological and structural features present in the borehole wall. Optical televiewers (OTVs) illuminate the borehole wall and use a charge coupled device camera to record a direct image. They can operate in a wide range of borehole diameters and produce very high-resolution 24-bit RGB (red-green-blue) images with a vertical resolution of the order of 1 mm and a commercially available horizontal/circular resolution of up to 1,440 pixels. Both ATVs and OTVs are oriented using axial magnetometers and accelerometers contained within the instrument.

Some of the added advantages of ATVs and OTVs include the availability of sophisticated software for interpreting and displaying image logs. Manual or automatic highlighting of fractures and the determination of dip and azimuth from the logs can be undertaken. Data can be presented on image logs using tadpole and stick plots, stereographic projections, and frequency plots. Commercially available software allows for powerful interpretation of the data from multiple logging sources. Three-dimensional (3-D) virtual cores can be produced that are very useful in comparing logs with the actual core and investigating breakouts and borehole deformation. Figure 8.5-1B shows an example of a borehole breakout in a televiewer log from INCO's Totten mine in Canada, as reported by Maybee et al. (2002). The breakout is identified by the dark vertical bands located on opposite sides of the borehole image, indicating that the major principal stress is approximately east–west (i.e., 90° to the north–south breakout direction).

Borehole Geophysics

Nonintrusive and nondestructive, borehole geophysics provide valuable subsurface information for developing mine geological and geotechnical models. Surveys may be conducted such that both the source (seismic, radar, electric, etc.) and receiver are located together on a downhole probe or spaced through different configurations of borehole and surface source and receiver groupings (Figure 8.5-2). For effective application, it is important to ensure that all aspects of a geophysical survey are properly implemented. The International Society for Rock Mechanics (ISRM) has published suggested methods for borehole geophysics (Takahashi et al. 2006).

Geophysical logs. Wireline tools involve a variety of different sensor types, including mechanical, acoustic, electric and electromagnetic, and nuclear (Table 8.5-2). Some involve passive sensors (without excitation), and others involve active sources of excitation combined with detection sensors. Each

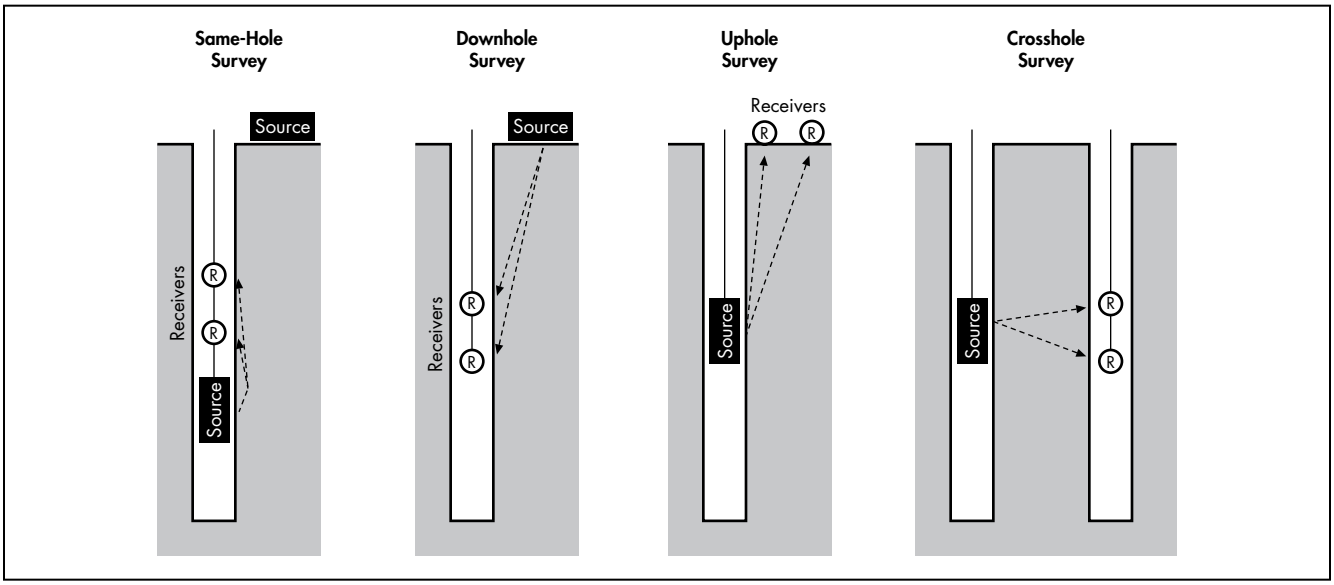


Figure 8.5-2 Example borehole and surface source and receiver configurations

Table 8.5-2 Common borehole geophysical tools used for geotechnical investigations

Source	Examples	Operation Principles and Applications
Geometry	Caliper	Measures variations in borehole diameter using spring-loaded mechanical arms that conform to borehole walls
Acoustic	Velocity; full waveform sonic; dipole shear imager	Measures P-wave or P- and S-wave velocity profiles along borehole; full waveform can be used to generate an attenuation log; provides information on rock composition, degree of fracturing/ weathering, and rock properties
Electric and electromagnetic	Resistivity; spontaneous potential (SP); induction; full bore formation micro-imager	Profiles the resistivity of geological formations/fluids along a borehole; SP uses passive electric logging to measure natural electric potentials along a borehole; induction logging utilizes electromagnetic induction to profile resistivity; provides information on geological contacts, lithology, permeable formations, groundwater level, degree of weathering, and variations in clay
Nuclear	Natural gamma; spectral gamma; gamma gamma; neutron	Includes active methods (gamma gamma, neutron), which measure the formation's response to induced radiation; includes passive methods (natural gamma) that measure the natural radiation of the formation; provides information on geological contacts, lithology, clay content, structural features, density, porosity, and water content

sensor type and tool has its own advantages for identifying rock lithologies or measuring certain rock or fluid properties, either directly or indirectly through empirical relationships. For example, full wave sonic tools measure P- and S-wave velocities, for which there are empirical relationships to calculate porosity, quartz content, and clay content. When combined with density data, Poisson's ratio, shear, bulk, and Young's modulus values can be calculated. The use of multiple tools and composite plots allow comparison and validation (e.g., Figure 8.5-3).

Vertical profiling. Borehole geophysics can be combined with surface surveys to derive more information regarding the subsurface conditions. These can then be used to resolve geological features, or they can be combined with density logs to calculate the various elastic moduli along the borehole profile. There are several variations in the measurement methods, depending on source and receiver configurations split between the borehole and surface (see Figure 8.5-2). Variations include downhole, uphole, and crosshole techniques. Downhole surveys involve seismic, radar, or electric sources placed on the surface with signals measured at regular intervals down the borehole using a string of receivers or a single receiver moved incrementally up and down the hole. Uphole surveys place the receivers on the surface and place the source in the borehole. In the case of a vertical seismic profile, the P-wave arrival times for each receiver location are combined to produce travel time versus depth curves for the complete hole.

Crosshole tomography. Borehole tomography involves the measurement of seismic/radar signals between two or more boreholes to derive an image of velocity/resistivity in the intervening ground. Data are collected using one borehole for the source and additional boreholes for a string of receivers. This results in a network of overlapping ray paths that can then be used to model the velocity/resistivity profile. The resulting image is termed a *tomogram* and enables identification of anomalous velocity/resistivity zones between boreholes, as well as imaging individual velocity/resistivity layers.

Ground Characterization: Remote Sensing

The use of digital remote sensing techniques for characterizing rock mass structure in underground and surface mine environments has increased significantly in recent years. A

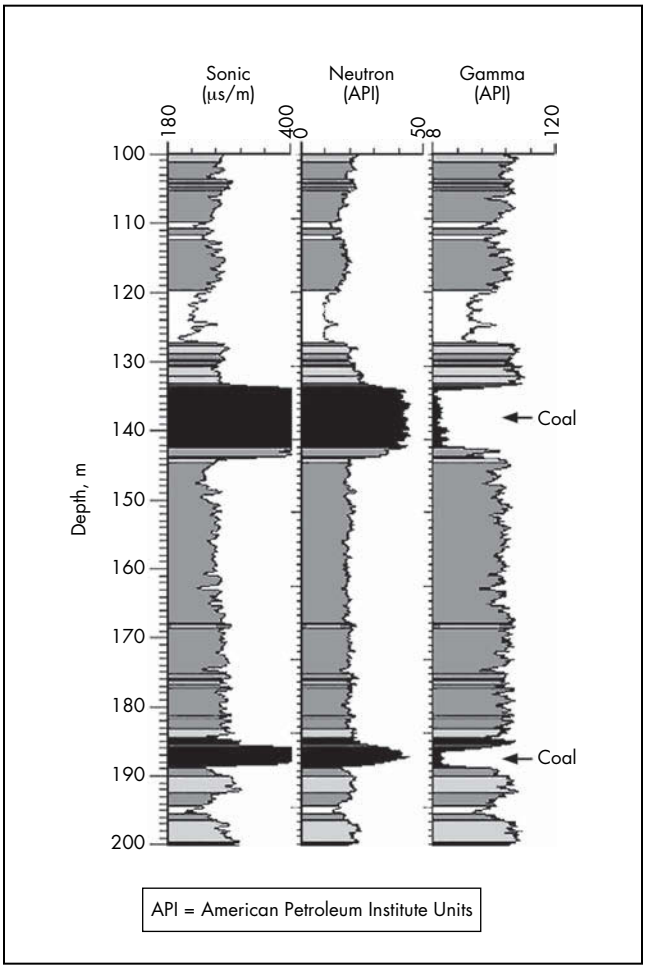

Figure 8.5-3 Example of composite geophysics log plot used to identify coal seams

major advantage of these methods is that they are able to provide data for remote and inaccessible areas, where safety concerns often preclude conventional mapping. Notwithstanding, Sturzenegger and Stead (2009a) and Lato et al. (2010) emphasize that these techniques suffer measurement bias (e.g., orientation, truncation, and censoring), which must be fully considered during processing, analysis, and interpretation of the data.

LiDAR

Light detection and ranging (LiDAR) is an optical remote sensing technique that measures properties of scattered light to determine the range of a distant target. Details on the theory of LiDAR measurement techniques are presented in Lichti et al. (2002) and in Lichti (2004). The product of a ground-based LiDAR laser scan is a 3-D point-cloud image of a pit slope or mine excavation wall, each point having x, y, and z coordinates and a pixel intensity value. The intensity may be in gray scale (Figure 8.5-4) or in color and may be draped on a photograph of the outcrop. A permanent 3-D digital image of the rock mass allows sections to be easily constructed wherever appropriate and imported into mine design and numerical modeling computer codes.

Using commercially available software (e.g., SplitFX, PolyWorks), orientation measurements of discontinuities may

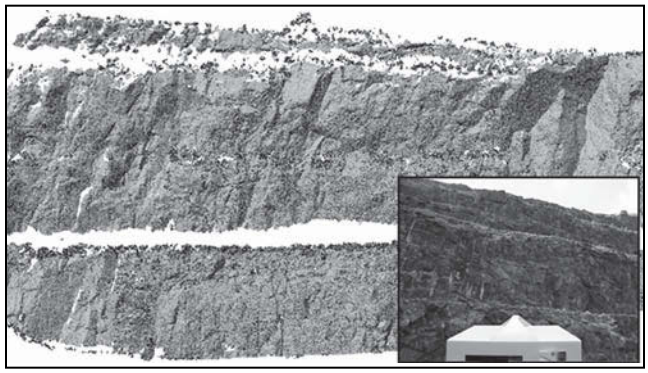

Figure 8.5-4 Three-dimensional point cloud from a LiDAR scan of open-pit benches at the Palabora mine in South Africa

be made from surfaces and traces in the point cloud, allowing for definition of discontinuity sets for future engineering analysis. The point cloud may also be used to provide data on discontinuity spatial location, persistence (trace length), and spacing (intensity). LiDAR has been used to characterize large-scale roughness and waviness; small-scale roughness still requires the use of conventional mapping surveys, as does the assessment of other parameters such as aperture and discontinuity infill. Comprehensive works on the use of LiDAR in rock mass characterization include Tonon and Kottenstette (2007), Kemeny and Turner (2008), Stead et al. (2009), and Sturzenegger and Stead (2009a). The use of LiDAR underground is less common than that on the surface, although excellent results can be obtained, as illustrated by Warneke et al. (2007).

Digital Photogrammetry

Ground-based digital photogrammetry is now routinely undertaken at large open-pit and underground mines. The use of this technique was pioneered by CSIRO Australia though the development of the Sirovision and Sirojoint software programs. Today, these codes, in addition to 3DM Analyst and 3G software programs, have found widespread use in the characterization of rock masses in open pits and underground mines (e.g., Birch 2006, 2008; Poropat and Elmouttie 2006). Using off-the-shelf digital cameras, stereo images of rock slopes and underground mine walls can be constructed and used to determine the orientation of discontinuities and derive joints sets in addition to obtaining similar geometric information as was discussed for ground-based LiDAR.

The advantages of stereo photogrammetry over LiDAR include the relative low cost for the hardware (a digital camera as opposed to a laser scanner) and the current ability to obtain 3-D stereo models from greater distances when using telephoto camera lenses (e.g., Sturzenegger et al. 2009; Sturzenegger and Stead 2009b). It is possible to form 3-D photo models of an open-pit mine at varying scales using a range of focal length lenses from 20 to 400 mm. This allows rock mass structures to be investigated at different image resolutions.

Figure 8.5-5 shows a 3-D photo model of the Palabora open pit using a 20-mm focal length lens and a model of pit wall benches using a 400-mm lens taken at a distance of more than 1.5 km. Figure 8.5-6 shows a photo model of a pillar using a 20-mm lens and an AdamTech underground lighting system. Both photogrammetry and LiDAR techniques complement each other and provide very similar data in terms of a point cloud and the derived rock mass parameters.

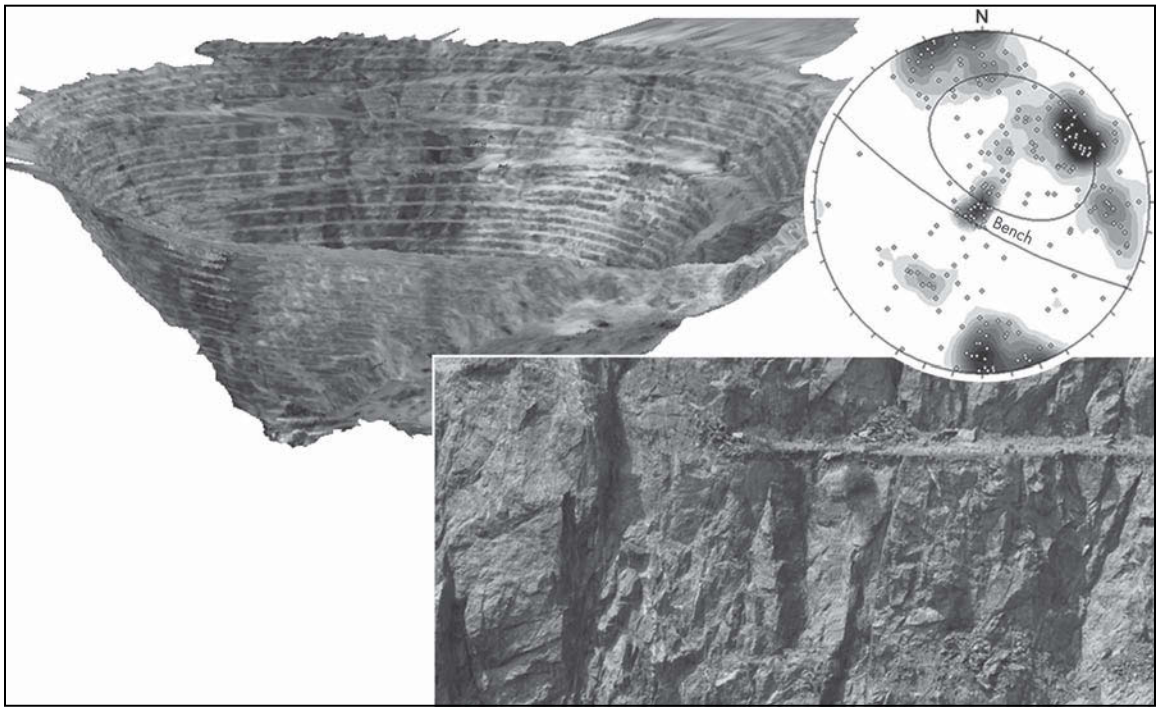

Figure 8.5-5 Three-dimensional photomodel of the Palabora open-pit mine in South Africa (20-mm lens), superimposed with a bench-scale photomodel (400-mm lens) and derived stereonet of discontinuity orientations

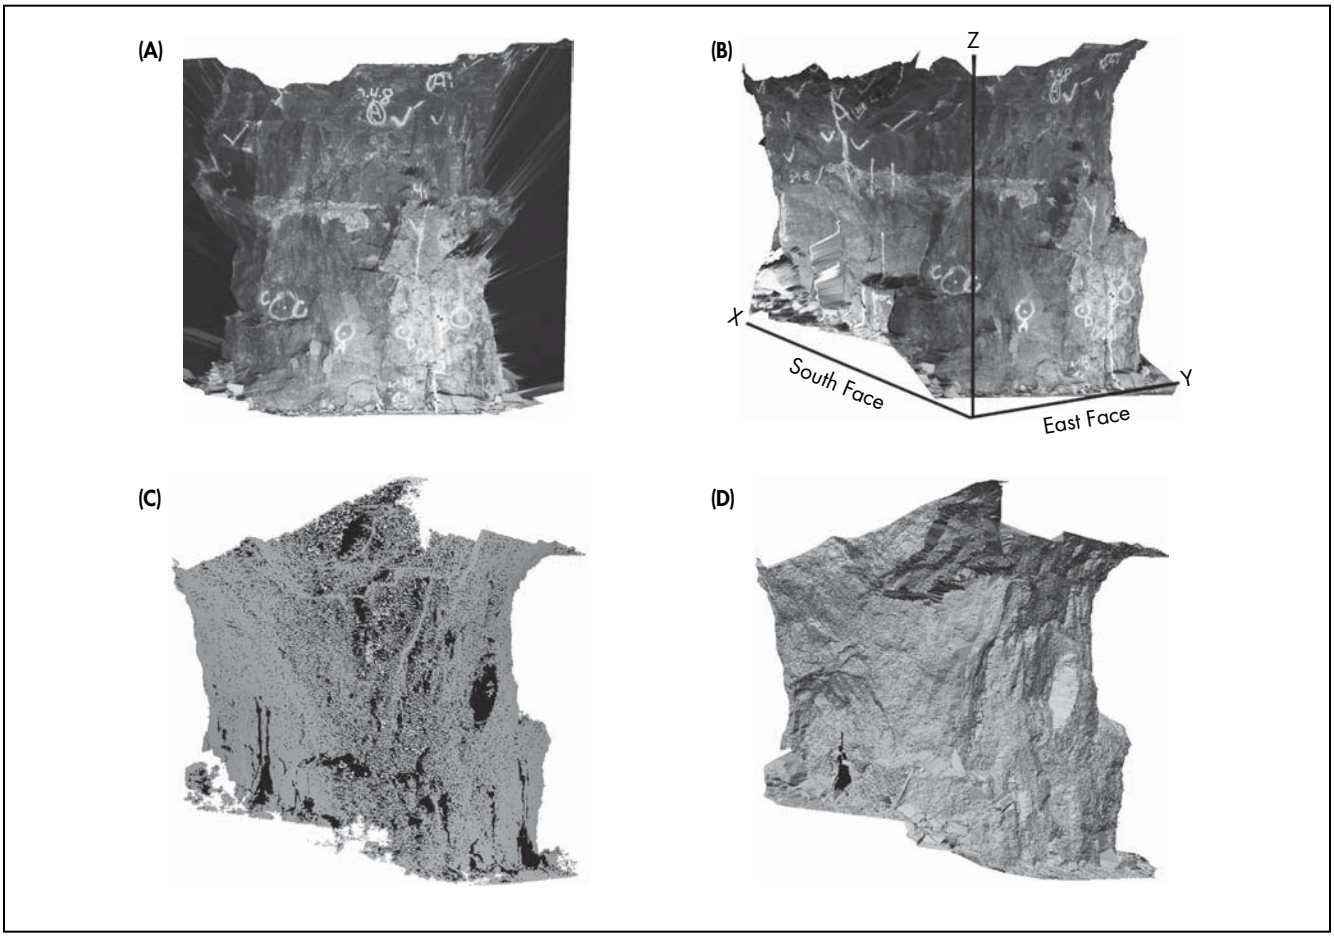
Surface Geophysics

Three-dimensional surveys (seismic, radar, etc.) can provide detailed information on geological contacts, faults, and other geological features important to mine design. Advantages over conventional two-dimensional (2-D) surveys include high-density data coverage, improved spatial delimitation of geologic and stratigraphic features, and the ability to visualize geologic, stratigraphic, and structural features in ways not possible with 2-D profiles.

The strength of 3-D surveys lies in their ability to establish continuity across subtle geological features. For example, Larroque et al. (2002) discuss how high-resolution 3-D seismic data were used to detect thin-layered platinum ore bodies at the Karee mine in South Africa, together with faults and other geological features that disrupted their continuity. These disturbances were of prime importance for implementing galleries, optimizing reef extraction, and positioning the shafts. Eso et al. (2006) demonstrated the application of a 3-D electrical resistivity survey to image a water-infiltrated void ahead of a mine drift in an underground potash mine. The detection of such voids is of prime importance in these mines to avoid flooding.

Ground-penetrating radar (GPR) is another surface geophysics technique that has been successfully applied in the mining industry (Pittman et al. 1982). The technique involves pulling a high-frequency radio transmitting and receiving antenna over the ground surface and recording any variations in the reflected return signal. GPR is used to map near-surface geologic conditions, including faulting and old workings that pose a hazard to miners, locating water tables, and detecting contaminant plumes. GPR can also be applied underground. White et al. (1999) provide several examples of routine use of GPR in South African mining, including ore-body delineation, mapping of faults and intrusives, and delineation of roof discontinuities.



Groundwater Characterization

The determination of the water level and water pressures is an extremely important input for mine design, particularly for open-pit slopes. Pore water pressures can critically influence the stability of rock, waste rock, and soil/fill slopes. Measurement of pore water pressures is also important for monitoring the effectiveness of slope dewatering/depressurization schemes and the investigation of seepage and groundwater movements.

Piezometers

Piezometers are devices used to monitor pore and joint water pressures in boreholes. The most commonly used device is an electrical water level sensing probe that is used in combination with uncased boreholes (observation wells) to determine the depth to the water table by means of lowering the probe down the borehole. When the probe comes in contact with the water, an electrical circuit is completed, and the device makes an audible noise. Although this technique is quick and inexpensive and provides useful data in the initial stages of a project, it may be unreliable, especially in the presence of perched water tables, vertical groundwater gradients, and artesian conditions.

Open standpipe piezometers (Casagrande piezometers) involve cased boreholes, perforated at the depth of interest, in combination with a polyvinyl chloride (PVC) standpipe with a sealed-off porous filter element attached at the end. A sand filter zone is placed in the annulus around the filter tip up to the top of the filter zone with the remaining borehole backfilled with a bentonite grout to prevent any flow of water into the filter from other horizons. An electrical sensing probe can then be used to measure the water level corresponding to the groundwater pressure for the monitored interval. Combined standpipe/inclinometer installations are possible and are commonly used at surface mining operations.

Adapted from Styles et al. 2010.

Figure 8.5-6 (A, B) Three-dimensional photomodel of a pillar using photos of the four faces, and the corresponding (C) triangular mesh and (D) point-cloud representations developed from the photomodel

Although more complex, piezometers are also commercially available that provide a direct, reliable, and accurate reading of the pore water pressure at a specific depth in a borehole. They have rapid response times and the ability to be automatically logged. In rock masses, the correct location of these devices with respect to permeable fracture zones is very important. The principal differences between the various types of piezometers include the following:

- Single-point or multipoint measurements
- Vibrating wire, pneumatic, fiber-optic, strain gauge, or micro-electromechanical system- (MEMS-) based sensors (see the "Instrumentation for Monitoring" section of this chapter for a general description of instrument sensor types)
- Conventional installation or push-in types for soft ground

There has recently been considerable discussion as to the preferred method of piezometer installation. Many authors recommend fully grouted installations that have excellent zone isolation and rapid response to pore pressure changes. The reader is referred to Dunnicliff (1993), McKenna (1995), Contreras et al. (2008), Weber (2009), and Read and Stacey (2009) for further information on piezometer completions.

Multipoint piezometers offer the advantage of monitoring pore water pressures at selected intervals along the borehole. Several commercial varieties exist that vary principally on the method of measurement and isolation. Strings of piezometers can be connected on a single cable and fully grouted within the borehole. Installations include those for conventional vertical boreholes as well as horizontal boreholes in open-pit slope walls as part of a horizontal drain drilling program (Read et al. 2009).

Another popular multipoint system is the Westbay MP system, which comprises a modular casing system that allows for a large number of monitoring zones to be established in a single borehole. Access to individual zones is provided through port couplings with a filter on the outside and a spring-loaded check valve on the inside. Seals between monitoring zones are provided by either grout backfill or hydraulically inflated packers. Wireline tools and instruments are then used to operate the monitoring system by accessing the ports. Measurement ports not only allow pore water pressures to be monitored at any number of monitoring zones, but they also provide locations for fluid sampling. Pumping ports also provide the capability to undertake hydraulic-conductivity testing.

Table 8.5-3 In-situ stress measurement methods and key issues related to their applicability

Method	Advantages	Limitations	Suitability
Overcoring	Most developed technique in both theory and practice; three-dimensional (3-D)	Scattering due to small rock volume tested; requires drill rig	Measurement depths to 1,000 m
Doorstopper	Works in jointed and high-stressed rocks	Only two-dimensional (2-D); requires drill rig	For weak or high stressed rocks
Undercoring	Simple measurements; low cost; can utilize existing underground excavation	Requires measured local stresses to be related to far-field in-situ stresses; rock may be disturbed	During excavation
Hydraulic fracturing	Can utilize existing boreholes; tests large rock volume; low scattering in the results; quick	Only 2-D; theoretical limitations in the evaluation of maximum horizontal stress (σ_H)	Shallow to deep measurements
Hydraulic testing of preexisting fractures	Can utilize existing boreholes; 3-D; can be applied when high stresses exist and overcoring and hydraulic fracturing fail	Time-consuming; requires existing fractures in the hole with varying strikes and dips	Where both overcoring and hydraulic fracturing fail
ASR, DSCA, and RACOS*	Usable for great depths	Complicated measurements on the micro-scale; sensitive to several factors	Estimation of stress state at great depth
Acoustic emissions (Kaiser effect)	Simple measurements	Relatively low reliability; requires further research	Rough estimations
Focal mechanisms	For great depths; existing information from earthquake occurrence	Information only from great depths	Seismically active areas
Core discing	Existing information obtained from borehole drilling	Only qualitative estimation	Estimation of stress at early stage
Borehole breakouts	Existing information obtained at an early stage; relatively quick	Restricted to information on orientation; theory needs to be further developed to infer stress magnitudes	Deep boreholes or around deep excavations
Back analysis	High certainty due to large rock volume	Theoretically, not a unique solution	During excavation
Geological indicators	Low cost; 2-D/3-D	Very rough estimation; low reliability	At early stage of project

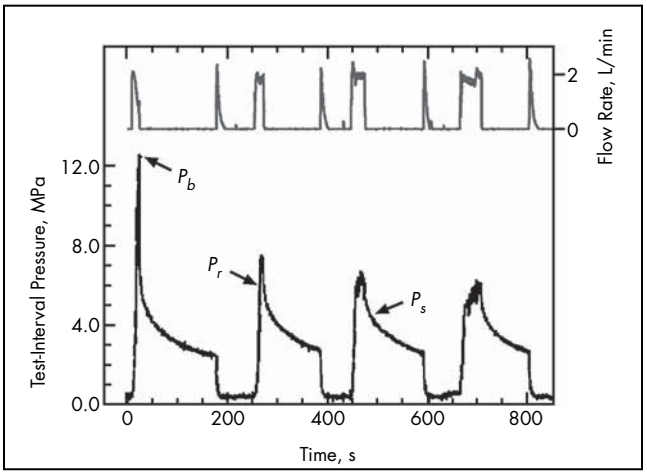
*ASR = anelastic strain recovery; DSCA = differential strain curve analysis; RACOS = rock anisotropy characterization on samples.

Groundwater Flow Testing

The collection of data on groundwater flow is an important area of geotechnical instrumentation, particularly in large open-pit design where slope depressurization may be critical to slope stability. Beale (2009) and Read and Stacey (2009) provide detailed descriptions of the importance of developing an adequate hydrogeological model and the requirements of slope depressurization programs. The characterization of groundwater response in fractured rock masses involves the use of drill-stem injection testing, falling or rising head tests (slug tests), packer testing, and pumping tests. Read and Stacey (2009, Appendix 1) provide an excellent summary.

In-Situ Stress Measurement

In-situ stress measurement provides an important boundary condition and input for mine design, including the selection of mining method, assessment of short- and long-term performance of underground openings, design of rock support and ground improvement (e.g., grouting), and assessment of rock burst potential. Hudson et al. (2003) discuss strategies for rock stress estimation, and Amadei and Stephansson (1997) and Ljunggren et al. (2003) provide comprehensive reviews of in-situ stress measurement methods. These may be classified according to methods that involve direct measurements, for example, the rock mass's response to hydraulic fracturing or induced strains from overcoring and those that involve indirect observations (indicator methods). The second category includes borehole breakouts, core disking, acoustic emissions (Kaiser effect), strain recovery methods, earthquake focal mechanisms, geological observational methods, and statistical treatment of databases. The advantages and limitations of these techniques are summarized in Table 8.5-3.



Overcoring

Overcoring is a stress-relief method that involves isolating a rock sample from the stress field that surrounds it and monitoring the strain response. As such, the measured stresses are not related to applied pressures but are inferred from strains generated by the unloading process.

Suggested methods for overcoring stress measurements are provided by Sjöberg et al. (2003). The method involves first drilling a large-diameter borehole followed by a smaller pilot hole in which a strain measuring device is inserted and fastened. The large-diameter hole is then resumed, relieving stresses and strains in the hollow rock cylinder that is formed. Changes in strain are recorded with the instrumented device as the overcoring proceeds past the plane of measurement. The in-situ stresses are calculated from the measured strains with knowledge of the elastic properties of the rock. Hence, overcoring requires the assumption of continuous, homogeneous, isotropic, and linear-elastic rock behavior. Sjöberg et al. (2003) noted that errors are introduced because these conditions are seldom encountered in rock masses. Even when seemingly ideal conditions apply, some scattering of the results always occurs.

Hydraulic Fracturing

Haimson and Cornet (2003) describe in detail the two main hydraulic methods used for rock stress estimation: hydraulic fracturing (HF) and hydraulic testing of preexisting fractures (HTPFs). For the HF method, a borehole interval devoid of natural fractures is sealed off and pressurized with water pumped under a constant flow rate until a fracture initiates in the rock. The following pressure measurements are then made: the water pressure at which the fracture occurred (the breakdown pressure), the subsequent pressure after pumping

Source: Adapted from Haimson and Cornet 2003.

Figure 8.5-7 Example of a hydraulic fracturing test showing the breakdown pressure (P_b), shut-in pressure (P_s), and reopening pressure (P_r)

is stopped and the fracture closes (the shut-in pressure), and the pressure required to later reopen the same fracture (the reopening pressure). These cycles may be repeated to provide redundant readings. A typical HF record is shown in Figure 8.5-7.

In a vertical borehole, the shut-in pressure, P_s, is assumed to be equal to the minimum horizontal stress, σ_h. The direction of σ_h is obtained directly from the orientation of the hydraulic fracture; vertical HFs propagate perpendicular to σ_h. The maximum horizontal stress, σ_H, is calculated based on the breakdown pressure, P_b. In this calculation, the breakdown pressure has to overcome the minimum horizontal principal stress (concentrated three times by the presence of the borehole) and the in-situ tensile strength of the rock, such that in the absence of pore fluid pressure the maximum horizontal stress, σ_H, is as follows:

$$\sigma_H = T + 3\sigma_h - P_b$$

The orientation of σ_H is taken to be perpendicular to the σ_h direction (i.e., the direction of fracture propagation). Other assumptions include that of homogeneous, isotropic, linear elastic behavior of the rock surrounding the borehole, and impermeability of the host rock so that pumped water has not significantly penetrated the rock and affected the stress distribution. Also, classical interpretation of an HF test is possible only if the borehole axis is parallel to one of the principal stresses and is contained in the induced fracture plane (Haimson and Cornet 2003).

The HTPF method follows a similar procedure of sealing off a borehole interval, but it involves reopening an existing fracture of known orientation. By using a low fluid-injection rate, the fluid pressure, which balances exactly the normal stress across the fracture, is measured. The method is then repeated for other nonparallel fractures of known orientation. By determining the normal stresses acting across several nonparallel fractures and knowing their orientation, a system of equations can be created to determine the six in-situ stress components without making any assumptions with regard to the orientation of the principal stresses.

Table 8.5-4 Systematic approach to planning a monitoring program

Step	Description
1	Define the project conditions.
2	Predict mechanisms that control behavior.
3	Define the geotechnical questions that need to be answered.
4	Define the purpose of the instrumentation.
5	Select the parameters to be monitored.
6	Predict the magnitudes of change.
7	Devise remedial action.
8	Assign tasks for design, construction, and operation phases.
9	Select the instruments.
10	Select instrument locations.
11	Plan recording of factors that may influence measured data.
12	Establish procedures for ensuring reading correctness.
13	List the specific purpose of each instrument.
14	Prepare the budget.
15	Write the instrument procurement specifications.
16	Plan the installation.
17	Plan regular calibration and maintenance.
18	Plan data collection, processing, presentation, interpretation, reporting, and implementation.
19	Write contractual arrangements for field instrumentation services.
20	Update the budget.

INSTRUMENTATION FOR MONITORING

Predictive monitoring systems are best implemented after a period of investigative monitoring. Monitoring information must be assessed in the context of the physical setting and the conclusions of the investigation phase. Planning of a monitoring program should be logical and comprehensive because the measurement problem may require a number of different instrument types collecting information across a range of varying scales. Furthermore, because of physical limitations and economic constraints, all parameters cannot be measured with equal ease and success. To assist with these challenges, Dunnicliff (1993) proposed a detailed systematic approach to planning a geotechnical instrumentation program, which is outlined in Table 8.5-4.

The monitoring system can be viewed as connecting a transducer to a data acquisition system via a communication link. The transducer serves to convert a physical change in the parameter being measured into a corresponding output signal, which can be read manually or automatically. Reliability of the instrument is paramount; this therefore requires some understanding of the transducer housed within the instrument and its sensitivity to the surrounding environment (e.g., temperature extremes, presence of water or high humidity, dust and dirt, exposure to shock or vibrations, and erratic power supplies). Several transducer types are common to the various instrument types described in this chapter. These are summarized in Table 8.5-5 for reference.

Surface Displacements

Geodetic

Geodetic monitoring provides a means for measuring the magnitude and rate of horizontal and vertical ground movements. Methods are well established and are often entirely adequate

Table 8.5-5 Transducer types commonly used in geotechnical instruments

Sensor Type	Operation Principles
Linear variable differential transformer (LVDT)	An LVDT consists of a movable magnetic core passing through one primary and two secondary coils. An excitation voltage is applied and a voltage is induced in each secondary coil. When the core moves off center, the output voltage increases linearly in magnitude. LVDTs are commonly used in instruments to measure displacements.
Vibrating wire	This involves a high tensile strength steel wire fixed at both ends and tensioned so that it is free to vibrate at its natural frequency. The wire is magnetically plucked by an electrical coil, and its frequency is measured. When one end moves relative to the other, the tension in the wire, and therefore the measured frequency, changes. Vibrating wire transducers are commonly used in pressure cells, piezometers, and deformation gauges.
Accelerometer	This consists of a damped mass suspended in a magnetic field; under the influence of external accelerations (or motion), the mass deflects from its neutral position and the deflection is measured. Accelerometers are commonly used in tiltmeters and inclinometers.
Fiber optics	Light is emitted into and confined to a glass fiber core and propagates along the length of the fiber. Any disturbance of the fiber alters the guided light, which can then be related to the magnitude of the disturbing influence. Fiber optics is finding increased use in piezometers and deformation monitoring instruments.
Micro-electro-mechanical system (MEMS)	A MEMS is a small, integrated device that combines electrical and mechanical components on a submicrometer to submillimeter scale. This allows for transducers (e.g., accelerometers) that are much smaller, more functional, lighter, more reliable, and produced for a fraction of the cost of conventional transducers.

for performance monitoring. Measurement accuracy (and reliability) is controlled by the characteristics of reference datums and monitoring points. Checks are required to make sure these datums are located on stable ground. Geodetic survey methods represent the most commonly relied on slope and displacement monitoring system at surface mine sites. The reader is referred to Dunnicliff (1993) for a detailed coverage of survey methods for monitoring displacement.

Recent advances that are of particular importance are the incorporation of robotic total stations (RTSs) into mine monitoring networks. Cook (2006) describes an RTS as a survey instrument combining a theodolite (with automatic target recognition) and an electronic distance measurement device that can be operated remotely. The RTS monitors point by sighting prisms and tracking them as movement occurs. After the RTS has "learned" the location of the prism, it returns to redetermine the location of that prism during successive monitoring cycles; angular and distance measurements are made and the new prism locations are calculated. Many hundreds of targets can be included in the survey network. In addition to installation and operational issues and the factors controlling the accuracy of the RTS network, Cook (2006) provides a useful practical list of the advantages and disadvantages of an RTS as compared to conventional survey methods. Under optimal conditions, an accuracy of ±0.6 mm at 60 m is reported as achievable.

Little (2006) documented automatic prism monitoring at the Potgietersrus Platinum's open-pit operation in South Africa, where prisms were located on a highwall at 50 m horizontal and 45 m vertical spacing. At this mine, Leica Geosystems GeoMoS system was used and the automatic prism-monitoring network was integrated with the use of laser scanners and slope-stability radar. Cahill and Lee (2006) describe the use of an automated Leica system using more than 400 prisms at the Harmony pit at the Leinster Nickel mine in Australia. The continuity of the prism data allowed for the long-term assessment of wall movements. The geo-referenced nature of the data allowed it to be used for assessing vector movements of the pit walls and failure mechanism determination.

Brown et al. (2007) describe combining Global Navigation Satellite System (GNSS) receivers with RTS instruments to provide a stable reference frame for total stations sited in an unstable environment. Kim et al. (2003) describe a similar example for an RTS system georeferenced using GNSS/GPS at the Highland Valley copper mine in Canada. Such integration provides a fully automated, accurate, efficient, and cost-effective means for monitoring points in a large open pit where no stable location can be found to place the instrument and control points.

Global Positioning Systems

GPS surveys utilize the U.S. network of space-based global navigation satellites to provide reliable positioning of a GPS receiver. The GPS receiver calculates its position by precisely timing the signals sent by multiple satellites, computing the distances to each satellite to determine its own position (through trilateration). When paired with an antenna, automatic monitoring of pit wall movements is possible with millimeter accuracy.

GPS offers several advantages over traditional geodetic surveying techniques. In general, GPS is more efficient, highly automatic, less labor intensive, and line-of-sight is not required between stations. However, in an open pit a limiting factor for large-scale use of GPS is that, for automatic monitoring of deformations, each monitored point needs to be equipped with a receiver and antenna. This makes GPS an expensive option for slope monitoring. In addition, issues of data communication, power supply, and system control are difficult to resolve when GPS instruments are distributed at isolated points.

Another limitation of GPS involves its use with steep pit slopes. Stewart et al. (2000) describe the use of GPS to monitor more than 60 points within the Palabora pit in South Africa, generally to an accuracy of 5 mm. However, the accuracy of monitoring points deeper in the pit is less because of the limited satellite window available (i.e., satellite visibility is obstructed). This limitation can be overcome by linking a GPS receiver with multiple antennas mounted at several monitoring points, or by using pseudolites, small transceivers that transmit a local, ground-based GPS-like signal (e.g., Bond et al. 2007).

Extensometers

This group also includes crackmeters, jointmeters, strainmeters, crack gauges, convergence gauges, distometers, and sliding micrometers. Extensometers are devices used to measure the changing distance between two points. Measurement points may be located on the surface to measure ground

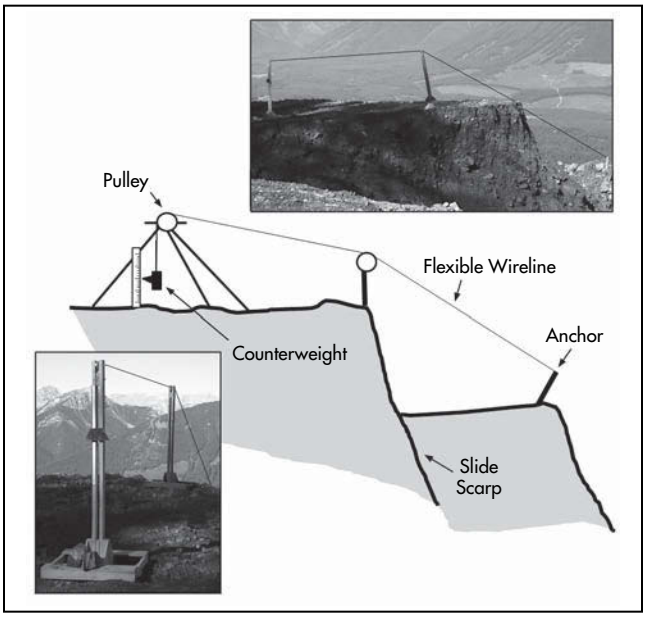

Figure 8.5-8 Schematic diagram (with inset photos) showing the use of a wireline extensometer to monitor waste dump movements at a British Columbia, Canada, coal mine

movements (e.g., spanning a tension crack to monitor its opening rate), or they may be located in a borehole to measure differential displacements along the borehole. Extensometers vary in type between those that involve manual measurements and those that are automated using vibrating wire electronics, differential transducers, or more recently fiber optics. Measurement accuracy and repeatability depend on the type of sensing device and the distance between the monitoring points. Typical accuracies range from submillimeter to millimeter over distances of less than a meter when using stiff sliding rods fixed between the monitoring points, and typical accuracies range from millimeter to centimeter over distances of meters or several tens of meters when extending a flexible tape or wire between the monitoring points.

In surface mining operations, wireline extensometers are frequently used to monitor pit slope and waste rock dump movements. These devices consist of a wire anchored in the unstable ground and tensioned across a pulley located on the stable ground behind the last tension crack using a counterweight (Figure 8.5-8). As the unstable portion of the ground moves away from the stable ground, the weight will move and the displacements can be recorded. These devices can be quickly positioned and easily moved, but care must be taken to minimize sag or thermal expansion/contraction in the wire, which can produce measurement errors. Rose and Hungr (2007) describe the use of wireline extensometer data at several mines in the United States to forecast the time of pit wall failure using an inverse velocity technique to interpret the data.

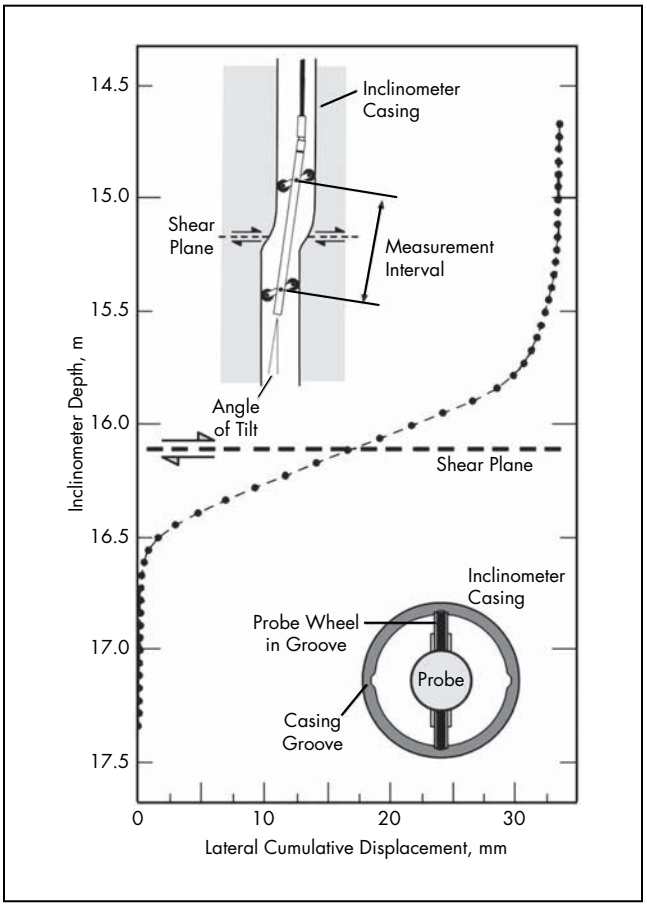
Tiltmeters

This group also includes clinometers and tilt sensors. Tiltmeters are devices used to monitor the change in inclination of a ground surface point. A detailed description is found in Dunnicliff (1993). The device consists of a gravity sensing transducer (servo-accelerometer, electrolytic tilt sensor, pendulum-actuated vibrating wire, MEMS) capable of measuring changes in inclination as small as one arc second. Tiltmeters may be uniaxial or biaxial, allowing measurement of tilt in two orthogonal directions. They are used to monitor slope movements where the landslide failure mode is expected to contain a rotational component. Advantages of using tiltmeters are their light weight, simple operation, and relatively low cost. Tiltmeters can be read manually or automated by connecting them to a data logger. They may be combined with inclinometers and extensometers in what have been termed as *integrated pit slope monitoring systems*.

Tiltmeters can be used to monitor pit-slope movements and ground subsidence above underground mines, particularly longwall and block cave operations. O'Connor et al. (2001) provides an example of a tiltmeter array used to measure the subsidence profile over an advancing longwall coal mine face. The array consisted of a series of tiltmeters connected to a central data acquisition system for automated real-time monitoring, with alarm thresholds set to warn of excessive ground deformations where the longwall panels crossed under an interstate highway.

Borehole Displacements

Probe Inclinometers



Probe inclinometers also include transverse deformation gauges and slope indicators. Inclinometers are devices used to monitor subsurface movements through a probe transducer (accelerometer, MEMS) designed to measure inclination with respect to vertical. A detailed description is found in Dunnicliff (1993). Operation involves lowering the probe down a borehole with inclinometer casing, which has two pairs of orthogonal grooves in which the probe wheels run. One pair of inclinometer casing grooves is usually oriented in the dip direction of the pit slope or in the anticipated direction of ground movement. Inclination is then measured at a number of fixed points as the probe is pulled back to the surface (Figure 8.5-9). Comparison of repeat periodic surveys provides an indication of differential displacements at depth as a function of time. Displacements are usually summed, resulting in profiles of cumulative displacement along the borehole (Figure 8.5-9).

When installing inclinometer casing, it is important to select the appropriate diameter. Large-diameter casing is better suited to shear zones, multiple shear zones, and slope failures. Moderate- to small-diameter casing can be used for short-term installations or slopes where smaller displacements distributed along the borehole are anticipated. Correct installation of the casing is important; and in deep holes, particularly the influence of helical deformation must be considered. A digital spiral sensor probe can be used to check the spiraling of the casing.

Inclinometer monitoring is widely used at the Syncrude oil sands mine in Canada to monitor highwall performance while draglines operate above it. McKenna et al. (1994) reported that approximately 20% of the highwalls have significant potential for slope failure, requiring intensive monitoring to ensure safe operation of the draglines. From 300 to 800 inclinometers were being installed each year to monitor shear movements and the development of slide surfaces at discrete depths (Figure 8.5-9).

In-Place Inclinometers

Where the depth of localized subsurface displacement is known or can be anticipated, an in-place inclinometer system

Source: Adapted from McKenna et al. 1994.

Figure 8.5-9 Inclinometer data of shear displacements at depth recorded for a highwall at the Syncrude oil sands mine in Canada, showing basic operation principles of a probe inclinometer

may be used to monitor continuous movements across known active shear surfaces. This system may also incorporate MEMS technology. In-place inclinometers consist of one (or several) inclinometer sensors housed within a stainless-steel enclosure. Sensors are separated from one another by stainless-steel rods and wheel assemblies. Sensors are installed in zones of expected displacement allowing remote automatic monitoring of pit slope movements.

Borehole Extensometers

Another variant from those previously discussed involves the use of mechanical or electrical probes (i.e., probe extensometers) to monitor changing distances between fixed points along a borehole as determined by the probe position. Typical accuracies for probe extensometers range from submillimeter to millimeter over distances of less than a meter.

A wide variety of borehole probe extensometers are commercially available, which differ according to the following:

- Single-point or multipoint measurement
- Measurement transducer/principle (dial gauge, resistance, magnetic, sonic, fiber optics, vibrating wire, and MEMS technology)

Multipoint borehole extensometers monitor displacements in a borehole at various depths within a slope or excavation wall/floor/roof. They usually comprise up to eight rods per drill hole and have manual readout or vibrating wire transducers with a measurement range of between 25 to 100 mm and a sensitivity of between 0.01 and 0.1 mm. Magnetic extensometers consist of spider magnetic anchors positioned along a PVC tube with a stable anchor at the base of the borehole (Figure 8.5-10A). The vertical movement of the anchors can be monitored manually with a probe.

Other versions of magnetic extensometers allow for automatic monitoring. The Increx system is comprised of brass rings located at fixed intervals along the outside of the PVC borehole casing (Figure 8.5-10B). A probe is used to measure the distance between successive rings, and the result is compared to an initial survey. Surveys taken at specific time intervals provide indications of whether compressive or extensile displacements have occurred. Changes as small as 0.001 mm can be measured with an accuracy of ±0.01 mm/m. Applications of the Increx system include the monitoring of vertical and horizontal deformations around underground and surface excavations.

A variety of sonic probe extensometers are also commercially available. The Sondex system installation consists of regularly spaced steel sensing rings and a corrugated Sondex pipe installed over inclinometer casing (Figure 8.5-10C). The annulus between the borehole wall and the Sondex corrugated pipe is filled with soft grout. This couples the pipe to the surrounding ground, so that the pipe and rings move with settlement or heave. As the probe passes a ring, an audible sound emits and the depth reading is taken. Settlement and heave are calculated by comparing the current depth of each ring to the previous readings of depth. Sonic extensometers have found considerable application in monitoring roof, wall, and floor deformations at specific depths. In stratified rocks, this allows for the estimation of dilation and bed separation around the opening.

Resistance wire extensometers are comprised of a pretensioned electrical resistance wire element fixed within a 1- to 2-m-long plastic tube and a strain gauge measuring readout. The wire is attached, under mild tension, to each end of the tube. The extensometer is installed by grouting into a borehole; a number of resistance wire extensometers can be installed end to end. Significant tensile strain can be measured with high sensitivity. Resistance wire extensometers are used for the monitoring of tensile strains around underground excavations and slopes. Applications have included pillar, roof, and stope wall displacement.

Convergence Monitoring Systems

Bock (2000a, 2000b) provides a useful summary of geotechnical instrumentation used in tunneling with particular focus on performance monitoring to assist with construction control. Measurements normally required include tunnel convergence, for which there are several instruments. Tunnel-profile monitoring systems comprise a series of linked rods fixed to the tunnel wall to monitor displacement; each rod has a high-accuracy displacement meter and a tiltmeter that record changes in displacement and tilt. The Bassett convergence system uses a system of articulated arms fitted with tilt sensors to monitor the movement of reference points that are mounted

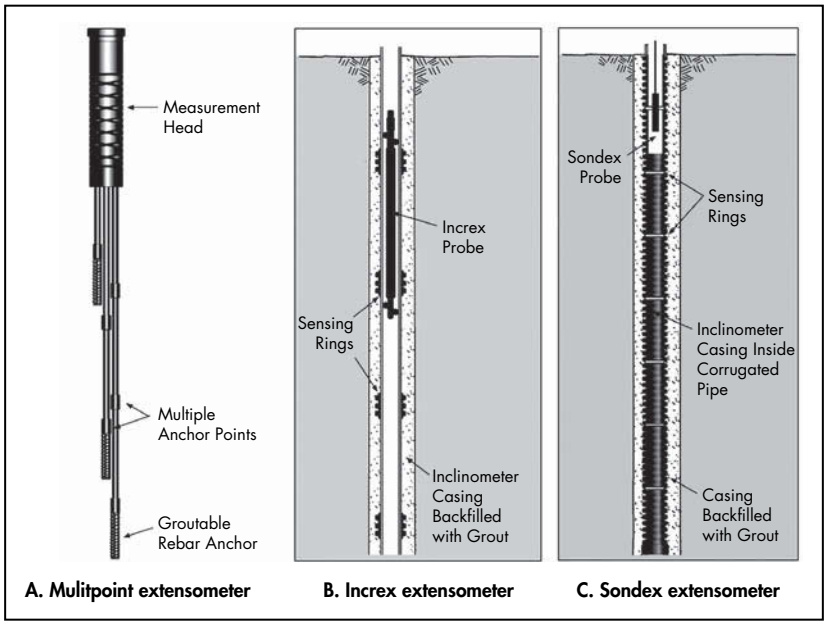


Figure 8.5-10 Types of borehole extensometers

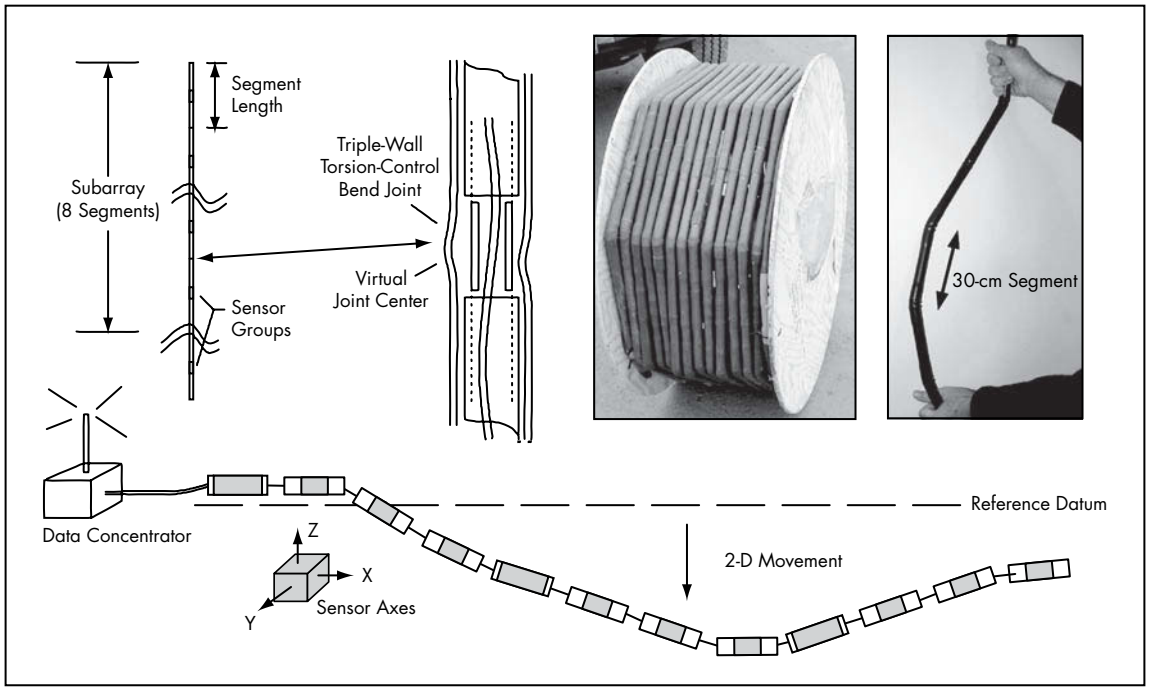
on the tunnel wall. Metje et al. (2006) describe a new fiber-optic-based Smart Rod tunnel monitoring system to measure structural displacements and deformations. The Smart Rod system was designed as a series of short rod sections, joined at fixing positions around the circumference of the tunnel.

Shaped Accelerometers

A new, wireless, MEMS-based system recently developed for real-time deformation monitoring is described by Abdoun and Bennett (2008). This system is based on triaxial MEMS accelerometer measurements of angles relative to gravity. Three accelerometers are contained in each 30-cm-long rigid segment for measuring x, y, and z components of tilt and vibration. The segments are connected by composite joints that prevent torsion but allow flexibility in two degrees of freedom. These rigid segments and flexible joints are combined to form a sensor called a ShapeAccelArray, which is capable of measuring 3-D ground deformation from within a borehole, for example, at 30-cm intervals to a depth of 100 m (Figure 8.5-11). The arrays consist of subarrays of eight segments connected end to end. Microprocessors, one per array, collect data from the groups of sensors.

Time Domain Reflectometry

Time domain reflectometry (TDR) is a standard electrical method for locating faults in cables. TDR is finding increasing use in mining geotechnical applications. The essential principle of TDR involves the effect of cable deformation on the passage of a voltage pulse along a two-conductor coaxial metallic cable, with the pulse being partially reflected by the deformation. TDR instrumentation allows for the location of the cable deformation using the travel time of the voltage pulse and the propagation velocity of the signal in the cable. Shearing of a TDR cable grouted in a borehole in rock or soil allows the location of the shear zone through changes in geometry and impedance between the inner and outer coaxial cable conductors. The magnitude of the soil and rock deformation over time can be determined, as it is proportional to the amount of cable deformation and hence changes in amplitude of the reflected voltage signal.



Dowding et al. (2003a, 2003b) provide a synopsis of the concept of TDR, its use in geotechnical engineering, and valuable practical experience gained in its use. Of particular interest are correlations between TDR magnitude and inclinometer displacements, the use of long (>300 m) horizontal TDR sensor cables above underground mines and parallel to both roads and slopes, monitoring at great depth (>500 m), and the use of TDR in geotechnical alarm systems (O'Connor 2008).

TDR has found application in surface mining, underground mining, and subsidence (Kniesley and Haramy 1992; Dowding and Huang 1994; Allison and de Beer 2008; Carlson and Golden 2008). Carlson and Golden (2008) describe successful use of TDR in remote monitoring of cave initiation at the Henderson mine (Colorado, United States). Allison and de Beer (2008) describe the monitoring system used to monitor the cave at the Northparkes mine (Australia), Lift 2. Displacement monitoring including TDR cables, convergence, and multipoint borehole extensometers are associated with damage mapping, borehole video, and microseismic monitoring. These authors emphasized the need to minimize the time between installation of TDR cables and the commencement of monitoring in order to reduce the possibility of cable damage.

Szwedzicki et al. (2004) clearly showed the applications and success in TDR monitoring at PT Freeport's Deep Ore Zone block cave mine (Indonesia). Results at PT Freeport from TDR cables monitored over a period of 2 years provided information on vertical progression of the cave and zones of dilation. Horizontal progression of the cave was monitored using cables installed from the undercut level. TDR at the Deep Ore Zone mine also provided information on the cave ratio (cave back height to height of draw) and the rate of progressive caving.

Fiber Optics

Fiber-optic technology (Table 8.5-5) is being increasingly used in the development of geotecthnical instrumentation.

Source: Adapted from Abdoun and Bennett 2008.

Figure 8.5-11 ShapeAccelArray subarray assembly

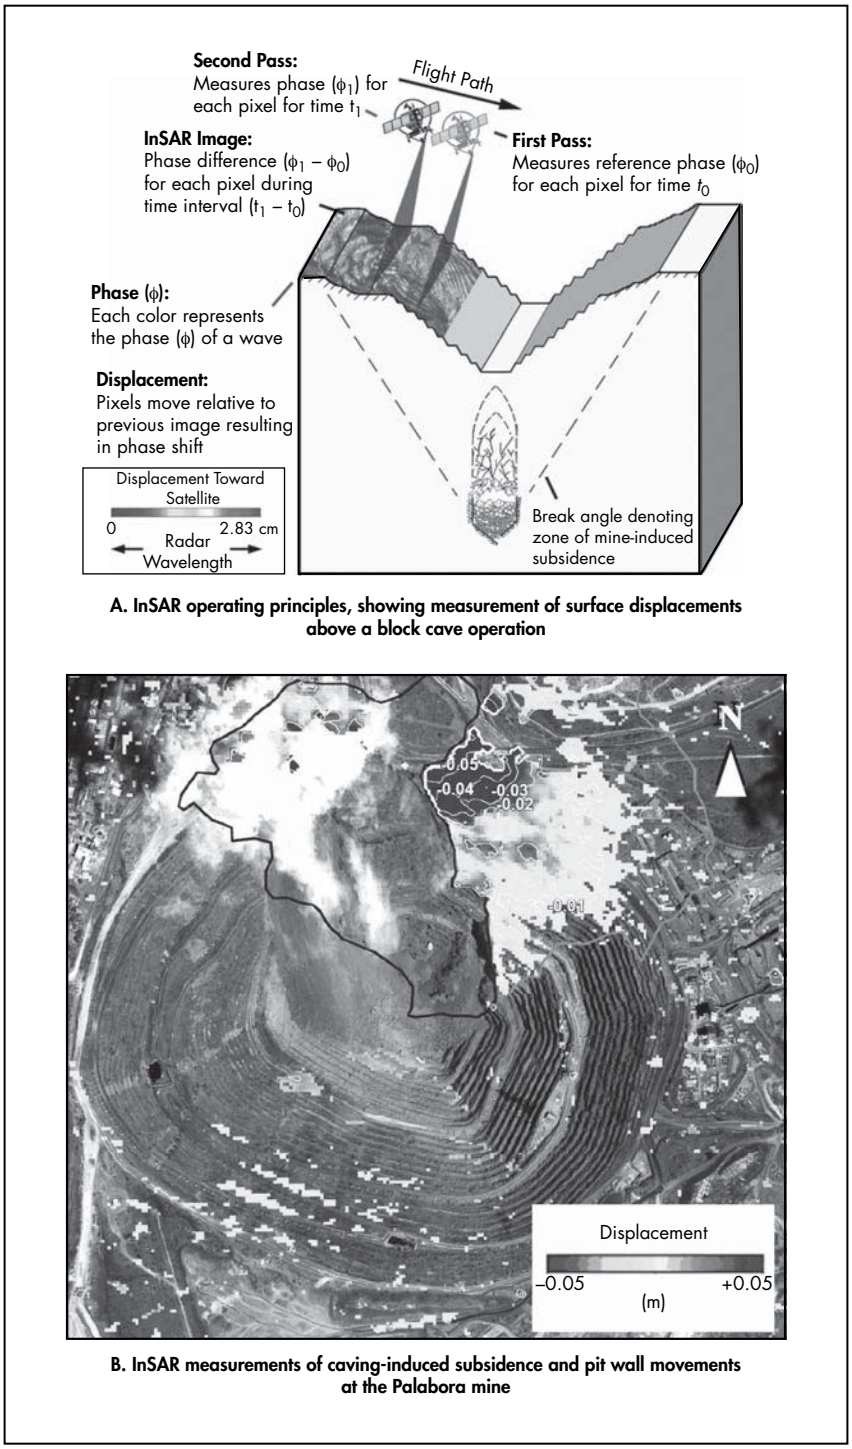
Commercially available fiber-optic-based instrumentation includes displacement transducers, piezometers, strain gauges, and temperature gauges. The following four main types of fiber-optic sensors exist:

1. Point sensors using Fabry-Pérot interferometric sensors
2. Multiplexed sensors using fiber Bragg grating sensors
3. Long-base sensors using interferometric SOFO sensors
4. Distributed sensors using either distributed Brillouin scattering sensors or distributed Raman scattering sensors

These sensors provide exciting new development potential for geotechnical instrumentation (e.g., Inaudi and Glisic 2007a). Of particular interest is the future potential of distributed sensors as reported by Bennett (2008) and Inaudi and Glisic (2007b). Distributed fiber-optic sensors can use a single optical fiber with a length of tens of kilometers to obtain dense information (every meter) on strain distributions across geotechnical structures or on the surface above underground mine excavations.

Remote Sensing of Ground Deformation

Satellite InSAR



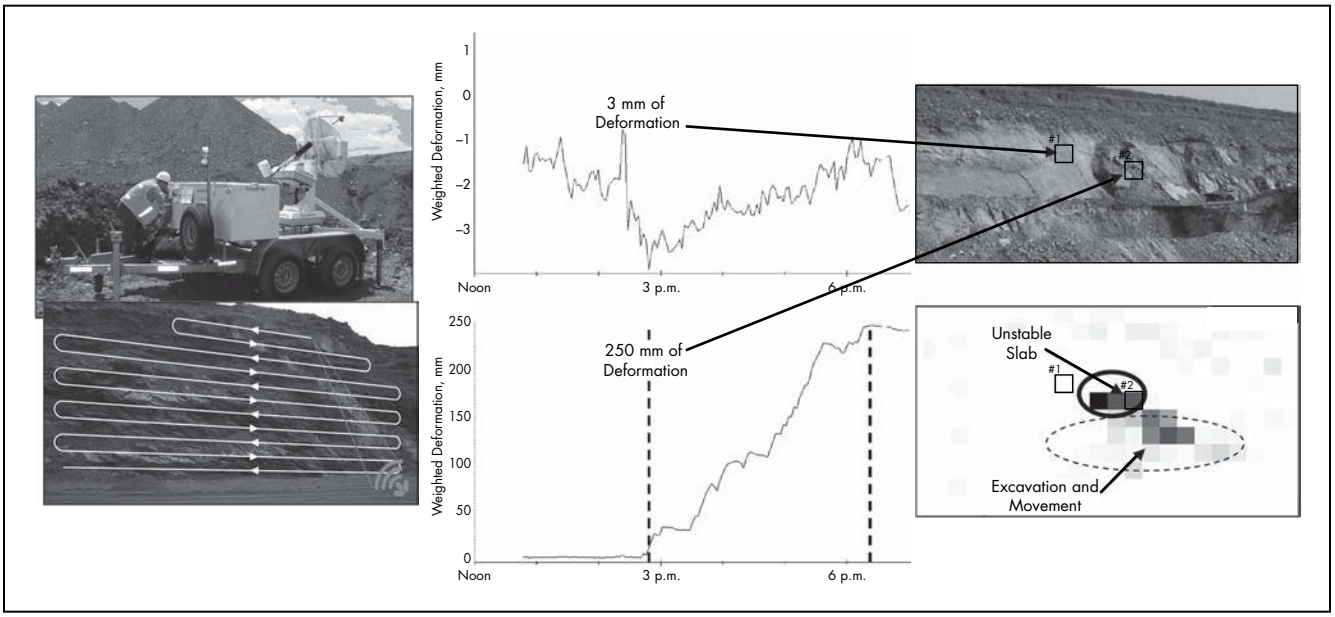
Space-borne interferometric synthetic aperture radar (InSAR) involves the use of satellite-based microwave radar to remotely monitor ground deformations. With repeated orbits and image capture (referred to as stacks), interferometric techniques can be used to resolve 3-D information of surface deformations by analyzing differences in the phase between waves being transmitted and received by the satellite (Figure 8.5-12A). Ground deformations on the scale of centimeters to millimeters can be detected for a surface area resolution of several square meters using these techniques.

Jarosz and Wanke (2003) describe the feasibility testing of InSAR for two mine sites in Western Australia. Results are provided for the Leinster Nickel mine, a sublevel caving operation beneath an open pit, for which InSAR was used to detect the extent of subsidence within the pit and active mining area. Kosar et al. (2003) used InSAR at the Island Copper Mine on Vancouver Island in western Canada to test its ability to provide adequate warning of potential failures during flooding of the pit during its decommissioning. Small ground movements along the steep pit slopes were successfully detected. This lead Kosar et al. (2003) to point to the continuous spatial coverage provided by InSAR compared to the large number of survey or GPS monuments that would have been required to cover the same area. Kosar et al. (2003) also pointed out the ability to remotely obtain data from sections of the pit that were otherwise inaccessible due to safety concerns.

Rabus et al. (2009) describe the use of InSAR to identify and map spatial movements within and around the Palabora open-pit mine due to block-cave mining beneath the finished pit (Figure 8.5-12B). This ability is important for protecting key mine infrastructure located near the pit rim.

Surface Radar

Since about 2000, ground-based radar has become an increasingly efficient method of monitoring open-pit slope movements (e.g., N. Harries et al. 2006; de Beer 2007). These systems are able to provide accurate displacement measurements along the line of sight of a high number of targets (natural or artificial reflectors) with submillimeter precision. The slope-stability radar (SSR) system, described by Harries and Roberts (2007), uses a real aperture on a stationary platform positioned 30 to 1,400 m away from the slope. Extended-range versions are now able to obtain a maximum range of 2,800 m.



Source: (A) Adapted from Rabus et al. 2009; (B) Adapted from AMEC 2006.

Figure 8.5-12 InSAR measurements

Figure 8.5-13 shows the SSR equipment, the generated data that scans a region of the pit wall, and comparisions of the phase measurement in each footprint (pixel) with a reference scan to determine the amount of movement of the slope.

Slope radar technology has revolutionized surface mine monitoring, providing full coverage of a rock slope and offering submillimeter measurements of wall movements. Adverse affects due to rain, dust, and smoke are minimized, although reduced precision occurs in pixels due to low coherence between scans, for example, due to vegetation. Harries et al. (2006, 2009) describe the application of the technology at numerous open-pit mines where it has been successfully used to monitor and provide impending warning of pit slope failures just tens of minutes to hours before failure. Cahill and Lee (2006), Joost and Cawood (2006), and Little (2006) provide well-documented examples of the benefits of this

Source: Adapted from Harries et al. 2006.

Figure 8.5-13 SSR system showing the continuous monitoring of millimeter-scale movements across the face of an unstable open-pit mine slope

technology in managing the risks due to slope instability at major open-pit mines.

LiDAR and Photogrammetry

In addition to pit slope and rock mass characterization, terrestrial LiDAR and photogrammetry can also be used for pit-slope displacement monitoring. Early use of terrestrial LiDAR monitoring focused on surface mine operations, in particular blast design and control. Coggan et al. (2001) illustrated the potential use of LiDAR in monitoring the retrogression of a mine slope failure in a china clay quarry pit. The use of ground-based LiDAR in an integrated surface mine monitoring program is described at the Potgietersrus Platinum mine (South Africa) by Little (2006), where two permanently mounted LiDAR scanners were used to scan a pit wall and help demarcate areas of slope deformation. The ground-based LiDAR at this mine was used in combination with prism surveying and also with slope-stability radar.

Terrestrial photogrammetry has an even longer history in the monitoring of surface mine slopes. Digital photogrammetry forms an excellent record of slope performance and rockfall activity. Tunnel scanners are used for profile scanning (e.g., determination of overbreak, to verify shotcrete thickness, tunnel face change detection with time, and tunnel surface deformation). Systems may be either LiDAR or photogrammetrically based. Wilson and Talu (2004) describe the use of a tunnel scanner at the Finsch mine (South Africa) for providing data on deviation of tunnel profiles from planned and actual, tunnel shape, damage, and alignment.

Photogrammetric systems may use either two digital cameras mounted on a portable fixed bar or one camera with a specialized tripod head allowing controlled repeatable multi-imaging of the tunnel. All systems provide a digital 3-D stereo image of the tunnel. Birch (2008) and Wimmer et al. (2008a, 2008b) describe the use of photogrammetry in underground blasting and fragmentation studies.

Stress Change and Pore Pressures

The change in stress associated with various stages in mining is of significant importance. This can range from monitoring pressures within pillars as adjacent rooms are excavated to the monitoring of pressures in the roof of excavations. Often the associated instruments are used in association with convergence and borehole extensometers to provide data for optimizing future mine design using numerical models and ensuring safety.

Pressure Cells

Borehole pressure cells typically have a measurement range of 0 to 70 MPa. They may be a flat jack (two steel plates welded together with hydraulic oil in between) configured to detect changes in stress perpendicular to the cell, or they may be cylindrical in design measuring the average change in pressure in the plane perpendicular to the borehole. Push-in (or spade) pressure cells are particularly useful for applications such as measuring total pressures in earthfills. These cells can be fitted with integral piezometers to allow measurement of pore water pressures and derivation of effective stresses. Push-in cells have standard ranges of operation up to 5 MPa. Shotcrete stress cells generally consist of two rectangular steel plates welded together with de-aired fluid in between. Changes in pressure in the shotcrete lining are recorded by a change in pressure in the fluid within the cell; electrical resistance or vibrating wire technology is used to record this change in pressure. Standard measurement ranges from 2 to 35 MPa are common.

Direct measurement of stresses in tunnel linings can also be undertaken using the slot-relief or flat-jack compensation method. This involves locating measurement points positioned adjacent to a future diamond saw cut, cutting a narrow slot and measuring the convergence across it due to stress relief between the measurement points, and inserting a flat jack and inflating it until the convergence of the points is fully

reversed. This value is termed the *compensation pressure* and approximates the value of stress in the shotcrete.

Variations in pore water pressure during the lifetime of a mining project are likewise an important component of geotechnical instrumentation and design. Piezometric instrumentation was described previously in the "Groundwater Characterization" section. Ongoing monitoring of pore water pressures can be compared with deformation measurements used to provide an indication of groundwater conditions ahead of the mining front, used to provide information for remediation measures, and used as an input for numerical modeling.

Microseismicity

Microseismic monitoring provides mining and rock mechanics engineers with information on the stress conditions in the rock mass and how the ground is responding to induced stresses due to changing mine excavation geometries. The location of seismic events and their characteristics provides valuable information, both in terms of improved mine safety, and optimization of mine design and sequencing. Commercial microseismic monitoring systems have been in use since the 1970s and were originally used in underground rock-burst-prone mines (see Blake and Hedley 2004). The systems are now increasingly being used in both underground and surface mines.

Numerous companies provide state-of-the-art 24-bit digital seismic recorder systems that integrate into local area networks (LANs) or wireless networks. Hudyma and Brummer (2007) address the key questions in the design of a seismic monitoring system, mainly the optimal number, type, and location of the sensors. Seismic sensor arrays are usually composed of uniaxial and triaxial sensors. Triaxial sensors can provide seismic source parameters (energy, seismic moment, and magnitude), whereas uniaxial sensors primarily provide accurate seismic locations.

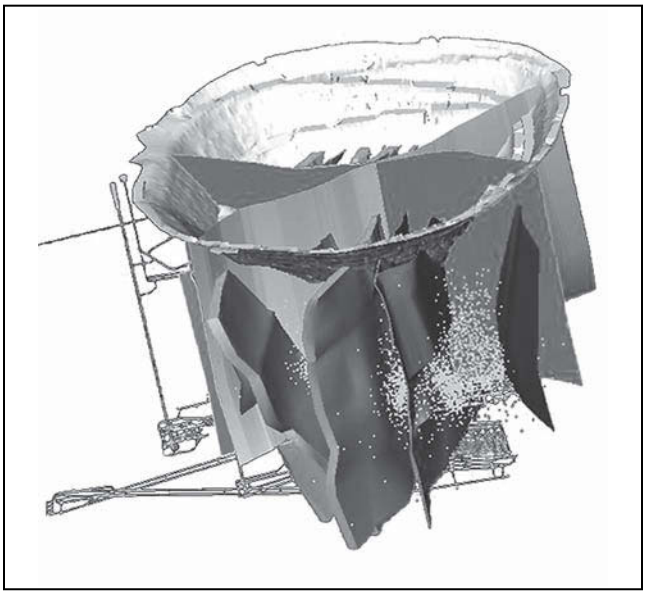
The sensitivity of a seismic array is directly proportional to the number of sensors used. The source location accuracy is also proportional to the number of sensors in the seismic array. Hudyma and Brummer (2007) present a guideline that the system source location should be approximately 5% to 10% of the intersensor spacing. Where possible, the seismic array should surround the rock mass of interest, but if this is not practical, the array should be spread geometrically in three dimensions. If there are an insufficient number of triaxial sensors, the seismic parameters may be influenced by attenuation or by seismic-event energy radiation patterns.

The reader is encouraged to consult Hudyma and Brummer (2007) for further useful discussion of the practical aspects of seismic array design in underground mines, including design for future mining stages, sensor installation, automatic source location reliability, system calibration and maintenance, seismic data analysis, and ensuring optimal performance from seismic systems. These authors emphasize that microseismic monitoring in underground mining can be optimized through good system design, frequent data analysis, and routine auditing of the system. Delgado and Mercer (2006) provide an interesting description of one of the largest mine microseismic systems in the world at the Campbell mine in Red Lake, northern Ontario, Canada. Also discussed are some of the issues faced.

Recent years have seen an increase in the successful use of microseismic systems in open-pit mines, spurred on by the ever-increasing depths of large open pits and the presence of underground mines beneath open-pit slopes. Lynch and Malovichko (2006) describe how microseismic monitoring in open-pit slopes has been routinely practiced since 2002 at mines in Namibia, South Africa, and Australia. They report that monitoring had been conducted for more than 25 open-pit slopes, all of which showed signs of brittle fracturing, in one case at a slope height of only 80 m. They emphasize that for reliable event locations, the seismic sensors array should surround the volume of rock being monitored, which in an open-pit mine means that they must be located near to the surface as well as at the bottom of the monitored volume.

In practice, potentially unstable slopes are monitored rather than the entire pit. Typical sensor separations are in the order of 100 to 200 m. The system described by Lynch and Malovichko (2006) involved near-surface sensors installed in short (i.e., 10 m) vertical boreholes using 4.5-Hz geophones, and in long inclined holes (i.e., 100 to 300 m) using 14-Hz omnidirectional geophones. These authors show correlations between microseismic activity and mining at the base of the slope, removal of broken rock, and the location of seismically active structures behind the pit wall.

Wesseloo and Sweby (2008) emphasize the increasing role that microseismic monitoring will be required to play as open pits increase in depth with a consequent increase in stress and a greater uncertainty in the pit slope deformation mechanisms. These authors provide an overview of microseismicity in rock slopes and in mine slopes in particular. They also provide an excellent account of microseisimic response to mining, event size (energy), and S-wave to P-wave ratios. An informative case study of microseismicity at an Australian open pit is presented by Wesseloo and Sweby demonstrating the future potential of this monitoring technique in open-pit environments.



DATA AQUISITION AND PRESENTATION

Data reliability is of primary importance, requiring mine personnel to have confidence in the performance of an instrument. This can be gained, in part, through the performance of routine calibration checks, instrument inspections, and maintenance. Data integration and data management are also key issues. Important new elements such as Web geographic information system (GIS) services can be integrated into the operational resources of decision makers. These services are linked to early warning systems through wireless data acquisition and transmission technologies, which enable real-time data from multiple remote monitoring sites to be accessed and viewed by mine geotechnical staff, both on- and off-site, by means of the Internet. This is proving to be a highly valuable resource where an unstable pit slope threatens production and/or worker safety. Spatially and temporally distributed measurements should be combined with a knowledge engine and an evolving rule base to form the hub of a decision-support system (Hutchinson et al. 2007).

Wireless Data Transmission

Wireless technology enables continuous real-time monitoring of production activities and rock mass response to mining throughout an operation. Although automatic data-acquisition systems cannot replace engineering judgment, when combined with wireless data transmission, the following advantages can be gained (Dunnicliff 1993):

- More frequent readings
- Retrieval of data from remote/inaccessible locations

Source: Adapted from Woo et al. 2010.

Figure 8.5-14 Integrated mine-data model combining surface and underground mine plans, geology, and microseismic data

- Instantaneous transmittal of data over long distances
- Measurement of rapid changes/fluctuations in monitored parameter
- Increased reading sensitivity
- Reduction of measurement and recording errors
- Increased flexibility in selecting, managing, and storing data

From a system's operation perspective, automated wireless systems increase safety and lower costs. The fundamentals of a communication system include a transmitter, a receiver, and a surge arrestor, which allows reliable communication over distances of a few kilometers. The advantages of these systems over satellite or cell phone communication include lower costs and ease of use. The disadvantages include the requirement to use repeaters if a line of sight over long distances is not possible. It is vital that the network be reliable and always available, even in difficult terrain and harsh weather conditions.

Data Immersion and Visualization

The acquisition of geotechnical mine data can lead to the generation of massive volumes of data from in-situ surveys and mine operations, making managing, storing, and utilizing the data difficult. Improved computer performance and new software developments are changing this situation. Easy-to-use integrated geotechnical data-management systems with 3-D visualization and data immersion can be envisaged, linking monitoring, analysis, prediction, and remediation.

These attempts at data "fusion" are moving toward the adoption of virtual reality technology, where the identification of hidden relationships, the discovery and explanation of complex data interdependencies and the means to compare and resolve differing interpretations, can be facilitated (Kaiser et al. 2002). Spatial databases can be developed to integrate the different data sets being used for mine design and geotechnical analyses (geological, geotechnical, operational, etc.) into an interactive 3-D visualization and virtual reality environment (Figure 8.5-14).

CHAPTER 8.6

Hard-Rock Ground Control with Steel Mesh and Shotcrete

John Hadjigeorgiou and Yves Potvin

Ground control practices in underground mines are constantly evolving, always with the goal of improving mine safety and economics. These changes are often influenced by the mining methods used, the level of mechanization and types of equipment used, and the labor cost and skill set. Ground control practices are further defined by rules and regulations linked to risk tolerance and to the mining cultures of different jurisdictions or countries.

In this chapter, a distinction is made between reinforcement and surface support:

- *Reinforcement* is a technique in which elements such as rock bolts are applied internally to the rock mass. Chapter 8.8 provides a thorough review of reinforcement techniques.
- *Surface support* is a technique in which elements such as shotcrete or steel mesh (the term *screen* is also commonly used in North America) are applied to excavation surfaces externally to the rock mass. This chapter examines surface support as it is used for underground metal mining. A comprehensive collection of surface support applications in mines is presented in Potvin et al. (2004).

The traditional approach to ground control in underground metal mines was to install reinforcement to stabilize potential wedges and blocks that might "daylight" at the surface of excavations. This required good ground-awareness skills on the part of the mine workers, who used their experience to read the ground and install reinforcement at appropriate locations to stabilize the rock mass around excavations. Small blocks or "scats" that formed at the rock surface around the excavations due to stress changes and blast vibrations were controlled by frequent scaling. When ground conditions were less competent, the rock surface was controlled with mesh. The main role of surface support was to support the dead weight of smaller rock blocks between the rock bolts.

Since about 2000, a concerted effort toward minimizing the risk of rockfall injuries has accelerated the development of improved ground control practices. When it was recognized that small rock falls cause many injuries, the systematic use of surface support became common practice in most mechanized mines (Nedin and Potvin 2005). Several mines changed their ground support strategy, designed originally to suit local conditions, to the systematic application of pattern bolting and surface support. Current ground support standards are well documented and reflect the current industry's low-risk-tolerance approach to rock falls.

In this new ground support strategy, reinforcement elements hold or pin larger blocks, and surface support elements catch smaller blocks. However, this approach is less applicable in ground conditions where the rock mass is already in a postfailure or yielding state due to excessive static or dynamic loading. In these cases, the excavation often experiences large displacements and the surrounding rock mass crumbles. To maintain the integrity of the excavation surface (wall or roof), surface support should be capable of containing the bulk of the broken rock mass and later movement resulting from stress changes such as stoping. The surface support must deform with the rock mass while the load transfers from the surface support, through the plate or surface fixture arrangements, to the reinforcement. The function of reinforcement is to retain the surface and limit displacement or convergence. Thus, reinforcement and surface support are part of an integrated system that transfers and shares load until the excavation surface is stabilized or until the support system fails at its weakest link.

SURFACE SUPPORT ELEMENTS

Although a wide variety of rock bolts are available, the choice of surface support elements is limited to steel mesh, straps, and shotcrete. Steel mesh is the most popular in metal mines, but shotcrete has been gaining in popularity since its introduction in the late 1980s. Straps, also considered to be surface support even though they do not completely cover the rock surface, are used to contain the rock mass between reinforcement elements and distribute load between the reinforcement elements used to install the straps.

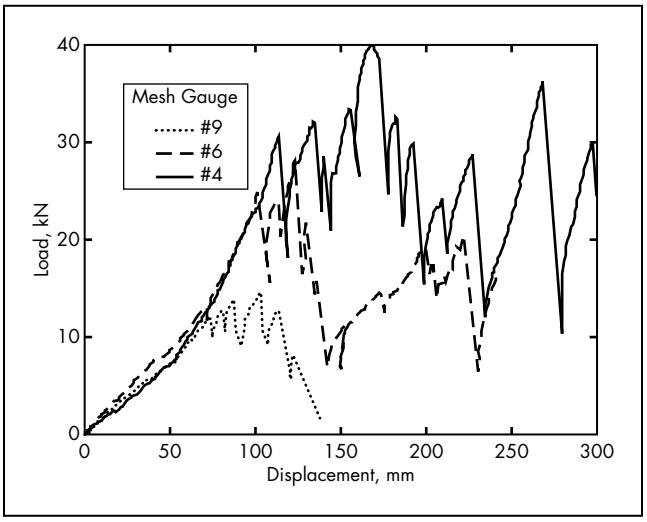
Steel Mesh

Two main types of steel mesh are used in the mining industry: welded-wire mesh (weld mesh) and chain-link mesh, also called diamond mesh. Expanded metal mesh is also available but is not widely used. Mines that use a mechanized approach to mesh installation use predominantly precut sheets of welded-wire mesh.

Welded-Wire Mesh



Sheets of welded-wire mesh are precut to customized dimensions. In Australia, sheets are generally large (2.4 × 3.0 m [8 × 10 ft]) to promote productivity; accounting for overlap, a row of six sheets is commonly used to cover 40 m^2 (~130 ft^2). In North America, installation involves more manual handling, and sheets tend to be smaller (1.2–1.5 × 3.0 m [4–5 × 10 ft]) and thus lighter in weight. Typical dimensions for welded-wire mesh are shown in Figure 8.6-1.

Notwithstanding quality control issues and assuming the use of standard-aperture welded-wire mesh, wire thickness (*T* in Figure 8.6-1) is the main influence on wire performance. In North America, wire thickness is expressed in terms of gauge; #4, #6, and #9 gauge (5.8-, 4.9-, and 3.7–3.8-mm diameters, respectively) are most commonly used. In Australia, a diameter of 5.6 mm is most commonly used, but sometimes diameters as small as 4.95 mm are also used.

Selection of mesh aperture (*S* in Figure 8.6-1) is in theory based on the smallest block that the mesh must contain. In North America, mesh aperture is often standardized at 100 × 100 mm (4 × 4 in.). A smaller aperture (such as 50 × 50 mm or 75 × 75 mm [2 × 2 in. or 3 × 3 in.]) is used where extra load-bearing capacity is required. A larger aperture (such as 150 × 150 mm [6 × 6 in.]) can be used when shotcrete is to be sprayed over the mesh; the larger aperture allows for good penetration of the shotcrete through the mesh. When the mesh is expected to provide support for a long time or in corrosive environments, galvanized coating is used to protect against corrosion.

Welded-wire mesh is relatively inexpensive and can be installed quickly because it is easily attached to existing reinforcement by means of plates and rock bolts. It can support small blocks and its energy absorption properties enable it to provide some control during rock bursts. It can also be used with shotcrete. No. 9 gauge mesh is susceptible to damage from fly rock. No. 6 gauge mesh can be a good substitute but is less flexible and more difficult to install around corners. Mesh is fabricated using longitudinal wire to which cross wires are spot-welded. When it is to be installed near an advancing face, optimally the cross wire should be laid against the rock surface and the longitudinal wire laid on the outside (facing the opening) and along the drift axis. This procedure mitigates blast damage by flying rocks, which are less likely to catch into cross wires.

In North America, it is popular to install ground support systems using dedicated bolting machines. The MacLean bolter features a scissor platform with a rock-bolting boom mounted at the tail end and operator controls mounted at the front end (Figure 8.6-2). Hooks to hold sheets of mesh are

Source: Tannant 2004.

Figure 8.6-4 Load vs. displacement for three gauges of welded-wire mesh

located on the side of the platform. Installation of bolts and mesh in a single pass requires some manual handling of the mesh during bolting. Mesh can also be installed in a second pass, after bolting is completed, by means of pressure plates fitted over installed threaded bars (Figure 8.6-3).

Welded-wire mesh is commonly installed manually by means of an air leg, which is often the only option in countries where mining mechanization is low. Manual installation is performed with a handheld drill in smaller excavations, or from scissor platform trucks or integrated tool-carrier baskets in larger drifts. In practice it is difficult, especially with large-diameter wire or stiff welded-wire mesh, to ensure that the mesh sheets are installed tightly against the rock mass surface, and manual installation increases the risk of minor injuries.

A number of other quality control issues are common to all welded-wire-mesh installations. In particular, poor overlap between sheets is highly undesirable, because it may later expose mine personnel to rockfall hazards. Standard practice is to overlap three squares of mesh, but in difficult ground conditions, drift profiles are often erratic and proper overlap can be difficult to obtain.

Villaescusa (2004) identified three modes of mesh failure:

1. Shear failure at the weld point, presumably due to the technology used for welding and to quality control issues such as dirty electrodes or dirty wire
2. Heat-affected zone failure, due to excessive weld head pressure and temperature
3. Tensile failure of the wire, due to excessive tensile load

The load and displacement capacity of mesh depend on the type of metal and size of the wire and dictate the load-bearing capacity of the wire and weld. It follows that weld capacity should be comparable to wire strength.

Tannant (2004) and Thompson (2004) developed testing procedures to better define the capacity of mesh and published pull-test results for a variety of mesh and bolt arrangements. On tests of standard (5.6-mm diameter) Australian welded-wire mesh, Thompson found load capacity to be ~20–40 kN with displacements of 100–350 mm [4–14 in.]. The variability of results arises from variations in simulated bolt patterns and test procedures. In general, a smaller bolt pattern (1 × 1 m [3.3 × 3.3 ft]) supports higher loads but produces a stiffer response than does a larger bolt pattern (1.5 × 1.5 m [5 × 5 ft]). Tannant tested load as a function of displacement for the three common mesh gauges used in Canada in a simulated bolt pattern of 1.2 × 1.2 m (4 × 4 ft) (Figure 8.6-4).

Chain-Link Mesh

Chain-link mesh is used less than welded-wire mesh. Its main advantage is its energy absorption capacity, which is associated with its greater displacement capacity. Consequently, one application of chain-link mesh is part of a rock burst support system. Its main disadvantages are that it tends to unravel when damaged and that it is difficult to apply shotcrete through it. Typical chain-link mesh dimensions are shown in Figure 8.6-5.

Chain-link mesh differs from welded-wire mesh in its ease of installation and its deformation capacity. It has very low rigidity, which makes handling and installation awkward and difficult. It comes packaged in rolls and needs to be gradually and manually unrolled during installation to its final position against the rock surface. Installation is labor-intensive and difficult to mechanize. As a result, it is not widely used in highly mechanized underground mines but remains popular in the mines of, for example, South Africa and South America.

Mechanization of chain-link-mesh installation is currently being addressed by development of the Rock Mesha mechanized mesh handler, which can be mounted on one of the booms of a twin-boom jumbo drill (Figure 8.6-6) (Coates et al. 2009). One boom unrolls the mesh against the rock surface while the other boom installs bolts. A prototype of this equipment is being tested in Australia.

Interestingly, the low rigidity of chain-link mesh can be an advantage in terms of its deformation capacity. Tannant (2004) pull-tested three types of mesh: chain-link, welded-wire, and expanded-metal (Figure 8.6-7 and Table 8.6-1). Expanded-metal mesh is seldom used in underground mines and is not discussed here. Chain-link mesh demonstrated a displacement capacity of ~400 mm (16 in.) at peak load with good post-peak behavior, retaining >50% of its load capacity at 800-mm (32-in.) displacement. The load capacity of chain-link mesh, like that of welded-wire mesh, is largely a function of wire size and the type of steel used. In Canada, #9 gauge (3.7-mm) wires are commonly used; in South Africa, wires of 3.2–4 mm are standard.

High-tensile, light steel chain-link mesh is also available for use when ground conditions require extra load-bearing capacity, whether the situation is static or dynamic (Coates et al. 2009). For example, high-tensile Tecco mesh, which uses wire 4 mm in diameter and weighs only 2.6 kg/m^2 (0.53 lb/ft^2), was tested at 110 kN using the test procedure described in Player et al. (2008).

Load Transfer Between Mesh and Reinforcement

The load-bearing capacity of mesh is well suited for containing small blocks that can detach between reinforcement elements. Standard reinforcement patterns used in mines generally call for elements to be spaced 1–1.5 m (3.3–5 ft) apart in both directions, so that the maximum block weight that can fall from between the bolts is ~2 t, or metric tons (~20 kN), well within the capacity of most mesh.

The detached blocks exert a pulling force, which is transmitted from the mesh to the bolts via the bolt plate. The role of the bolt plate is to transfer force to the mesh, maintain tension

in the bolts, keep the mesh and straps in place, and maintain the confinement of rock blocks beneath the collar.

When bolt plates are small, sharp, and square, the total force may be transmitted entirely through only a few wires, and the sharp edge of a plate can cut the wire. This situation can be remedied by using larger plates to distribute load to more wires or by using shaped plates to minimize cutting edges. Circular plates are available, as are other specially designed plates such as butterfly plates, which are large, thin, and deformable. The more popular bolt plates are shown in Figure 8.6-8 and their dimensions are listed in Table 8.6-2. It is generally accepted that domed plates provide the best contact for irregular rock surfaces. If the rock surface is very irregular, more flexible plates (6 mm [0.25 in.]) should be used.

The weakest link of the total support system can be the mesh, the plate, the connection between the plate and the mesh (e.g., due to plates cutting wires), or the rock bolt. Rock bolts and plates are designed to fail at comparable loads so as to avoid a weak link. However, this is true only under ideal tensile conditions. When the load has a strong shearing component, or a point load is applied to one component because of incorrect installation, early failure of the bolt heads or the plates can occur. The heads (ring) of friction bolts are particularly prone to early failure when bolts are installed at an angle to the rock surface or when they are hammered in too hard.

In squeezing ground or in rock burst conditions where the rock mass experiences large deformation, both the load capacity and the deformation capacity of the support system are tested. Comparison of the load and deformation capacities of mesh and bolts shows a clear mismatch in their properties. Grouted bolts are stiff and allow displacements of only a few millimeters before failure, but they have a load capacity in the range 150–200 kN. In contrast, mesh allows large displacements of several hundreds of millimeters but has a load capacity of only ~20–40 kN. As the ground deforms, mesh deforms with it but fails when either the local load exceeds 20–40 kN or the displacement exceeds 100–350 mm (4–14 in.). In these cases, mesh is incapable of transmitting loads that exceed its own load or displacement capacity to the bolts. A tighter bolting pattern in such cases divides the excavation surface into smaller areas between the bolts, resulting in lower local loads for the mesh to contain. Where ground displacement is considerable, bleeding the mesh and rehabilitating the ground support is a recurring issue.

Straps

Straps are generally used as surface support in special applications rather than as a part of a systematic support system in

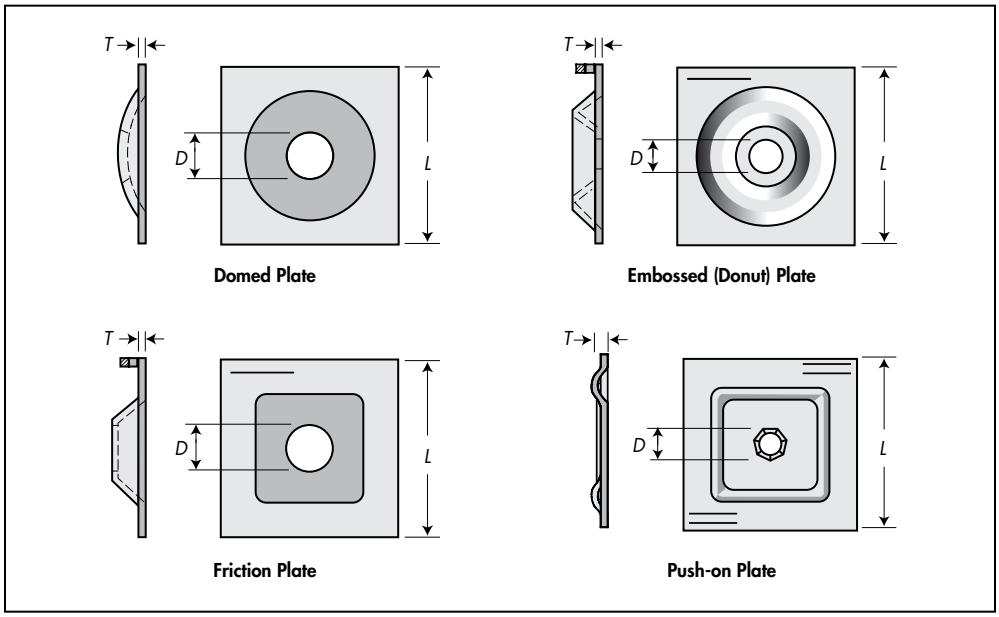

Figure 8.6-8 Common types of bolt plates for installing mesh

Table 8.6-2 Bolt plate dimensions

Plate Type	*L*, mm (in.)	*T*, mm (in.)	*D*, mm (in.)
Domed	125, 150, or 300 (5, 6, or 12)	6.4 or 9.5 (¼ or ⅜)	Variable
Embossed (donut)	150 or 200 (6 or 8)	21 to 29 (13⁄16 to 1⅛)	21 to 29 (13⁄16 to c⅛)
Friction	150 (6)	33-mm bolts: 4.8 (3⁄16)	33-mm bolts: 36 (1 7⁄16)
		39-mm bolts: 4.8 (3⁄16)	39-mm bolts: 41 (1⅝)
		46-mm bolts: 6.4 (¼)	46-mm bolts: 48 (1⅞)

mines. They can be installed either on their own against the rock mass surface by means of rock bolts or over mesh to provide extra strength and stiffness to the surface support. When used alone, they can support key blocks between rock bolts. However, if key blocks behind the straps loosen and fall, the strap no longer has good contact with the rock surface and may become ineffective in this area. Best results are obtained when the straps are installed tightly across the most prominent structures. Common practice is to wrap straps around pillar "noses" to prevent progressive deterioration of the pillars, particularly those submitted to vertical load. The three types of strap used in mining operations are steel straps, mesh straps, and Osro straps.

Steel Straps

Steel rock bolt straps are long rectangular bands of steel with preperforated holes through which rock bolts are inserted for installation purposes. Two types of steel straps are available: the plain steel strap (Figure 8.6-9) and the W steel strap (Figure 8.6-10). The plain steel strap is often thicker (up to 6 mm [0.25 in.]) and narrower (100 mm [4 in.]), and is variable in length (0.9, 1.2, 1.4, 1.8, or 2.4 m [3, 4, 4.6, 6, or 8 ft]) to accommodate different situations. It has elongated holes to facilitate installation. The W steel strap is thinner (up to 4 mm [0.15 in.]), has circular holes often spaced every half meter, and has shaped edges to increase rigidity and resistance to bending. It is available in variable widths (~125–330 mm [5–13 in.]) and lengths (~1.3–6 m [4–20 ft]).

It is sometimes difficult to achieve a quality installation with steel straps because the preperforated holes do not always line up with areas where rock bolt holes can be easily collared and drilled. As a result, the straps cannot always be installed very tightly against the rock mass and can therefore be less effective in containing key blocks.

Mesh Straps

Mesh straps are bands of heavy #0 gauge welded mesh, available in precut lengths of ~1.2–4 m (4–13 ft) (Figure 8.6-11). They are easy to install because bolts can be fitted at convenient locations through the mesh, and are therefore used increasingly in underground mines.

Mesh straps are particularly popular in difficult ground conditions, such as areas of squeezing ground or areas prone to rock bursts, where they are installed over welded-wire mesh to provide extra load-bearing capacity, limit bulging of the mesh, and facilitate load-sharing between bolts (Figure 8.6-12).

Osro (Oslo) Straps

The Osro (also known as Oslo) strap was developed for deep South African rock-burst-prone gold mines. It is strong and flexible for high-energy absorption. It is made of a series of (usually five) longitudinal, parallel, round, smooth bars, typically of 6–10 mm in diameter although larger diameters can be used. The longitudinal bars are attached together with strapping crossbars of 5.5 mm in diameter (Figure 8.6-13). The crossbars are not welded to the longitudinal bars but rather are loosely twisted around them so as to allow free rotational movement of the longitudinal bars. This adds to the ductility

and therefore the energy absorption capacity of the strap when it is submitted to large deformation or dynamic events. Strap widths vary from 250 mm to 1 m (~10 to 40 in.); lengths vary from 1 to 6 m (~3 to 20 ft).

Cable Lacing

A technique known as cable or rope lacing is commonly used in deep South African gold mines as a surface support in rock-burst-prone areas. It is also sometimes used to support drives in highly deformable kimberlite in diamond block caving mines in South Africa. The technique consists of installing destranded, degreased hoisting cables to form a cable web on the surface of an excavation, generally over wire mesh or alternatively over shotcrete (Figure 8.6-14). It allows for large deformation and provides high load-bearing capacity. Tests performed by Stacey and Ortlepp (2007) show it to have the highest dynamic energy absorption capacity of all surface support techniques, with excellent load-transfer capability to rock reinforcement.

In the late 1980s, some Canadian mines used cable lacing in specific rock-burst-prone areas. Although it was very effective for controlling rock burst damage, the technique was seen as being too labor-intensive and costly, and is seldom used in countries that practice mechanized mining.

SHOTCRETE

Shotcrete is concrete that is applied to the rock surface by pneumatic shooting at high velocity using specialized equipment. It is composed of 15%–20% cement, 30%–40% coarse aggregates, 40%–50% fine aggregates, and 2%–5% additives. Water is added to the mix to hydrate the cement and initiate the chemical reaction whereby the concrete gains strength. The water must be clean and free of chemical components that are potentially detrimental to the reaction. The water/cement ratio (expressed in units of liters per kilogram) influences cement hydration. The final product should be in the range 0.3–0.5 L/kg. Often steel or synthetic fibers are added to the mix to improve the post-peak behavior of the concrete; the resulting product is commonly called fiber-reinforced shotcrete (FRS) or Fibercrete.

The use of shotcrete as a surface support, as well as for construction applications in mines, has increased rapidly since the 1980s. The flexibility of the equipment, the choice of mixing methods, and the availability of shotcrete has contributed to its growing popularity as the preferred surface support method in underground mines. Shotcrete is often perceived as the surface support method of choice when the rock mass is heavily fractured. Its initial adhesion properties lend it a glue-like effect on heavily broken rock mass, which helps prevent the rock mass from crumbling. Contrary to the case for mesh, which contains blocks of rock only after they detach from the surface and therefore begins its action after the rock mass has failed, shotcrete provides immediate reactive support action at very low displacement, as soon as the rock mass starts to move and long before it reaches a yielding state. As a result, shotcrete is much more efficient at preserving the confinement within the rock mass surrounding an excavation.

In recent years, systematic application of shotcrete after each blast, also known as "in-cycle shotcreting," has gained popularity as an alternative to the so-called "campaign shotcreting" of an entire section of tunnel. In-cycle shotcreting has a number of advantages and disadvantages. Its advantages are as follows: (1) its rapid application minimizes time-dependent

rock mass deterioration; (2) it allows for reinforcement to be installed after the shotcrete, by means of bolts that pin the shotcrete to the wall; and (3) it favors good load transfer between the surface support and the reinforcement. A disadvantage is that the rock mass is covered immediately after being exposed, leaving little opportunity for geological and geotechnical data to be collected. New data-collection techniques such as digital stereophotogrammetry are being used to overcome this problem.

Two main techniques exist for applying shotcrete in mines: dry-mix and wet-mix. In the dry-mix technique, water is added to the mix only at the nozzle. Advantages and disadvantages of the technique are as follows (based on ACI Committee 506 [2005] and the authors' experience).

- Advantages of the dry-mix technique:
  - Maximum flexibility in delivery in terms of time, because curing begins only when the shotcrete is applied
  - Flexibility in terms of transportation, because shotcrete ingredients can be carried even long distances to the workplace in premixed bulk bags, and the necessary equipment (including mixers, pumps, hoses, and more) is compact and mobile; this flexibility makes this method very popular in deep mines that are accessible only by shaft
  - Instantaneous control over mixing water and consistency of the mix at the nozzle to meet variable field conditions
  - High suitability for placing mixtures containing lightweight aggregates or refractory materials
- Disadvantages of the dry-mix technique:
  - Large percentage of rebound
  - Dusty environment created
  - Low application productivity
  - Low volume per hose size

In the wet-mix technique, shotcrete mix is prepared at a custom-built concrete plant often located on the surface but sometimes underground, or from a local supplier. Shotcrete is transported by agitator truck from the plant to the point of application. Alternatively, a slick-line can be installed to alleviate some of the transportation difficulties of bringing underground shotcrete and other concrete used for construction. Advantages and disadvantages of the technique are as follows (based on ACI Committee 506 [2005] and the authors' experience).

- Advantages of the wet-mix technique:
  - Generally minimal quality control issues, because mixing is done in a controlled plant environment
  - Relatively low sensitivity to the skills of the nozzle operator
  - High delivery rates
  - Low percentage of rebound
  - Minimally dusty environment
  - Ease of mechanization
  - Control of mixing water at the delivery equipment, where it can be accurately measured
  - Good assurance that mixing water mixes thoroughly with other ingredients
  - Minimal dust and cementitious materials lost during the shooting operation
  - Normally low rebound, resulting in less waste
  - High volume per hose size
- Disadvantages of the wet-mix technique:
  - Transport and delivery logistics are difficult in deep mines having shaft access only
  - Equipment is more expensive
  - Not suitable for small-volume applications

A prerequisite for the successful application of shotcrete is the use of properly operated and maintained equipment by qualified personnel. In general, dry-mix equipment consists of either single- or double-chamber guns (batch) or rotary continuous-feed guns. With batch guns, a charge of material is placed in the chamber and the chamber is closed and pressurized, feeding the material into a delivery pipe or hose. With double-chamber guns, the upper chamber serves as an airlock during the charging cycle to allow for continuous operation. Rotary guns use the rotating airlock principle to supply a continuous feeding action.

Wet-mix applications make use of pneumatic feed guns. Slugs of material are introduced into the delivery hose and compressed air is added at the discharge sump at the nozzle to increase the velocity of the mixture. Positive displacement

guns can also be used. A solid column of shotcrete is forced by mechanical, air, or hydraulic pressure through a hose in a continuous stream to the nozzle. Air is injected at the nozzle to break up the stream and increase exit velocity.

Basic Components of Shotcrete

The main components of shotcrete—cement, aggregates, water, admixtures, and potential cementitious additions—are described in Vlietstra (2009) and ACI Committee 506 (2005).

Cement

The binding agent in shotcrete is cement, quite often an ordinary portland cement. Portland cement contains lime, silica, alumina, and iron oxide. Lime is the main component; the other three are included to balance the chemical composition of the cement. To control the initial reaction of the cement with water (the hydration process), gypsum is also added. The chemical reaction of hydration is complex and beyond the scope of this chapter. It is important to note, however, that the process is time-dependent, being slower during the first few hours. It is also temperature-dependent, being faster at higher temperatures. The other factor affecting the hydration process is grind size, which is often measured in terms of surface area and quantity of 45-μm residue. Finer grind facilitates more rapid hydration and earlier strength gains.

Aggregates

Aggregates form the matrix of the shotcrete and are bound together by a cementitious paste to become concrete. Both coarse and fine aggregates are used. The combined aggregate should generally comply with one of the gradations listed in Table 8.6-3. Maximum aggregate size is dictated by pumping limitations and the need to minimize rebound. Coarse particles can block the nozzle and subsequent cleaning can be time-consuming. Larger particles tend to rebound when sprayed on a hard surface. They can also penetrate already placed shotcrete and produce craters that are difficult to fill (Melbye et al. 2001). A guideline to avoid segregation and clogging is to ensure that ≤30% passes through a 0.3-mm sieve. If the proportion of fine material exceeds this, more water is required for hydration.

Aggregates should be clean—that is, free of dirt, chemical impurities, and organic material. The mineralogical composition of the aggregate should be inert under normal mining conditions, and free of sulfides and other reactive minerals. Equidimensional aggregate particles generally give better results than do those with elongated or platy shapes, and a rough surface assists cement paste bonding. Aggregates must be at least as strong as the specified concrete final product.

Water

Mixing and curing water should be clean and free of material that can be detrimental to concrete. If potable water is not available, the water must be tested to ensure that the strength of mortar cubes made with it is ≥90% of the strength of mortar tubes made with distilled water.

Admixtures

Admixtures are chemicals that are put into concrete to affect the mixing, placing, and curing processes. Typical admixtures are accelerators, air-entraining agents, and pozzolans.

For wet-mix shotcrete, a consistency corresponding to a target slump of ~150 mm (~6 in.) facilitates mixing, pumping, and shooting. In a slump test, a concrete sample is placed in a metal slump cone of height 300-mm (12-in.), bottom diameter of 200 mm (8 in.), and upper diameter of 100 mm (4 in.). The concrete is tapped down following ASTM C143/C143M 2009 procedures and the cone is lifted vertically to remove it without disturbing the sample. The sample is allowed to slump until it stabilizes. The slump height is the distance that the sample settles below its original 300-mm (12-in.) height.

Table 8.6-3 Gradation limits for combined aggregates

Sieve Size (U.S. Standard square mesh)	% by Weight Passing Individual Sieves	
	Gradation #1 (fine-aggregate grading)	Gradation #2 (coarse-aggregate grading)
19 mm (¾ in.)	—	—
12 mm (½ in.)	—	100
10 mm (⅜ in.)	100	90–100
4.75 mm (No. 4)	95–100	70–85
2.4 mm (No. 8)	80–98	50–70
1.2 mm (No. 16)	50–85	35–55
600 μm (No. 30)	25–60	20–35
300 μm (No. 50)	10–30	8–20
150 μm (No. 100)	2–10	2–10

Source: ACI Committee 506 (2005).

Because consistency and slump are controlled mainly by the water/cement ratio, which in turn influences the final strength of the shotcrete, water-reducer admixtures (plasticizers and superplasticizers) are often used to achieve the desired consistency for shotcrete application. Hydration controllers are also often required to delay hydration and accommodate the time required for the wet mix to be transported from the plant to the working face. Without admixtures, shotcrete shelf life would be only 1 to 2 hours, depending on ambient temperature. Hydration controllers can extend shelf life up to 3 days without affecting the short-term or long-term strength of the shotcrete.

An accelerator can be added at the nozzle to cancel the retarding effect of the hydration controller. For both dry-mix and wet-mix techniques, accelerators are required to obtain early adhesion to the rock surface and induce rapid gains in shotcrete strength. Accelerators are also used to apply thick layers of shotcrete in a single pass. Unfortunately, however, accelerators tend to reduce the final strength of shotcrete. Accelerator dose is generally expressed as a percentage of the total weight of cementitious content. Doses are typically 2%–5% for dry mix and 3%–10% for wet mix. A number of accelerators are available and performance testing is strongly recommended prior to product selection because local cement can respond differently to accelerators. Noncaustic alkali-free accelerators are gaining in popularity because they are relatively environmentally friendly and induce rapid gains in shotcrete strength with minimal long-term loss of strength.

Cementitious Additions

It can be advantageous to replace a portion of the cement with pozzolanic material such as microsilicia (silica fume) or fly ash. If these materials can be obtained at reasonable cost, they can accrue economic benefits and improve some of the short-term and long-term properties of shotcrete.

Silica fume is an ultrafine material (particle diameter of 0.1–0.2 μm) whose spherical particles have high pozzolanic

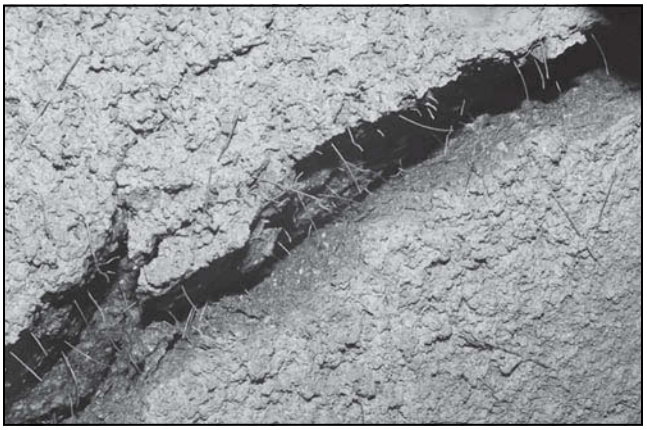
properties. In the short term, it has a lubricating effect on the mix, increasing flowability and reducing equipment wear. It also minimizes rebound and aids adhesion to rock. In the long term, it improves shotcrete strength and durability.

Fly ash is a coarser material (particle diameter of <50 μm). Compared to silica fume, it is generally less expensive but also less effective in improving shotcrete properties.

Reinforced Shotcrete

Concrete (including shotcrete) is a brittle material with high compressive strength but low tensile and flexural strength. The failure mechanism for shotcrete is discussed in the "Shotcrete Stabilization Mechanisms" section. The way it is applied in underground mining causes it often to be subject to bending and flexural forces. Therefore, some type of reinforcement is required in most mining applications. Two common types of reinforced shotcrete are used in mines: mesh-reinforced shotcrete and FRS. Both are widely used and have a number of variations.

Mesh-Reinforced Shotcrete



In the early days of shotcrete application in Canadian mines in the 1980s, it was common practice to apply shotcrete over mesh as a reactive action, particularly when ground conditions were deteriorating. The results were often very good and acceptance of the technique was rapid. The technique then became proactively used as a high-capacity surface support system, applied in areas where difficult conditions were anticipated. Mesh-reinforced shotcrete remains widely used in Canada and South Africa.

In extreme conditions, mine operators have tried to embed welded-wire mesh inside shotcrete by placing a layer of shotcrete first, installing mesh over this first layer, and then placing a second layer of shotcrete. The result is a thick shotcrete liner that can maintain a good proportion of its load-deformation capacity after the shotcrete cracks. However, when deformation reaches 10–20 mm, the wires in the mesh, which are point-loaded by the shotcrete crack, tend to fail in tension.

An alternative approach that takes advantage of the ductility of the mesh is to install it as the final layer over the shotcrete—preferably FRS. Then, when the shotcrete cracks, it is contained by the mesh, which is then free to deform to its full capacity of 100–350 mm (4–14 in.). Installing mesh over FRS tends to be the preferred option in Australian mines facing difficult ground conditions.

Fiber-Reinforced Shotcrete

Fiber-reinforced shotcrete is also called FRS or Fibercrete. The addition of steel or synthetic fibers improves the postfailure behavior of shotcrete when it is submitted to bending or flexural forces. Fibers have no effect until the ultimate strength of the shotcrete is reached and cracks start to propagate through the shotcrete layer. The fibers then bridge and prevent further opening of the cracks, so that a significant fraction of the load-displacement capacity of the yielding shotcrete is maintained (Figure 8.6-15).

Courtesy of the Australian Centre for Geomechanics.

Figure 8.6-15 Fiber-reinforced shotcrete, showing fibers bridging cracks

To fulfill their role, shotcrete fibers must have both high tensile strength and a strong bond with the shotcrete. A strong bond is achieved with hooks or cavities.

Two factors particularly affect the bridging performance of fiber. The first factor is the length/diameter aspect ratio of the fiber. In calculating this ratio, the diameter can be taken as the equivalent diameter of a circle whose area is equal to the cross-sectional area of the fiber. A high aspect ratio contributes to better bridging. The second factor is the fiber dosage. Greater numbers of fibers that can bridge cracks contribute to better bridging.

Several types of steel and synthetic fiber are available (Figures 8.6-16 and 8.6-17). Synthetic fibers are usually made of organic polymers that are small enough to permit even distribution in the sprayed mixture during mixing and spraying. Fibers with equivalent diameters of >0.3 mm are called *macrofibers*; fibers with equivalent diameters of <0.3 mm are called *microfibers*. Typical macrofiber aspect ratios are in the range 40–65 for common fiber lengths of 19 to 50 mm (0.75 to 2 in.). Steel fiber lengths are generally <38 mm (1.5 in.); synthetic microfiber lengths vary from 6 to 50 mm (0.25 to 2 in.) (ACI Committee 506 [2008]).

Originally, steel fiber was used in FRS applications for both civil tunneling and mining. Recently, synthetic fiber has been gaining in popularity in civil tunneling and in Australian underground mines. Among the relative advantages of synthetic over steel fiber is its greater resistance to corrosion, lower abrasiveness, and significantly lighter weight. Lighter weight allows for a significantly higher dosage of fibers. Similar performances are obtained with one-fourth the weight of synthetic fiber (which is also twice the volume) as compared with steel fiber. The elastic modulus of synthetic fiber (3,400–4,800 MPa [~500,000–700,000 psi]) can be ~50 times less than that of steel fiber. With more and stiffer fibers per unit volume, synthetic fiber locks cracks earlier and transfers load to the concrete better, promoting preferential formation of multiple local cracks rather than a single crack opening progressively. The main disadvantage of synthetic fiber is that it floats and can plug the pumps of underground sumps or cause problems in flotation cells.

Bernard (2004) investigated the creep behavior of both steel and synthetic fibers and concluded that they have similar resistance to load deformation. Creep is an issue when shotcrete cracks. With steel-fiber-reinforced shotcrete, if a crack develops, there is potential for corrosion of the fibers and loss of ductility. Load energy continues to be absorbed but there is a risk of sudden rupture. In contrast, with synthetic-fiber-reinforced shotcrete, development of cracks is not associated with corrosion. If the load continues, synthetic fibers stretch rather than suddenly fail, and continue to absorb load energy.

Figure 8.6-17 Typical synthetic fibers

This provides an opportunity to take remedial action before the capability of the reinforced shotcrete is surpassed. Table 8.6-4 lists typical recipes for dry and wet mixes.

Often, a certain fiber dosage and a certain compressive strength are specified for a shotcrete application. However, it is more appropriate to specify the required shotcrete performance under flexural load, which is a measure of toughness or energy absorption capacity. This capacity is expressed as the surface under the load-displacement curve, measured in joules, during flexural tests. The EFNARC test (EFNARC 1996) and the round determinate panel (RDP) test (Bernard and Pircher 2001) are accepted methods for measuring shotcrete toughness. The RDP test has become the more accepted of the two tests in recent years because it generates more repeatable results. In the RDP test, a panel is supported at three points spaced 120° apart. A point load applied at the center of the panel is measured as a function of deflection.

Table 8.6-4 Typical steel-fiber-reinforced silica-fume shotcrete mixes

	Wet Mix		Dry Mix	
Component	kg/m³	% wet materials	kg/m³	% dry materials
Portland cement	420	18.1	420	19.0
Silica fume additive	40	1.7	50	2.2
Aggregate	1,600	68.9	1,670	75.5
Steel fibers	60	2.6	60	2.7
Accelerator	13	0.6	13	0.6
Superplasticizer	6 L	0.3	—	—
Water reducer	2 L	0.1	—	—
Air-entraining admixture	If required		—	—
Water	180	7.7	Controlled at nozzle	
Total	2,321	100	2,213	100

Source: Wood 1992.

The geometry of the test is such that failure always occurs between the points of support, and hence enables test repeatability (Figure 8.6-18).

The standard procedure is to consider the energy absorbed at a maximum deflection of 40 mm (1.6 in.) for a specimen of standard size (800-mm [31-in.] diameter, 75-mm [3-in.] thickness; Bernard and Pircher 2001). For a specimen of thickness other than 75 mm, the following series of correction equations is used to scale the load and energy capacity of the panel so as to be equivalent to those of a panel of standard dimensions.

$$W = W'\left(\frac{t_o}{t}\right)^{\alpha}\left(\frac{d_o}{d}\right) \tag{42-1}$$

$$\alpha = 2.0 - \frac{\delta}{80} \tag{42-2}$$

where (all dimensions are in millimeters)

W = "corrected" energy absorption
W' = energy absorption of the specimen of nonstandard dimensions
t_o = thickness of the standard specimen
t = thickness of the nonstandard specimen
d_o = diameter of the standard specimen
d = diameter of the nonstandard specimen
δ = central deflection of a panel, taken to be 0 at cracking

Surface Preparation, Profile, and Shotcrete Thickness

Good rock-surface preparation before shotcrete application involves removing or scaling down loose rocks and cleaning the rock surface of dirt, grease, residues from blasting and diesel exhaust, and more. Kuchta et al. (2004) recommend the use of high-pressure water jets for scaling down loose rocks in mine openings in order to maintain mine safety. Good preparation improves the adhesion strength of the shotcrete, usually defined as the strength of the interface between two materials—in this context between rock and shotcrete.

Malmgren et al. (2005) reported the results of an extensive failure-mapping investigation in 7 km (4.4 mi) of shotcreted drifts at the Kiirunavaara mine in Sweden. Shotcrete was found most likely to fail where the shotcrete layer is thin (<20 mm) and adhesion to the rock is poor to nonexistent. The main factors that contribute to shotcrete failure are rock deformation and dynamic loads due to blasting.

Figure 8.6-18 Round determinate panel test for measuring shotcrete performance under flexural load

Table 8.6-5 Determination of the roughness factor based on ground condition and drill-and-blast process

Ground Condition		Drill-and-Blast Process			
		Perfect (half barrels throughout)	Good (half barrels across back)	Fair (moderate overbreak)	Poor (considerable overbreak)
	Factor	1.05	1.10	1.15	1.25
Excellent (designed surface area)	1.00	1.05	1.10	1.15	1.25
Good (slightly rough surface)	1.20	1.26	1.32	1.38	1.50
Fair (broken surface)	1.40	1.47	1.54	1.61	1.75
Poor (very blocky ground)	1.60	1.68	1.76	1.84	2.00

Source: Adapted from Wood 1999.

Windsor and Thompson (1999) argued that traditional shotcrete layers of uniform thickness are suitable only for regular and smooth or irregular and evenly coated excavations. They suggested that, depending on the excavation profile, different cover techniques can be used. Wood (1999) built upon this work, developing a methodology for estimating the volume of shotcrete required for any particular project. Such estimates are of particular interest for operations in which shotcreting is contracted out and it is necessary to determine the volume of shotcrete based on the design profiles of excavations.

The estimated volume is based on roughness and rebound. The roughness factor is determined by multiplying the rating that represents the irregularity of the surface of the ground and the rating that represents the quality of the drill-and-blast process (Table 8.6-5). In excellent ground conditions, the final perimeter of the excavation is according to the design specifications. Good ground conditions are characterized by the presence of joints and slightly rough surfaces. Fair ground conditions are characterized by blocky ground and smooth surfaces. Finally, in poor ground conditions with very blocky ground, polished surfaces, possible fault zones, and wet ground, the rock mass has a significant influence on the perimeter of the excavation and is assigned a higher ground-condition factor. The quality of the drill-and-blast process is characterized by the degree of overbreak. A good drill-and-blast process, defined by half barrels across the back and some additional overbreak beyond design, would be assigned a drill-and-blast rating of 1.10. If this was observed in good ground conditions with a ground-condition rating of 1.20, the resulting roughness factor would be 1.32.

The roughness factor and the rebound factor can be used to calculate a specific volume factor for any particular mining project (Table 8.6-6). Rebound varies during the course of shotcrete shooting; it is high at the beginning of the shoot and decreases with increased shotcrete thickness. A site-specific chart can be developed to quantify cumulative rebound with respect to average thickness of shotcrete placed based on shotcrete trials. This can be used to establish a rebound factor. Wood (1999) presents an example in which the design calls for a minimum shotcrete thickness of 25 mm (1 in.), so an average of 50 mm (2 in.) of shotcrete is probably needed to provide the desired cover, associated with a minimum of 15% rebound. Similarly, a minimum design thickness of 50 mm (2 in.) requires an average thickness of 75 mm (3 in.) and the rebound is lower, resulting in a lower rebound factor. The rebound factor can then be multiplied by the roughness factor obtained from Table 8.6-5 to generate a site-specific volume factor.

Gaps in the table indicate situations that are unlikely to occur in practice. For example, it is unlikely that a rock mass with poor roughness would require only 50 mm (2 in.) of shotcrete. Similarly, there is little justification for 100 mm (4 in.) of shotcrete in a high-quality, well-excavated rock mass.

A practical consideration in rapid-development headings is the time required after shotcrete application before it is safe to reenter under newly secured ground. Clements (2004) reviewed the following tests to determine in situ early strength of shotcrete: soil penetrometer test, Meyco needle penetrometer test, sprayed-beam compression test, Hilti nail-gun pull-out test, and standard cylinder uniaxial compressive strength test. Although the sprayed-beam compression test is the most reliable technique for determining in-situ strength at the face, the tool is difficult to handle and unlikely to be used for daily quality control. Clements suggested that the Meyco needle penetrometer may be the more useful, albeit conservative, tool.

Bernard (2008) argued that traditional empirical design methods for FRS are based on term-of-life performance and are not necessarily applicable for early-age shotcrete. Early-age shotcrete fails in shear in response to applied loads from individual loose rocks. As shotcrete strengthens, its failure mode transitions from shear to delamination from the substrate and flexural failure. Thus the relationship between shear and compressive strength over the first few days of strength gain differs from that for mature shotcrete. Bond strength between FRS and the underlying rock surface increases to a maximum

Table 8.6-6 Determination of the volume factor based on roughness and thickness rebound factors

Roughness Factor*		Average Thickness Rebound Factor		
		50 mm (2 in.)	75 mm (3 in.)	100 mm (4 in.)
	Factor	1.15	1.10	1.08
Excellent	1.05	1.2	1.5	—
Good	1.32	1.5	1.8	—
Fair	1.61	—	—	1.8
Poor	2.00	—	—	2.2

of 0.2 MPa (2 bar or 29 psi) at 24 hours. These factors must be considered in order to establish safe reentry times.

Dynamic Testing of Surface Support

The EFNARC and RDP tests are quasi-static tests, where load is applied to the sample at a relatively slow rate. Because deep underground mines often encounter seismically active conditions where loads impact the support system via dynamic shockwaves, it is important to understand the response of surface support under dynamic loading.

Stacey and Ortlepp (2007) summarized results from dynamic testing programs performed in South Africa using a drop-weight testing apparatus. In this test, the dynamic-energy impact is delivered through a pyramid of bricks to distribute load and simulate the broken rock mass surrounding deep South Africans mines. Table 8.6-7 shows the average dynamic-energy impact and displacement values at failure for different surface support systems. It is important to realize that a significant amount of energy dissipates in the brick pyramid and only a fraction (~50%, according to Human 2004) is absorbed by the support system. An advantage of this test is that it examines the complete support system, including interaction of the reinforcement (1 × 1 m bolting pattern using both stiff and yielding bolts) with the surface support.

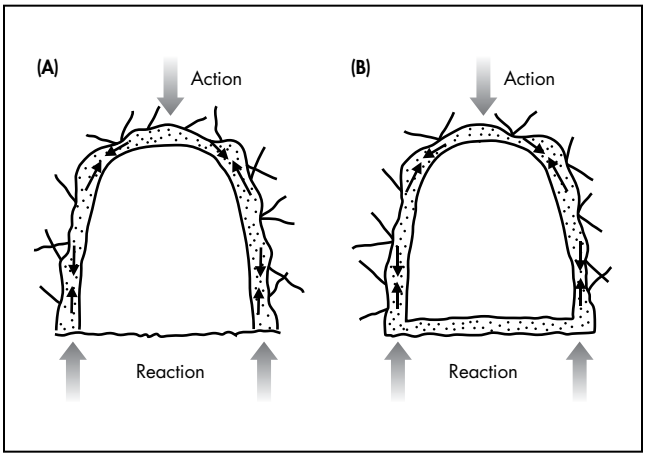
Player et al. (2008) conducted a series of dynamic tests on 1.3 × 1.3 m (50 × 50 in.) panels of two types of mesh: galvanized wire mesh (5.6-mm diameter) welded into a 100-mm (4-in.) square grid pattern and high-strength steel-wire chain-link mesh (4-mm diameter). The average dynamic rupture displacement for welded-wire mesh is 200 mm (8 in.) and for chain-link mesh is 300 mm (12 in.). The average dynamic rupture force for welded-wire mesh is 55 kN and for chain-link mesh is 185 kN. The average dynamic rupture energy for welded-wire mesh is 2 kJ and for chain-link mesh is 9 kJ. Comparisons among different testing programs are difficult because of the different testing methods.

Shotcrete Stabilization Mechanisms

In its original tunneling applications, shotcrete was generally designed to work as a compressive arch, taking advantage of the high compressive strength of concrete. Tunnels were generally either circular or horseshoe-shaped, promoting strong arching action of the shotcrete layer. The surface support layer was often applied floor to floor or all around the tunnel, allowing for good load transfer from the roof and wall to the floor (Figure 8.6-19).

In mining applications, however, because of cost and time constraints, the short-term nature of excavations, and the fact that the general public is not exposed, the application

Table 8.6-7 Energy-absorbing capacities and deformation limits of surface support lining components and systems



Membrane Component/System	Input Energy Capacity, kJ	Estimated Capacity with Yielding Rock Bolts, kJ	Characteristic Deformation Limit, mm

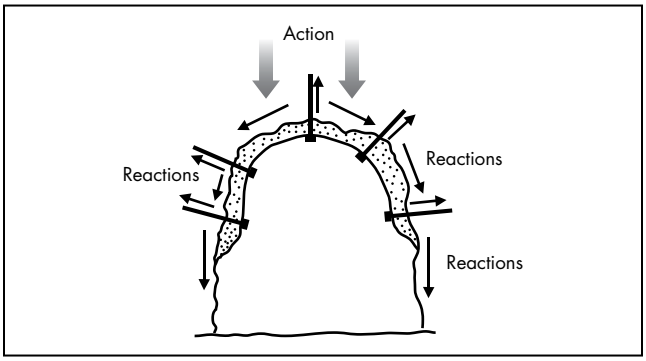
†Wire rope lacing has some inherent yield capacity.

of shotcrete differs considerably from the case for tunneling applications. The floor is very rarely supported. Surface support sometimes does not extend all the way to the floor; or when it does, the layer can be very thin. As a result, the compressive strength of shotcrete is not really brought into play (Figure 8.6-20). Surface support is provided through the adhesion and/or shear strength between rock and shotcrete, the flexural strength of the shotcrete, and load transfer to the rock reinforcement.



Stacey (2001) has identified the various support mechanisms provided by shotcrete. These mechanisms can occur individually and in combination:

- **Promotion of block interlock.** The immediate reactive support generated by the bond between the liner and the rock mass promotes block interlocking and prevents loosening of the rock mass. A number of submechanisms take place in this process:
  - Interlock due to bonding of shotcrete to the rock and the tensile strength of the shotcrete (Figure 8.6-21A). Shear resistance between the rock mass and the shotcrete is produced by the bonding, restricting blocks from moving, rotating, or loosening.
  - Development of shear strength on the interface between shotcrete and rock (Figure 8.6-21B). This is the case in poorly bonded shotcrete.
  - Penetration of shotcrete into joints and cracks (Figure 8.6-21C). Penetration of shotcrete into surface cracks inhibits the movement of blocks.
  - Applying a thin layer of liner to contain stress-induced spalling (Figure 8.6-21D). A layer of liner applied at an early stage of fracturing inhibits the fracturing process. This is particularly relevant in high-stress

Figure 8.6-19 Shotcrete in compression after application either (A) to the tunnel floor or (B) all around the tunnel

Source: Clements 2009.

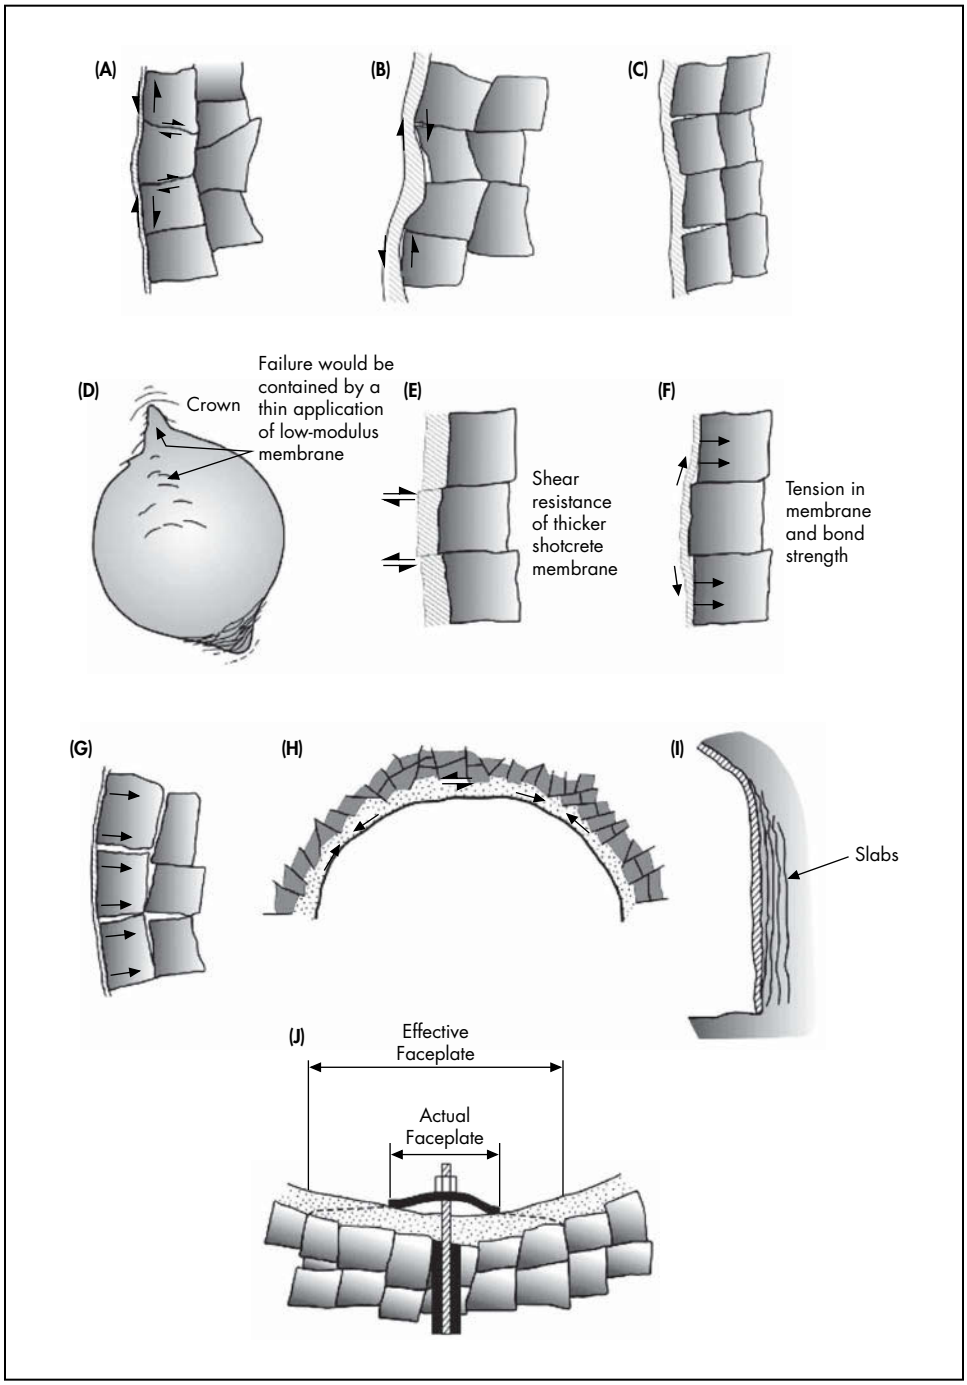
Figure 8.6-20 Shotcrete in compression after application that terminates above the tunnel floor as in a typical mining operation

situations where some loosening of the blocks would have already occurred.
  - Applying a thick shotcrete layer (Figure 8.6-21E). The internal shear strength of the shotcrete prevents larger failure.
  - Applying a thin shotcrete layer (Figure 8.6-21F). Adhesion between the shotcrete layer and the rock fails locally, causing the tensile or flexural strength of the shotcrete to be solicited to resist movement and loosening.
- **Basket mechanism** (Figure 8.6-21G). When the rock mass behind the shotcrete is crushed and is in a yielding state, the action of the shotcrete layer becomes similar to that of mesh and is required to contain the broken rock mass, somewhat like a basket. In this situation, the toughness of the shotcrete becomes critical to resist deflection of the broken rock mass, which can be exacerbated by stress changes due to stoping nearby. Because the tensile strength of concrete is low, the liner is expected to crack early and therefore must rely heavily on reinforcement material such as mesh or fibers to contain the deflection.
- **Structural arch** (Figure 8.6-21H). The arched shape solicits the compressive strength of the shotcrete to resist movement. Also contributing to the resisting forces is the shear strength between the shotcrete and the rock surface. If only the crown of the arch is supported, as is often the case in mining, the support mechanism relies on load transfer between the shotcrete and the reinforcement, as well as the adhesion, shear strength, and flexural strength of the shotcrete.
- **Slab enhancement** (Figure 8.6-21I). Laminated rock masses, particularly when strong foliation or bedding runs parallel to one of the excavation surfaces, may fail due to buckling. A shotcrete layer effectively thickens the slab, decreasing its slenderness and increasing its resistance to buckling.
- **Extended faceplate** (Figure 8.6-21J). The application of shotcrete extends the area of influence of rock bolt faceplates. It also enhances load transfer from the excavation surface to the reinforcement. Installing bolts after the shotcrete is also highly desirable because if the layer cracks, the bolt can then pin the broken shotcrete pieces to the rock mass and prevent them from falling off and becoming a hazard. The effect of an extended faceplate is lost where shotcrete is applied over mesh or FRS is applied after bolting.
- **Surface protection.** Certain rock mass may be prone to deterioration when subjected to wetting or drying. Shotcrete can act as a protective layer against the environment or mechanical deterioration from blast vibration, equipment collision, and so forth.

Shotcrete Failure Mechanisms

From the stabilization mechanisms just described, Stacey (2001) derived the corresponding failure mechanisms commonly observed in shotcrete (Figure 8.6-22).

Wedge and Block Loading



Discrete blocks or wedges defined by local discontinuities can move because of stress and/or gravity and load the shotcrete layer at specific locations (Figure 8.6-22A). As noted previously, if the shear strength and adhesion between the rock mass and the shotcrete holds, failure is likely to occur by shearing of the shotcrete layer. If the shotcrete layer debonds, flexural failure of the shotcrete is the likely mechanism.

Distributed Surface Loading

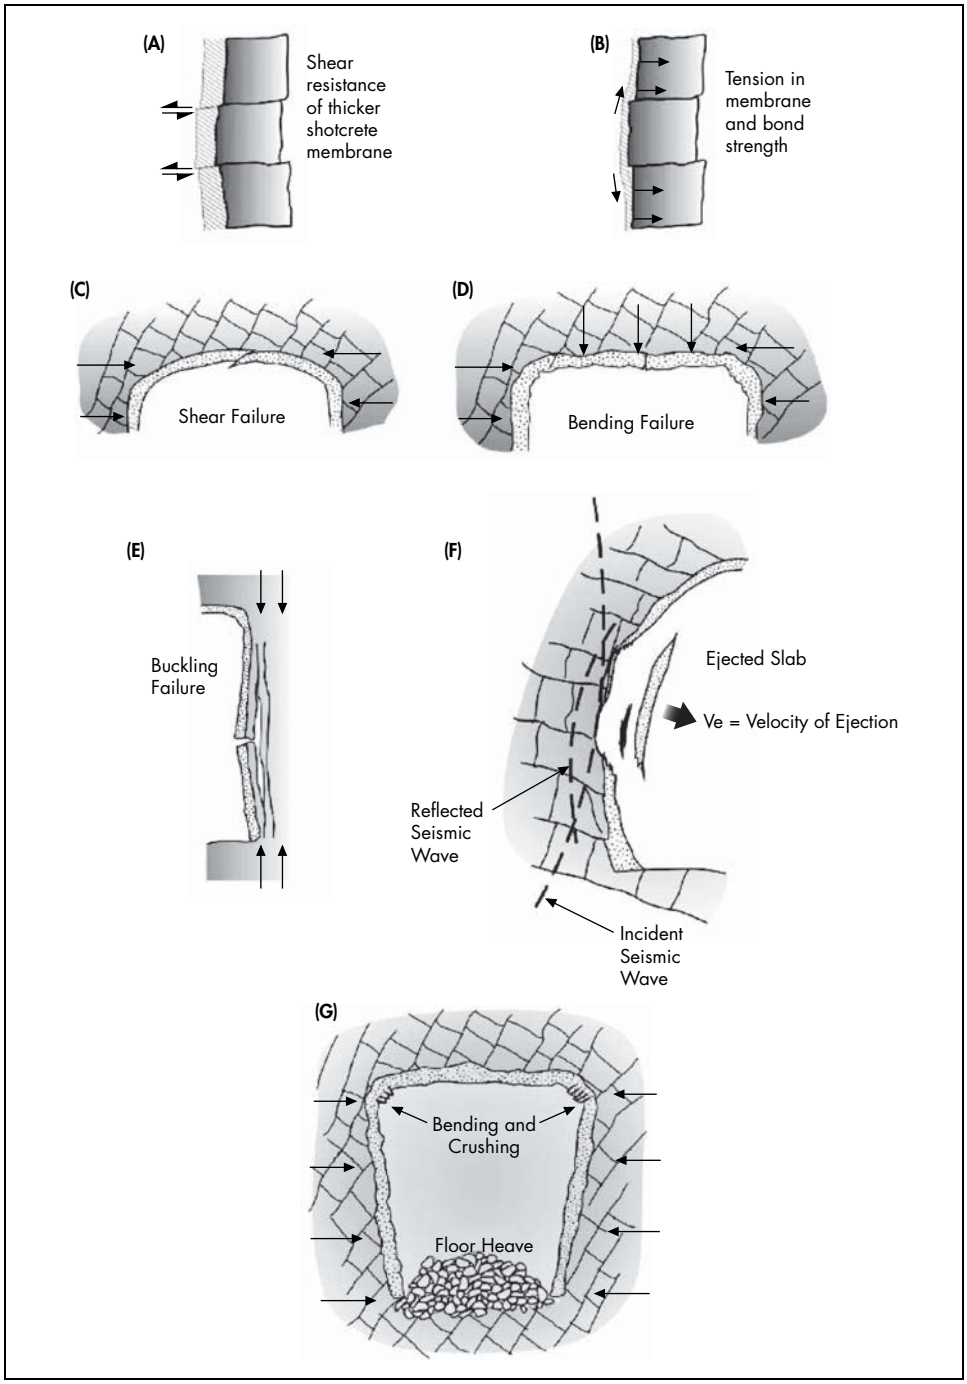
Distributed loading of the surface can be due to a number of rock-mass-yielding mechanisms, such as gravity acting on failed rock, squeezing ground under high stress, or dynamic loading from seismic events. This mechanism is related to the basket mechanism (Figure 8.6-22B). The surface support must work with the rock reinforcement as a system and, unless a good arch is formed by the liner, failure is likely to be by flexural bending.

Stress-Induced Loading

If a strong bond is achieved between the shotcrete liner and the rock mass, the two deform as a unit. Because concrete is brittle, a number of possible stress conditions can develop within the shotcrete layer, resulting in different modes of failure, including the following: shear failure (Figure 8.6-22C), bending failure in the roof (Figure 8.6-22D), and buckling failure in the walls as a result of floor heaving (Figure 8.6-22E). Complex failure

Source: Stacey 2001.

Figure 8.6-21 Surface support stabilization mechanisms



modes involving combinations of the above are also possible. In rock-bursting conditions, a common failure mechanism for shotcrete is slab ejection (Figure 8.6-22F). If a shotcrete shell is not properly drained in areas where groundwater is flowing, water pressure can build up and cause flexural failure. In high horizontal stress conditions where significant floor heaving and wall convergence are observed, the shotcrete shell will bend with the inward wall displacement, resulting in the crushing of the shotcrete at the corners of the excavation (Figure 35-22G).

Design of Shotcrete Liners

Load and failure mechanisms involving liner support can obviously be quite complex. Shotcrete liners can be designed either empirically or deterministically.

Empirical Design Approaches

A reasonable starting point to an empirical approach is to consider the common practice of applying reinforced shotcrete of thickness 50 mm (2 in.) (or 100 mm [4 in.] if the excavation

Source: Stacey 2001.

Figure 8.6-22 Surface support failure mechanisms

span is large) in short-life mining excavations. Hoek (2007) lists recommended shotcrete applications in underground mining for different rock mass conditions.

Several mines rely on rock mass classification systems to define rock mass quality and select what they consider appropriate shotcrete support to complement their reinforcement strategy. One such system, the Q system proposed by Barton et al. (1974), makes specific recommendations for the use of shotcrete and mesh-reinforced shotcrete in combination with rock bolts. Grimstad and Barton (1993) revised the Q system to encompass the use of FRS, which was an unknown product when the system was first published in 1974 (see Figure 8.8-8 in Chapter 8.8). When FRS is used, the spacing of the rock reinforcement (rock bolts) can be expanded by ~20%–40% compared to the case for bolting only.

Grimstad and Barton (1993) proposed an approximate relationship between FRS thickness as a function of rock mass quality Q and excavation size (Figure 8.6-23). Melbye et al. (2001) proposed that when high-performance steel-fiber-reinforced shotcrete is used as a wet mix, the required thickness

proposed by Grimstad and Barton can be further reduced (Figure 8.6-24).

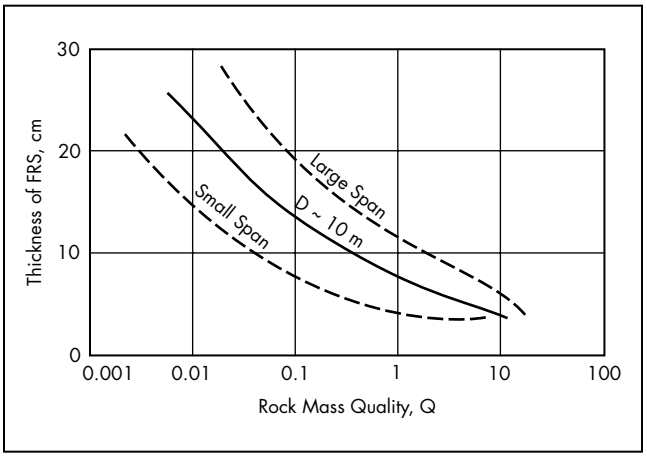
Grant et al. (2001) argued that the recommendations of Grimstad and Barton (1993) were inadequate because they did not consider the impact of the toughness of FRS. Papworth (2002) expanded this work by including reference to the RDP test. Figure 8.6-25 provides further guidelines on the recommended FRS toughness for different rock mass qualities as defined by the Q system. In areas of anticipated significant deformation, seismicity, or potential strain burst, a minimum energy absorption capacity of 400 J should be used based on RDP_{40mm}. In extreme cases, this should be increased to 540 J. Papworth further suggests that, wherever possible, bolting should be done through the FRS.

Deterministic Design Approaches

Fernandez-Delgado et al. (1981) proposed a deterministic model to calculate the shotcrete thickness t required to support the dead weight of a wedge based on arching theory and the compressive strength of shotcrete.

For the rock-reinforcement scenario shown in Figure 8.6-26, Barret and McCreath (1995) proposed deterministic design models to analyze the worst-case scenario of discrete blocks that could develop in between the rock reinforcement. The models consider four failure mechanisms: adhesive, direct shear, flexural, and punching shear (Figure 8.6-27). Model calculations are shown in Table 8.6-8.

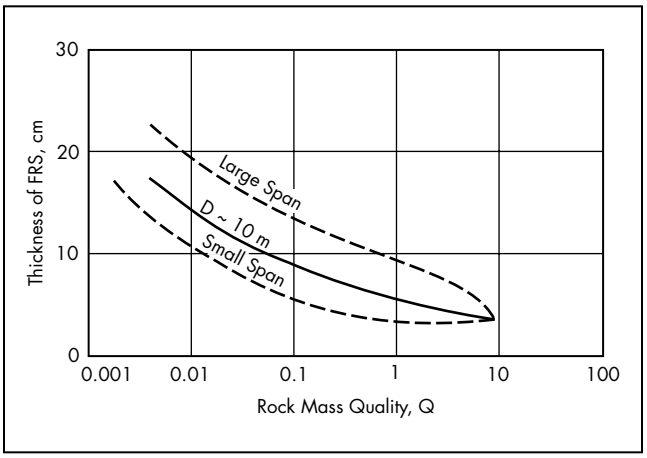
Shotcrete Support for Rock Wedges



Software is available to conduct kinematic and limit equilibrium wedge analysis for underground excavations. An example of this type of software is Unwedge (Rocscience), which investigates the influence of both rock reinforcement (bolts) and surface support such as shotcrete. A basic assumption is that shotcrete fails in direct shear. A structurally defined wedge shears through an area of shotcrete that is given by the product of the perimeter of the exposed face and the thickness of the shotcrete. The shotcrete acts in a direction normal to the excavation wall that it supports.

Numerical Modeling Approaches

Several numerical models can model shotcrete, either individually or as part of a rock bolt support system. These models are more often used to investigate the impact of different shotcrete characteristics and properties on the stability of excavations rather than for design purposes.



Kuchta et al. (2004) used a distinct element approach to construct a simple drift model containing a triangular wedge in the crown. The model evaluates the relationship between shotcrete thickness and interface strength, and demonstrates that tensile bond strength is more important than cohesive bond strength in determining interface strength.

Malmgren and Nordlund (2008) performed a comprehensive numerical study on the interaction of shotcrete and rock bolts related to conditions at the LKAB underground mine in Kiruna (northern Sweden). Their models demonstrate that rock strength and surface roughness have a significant impact on the number of failures at the rock–shotcrete interface and in the shotcrete lining. They also show that shotcrete lining is sensitive to small amplitudes of surface roughness. The implication is that shotcrete performance depends on the method of excavation (drilling and blasting) and the quality of ground preparation. In all cases, high interface strength is favorable.

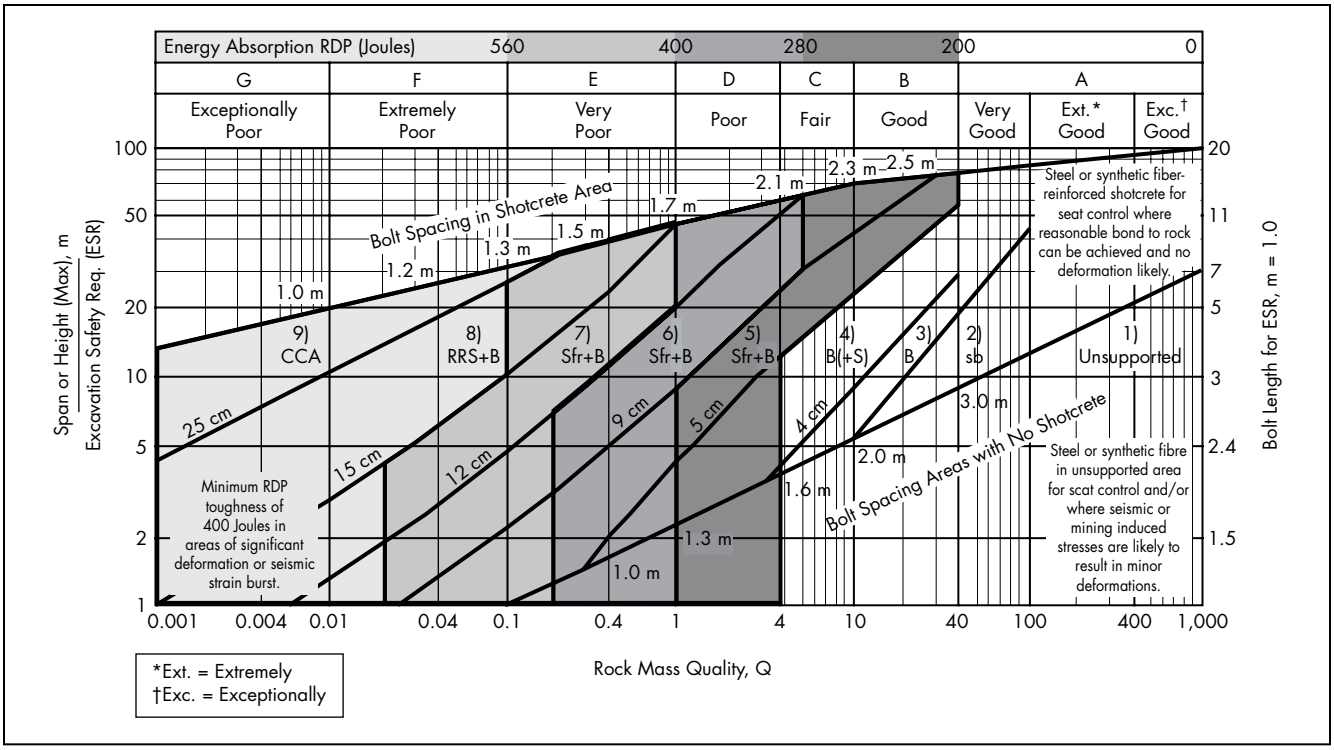
Figure 8.6-23 Permanent-support recommendation for FRS as a function of tunnel span and Q value

Source: Melbye et al. 2001.

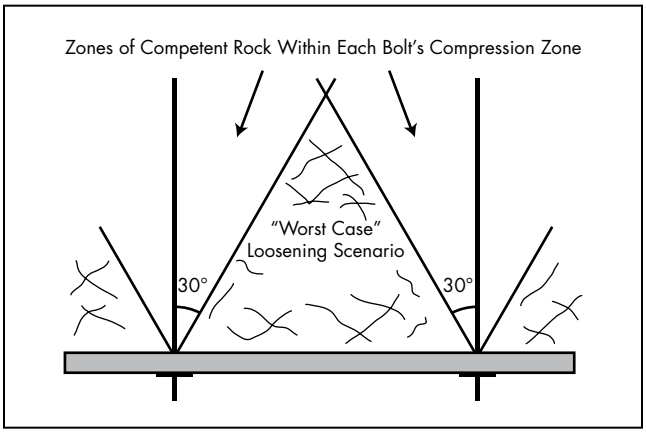
Figure 8.6-24 Permanent-support recommendation for high-performance steel-fiber-reinforced shotcrete as a function of tunnel span and Q value



Because the performance of thick shotcrete lining depends on bond strength, there are limited benefits to using thicker shotcrete lining.

Shotcrete Performance

The performance of ground support systems in underground mines is generally intimately related to the quality of their installation, and shotcrete is no exception. Some of the guidelines relevant to quality control of shotcrete are briefly discussed in the following sections.



Quality Control

Shotcrete performance in underground mines is influenced by the implementation of appropriate quality control procedures concerning design, materials, application equipment, craftsmanship, and installation techniques. Spearing (2001) identifies the following requirements for a quality control program: it must be reliable, meaningful, timely, simple, and relatively inexpensive. For shotcrete designs derived either empirically or analytically, quality control ensures that shotcrete is applied as designed.

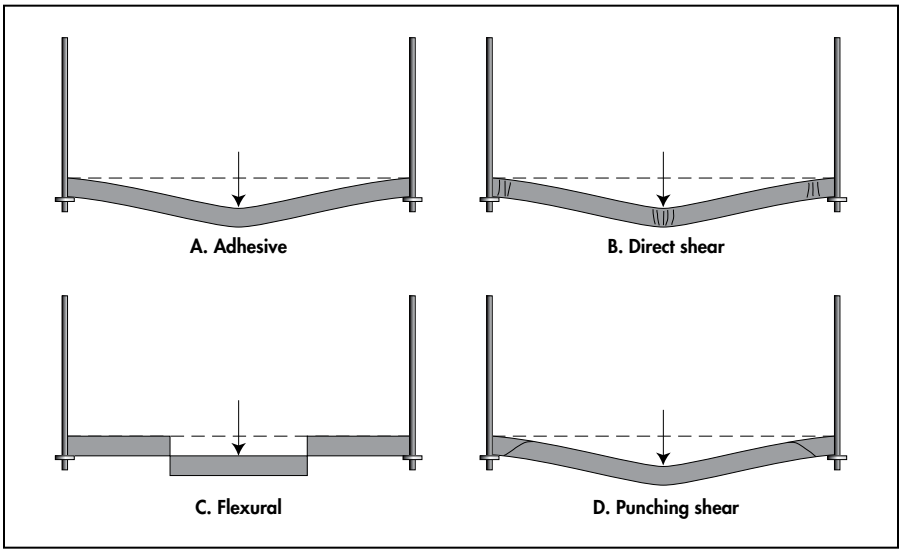
Figure 8.6-26 Rock-reinforcement scenario for estimating shotcrete support requirements, showing the volume of loose ground that applies load to the shotcrete between the bolts



The *Guide to Shotcrete* from the American Concrete Institute (ACI Committee 506 [2005]) specifies the requirements for a comprehensive quality-control program, including material properties and mix design. Shotcrete equipment (compressors, shooting equipment, mixers and batchers, and hoses) should be properly maintained, cleaned, calibrated, and checked regularly for proper function. During a spraying shift, air volume and pressure should be checked regularly. Spearing (2001) reports the following typical requirements:

- For dry shotcreting at 5 m^3/h (3 ft^3/min), air consumption should be ~15 m^3/h (9 ft^3/min) at a pressure in the range of 300,000 to 600,000 Pa (44–87 psi).
- For wet shotcreting at 15 m^3/h (9 ft^3/min), air consumption should be ~12 m^3/h (7 ft^3/min) at a pressure of ~600,000 Pa (87 psi).

An important aspect of quality control is to test the shotcrete before, during, and after application. Quality control tests include slump tests and panel tests. In the latter, variously sized boxes are sprayed with concrete. After hardening, samples are taken with a core saw and tested for uniaxial compressive strength. Normally testing is done at 7 and 28 days, although this can vary. Beaupré et al. (2005) recommend the use of a Schmidt hammer for measuring the compressive strength of underground shotcrete. This method is inexpensive and fast, and the hammer is easy to use, easy to carry, and relatively maintenance free. The precision of the hammer is acceptable, provided that several readings are recorded at a given location.

A good indicator of shotcrete quality is the degree to which the shotcrete adheres to the rock surface. Drill cores can be taken from the wall or back of an excavation and used to expose the layers of shotcrete and the bond between the rock surface and the shotcrete. A simple test is to hit the shotcrete surface with a hammer and judge adhesion quality from the resulting sound; a clear ring indicates good adhesion, a hollow sound indicates poor adhesion, and a "drummy" sound indicates very poor adhesion (NORCAT 1998).

Several simple techniques exist to verify shotcrete thickness. One technique is to install double-headed nails on the

Source: Barret and McCreath 1995.

Figure 8.6-27 Shotcrete failure modes

Table 8.6-8 Deterministic design models for shotcrete

Adhesive Failure

The capacity of shotcrete lining to resist debonding, c_a, is

$$c_a = 4\sigma_a sa$$

where

σ_a = adhesive strength of the shotcrete
s = bolt spacing
a = adhesive bond length, defined as the distance from the panel perimeter

For standard 1.2 × 1.2 m bolt spacing, shotcrete lining with an adhesive strength of 1.5 MPa at 28 days and a bond length of 50 mm can support a dead load of 36 t in adhesion.

Direct Shear Failure

The capacity of the shotcrete to resist direct shear failure is

$$c_{ds} = \tau_{ds}\, st$$

where

c_{ds} = shear strength
s = spacing of the bolts
t = shotcrete thickness

This analysis ignores the stabilizing effect of any axial thrust in the lining developed through arching.

Flexural Failure

The capacity of unreinforced shotcrete lining to resist these moments, c_{flex}, for a slab with a rectangular cross section is

$$c_{flex} = \sigma_{flex}\left(\frac{t^2}{6}\right)\left(\frac{s}{2}\right)$$

where

σ_{flex} = flexural strength of the shotcrete
t = shotcrete thickness
s = bolt spacing

Even if the shotcrete completely debonds, the shotcrete can still be effective in preventing the rock mass from loosening by acting as a slab in bending, provided that it is reinforced by rock bolts.

Punching Shear Failure

In punching shear mode, failure occurs close to the supports where shear forces are at a maximum. Failure occurs not along a vertical plane but rather along planes inclined at approximately 45° to the horizontal, perpendicular to the diagonal tensile stresses in the slab. Thus, the slab actually fails in tension rather than in shear, although normally it is the shear load required to induce diagonal tensile failure that is determined, rather than the diagonal tensile stress itself.

Thus, for a square faceplate, the perimeter of the failure surface is 4 ($c + d$), and the capacity of the slab to resist punching shear failure is

$$c_{ps} = \sigma_{ps} 4(c + d)t$$

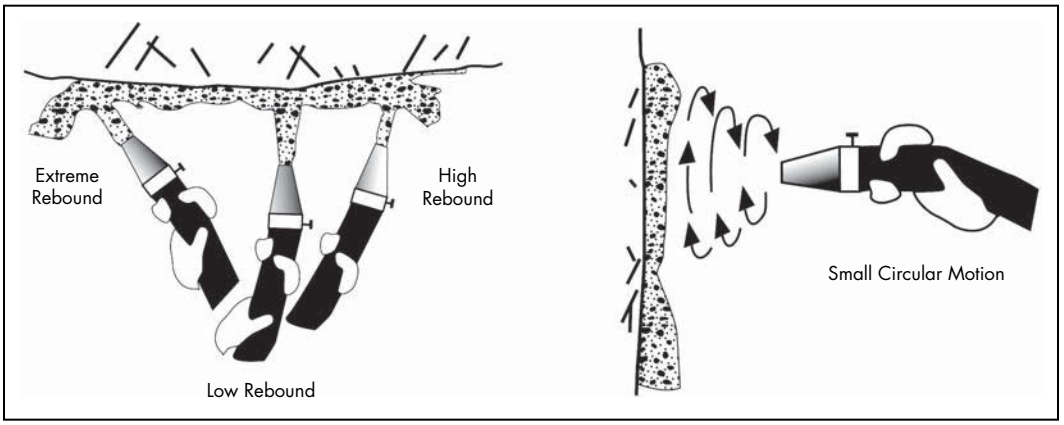
Failure is understood to occur along an equivalent vertical plane located a distance $d/2$ from the edge of the faceplate, where d is

$$d = \sqrt{\left(\frac{c}{4}\right)^2 + \left(\frac{V}{4\sigma_{ds}}\right)} - \left(\frac{c^2}{4}\right)$$

where

c = faceplate width
s = bolt spacing

The tributary area for the critical shear load V is determined by the dimensions of the shotcrete panels surrounding a particular bolt and where



$$V = w(s^2 - c^2)$$

where w is the uniformly distributed load across the tributary area.

Source: Adapted from Barret and McCreath 1995.

excavation walls before shotcrete application. If the nails remain exposed after application, then the shotcrete thickness can be assumed to be insufficient. Another technique is to install nails after shotcrete application using a Hilti nail gun. Eventually it is expected that automated shotcrete spraying machines will be used to scan surfaces before and after application.

Finally, it is important that shotcrete operators be sufficiently trained in the proper application technique. They should manipulate the nozzle so that shotcrete emerges in a steady, uninterrupted flow, ideally perpendicular but never more than 45° to the ground surface, and they should rotate the nozzle steadily in a series of small oval or circular patterns

Figure 8.6-28 Proper shotcrete application technique for low rebound and smooth application

(Figure 8.6-28). Failure to apply this technique correctly can result in an uneven, wavy surface that traps significant amounts of rebound and overspray.

Shotcrete Damage Classification

Shotcrete in underground mines, even when damaged, can still maintain some support capacity. Espley et al. (2004), from a series of comprehensive field trials at several Inco mines, identified three levels of damage and required reconditioning (Table 8.6-9).

Where the shotcrete liner is damaged, the area can be rehabilitated with another thin coating of shotcrete. Where excessive damage is accompanied by cracking and shear failures, additional support should be applied using rock bolts and mesh.

OTHER SURFACE SUPPORT TECHNIQUES

A number of specialized techniques have been applied as surface support in underground metal mines, albeit to a lesser extent than mesh, straps, and shotcrete. Three such techniques are briefly discussed: thin spray-on liners, shotcrete pillars, and reinforced shotcrete arches.

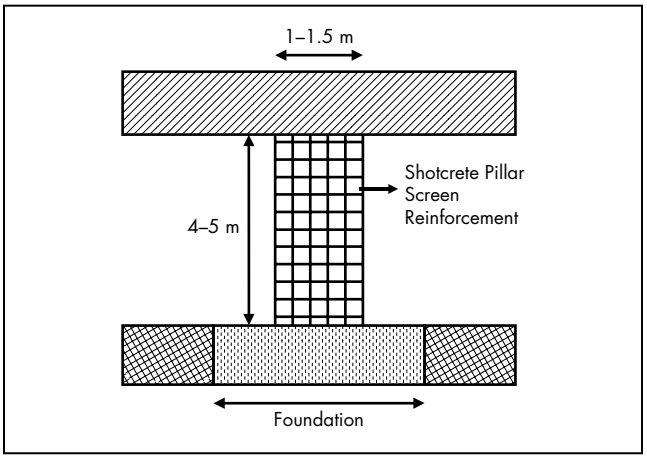
Thin Spray-on Liners

Thin spray-on liners (TSLs) are multicomponent polymer materials that can be applied to the rock mass surface as a sealant or as surface support. After more than 20 years of research, development, and trials in mines, the use of TSLs in underground metal mines is still limited to special applications rather than to general application as a systematic surface support such as mesh and shotcrete. Nevertheless, their popularity in certain coal mines and in some less mechanized South African mines has been growing in recent years. The evolution of TSLs until 2004 is covered in Potvin et al. (2004), which includes product reviews, testing and quality control procedures, and case studies.

A main advantage of TSLs is their rapid and easy application, since only a thin layer (~5 mm) is required. The equipment used for application is small and versatile.

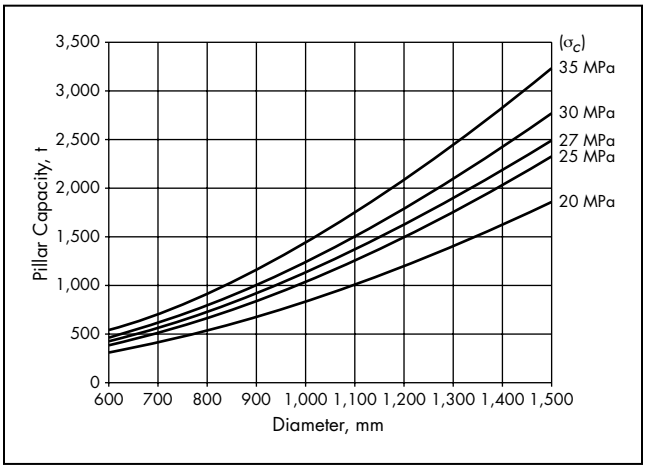
A variety of TSL products exist with different chemical components and properties. They can be divided into two categories: those that contain isocyanates and those that do not. The first category includes polyurethanes and polyresins; the second category includes water-, cement-, or latex-based methacrylates and acrylates.

Table 8.6-9 Shotcrete damage classification and reconditioning requirements



Level of Damage	Reconditioning Required?	Examples
Minor	No	• Fine cracks <3 mm thick, <1.5 m (5 ft) long, spaced at >1.5 m (5 ft) • Drumminess or peeling of shotcrete liner covering an area of <0.25 m^2 (10 $in.^2$)
Moderate	Sometimes	• Intersecting cracks >3 mm and <10 mm thick, >1.5 m (5 ft) long, spaced at <1.5 m (5 ft) • Drummy area of >0.25 m^2 (10 $in.^2$) and <3 m^2 (10 ft^2)
Major	Always	• Shear failure • Drummy area of >3 m^2 (10 ft^2) and intersecting cracks spaced at <1.5 m (5 ft) to complete failure of shotcrete liner or fall of ground

Source: Adapted from Espley et al. 2004.



With regard to structural properties, TSLs that contain isocyanates are generally superior to those that do not. Unfortunately, however, isocyanate products have serious toxicity issues, because they contain methyl disphenyl isocyanate (MDI), which in part of the population can induce a severe allergic reaction and even death. Therefore, rigorous health and safety procedures must be followed if these products are to be used.

TSLs have been used successfully for specialized applications, including sealants in South African mines and over shotcrete in Canadian mines to further safeguard against cracking in critical excavations.

A review of the literature indicates that TSL performance assessments are not consistent. In particular, the critical properties and the laboratory and field tests required to estimate these properties are still the object of discussion among scientists and practitioners. The main suppliers of TSL products currently include Minova (Tekflex), BASF (Masterseal), SA Mining & Engineering Supplies (Tunnel Guard), 3M (3M Mining Liner), and Spray On Plastics Ltd. (RockWeb). Most of these products are still under study and field trial and no reports yet exist about TSLs being systematically applied as surface support in mines. Therefore, the technology should be deemed not yet mature and still under development.

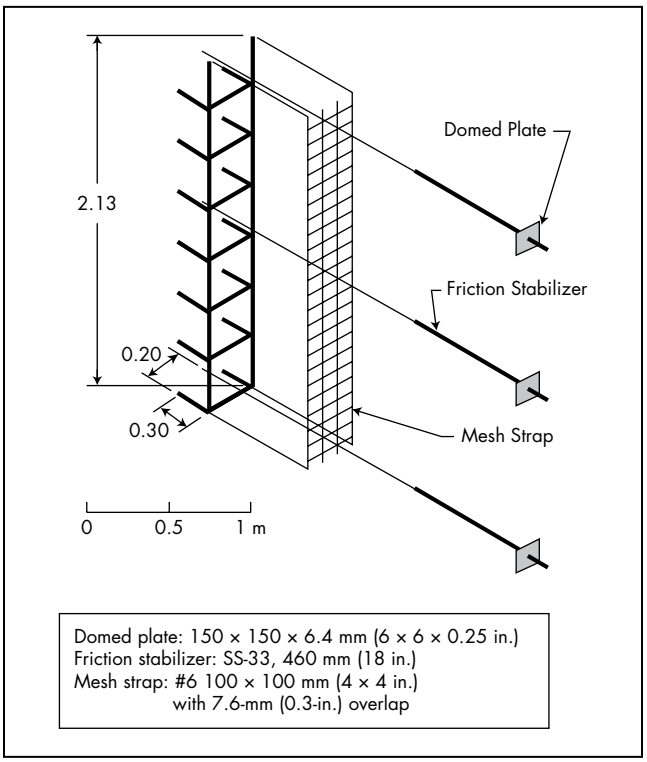
Figure 8.6-29 Shotcrete pillar

Source: Hadjigeorgiou et al. 1999.
Figure 8.6-30 Shotcrete pillar capacity as a function of diameter and compressive strength

Shotcrete Pillars

Shotcrete pillars, used mainly in Canadian underground metal mines, are a specialized form of surface support that does not cover the entire rock mass surface. Rather, it is external to the rock mass and stabilizes the roof of an excavation. Use of this method of support depends on factors such as excavation access, potential rock mass failure mechanism, support capacity required, and economics.

Pillar construction is very simple. On solid rock, a pillar is built as a column of shotcrete with a diameter (including final cover of shotcrete) in the range of 1.3 to 1.5 m (4.25 to 5 ft) (Figure 8.6-29). Casing, when used, is made of a #9 mesh cylinder of slightly smaller diameter. Contacts at the floor and back are slightly expanded to give it an hourglass shape.



Methods for calculating critical design parameters such as pillar dimension and pillar reinforcement are presented in Hadjigeorgiou et al. (1999). Figure 8.6-30 shows a graphic tool for estimating the capacity of mesh-reinforced shotcrete pillars as a function of pillar diameter and shotcrete compressive strength.

Reinforced Shotcrete Arches

Reinforced shotcrete arches provide stiff, high-capacity surface support. They can be installed quickly and efficiently in an underground mine. Gaudreau et al. (2004) examined shotcrete arches at the Brunswick (Canada) mining and smelting operation, including their method of construction. They are assembled by juxtaposing prefabricated steel frames made of #3 reinforcing bars and #0 mesh straps (Figure 8.6-31). Reinforcing frames are secured to the rock mass surface by means of friction bolts or grouted bars and plates to form a complete arch from floor to floor. The arch is then filled with shotcrete to a thickness of ~50 mm (2 in.), starting from the base, until the entire frame is covered.

Double or triple arches can be built side by side to increase capacity and improve coverage of the supported area when necessary, such as for large spans or very difficult ground conditions. Table 8.6-10 lists the general rules used at the Brunswick mining and smelting operation to select single, double, or triple arches according to the span of the excavation.

When multiple arches are used, they are typically installed every 3 m (10 ft), but this distance can vary when

mining in extremely poor rock mass or when rehabilitating collapsed areas. Arches can also be installed in combination with shotcrete pillars, offering versatile solutions to difficult ground conditions.

SUMMARY

Reinforcement and surface support interact to provide an integrated ground support system. Their roles are dictated by the mode of interaction with the rock mass: whereas reinforcement elements preserve the integrity of the rock mass, surface support links reinforcement elements together to resist surface deformation or to contain rock fragments from falling or ejecting.

The main surface support elements used in the metal mining industry are welded-wire mesh, shotcrete, and, to a lesser extent, steel straps. Important properties of surface support include stiffness, load capacity, and deformation capacity.

Welded-wire mesh is soft with high displacement and relatively low load-bearing capacity; its support action generally starts only when the rock mass has failed. Shotcrete is stiff with low deformation capacity and relatively low load-bearing capacity in mining applications because the concrete is often not loaded in compression; its support action begins as soon as the rock mass starts to deform. Straps do not cover the entire surface and are often used over mesh or in special applications.

Innovative support techniques such as shotcrete pillars and reinforced shotcrete arches provide more ground control options. Thin spray-on liners, still under development, are used primarily for special applications in metal mines, although they are increasingly used in coal mines and in deep underground South African mines.

CHAPTER 8.7

Soft-Rock Ground Control

Rod Stace

Ground control is "the science that studies the behavior of the rock mass in transition from one state of equilibrium to another. It provides a basis for the design of support systems to prevent or control the collapse or failure of roof floor and ribs both safely and economically" (Peng 1978).

Around the world, many mined minerals occur as soft rocks themselves or are found within a rock mass comprised largely of soft rocks. The mining of these resources presents many unique problems. Significant among these is the need to provide supports that are both temporary and permanent, their installation being part of the overall mining system. This chapter deals with this key issue of support by examining the types of mining system that have become widely used around the world to extract these important minerals. It covers changes in stress distribution and rock displacement brought about by mineral extraction and the types of support system that have been used successfully in this complex environment. It concludes by examining planning and design methodologies for support in soft rocks.

In the interests of brevity and efficiency, this chapter concentrates on the working of commonly found sedimentary deposits such as coal but with occasional reference to the working of evaporite deposits.

WHAT IS SOFT ROCK?

Rock is an engineering material having a unique set of engineering parameters. These parameters most commonly include not only uniaxial compressive strength but also tensile strength, stiffness (Young's modulus), the ratio of lateral to vertical strain under load (Poisson's ratio), and behavior when confined, which is defined by the angle of friction and its cohesion.

However, these properties are not the only factors that define the behavior of this material when subjected to stress changes brought about by mining. Material properties measured from small samples in a laboratory give only guidance to a wider understanding of that rock type's behavior within the rock mass. The pattern and frequency of jointing within a rock mass, together with the presence of geological anomalies such as faulting, folding, and weathering, greatly affect the way a rock type might behave in a certain mining application. These factors have been quantified within rock mass classification systems, the most significant of which are the rock mass rating (RMR) system developed by Bieniawski over many years and the Norwegian Q system developed by Barton. The presence of water has a particularly large effect on rock stability, as many soft-rock types are negatively affected by exposure to water.

Another element influencing mining support in soft-rock conditions is time dependency. Excavations in soft rocks become subject to closure with time, due to characteristics of the rock and of the ground mass. The rock types themselves exhibit creep properties—that is, the propensity for strain to increase under a constant load. This is most notable in rock-salt deposits. Additionally, variations in the stress fields within the ground mass and subsequent development of fracturing due to the mining process also result in deformation of the excavation. The support applied to excavations in soft rock must take this movement into account.

The general term *soft rock* is often used to describe a group of rocks with the following specific properties, but it is also a comparative term used to contrast with the other widely used term, *hard rock*. Soft rocks have uniaxial compressive strengths, determined by laboratory testing, in the range <50 to >0.6 MPa (below which the material is termed *very stiff soil*). This range can be further subdivided as follows:

- Moderately weak rock: 10–50 MPa
- Weak rock: 1.5–10 MPa
- Very weak rock: 0.6–1.5 MPa

In the RMR system within the soft-rock range, rocks with an RMR in the range 20–40 are described as *poor rock* and those with an RMR of <20 are described as *very poor rock*.

From the point of view of support, the yield characteristic of a soft rock is more nearly plastic as opposed to brittle. The latter tends to be more characteristic of hard rock.

The terms *soft rock* and *hard rock* are often used to determine the difference between two groups of mines and their mining methods:

Rod Stace, Associate Professor, Department of Civil Engineering, University of Nottingham, Nottingham, UK

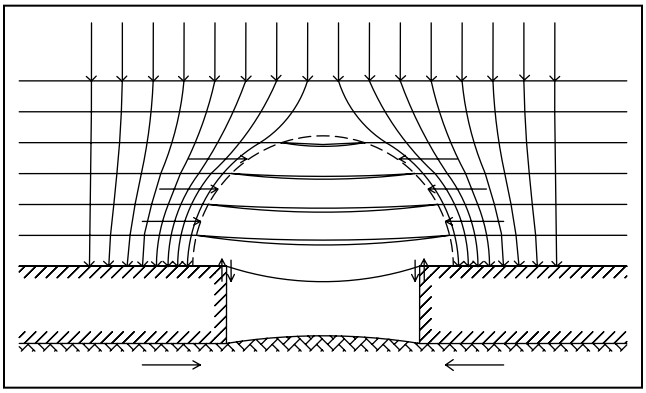

Figure 8.7-1 Forces around an excavated mine opening

Figure 8.7-2 Typical floor lift in a mine roadway

- Soft-rock mines include all coal mines plus, potentially, mines using typical coal-mining methods such as longwall and room-and-pillar. These might include, as examples, mines of gypsum, rock salt, limestone, and potash. The strata are sedimentary in origin.
- Hard-rock mines include those using nearly all the metalliferous mining methods, such as stoping in its many forms. The rock types are almost exclusively igneous or metamorphic.

These are very general classifications, and although there are exceptions, the general rule normally applies. Many examples exist around the world of coal being worked in a rock environment in which a substantial proportion of the rock types exceeds the arbitrary values listed above. However, the problems of mining support in soft rock are significant, and it is the solutions to these that form the basis of this chapter.

THEORETICAL BACKGROUND

This section examines the stress changes around an excavation caused by mining and the influence of these changes on roadway closure. The study of stress change and strata displacement around soft-rock excavations is very mature, much of the work having commenced up to 80 years ago and being developed and refined in the period after the Second World War and up to the 1990s. As a result, although the references quoted and images used may seem rather elderly to the younger mining engineer, their relevance has not diminished with time nor have the findings been superseded.

Stress and Displacement Around an Excavation

In soft rocks found in coal measures or evaporite deposits, stresses as redistributed into the rock mass often exceed the elastic bounds of each rock type. In these circumstances, support plays a significant role in the stability of the excavation.

Soft-rock mechanics is often called strata control. In the longwall method of mining, there is substantial controlled rock-mass movement from the excavation level through to the ground surface. In-built yield is a key design element of many support types used in the soft-rock domain. This process of controlling rock-mass movement is particularly evident when considering choices of support at a longwall face and in the roadways serving the longwall.

Early researchers in the United Kingdom characterized the redistribution of vertical stresses around a coal-mining excavation as a pressure arch (National Coal Board 1950). Although this theory was later modified, the fundamental redistribution of these stresses around an excavation to form high-stress concentrations, known as abutments, around the perimeter of the excavation is widely recognized. An understanding of the nature and role of the components of horizontal stress is also important, although horizontal stress did not really become widely understood in the European coal-mining community until the major move to rock-bolted support at the end of the 1980s. This understanding was based primarily on the work of Gale (1991) in Australia.

In the worst cases, high-stress concentrations at the sides (or ribs) of an opening caused rib-side failures, resulting in effective widening of the excavation. Horizontal stresses that become concentrated in roof and floor measures cause buckling of those rocks above and below the excavation, as evidenced by roof buckling and floor heave (Figures 8.7-1 and 8.7-2). The degree of closure or rock failure depends on the stress values and the strength of the rocks.

Horizontal stresses are often characterized by directionality, the component of stress in one direction having a significantly higher value than the component in the direction at right angles. This can dictate the choice of mine layout, as there are advantages to driving the most important roadways parallel to the maximum component direction to minimize closure. Also, in some shallow deposits, the magnitude of the maximum horizontal stress can be greater than thatt of the vertical stress, which depends largely on depth.

The role of the support member in soft-rock excavation is to accommodate strata displacement in the roof and sides of the excavation in a controlled manner rather than to prevent it entirely. The support action of the rock bolt is an exception to this rule. Support of the floor has always been viewed as technically difficult because any system adopted will interfere with mining activities and infrastructure within the excavation. This support is also difficult to replace or renew should failure occur. Support placed to the sides and roof of a working area or access roadway is normally easier to supplement or replace.

Interaction

Interaction is a mining phenomenon in which the working layout at one horizon influences the stability of workings at another horizon in the mine. This phenomenon is normally experienced only in the mining of stratified deposits where

work is conducted at more than one horizon in the deposit. It is a common feature of coal mining where several seams are worked in the vertical succession.

Planning for interaction has been a feature of coal-mine design in the United Kingdom and Europe for many years. It is increasingly recognized as a constraint on the development and working of coal reserves in the United States, South Africa, and Australia where second-seam working is now practiced more widely.

Interaction can be subdivided in a number of ways. It has been described as being split into "static project" and "dynamic project" activities (Auriol 1972). A static project is one in which an existing working passes into a zone in which the field stress has been modified by previous workings, often long since abandoned; these can be old workings above or below the present working level. A dynamic project is one in which existing excavations—working areas or main roadways—can be influenced in some way by current working activity at another horizon as a result of stress redistribution, ground movement, or both.

Interaction can take a number of forms. It can be solely a redistribution or modification of the stress field being encountered. It can also be induced fracturing caused by previous workings. In addition, in a dynamic project, if the affecting workings are below a horizon, it can be ground displacement caused by the onset of subsidence.

Ground displacement can also lead to induced ground fracturing in the form of tension cracks formed around excavation edges and possible mobilization of fault planes allowing for pathways to be formed for water or gas flow into existing workings.

In early observations of interaction, researchers noted its effects and attempted to ascribe theories to what they had experienced underground. The empirical studies of Walker and associates in the North East England coalfield of the early 1950s were typical of this, as espoused in their pressure arch theory mentioned previously (National Coal Board 1950–1951). Observations of damage to mining excavations suggested that the pressure arch extends both above and below the working horizon, and any subsequent working in another seam that intersects the pressure arch experiences difficult mining conditions (National Coal Board 1953–1954).

The extent of the pressure arch above and below workings was given as twice its width. As an example, for workings at a depth of 610 m, the pressure arch is said to extend 220 m above and below the seam. The magnitude of the stress levels in the pressure-arch legs is related to depth, varying from 1.5 times the cover load at shallow depths and stress concentrations to over 3 times the cover load at depths of ~600 m (the maximum extent of the field data obtained by the investigators).

Subsequent researchers, most notably Whittaker, took this theme further, publishing a set of values showing increased stress at levels above a single rib edge. He states the following: "The mirror image of this pressure profile is valid for the state of stress underneath the solid rib-side except that the magnitudes of the pressures are slightly increased owing to the greater depth" (Whittaker 1972).

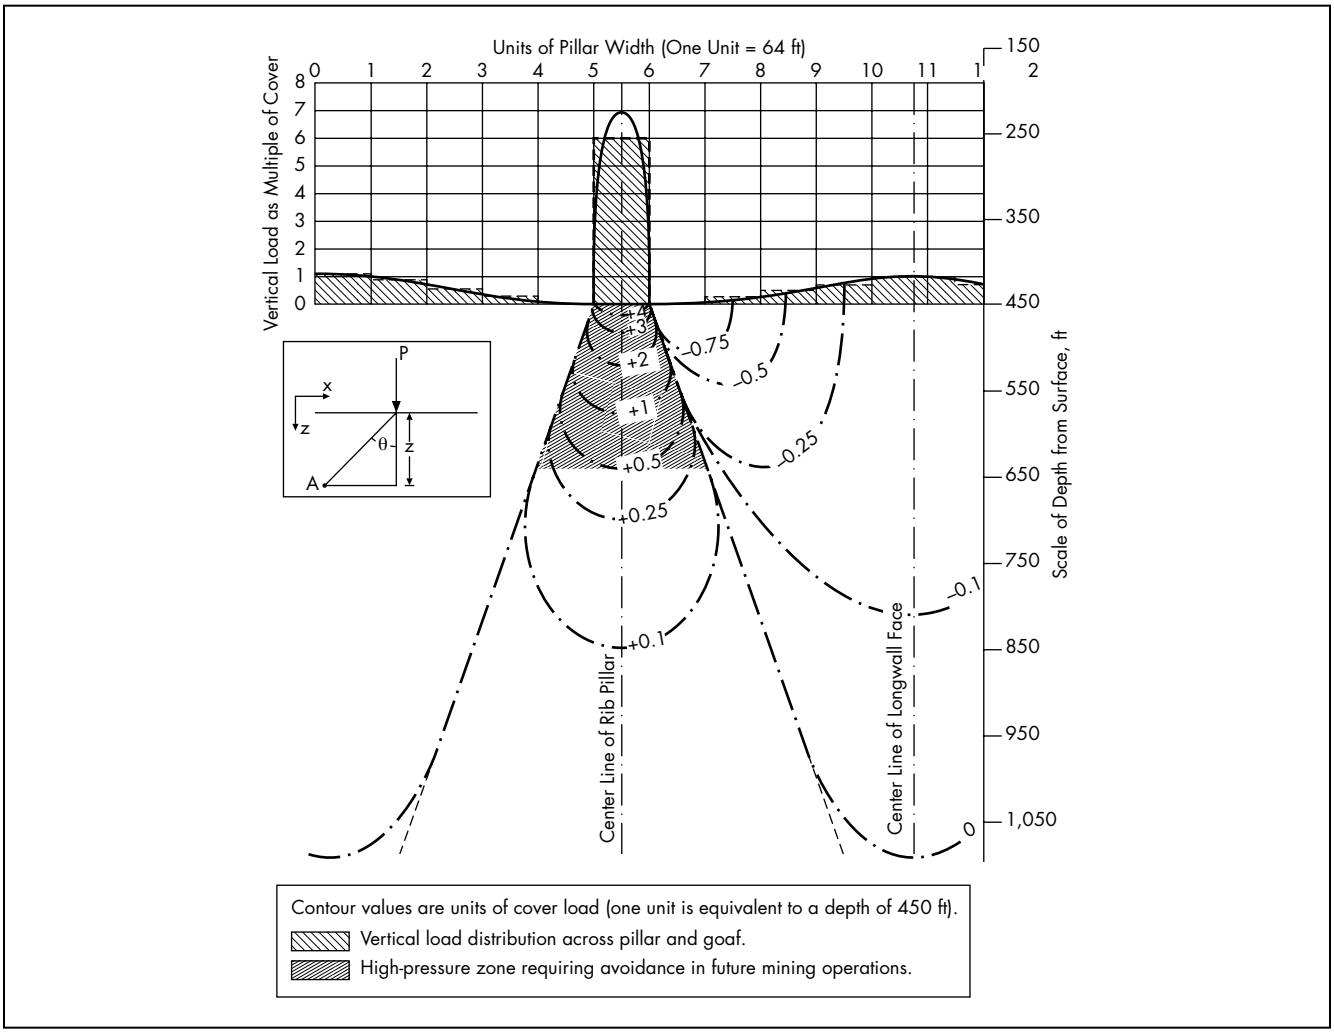
King and Whittaker (1970) published a diagram that demonstrates the development of stress contours below a remnant pillar (Figure 8.7-3).

The large body of subsequent published work, especially that appearing in the yearly proceedings of the Annual Conference on Ground Control in Mining (which is hosted by the University of West Virginia [United States] and the U.S. Bureau of Mines and its successor bodies, and is regarded by many as the premier world forum on soft-rock mechanics research), reviews the effects of interaction and its influence on working layouts and excavation stability. This work is dominated by reviews of experience in U.S. mines with occasional Australian, South African, and European examples.

Other research associated with multiseam mining interaction can also be found in the final reports of some of the research projects funded by the European Coal and Steel Community up to 1992, thereafter the Research Fund for Coal and Steel (RFCS).

Stress prediction is important but still must be related to its effect on basic roadway stability in the affected zone; that is, one can mine through a high-stress zone and stability may not be affected or the reverse might apply. Until the late 1980s in U.K. coal mines, roadways were normally formed to an arch profile and supported by steel supports. Roof closure experienced in advancing gate roads of longwall coal faces frequently amounted to more than 50% of the extracted seam section. Floor lift was also commonplace. Closure therefore was expected and a meter of convergence was not uncommon. An additional increment of closure of a few centimeters due to interaction stresses was often not noticeable unless measurements were taken.

When rock bolts became the principal support in rectangular-section retreat roadways and measurement of closure and adjacent ground movement became routine, the effects of interaction began to be recognized. With ground-movement action levels at which additional support is to be set now quoted in millimeters, any additional roadway closure due to interaction effects is identified and significant. The influence of interaction is therefore related to the fundamental stability of the affected roadway.



MINING METHODS

Soft-rock mining methods can be subdivided into longwall and derivatives of rock and pillar.

Longwall Mining

Throughout the world, the longwall method of mining produces the highest levels of bulk tonnage of mineral, particularly but not exclusively in coal mining. Coal was worked for many years by mining systems that relied on manual effort for coal extraction and transport. These systems included the extraction-operation elements that form the origins of today's longwall face. From the invention of the armored flexible conveyor, power loader, and powered self-advancing support in the late 1940s and early 1950s, the system of longwall operations that we know today emerged. Single longwall faces between 100 and 150 m long, served by two gate roads in the advancing mode, became the European standard. The gate roads were formed behind the face line at each extremity of the longwall, usually by the removal of seam roof to give additional height for access and ventilation. Working height at the coal face was limited not only by seam thickness but also, in thicker seams, by support designs available for use on the longwall face.

Support of the gate roads was provided by steel standing supports, usually in an arch configuration. On one or both rib sides, where coal had been extracted, packs were built from stone, timber, or other imported materials.

Source: King and Whittaker 1970, reproduced with permission from The Institution of Mining Engineers, now The Institute of Materials, Minerals and Mining.

Figure 8.7-3 Contours of vertical stress below a pillar

Fundamentally little has changed in longwall mining except for the equipment used. Higher-powered, more robust, flexible conveyors now allow face lengths of more than 300 m. More powerful power loaders have increased production by virtue of their speed, the width of web they cut, and the height that they can extract from the seam in a single pass. Powered roof supports now have yield capacities of >1,000 t per unit and are capable of supporting working heights of >5 m at the face.

Additionally, the major underground coal producers of the world have all chosen to practice retreat rather than advance longwall mining. In a retreat system, gate roadways are driven to the extremity of the reserve prior to the commencement of coal extraction (distances of >5 km are not uncommon). Longwall faces are then formed in the seam to work back between them, after which they are abandoned in the longwall waste.

Roadways for retreat faces can be single drivages formed at or near seam height with a rectangular cross section or multiples of two, three, or four parallel roadways connected at frequent intervals by crosscuts. Single-gate roadways are commonplace in the deeper workings of Europe (Figure 8.7-4), whereas multiple-gate roadways serving the longwall are commonplace (and legally required) in mines where the coal seams are substantially shallower, as in the United States and Australia (Figure 8.7-5).

The versions of longwall mining described above were appropriate for coal seams <5 m thick, laid down as near-horizontal deposits. Systems have been developed to work exceptionally thick seams by the longwall method using derivatives of the sublevel caving idea in which caving waste, which is comprised largely of coal, is accessed through the rear shield of the powered support and loaded onto the face conveyor.

Many seams around the world, most notably in northern Spain, are highly inclined. Versions of the longwall method are used with individual gate roadways maintained on the strike of the seam with the production face at or near full dip (Figure 8.7-6). In the United Kingdom, there was always considered to be a limiting seam angle of inclination, in the range 45°–50°, beyond which relatively standard longwall techniques and equipment could not be used. Above this angle, specialist systems and equipment were required.

As production from relatively thick coal seams that lie in near-horizontal deposits can be obtained in substantial

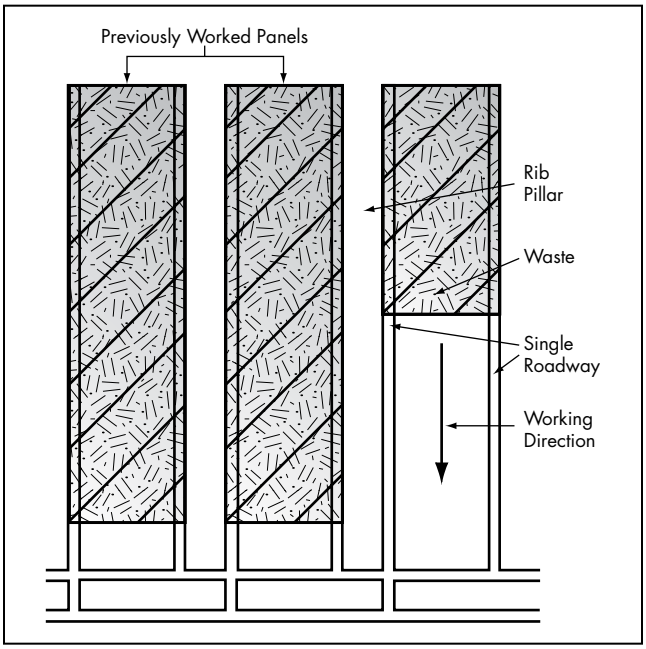


Figure 8.7-4 Typical single-gate roadway layout for longwall retreat

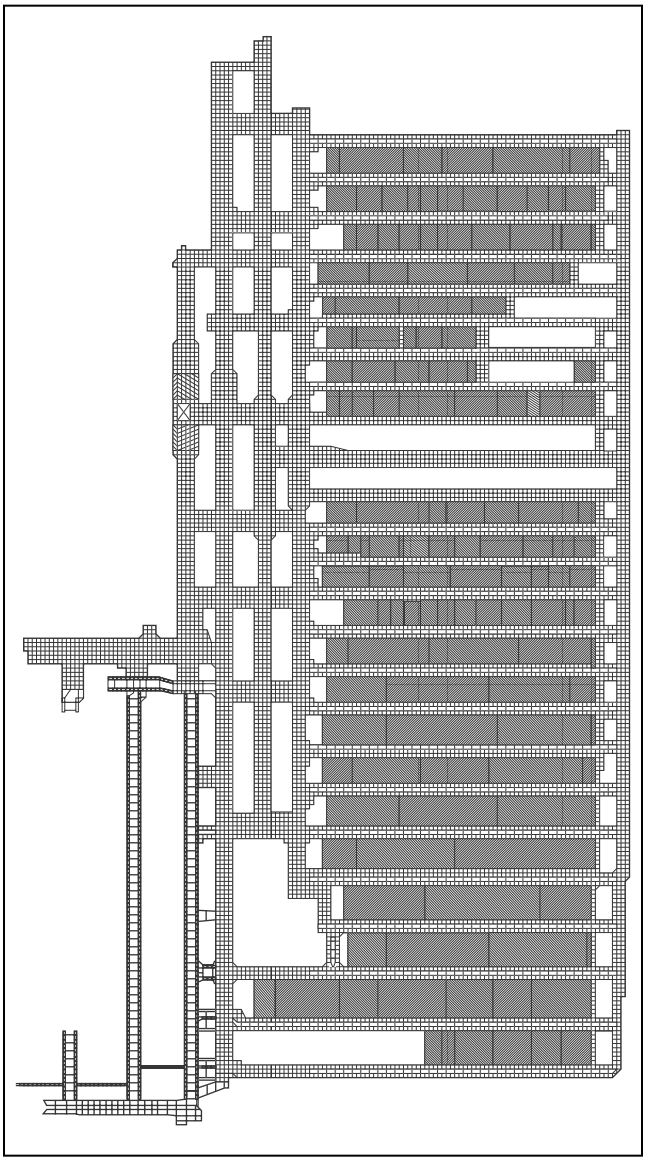
quantities and at very low cost by longwall methods, extraction of coal from thin seams or from steeply inclined or geologically disturbed deposits that require special techniques has waned in importance. Thus this chapter concentrates on standard support techniques required for higher-performing longwalls.

Room-and-Pillar Mining

The alternative to longwall soft-rock mining methods comes under the generic heading *room and pillar* (*R&P*). R&P methods require the driving of multiple parallel roadways in the mineral deposit, joined by crosscuts to form a matrix of unworked pillars of mineral that are stable enough to provide overall long-term support for the mining section (Figure 8.7-7). This is fundamentally an advancing mining system. When mining operations have extended to the planned or natural boundary, the choice remains to either abandon the section or operate a secondary mining system that removes some or all of the pillars upon retreat. Secondary mining requires specialized support systems in which waste is formed by extraction of the support pillars. The extent of this waste must be controlled by temporary supports that separate the remaining pillars and accessible roadways from those where caving is occurring. In recent times, mobile powered roof supports have been used for this purpose with great success.

Many alternative R&P versions exist. Some involve a herringbone-pattern layout; some have pillars that are deliberately smaller than would normally be regarded as large enough for long-term stability; and some have short headings driven into the flank of the panel to maximize extraction. Support requirements for some of these systems are covered in this chapter, but individual systems are too many and varied to be covered here in detail.

R&P methods rarely match the production capacity of longwall methods, but they do offer a low-cost alternative where capital investment is limited or some restrictions exist



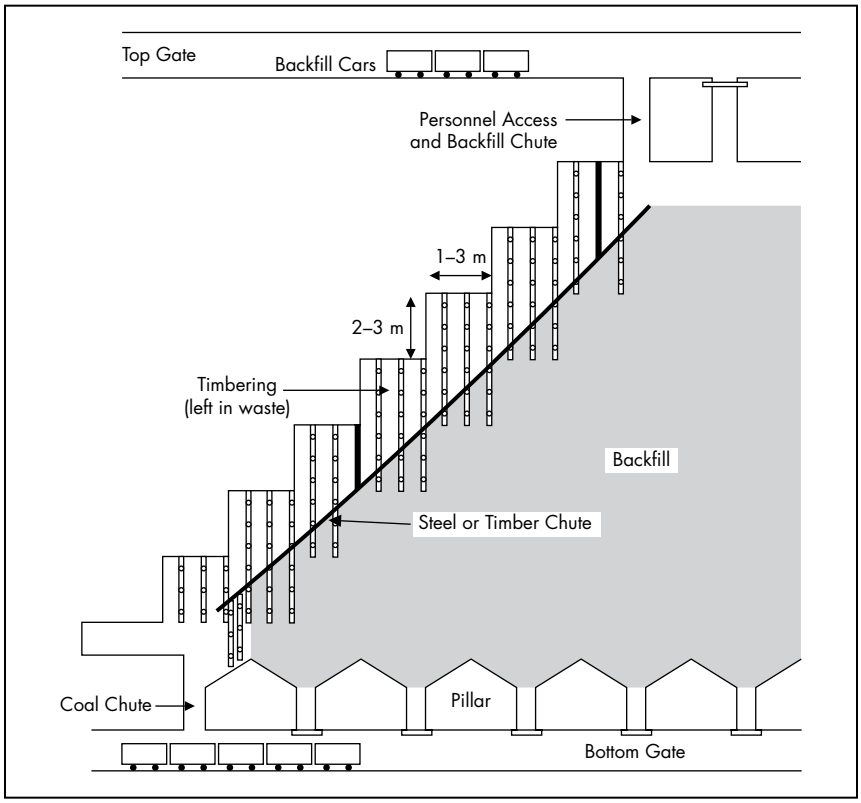


Figure 8.7-5 Typical multiple-gate roadway layout for longwall retreat

on the choice of mining method because of the need to preserve surface features from the effects of subsidence. R&P methods are also used where the roof is so competent that it would not be expected to cave in a regular and controlled manner if longwall were used.

The major restriction on the use of R&P methods is the depth at which they can be efficiently and safely used. It is unusual to find R&P methods used in coal mining at depths greater than ~500 m from the surface. Below this depth, the pillar sizes required to support the district become so large that percentage extraction becomes too low and distances between each advancing heading become too high for efficient operation of the mobile plant normally found in these systems. Additionally, the cost of support required to maintain safe conditions in all the roadways mined can become significant.

Interestingly, some evaporite deposits, most notably potash, are being worked at much greater depths (1,000–1,300 m)

Source: Roberts 1994.

Figure 8.7-6 Typical roadway layout for working steeply inclined seams

by R&P versions in which pillar sizes are small enough to yield with time (Figure 8.7-8).

CHOOSING A TYPE OF SUPPORT: A BRIEF INTRODUCTION

The support that is selected for mining excavation has a number of roles to satisfy. It must apply constraint to the yield zone of failed rock immediately next to the excavation to assist in the natural strengthening of that zone and enable the excavation to remain stable for its designed life (whether 3 months or 50 years). It must provide sufficient working space for mining equipment and operations. It must prevent additional small pieces of loose material from the surface of the excavation from falling and striking people and machinery. Finally, it must provide people who travel through or work in the excavation with the confidence that they can do so safely.

A wide range of support options are available for soft-rock mining. Perhaps the only option that rarely arises is that of no support being needed. Examples of available support types are discussed in the following paragraphs.

Rock bolts reinforce the rock mass, giving it additional strength to withstand imposed stress concentrations. They are designed primarily to resist rather than accommodate strata yield. Rock-bolt systems are highly flexible patterns being altered to react to localized changes in support needs. They are relatively cheap and easy to transport, but require skill and supervision to install. There is also some opportunity for numerical design. Rock bolts are frequently used in conjunction with steel-mesh panels or lengths of geogrid that provide protection in the working area from spalling roof and sides of the excavation.

Steel standing supports (steel ribs) are commonplace in soft-rock excavations. They are erected from sections bolted together on-site and can be easily adapted to variations in roadway size or drivage direction. Although in earlier times they could be found in district development and gate roads in most European coal mines, the wider application of rock bolts has replaced them in a number of shorter-term roadways. Steel standing supports can incorporate yield mechanisms to accommodate rock movement around an excavation and are normally constructed from steel grades that fail in a ductile rather than brittle manner. These support types are relatively inexpensive and operate most effectively with backfill or in smoothly profiled excavations that give multiple points of contact with the rock. Design for these support types tends to be empirically based.

Injection of resins and grouts into fracture planes to improve strata strength has achieved much success in specific locations such as the area around the end of the retreat longwall face. The success of the technique depends on the presence of existing rock fractures. Thus it can be used not to prevent initial development of fractures but only to prevent fractured rock from becoming more fractured and threatening the stability of the mining excavation. It is normally used in conjunction with rock-bolt systems and frequently requires specialist operators and equipment to achieve successful results. Concerns exist about the sensitizing properties and flammability of many of the more successful injection products, especially those based on polyurethane. Targeting of injection in the required areas is difficult. The cost of the chemicals and specialist assistance makes injection relatively expensive.

Hydraulics revolutionized the support of longwall face roofs. A longwall requires temporary, moveable, and yielding

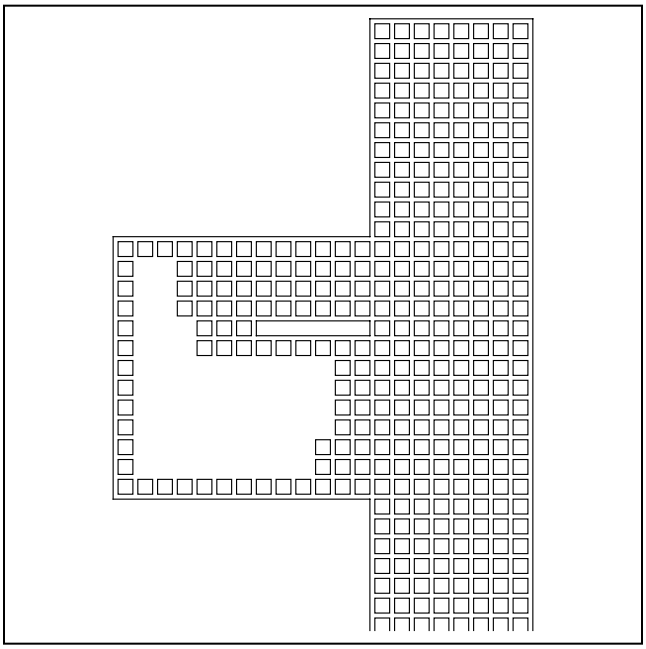

Figure 8.7-7 Room-and-pillar layout with pillar recovery in progress

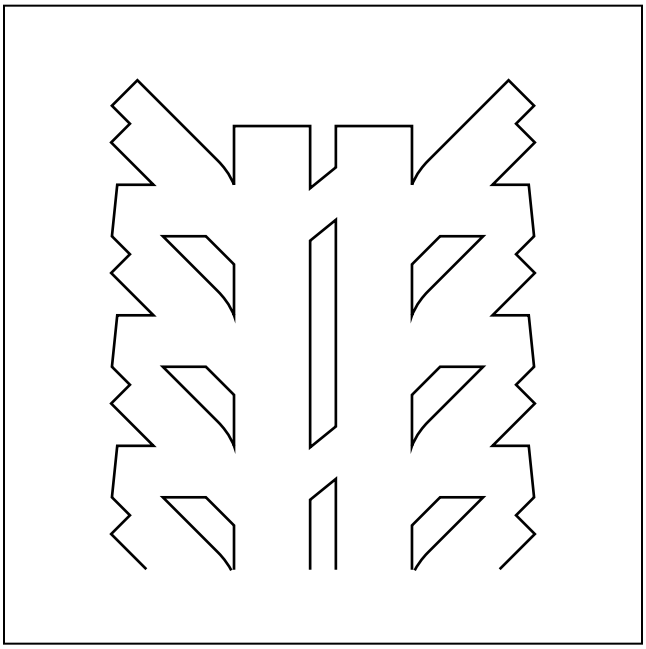

Figure 8.7-8 Room-and-pillar layout modified for deep evaporite extraction

support, and supports based on hydraulic cylinders meet all of these criteria. Single hydraulic props were replaced in a 50-year evolutionary process by powered roof supports that support the longwall working area, advance the face conveyor, and then advance themselves as extraction continues. Versions of powered supports have been used as mobile temporary supports for extracting pillars from R&P systems.

Sprayed concrete (shotcrete) can be applied as an initial temporary support measure, normally in a major drivage, to provide instant support until secondary, more permanent systems are erected. It plays a key role in large excavations such as tunnels, large roadway junctions, or shaft insets where fast-acting, good-quality temporary support is needed. This system requires skilled operators and specialist equipment and products. A potential drawback is that there is little scope for yield when ground eventually moves, and the fractured shotcrete liner itself becomes a safety hazard.

Concrete or cast steel segments are the ultimate in high-strength permanent lining, and are used mainly in shafts, major long-life underground drivages, and places where water inflow might threaten the mine, such as when driving through major faulting or driving shafts through water-bearing rock. These linings are expensive. They are specially designed for a specific excavation and normally require backfill or back-grouting to prevent point-contact loads from destroying their integrity. They are inflexible in that they are difficult to install in other than straight-line excavations and it is difficult to vary the dimensions of the opening. They require major logistical backup to bring them to where they are to be erected and special erection arrangements must be provided.

Packs constructed from stone, timber, concrete blocks, or pumped cementitious material have been used in many parts of a mine as supplementary support. Stone packs were originally a key part of longwall support when built as strips in the waste before the advent of powered supports. They were also used as additional roadside support in roadways of advancing longwall faces. In modern times, packs are frequently used in places such as retreat-face ends where significant additional support is required to retain access ahead of or ventilation flow behind the face line. Their key properties are their flexibility and their significant support-load-carrying capability, but they are labor-intensive to build and require import of materials.

The following sections examine in more detail some of these key support types.

Rock Bolts

Rock bolts are widely used in soft-rock mining, both as principal support and as supplementary additional support or temporary rock reinforcement. Their primary function is to reinforce near-seam rock so that it can experience loading without excessive deformation and, hence, deterioration to the extent that the mine opening is damaged.

Peng (1978) describes three main methods of support action:

1. Suspension of a soft-rock beam from a more competent upper bed
2. Formation of a composite beam by rock reinforcement
3. Increase in the frictional resistance of jointed rock across failure planes to help promote natural arching

Rock bolts were widely and successfully used in coal mines in the United States from the mid-1940s. Importantly, they complemented the normal R&P system of mining. They were also appropriate to strata strengths and stress conditions in U.S. mines. Rock bolts were initially introduced in the United Kingdom in the 1960s as mechanical anchorages, for which use they ultimately failed. They were reintroduced in the mid-1980s because competitive pressures on U.K. coal producers were driving the industry to rely on retreat longwall mining to deliver the required volumes of output at prices that the market could stand. The industry determined that the Australian experience with rock-bolted support in coal mines was appropriate

for U.K. conditions. These conditions dictated that rock-bolt systems must resist rock movement, whereas existing standing supports accommodated movement. There is very little scope for yield in a rock-bolt system and their success was judged on the degree of stiffness in the system.

Only rock bolts that are full-column-anchored with resin have been used successfully in U.K. coal mines. Their performance as a support in high-stress, soft-rock conditions is superior to that of alternative forms of rock anchorage. Much debate has ensued as to whether tensioning of a full-column-anchored rock bolt after installation contributes to its ultimate capability to support the rock strata. Research using numerical modeling (Saleh et al. 2004) has shown that the effectiveness of a pre-tension load varies with both rock-mass quality and in-situ stress level. The findings can be summarized as follows:

- The compression zone generated by tensioning a full-column-anchored bolt is very limited in extent.
- Pre-tensioning offers some advantages in a closely spaced bolting pattern in a weak jointed rock mass (RMR = 30).
- Pre-tensioning also offers advantages in a low in-situ stress field.

Mixed systems of support involving standing steel supports supplemented by rock bolts have been used in the United Kingdom. The support actions of each system differ and therefore do not necessarily complement one another. Because of these differences, the total support generated is not simply the sum of the contributions of each of the two systems. In the early stages of rock movement around a roadway, most resistance is provided by the rock bolts. When the roof has moved sufficiently to load the standing support, the bolts have often ceased to be effective. Only a mixed system, incorporating adequate support density to accommodate each of the components separately, can be expected to deal with a very heavily loaded roadway.

Other rock reinforcement methods used in U.K. coal mines have included the following:

- Reinforcement of geological fault zones encountered by the longwall (that have led to areas of broken roof and slabbing of the coal face) by means of 2-m-long hardwood dowels, full-column-anchored into the affected area. This method provides some cohesion to the rock mass so that mining can continue. However, its use has largely ceased as powered support designs have improved.
- Injection using resins and grouts. This method has found considerable success as a means of artificially bonding strata in the immediate vicinity of the face end to enable control of strata movement during mining. A bonding agent, based on resin or grout, is pumped under pressure into boreholes that are drilled into the roof and rib sides of the retreat roadway. This method is often used to best effect in conjunction with steel or cuttable rock bolts. It has been extended in extreme cases to the recovery of falls on longwall faces.
- Support of not only the roadway's roof but also its rib sides in high-stress, soft-rock conditions. Such support is important because high vertical stresses can create a fractured zone deep into the rib side. On the longwall-face side of the retreat gate road, support is achieved by means of cuttable bolts made of glass-reinforced plastic, full-column-anchored into the rib side during roadway formation. The axial strength of these bolts is comparable to that of steel bolts used in the roof. However, they can be easily cut by the shearer when it reaches the roadway.
- Cable bolts and flexible bolts. The length of rock bolts used in roadways is normally limited by the height of the driven roadway, unless some form of coupling is used to allow installation. Their use is appropriate when a combination of high strata stresses plus weak rock surrounding the excavation exists and tendons longer than 2.5 m are required. These longer tendons have been used to supplement steel rock bolts to provide principal support in heavily loaded roadways.
  - Cable bolts can provide support at depths of ~8 m. Full-column anchorage can be provided by pumping grout to the back of the hole after installation of the tendon. The flexibility of the cable allows the tendon to be bent during installation.
  - Flexible bolts tend to be shorter steel tendons (~4 m long) based on steel rope. They can be spun into resin capsules inserted into the hole, injected after installation, or a combination of both.

Steel Standing Supports

Development of steel standing supports has been led by the coal industries of the United Kingdom and Germany. However, since the 1940s, both countries have differed radically in the choice of standing support type used in roadways. In the United Kingdom, although advancing longwall mining was the predominant mining method, it was normal to support gate roadways with a two-piece or three-piece D-shaped steel rib known as an *arch*. The German industry also used a form of steel rib, but whereas the United Kingdom used rolled steel joists (RSJs) of H-shaped cross section (Figure 8.7-9) based on those specified for structural steelwork in civil-engineering applications, the German industry favored joists of V-shaped cross section with an inbuilt yielding mechanism at the joints. This latter has become known on both sides of the North Sea as the T-H yielding arch, after the original supplier, Toussaint–Heintzmann (Figure 8.7-10).

After the move to retreat mining began in earnest in the United Kingdom in the mid-1980s and in-seam rectangular-section roadways became an operational necessity, two major changes were effected. One was the introduction of rock bolts as principal support in roadways. The other, altogether less obvious and less heralded, was the move to flat-top or cambered-top steel arches (Figure 8.7-11).

Despite the increased use of rock bolting since the 1990s, many gate roads continue to be supported solely with arches or with a combination of rock bolts and arches (a so-called "mixed" support system). In the United Kingdom, arches also continue as the system of choice in many main trunk roadways, all cross-measure drivages, all drivages through goaf (known as scours), all roadways formed by blasting, and all advancing-face gate roads.

The British Colliery Arch

The colliery arch was based on the RSJ specified in British Standard BS 4 (1980). H-section joists (or I-section joists, as they are known in the civil engineering world) were designed to have the highest possible moment of inertia in the plane of bending. This requires that as much of the steel in the section as possible be away from the neutral axis. In civil engineering applications, there is normally only one plane of loading. Thus

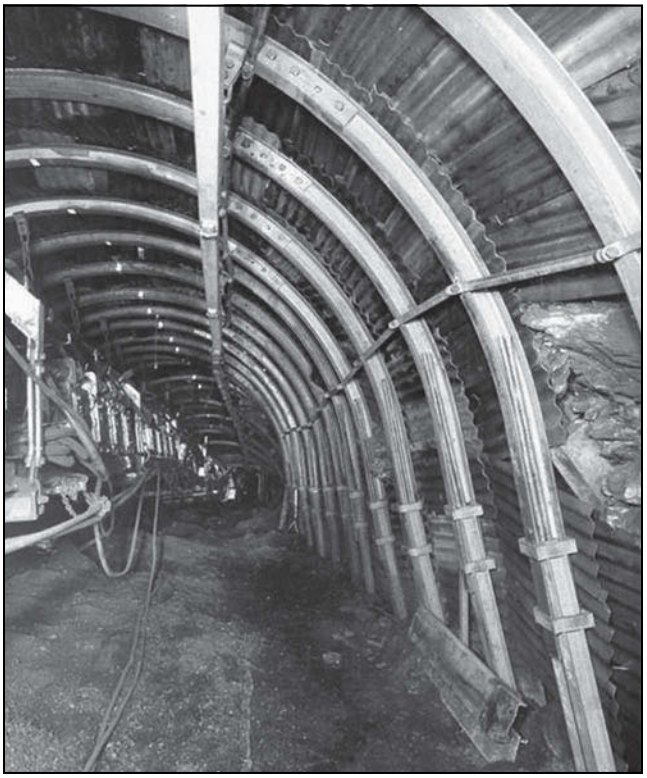

Figure 8.7-9 H-section steel arches

Figure 8.7-10 T-H yielding arches

Courtesy of British Coal Corporation.

Figure 8.7-11 Cambered-top steel arches

most of the steel is in the flanges, in long thin webs, as far as possible from the neutral axis.

In mining applications, loading usually occurs in more than one plane and is often unevenly spread and of a magnitude sufficient to cause the joist to yield. Therefore, mining section rollings always have most of the steel concentrated in the web and tend to have overall dimensions for flanges and webs set at values near one another (e.g., 127 × 114 mm, 152 × 127 mm).

A significant property of any standing support steel is its capability to fail in a totally ductile manner with no sign of brittle fracture. Therefore, most colliery arches, whether D-shaped or flat-topped, are constructed of grade Fe 430 B steel per BS EN 10025.

Arch supports are made by cold-bending steel rollings into roadway supports. This involves forming fishplate and strut holes in the web and sawing the arch into appropriate lengths for ease of handling and assembly. Supports are normally supplied into the mine in arch packs—that is, collections of arch segments packed together with fishplates, bolts, struts, stilts (if used), lagging, and, where appropriate, rock bolts and resin—that can support a given cycle of advance in the drivage of a roadway.

Arch Joints

Arches are formed from two, three, or even four sections of joist, generally connected by means of fishplated joints. However, these joints can become points of weakness affecting the overall strength and operational performance of the support unit.

In the early days of D-section arch supports, all fishplates were of an in-web rolled-steel design. The "wrap-around fishplate," introduced in the United Kingdom in the mid-1970s, gave additional strength to the fishplated joint, especially in the plane parallel to the roadway axis. It also satisfied the requirement for a fishplate that can be loosely assembled, enabling an arch to be erected in one piece, a technique known as whole-arch setting (Figure 8.7-12).

In the early 1980s, the pressed-steel in-web fishplate was introduced. Stronger than other existing fishplates, this one was also lighter and cheaper, a combination of qualities achieved by use of alloy steel containing a percentage of boron. Joint strength in both planes was greater than that of the original sections. Pressed steel plates were also used to form the chevron joints of camber-top and flat-top supports.

Other Arch Accessories

Arch supports are separated by spacers known as struts. The number of struts used between each setting normally depends on the length of the arch perimeter. Struts are either bolted through the joist web or clamped onto the joist.

The strongest and most expensive struts are tubular, fitted with flanges at either end that are bolted through the joist web. Laboratory tests show that a full set of struts, correctly assembled and fitted to arches, can contribute significantly to support-system strength.

A chief drawback for roadway supports, mentioned previously for H-section joists, is the lack of a yield mechanism in the support system as opposed to the yield of the steel itself. One way to overcome this is to use stilts. In theory, when fitted to the base of the arch legs, stilts allow a degree of yielding of the overall system without threatening the integrity of the arch joist or its joints. Many stilt designs have been made;

Courtesy of British Coal Corporation.
Figure 8.7-12 Wrap-around fishplate arch joint

however, all were expensive yet incapable of providing consistent yield under uncontrolled field conditions. Thus, the use of stilts eventually ceased.

Although the use of stilts ceased, the problem that they were designed to solve did not disappear. The yield mechanism in arches today is provided by packing material between arch and strata or by arch legs that penetrate the floor. The latter mechanism is thought to contribute to floor lift in roadways.

Roadway Support System Strength

With so many variables present in the roadway support system—including the most significant external variable, the loading condition to which each arch in a system is subjected—determination of the strength of a single support or a number of adjacent supports is based more on engineering experience than on science. All conclusions about product or system strength tend to be comparative.

Between 1986 and 1991, the European Coal and Steel Community funded a research project titled "Testing Roadway Support Systems." Project objectives were to provide basic data on the fundamental strengths and characteristics of a range of roadway supports and ancillary equipment. Project conclusions are given below (British Coal Corporation 1991):

- The most severe loading condition for a single arch is a single-point load. As the number of loading points increases and side restraint is offered, the capacity of an arch increases accordingly. The most favorable condition is a uniformly distributed load around the support.
- Support capacity can be increased by reducing support base width, reducing support centers, and increasing section size.
- For fishplated joints, increases in joint strength up to ~80% of the section strength increase overall support strength. Further increases in joint strength do not further increase overall support strength.
- Struts add to the ultimate strength of a support system. Stronger struts have the most favorable effects.

These conclusions, although already fairly well known to mining engineers, were quantified for a range of support types and loading conditions.

German Practice

The T-H-section arch joist was first introduced in Germany in the early 1930s. The principle behind arches made from this section is to allow the portions of the arch to slide relative to one another at the joints, making the arch effectively yield under load without damage to the section itself. The joints are formed by overlaps between the arch legs and the crown, and are secured by clamps. Resistance to yield can be varied by adjusting the torque on the clamp bolts. The T-H section also enjoys the advantage that the strength of the section is similar in both major axes.

Visitors to German mining operations would be hard-pressed to see a roadway support other than the T-H section. German mines are laid out as longwall systems. Gate roads frequently serve two longwalls and are thus subject to considerable closure. They are therefore formed initially much larger than are U.K. roadways, with the expectation that some closure will take place. The T-H section allows major closure without the arch losing its support integrity or suffering excessive damage. The roadway is often backfilled after formation to control the loading condition on the arches.

T-H-section arches have some drawbacks. They are set with the base of the V inward toward the roadway. This causes difficulties in the provision of struts and devices to hang cables and hoses. However, their chief drawback is that the yielding process, because it relies on friction, is difficult to control.

The definitive English-language work on roadway support in Germany is a book published in the United Kingdom by Fritz Spruth (1960). Spruth identified the importance of the joint friction clamp that allows yield and stated that clamps should do the following: (1) yield at a steady load; (2) operate automatically (some early designs relied on the miners having to periodically strike the joint to initiate a degree of yield); and (3) not snag on roadway lagging material during arch yielding.

In conclusion, when comparing U.K. and German arch roadway-support practices, the following can be concluded:

- Performance at yield is clearly better for arches made of T-H sections than for those made of H sections.
- Support dimensions are variable on setting for arches made of T-H sections, within limits; they are not for arches made of H sections.
- Costs are higher for arches made of T-H sections than for arches made of equivalent H sections, mainly due to the clamps.
- Lateral strength is greater for T-H sections and virtually nonexistent for H sections.
- Joints are strong points for arches made of T-H sections, due to overlap; they are often the weakest points for arches made of H sections.
- Versatility is greater for H sections in that they can be readily adapted to U.K. needs to use square-section or flat-topped arches in in-seam retreat roadways or R&P districts. The author is not aware of this need in Germany or of any developments along this line using T-H sections.

As a result of this mix of experiences and operational requirements, the two industries have developed their roadway support technology, as they have developed their mining systems, along different lines.

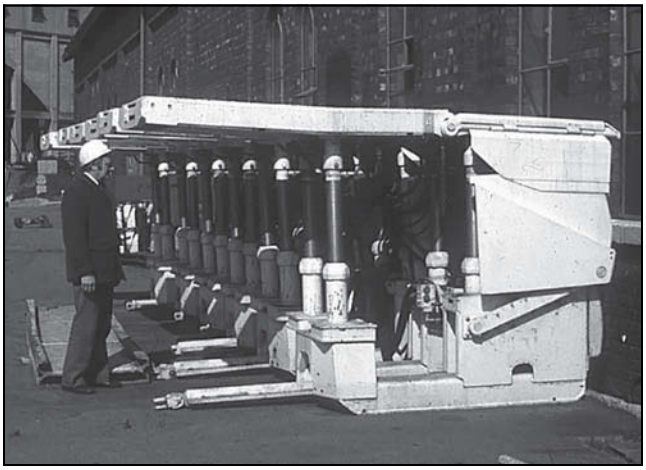
Face Support

Longwall support offers many challenges to the engineer. Among its basic strata-support capabilities, a support unit must do the following:

- Be capable of being set at a variety of working heights
- Impart an immediate positive load to the roof strata to prevent bed separation in the immediate roof strata and control the movement of bridging beds
- Yield in a controlled manner within a chosen load range
- Provide protective cover against falls of smaller pieces of rock into the working area
- Support the coal face laterally
- Prevent ingress of material or dust from the waste into the working area

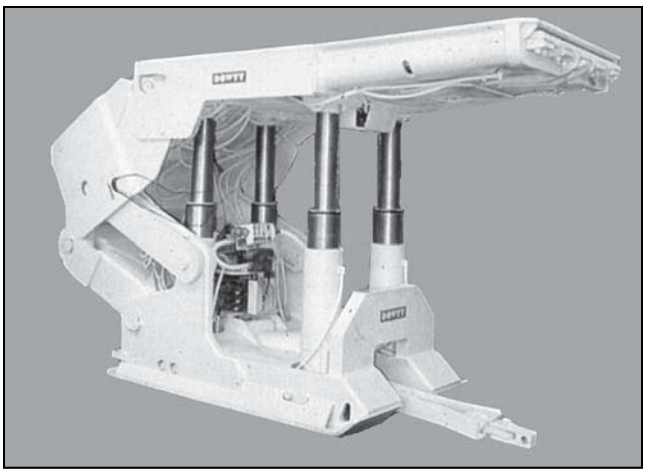
Additionally, the support unit must perform the following equally important operational tasks that are not necessarily linked to its ability to act as a roof support:

- Be capable of advancing the face conveyor and then moving the support structure forward
- Be capable of retaining its alignment relative to its neighbors
- Allow personnel access along the longwall
- Have a low collapsed height for ease of transportation among longwall applications
- Provide for both in-support and remote control of support operations
- Provide base positions for coal-face lighting installations



In the United Kingdom, investment in longwall plant and equipment has always been a major feature of the mining industry's capital expenditures, second only to that for new mines or major reconstruction projects at existing mines. By far the largest item in that expenditure is for powered roof supports. Because of their considerable cost, their design features are of significant interest.

Introduction of the lemniscate linkage to powered roof-support designs is arguably one of the most influential technical achievements in longwall mining in modem times. It unlocked the way toward the working of thicker seams in longwall systems. In the United Kingdom, the major powered roof-support manufacturers had developed chock-support technology to its ultimate. This was best demonstrated by the hugely successful six-leg 240-t yield support with full shielding, full-width canopy, and heavy-duty forepole (Figure 8.7-13).



Although designed for extractions up to 2.4 m thick, it was at its best in extractions of 2 m. Attempts had been made to develop chock-support technology for extractions of 3 m, but at this extraction height the stability of a 1.2-m-wide support was questionable, especially with regard to its lack of resistance to lateral loading due to its inability to operate successfully with coal-face support sprags and to be in contact with its neighboring supports.

The lemniscate linkage changed the internal stability of the support structure. It removed all lateral load from the support legs, so that leg restraint need no longer be provided by leg towers. Supports could now be designed with their side shields and canopy side flaps in contact with those of their neighbors, greatly reducing the ingress of material from the waste into the traveling track, which had been a major problem with chock-type supports. Supports could also be designed to advance while retaining contact with the roof, a feature unheard of in conventional chock design.

The lemniscate linkage also addressed another problem: that of spalling coal from the face, a well-known danger to workers that ultimately leads to exposure of unsupported roof at the face and increases the potential for broken ground or major falls. The solution to this problem was the use of face

sprags. Once again, the lateral resistance offered by the lemniscate protects the legs from any resultant lateral loading. Lemniscate linkage supports became known as shield supports.

The first shield supports used in the United Kingdom were four-leg chock shields (Figure 8.7-14). Operators traveled the longwall within the support structure behind the front legs. However, although they offered positive support to the roof, they did not have a particularly good working range.

Inclined-leg shields soon overtook them in all seam ranges. They enabled the use of shield technology in thinner seams and allowed passage through the face in front of the forward legs, providing better access to coal-face equipment. Additionally, the considerable range of working heights available with these types of support made them easy to transfer among different seams in the same mine, and, indeed, different mines.

Two-leg shields were a natural extension of inclined-leg designs (Figure 8.7-15). The rearward-facing inclined legs were replaced by stabilizing rams between rear shield and support canopy. Interest in their use in the United Kingdom developed as mining engineers became aware of the number of overseas applications. Individual leg ratings of >300 t for

two-leg shields led to a far superior density of support when compared with U.K. four-leg designs. However, the chief argument that slowed their U.K. application was the perception that the forward edge of the base would dig into the soft floors encountered in many U.K. coal mines. This valid concern was overcome by the introduction of the base lift, which lifts the front end of the base during support advance.

How Much Support Is Required?

Support ratings have increased over the last 30 years, in terms of both the *yield load* by which a support is defined and the applied *setting load*. The setting load has increased as a percentage of yield load in the United Kingdom from about 30% to >75%. However, the question has never been satisfactorily answered as to how strong a support should be for a particular circumstance.

The support acquisition process in the United Kingdom was based on the premise that the mine operator would select a support rating, and the manufacturer would supply to that specification and demonstrate by means of rigorous laboratory testing that the support structure and hydraulic legs met that specification. There is a history, especially in Europe, that powered supports have tended to become overdesigned for their duty in terms of nominal load-bearing capacity. However, in view of the substantial investment required to purchase supports, the long, arduous working life expected of them, and the uncertainty always attendant upon soft-rock mining, it has been regarded as prudent to have a significant factor of safety when applying powered supports.

Mechanical testing of support structures, initially identified as a guide to design safety, is now also used to measure design reliability. Such testing involves subjecting structures and hydraulic components to numbers of test cycles approaching those likely to be experienced during production life. These requirements are customer-led rather than imposed by regulatory bodies, as the international market is populated by mine operating companies that are now well aware of what they require from a support and how those features might be demonstrated by the potential supplier.

In 1999, mining regulations were introduced in the United Kingdom to control the application of support in underground mines. These constitute the first revision of the 1966 regulations that were drawn up when powered support designs were comparatively new. Before then, a maximum interval was specified between the coal face and the nearest support member of any given support design. This distance, generally 2 m, was taken as the measure of safe support and was the basic parameter that influenced face design, especially the design of the power loader and the armored face conveyor and its furnishings. Even in an era of relatively low-capacity face equipment, this distance was barely adequate to house the face equipment. As the power and size of all elements in a coal-face package increased, this "prop-free-front" distance plainly restricted potential production that could be won from the face. Some better measure of support had to be found.

Early work by the Mining Research Establishment (Ashwin et al. 1970) demonstrated empirically the minimum mean load density (MLD) required at the coal face to limit convergence during normal operations. At MLD >> 10.76 t/m^2, convergence differs very little from that at MLD = 10.76 t/m^2. At MLD < 10.76 t/m^2, convergence increases. These optimum

Courtesy of British Coal Corporation.

Figure 8.7-15 Two-leg shields, showing good access along the face line

MLD figures were later shown to vary with the seam section. Recommended load densities were then quoted as 11.8 t/m^2 for thin seams, 22.6 t/m^2 for medium seams, and 29.1 t/m^2 for thick seams up to a maximum of 2.4 m.

In 1982, the British Coal Corporation rewrote its internal owner rules governing the use of powered supports, moving away from the single measurements mentioned previously. Their document set down, for the first time, instructions for determining the minimum setting and yield load densities required in the various zones of a coal face. In the face zone, minimum values were set to the following: setting MLD = 7.5 H t/m^2 and yield MLD = 15 H t/m^2 (where H is the seam section, in meters). Thus, a 1-m section requires a setting MLD of 7.5 t/m^2 and a yield MLD of 15 t/m^2; a 2.4-m section requires a setting MLD of 7.5 t/m^2 and a yield MLD of 37.5 t/m^2.

The actual designed setting and yield densities for powered support have increased over the years, reaching values well above these minimum requirements. The focus of attention has since moved from yield density to setting density, with setting densities now approaching within a few percentage points of yield densities.

The question of the validity of MLD as the sole definition of a support's operational characteristic requires closer examination. As it is an average figure, its value must be qualified by reference to the distribution of the load on a support canopy and base. However, load-distribution profiles are somewhat academic in concept because they relate to the ideal situation of a roof beam in full contact along its whole length with a strata profile of matched shape—a long way from normal operational conditions under which powered supports operate. But it does demonstrate that, for a support to operate effectively, consideration must be given to not only MLD but also canopy-load distribution. Five- and six-leg chock supports, because of their geometry, exhibit a reasonably well-distributed load profile over canopy and base. Concern about maintaining an even load distribution in the base was one of the chief reasons that chock shield designs became so popular when the advantages of lemniscate supports were recognized by the industry.

The overall pattern of strata behavior around a longwall face has been widely researched since the early 1950s, for virtually as long as full caving of waste and powered support have been in existence. Difficulties in making measurements

in the strata above a working face have always dictated that information must be gathered from a number of sources—namely, observations of convergence and pressure profiles of the support legs in situ, physical and mathematical modeling, and pure hypothesis. That the debate continued into the 1990s was symptomatic of the uncertainty that surrounded the subject.

When a stratified deposit is extracted by the longwall method, the roof of the longwall is supported temporarily by powered supports until the system has advanced sufficiently that the supports can be removed and the roof allowed to freely collapse (or cave) behind them. This volume of broken rock is known as *waste*. The thickness of roof strata that collapses is governed by the type of strata that forms the roof. Soft friable rocks such as mudstones cave easily when unsupported, breaking into relatively small fragments, the volume of which is greater than the volume it originally occupied as intact rock. This bulking process dictates the height to which caving can occur. Uncaved beds above the caving beds are known as the bridging beds. These remain intact and subside over the caved waste in a manner controlled by the support offered by the unworked mineral ahead of the face, the action of the powered supports, and the compression of the caved material in the waste. This process is known as bulking-factor-controlled caving (Gorrie and Scott 1970; Wilson 1975; B.G.D. Smart, personal communication).

Calculations show that bridging beds commence a distance of twice the height of the mineral extracted at the face above the face roof. This gives an effective value to the weight of rock for which support must be designed. Convergence on a well-supported longwall is caused by the downward movement of the bridging beds being transmitted through the immediate roof beds while they remain intact.

The support offered to the roof by the powered support maintains the integrity of the immediate roof beds but does little to prevent convergence of higher bridging beds. When stronger rocks such as sandstone and limestone form the immediate roof of the mineral being worked on a longwall, they frequently do not cave immediately behind the powered supports but rather cantilever into the waste for some distance. This puts additional load on the supports. Furthermore, when this rock eventually caves, it does not fragment as readily as does weaker material; rather, it forms large lumps in the waste with an effectively much lower bulking factor. The distance up to the bridging beds thus becomes much larger. Beds can also cave to a well-defined parting plane, and the height of the parting plane above the mineral dictates the height of caving. This phenomenon is called parting-plane caving.

As a general rule, the depth of a working from the surface does not directly affect the loading to be expected on the powered supports. Support loads experienced 200 and 1,200 m below the surface can be similar. There is, however, one surprising exception to this rule. Perhaps the most difficult circumstances for longwall support come when working shallow (<150-m depth) seams with competent overlying strata. Caving in these circumstances often extends right through to the surface, such that the powered supports are asked to support a column of strata from working level to surface. In these circumstances, supports designed to yield at ≥1,000 t are applied.

These mechanisms are derived from hypothesis rather than measurements. For this reason, engineers purchasing and installing powered supports for a new application apply a significant factor of safety to ensure that the supports do not, at some time in their working lives, become overloaded.

It has become usual in Europe, with its long history of using powered support, for decisions on new support designs to be made empirically. Empirical selection of supports based on experience in comparable strata conditions rarely fails. The chief criticism that it attracts is that supports can sometimes be overengineered. This is not necessarily a bad practice, as the extra cost of the overdesign (which is difficult to precisely quantify) serves as an insurance premium against the unknown. In all but the thickest seams, yield load densities in the United Kingdom peak at ~100 t/m^2, which normally relates to support yield loads of 650–750 t in the mid-seam range. The cost of achieving this density, for the mine operator, is high and a compromise must eventually be reached between the equally strong desires to increase loading and to restrict the cost of powered supports. Matching support size to an actual application still owes as much to experience as to science and economic reality.

The modern shield support has displayed considerable mechanical reliability and is well equipped to deal with unreliable or unknown geology. However, no amount of technology can maintain high production levels in the most faulted, weak, water-bearing strata or where seam sections reduce. The inflexibility of the longwall method will always make it vulnerable to uncertain geology.

Standardization

In the late 1980s, the European Union issued a directive covering the basic safety of machinery. An amendment to that directive highlighted powered roof supports in mines as a type of machine that requires particularly careful treatment with respect to supply within the European Community member states.

A working group comprised mostly of U.K. and German delegates representing mine operators, the U.K. Mines Inspectorate, and powered-support suppliers put together a series of basic safety standards harmonizing European practice (BS EN 1804 series 2001–2006). However, this standard does not cover the use of support underground. Safety with respect to powered supports is still judged largely by performance under test. The major implications of this exercise are not to restrict the activities of U.K. and German support manufacturers, but rather to control trading within the European Union of potentially inferior products from suppliers outside the European Union.

Design Methodologies in Soft Rock

Siddall and Gale (1992) elegantly summarize a design philosophy appropriate to the identification of support systems to be used in soft-rock environments in the following quotation.

> The science of strata control would be best considered as the application of scientific principles to certain goals:
>
> - Understanding the behavior of rock or strata under known conditions
> - Determining methods to control the strata under known conditions
> - Determining methods to predict the response of strata under conditions other than those for which current experience allows assessment

- Determining methods of controlling the strata within limits dictated by mining operational viability in the conditions predicted outside those for which current experience allows assessment

Scientific principles cannot be applied unless the problems can be defined in a scientific format and the answers obtained can be seen to explain the actual site situation. To achieve this process, scientists and engineers need to:

- Obtain experience of the mine environment and understand the key factors influencing the behavior of the environment
- Determine the factors which can be quantified and those which cannot be directly quantified and may need to be extrapolated or assessed qualitatively
- Undertake measurement of the strata behavior and the influence of mining activity
- Formulate conceptual models of the mechanics involved and the interrelationship of the variables present.

A number of key decisions are required when selecting a support type for a soft-rock excavation. The following key questions must be answered:

- How much closure can be tolerated in the excavation? This question presupposes that some amount of closure may, on occasion, be accommodated within the mining system. This requirement suggests knowing not only the degree of final closure but also the patterns of closure related to both the passage of time and the continuation of working within the excavation. To deal with closure without premature failure, support must incorporate an appropriate yield mechanism—that is, one that provides a level of resistance prior to yield that is largely maintained during the yielding process.
- Is support required for the roof, sides, and floor? In soft-rock excavations, support must be provided not just to the roof of the excavation but also to the sidewalls and on occasion to the floor.
- What are the rock excavation formation methods? In most soft-rock excavations, the time interval between rock excavation and setting of support is an important consideration. Early setting of permanent support or introduction of temporary support measures are essential to providing early resistance to movement of newly exposed rock faces. This early application of support greatly influences the convergence process.
- How significant is cost containment? This is a key element in most soft-rock mining systems, as soft-rock minerals tend to be relatively low in value and therefore production costs must be maintained within tight bounds. The use of supports is a key element in mining costs, and often compromises must be made in choosing between the best support type and an adequate but less expensive alternative.

In designing support systems for soft-rock applications, the following approaches are taken either singly or jointly.

Experience

Support-system design in soft rocks is based largely on previously proven successful practices from the same mine or neighboring mines with perceived similar conditions. It is also often based on the personal experience of individual engineers.

This is a quite satisfactory approach and can provide safe and efficient support systems. But it can also perpetuate overdesign of the support system that can prove ultimately expensive. Although it is quite correct to set additional support within a previously applied system for a new site, only a brave or foolhardy engineer would decide to reduce support density in a mining system based purely on experience without recourse to measurement or rigorous design.

Measurement

A long tradition exists of measuring strata dilation around a mining excavation. In its simplest form, this is done by in-tunnel roof-to-floor and side-to-side convergence tape measurements. In general, the degree of roof, floor, or side displacement can be measured only to the centimeter level, and high levels of accuracy are unnecessary. Patterns of behavior can be identified and variations in the support applied can be evaluated by comparison of closure measurements.

With the introduction of rock-bolted support in coal-mine roadways in the United Kingdom in the late 1980s to early 1990s, a different approach to the design of roadway support was required. Rock bolts were a technology new to both mine management and miners, and confidence had to be gained that these supports were adequate and safe. This process coincided with a general renewal of U.K. health and safety legislation underway at the time. A significant feature of the format of new mining regulations in the United Kingdom was their lack of prescriptive detail. In place of prescriptive detail were general principles and a stated requirement for mine operators to conduct risk assessments of all underground operations before commencement.

The approach adopted to safely introduce the new rock-bolt support technology is to set down a process of geotechnical risk assessment largely based on site investigation, leading to selection of a support-system design. Key elements of this process are knowledge of the geology and stress field together with in-situ experimentation to establish the bond strength between resin and strata at all major roof horizons within the bonded length of the bolt. Knowledge of the typical pattern of strata dilation in relation to its distance from the face once exposed is also needed.

The design of the support system is, in practice, empirically based and site specific, taking into account certain general parameters such as minimum bolt length to be used (1.8 m), minimum bolt density in the roof (1 bolt/m^2), hole diameter ($\leq$7 mm larger than the bolt diameter), and the need to place rock bolts as near to the face of the heading as possible and as soon as practicable after the roof is exposed. Support of the sides is now considered part of the overall design.

Rock bolts, after installation, are subject to detailed and comprehensive monitoring by measurement of strata movement and rock-bolt load. Extensometers are used to measure, with a high degree of accuracy, much smaller displacements experienced between different strata sections in the rock mass around the excavation.

Operating rules also specify the presence of routine monitoring in every roadway in which rock-bolting provided the principal support. Monitoring takes two forms: dual-height telltales and multi-horizon extensometers. Dual-height telltales are installed to at least twice the bolt length (or 4.8 m, whichever is greater) at intervals of $\leq$20 m along the roadway.

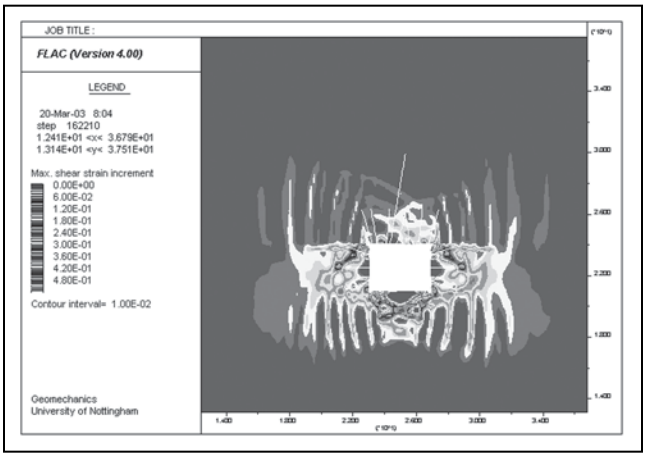

Figure 8.7-16 Typical FLAC output for stress distribution around a mine roadway

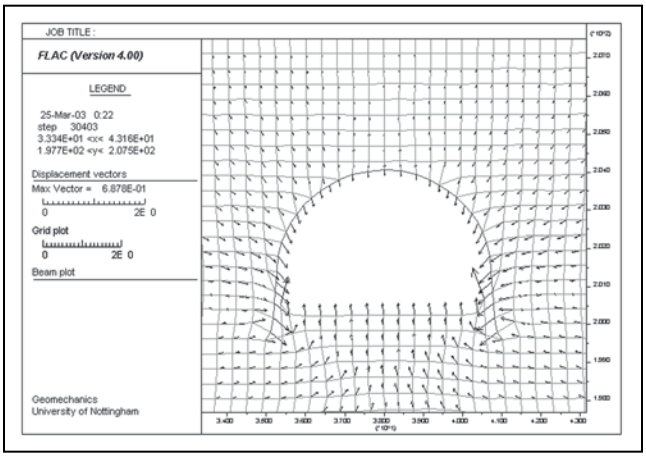

Figure 8.7-17 Typical FLAC output for strata displacement around a mine roadway

Additional telltales are required at every junction and other places where roof instability is known or suspected. Multi-horizon extensometers reading ground movement to ≥7 m above the roof of the roadway are installed at maximum intervals of 200 m. More importantly, the mine manager is required to put into operation a scheme in which these routine monitoring stations are read and reported upon. Supervisors at the mine are given action levels of movement to measure against and actions to take if these levels are exceeded (Great Britain Health and Safety Commission 1996).

Physical Modeling

In the early years of strata-control research, a number of key mining research institutes studied the mechanisms of strata movement and stress redistribution around mining excavations, especially longwall faces, by physical modeling of mining situations using plaster models loaded in large frames. This work was conducted in a number of coal-mining countries, and in its heyday was used to qualitatively explain the mechanisms of displacement that take place away from the mining excavation.

These physical models were expensive in terms of resources, and the results were often limited. The models were heavily dependent on the size of the model domain, the assumptions made, and the scale effects for work of this type. The results gave at best a broad qualitative view of large-scale rock-mass response to mining. They were far less effective in providing practical data on which a support system can be designed.

Numerical Modeling

Before the computer era, analytical solutions were developed that provided a conceptual understanding of rock-mass behavior. However, in most cases they assumed rock to be a linear elastic material, which is a large simplification, especially in soft-rock regimes. For many situations, they could solve only problems that had simple geometry and low dimensionality. Unfortunately, rock masses are generally anisotropic, inhomogeneous, and inelastic due to the presence of geological discontinuities such as joints, fissures, and faults. Most soft-rock mining problems are nonlinear, due to high levels of deformation, and involve complex shapes and boundary conditions that often cannot be described by simple mathematical functions.

With the development of high-speed personal computers in the last two decades, powerful computer-based numerical modeling techniques have become readily available for application to geotechnical materials. Numerical methods have become very popular in academia and, more recently, in industry for solving problems in rock mechanics. The development of these numerical methods has provided the design engineer with a way to predict the stress, displacement, and failure mechanisms of zones adjacent to an excavation formed within rock masses that exhibit complex nonlinear constitutive behavior.

A number of modeling-software products exist for solving geological and geotechnical problems. Both ABAQUS (for finite element analysis) and FLAC (Fast Lagrangian Analysis of Continua) software for finite-difference analysis are popular for determining the stress conditions and behavior of rock masses surrounding an underground excavation. FLAC has been used successfully for many underground problems in rock mechanics and is considered to be an industry standard in both its two-dimensional (Figures 8.7-16 and 8.7-17) and three-dimensional formats.

However, no matter how good a model is, a good prediction cannot be obtained unless the input data is of high quality. Unlike engineering materials, rock mass generally contains a lot of irregular discontinuities in the form of joints, bedding planes, fissures, and faults.

The engineering properties of in-situ rock strata are determined by many factors, such as intact rock properties, nature and orientation of planes of weakness, and presence of groundwater. The stiffness and strength of intact rock can be determined in the laboratory, providing some information about the upper limit of the engineering properties of the rock mass. However, it is practically impossible to determine all of the properties of the many discontinuities by direct testing and measurement. Therefore, the engineering properties of the rock mass may be estimated by means of a rock mass classification system to supplement direct measurement by testing.

Fortunately, several well-recognized engineering rock mass classification systems have been widely used to estimate the strength and stiffness of rock mass, including its discontinuities. As a powerful aid in design, rock mass classification has become an integral part of the empirical design methods popular in the industry and has been invaluable on many

underground construction and mining projects. However, rock mass classification systems alone are not the ultimate solution to design problems and they are now being applied in conjunction with numerical methods.

CHAPTER 8.8

Ground Control Using Cable and Rock Bolting

William F. Bawden

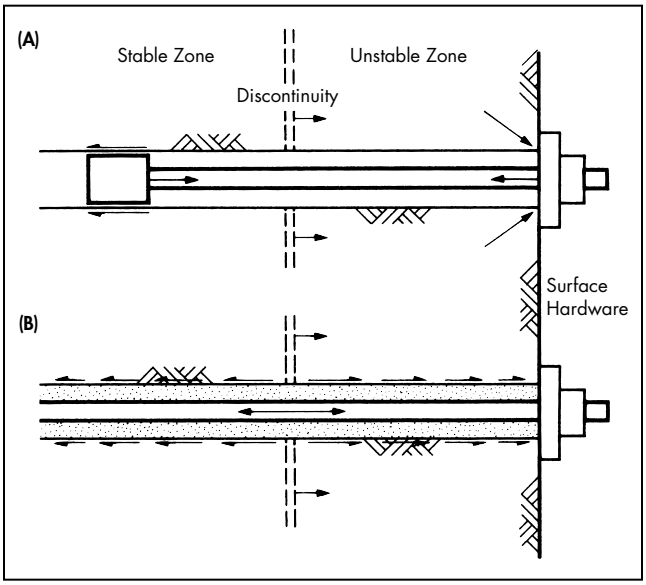
INTRODUCTION

Ground control is the art and science of maintaining safe and stable conditions at the surface of an excavation in a rock mass at or below the ground surface for the intended service life of the structure. Aggressive mining strategies, design constraints on excavation geometry, or unfavorable arrangements of rock stress, structure, or material properties often lead to the requirement for some form of rock mass improvement to maintain safe and stable conditions. Methods for achieving this improvement are given in numerous standard textbooks and conference proceedings (e.g., Hoek and Bray 1974; Hoek and Brown 1980; Stillborg 1986; Stephansson 1983).

The term *support* is widely used to describe procedures and materials that improve the stability and maintain the load-bearing capability of rock near the boundaries of surface and underground excavations. Rock improvement includes all techniques that seek to increase the strength and decrease the deformability characteristics of the rock mass. This includes the injection of chemical or cementitious grouts, ground freezing, presplitting, and drainage. Within the general category of rock improvement, rock reinforcement is a specific technique with the prime objective of improving the shear and tensile strength of the rock mass adjacent to surface and underground excavations. The term *support* can then be reserved for use in those cases in which the rock mass is truly supported by structural elements that carry, in whole or in part, the weights of individual rock blocks isolated by individual discontinuities or zones of loosened rock (Brady and Brown 2004).

Support and reinforcement are essential components in the design of all surface and underground excavations and are often combined to provide an overall or integrated system. In mining, they enable more economic extraction through steeper slopes in open pits or increased recovery rates from underground operations. In civil engineering, they enable increased excavation rates in tunnels and safer permanent surface and underground facilities (Windsor and Thompson 1993). In this chapter, the dominant reinforcement and support elements will be discussed along with installation procedures and major quality assurance/quality control (QA/QC) issues. Initially, however, some basic terminology will be defined in an attempt to minimize confusion due to the divergent jargon that has evolved in the industry.

ROCK REINFORCEMENT TECHNIQUES



Rock Support Versus Reinforcement

Rock reinforcement is often mistakenly taken to include methods more properly termed support. It is essential to the understanding of the underlying mechanics to differentiate between the concepts of reinforcement and support. The primary objective of rock mass reinforcement is to mobilize and conserve the inherent strength of the rock mass so that it becomes self-supporting. Ground support, on the other hand, should be restricted to structural elements that directly carry the weight or part thereof of discrete rock blocks.

Support and reinforcement should also be classified as active or passive. Active support imposes a predetermined load to the rock surface during installation and can take the form of tensioned rock bolts or cables, hydraulic props, expandable segmented concrete linings, or powered support for longwall faces. Active support is usually required to support the gravity loads imposed by individual rock blocks or loosened zones. A substantial body of work has been undertaken in the Australian coal industry to demonstrate that active support via bolt and cable pre-tension is a critical aspect of strata reinforcement where the objective is to control in-situ ground stresses rather than the weight of potentially unstable strata. Passive support or reinforcement is not installed with an applied loading but develops its loads as the rock mass deforms. In fact, many reinforcement schemes only operate when the rock mass reaches yield. Passive support may be provided by steel arches, timbered sets, or composite packs; or by untensioned, grouted rock bolts, reinforcing bars, or cables, these three often described as dowels.

Strata control describes the support and reinforcement techniques used in coal mining. Although the term is suitable, because it evokes the concept of the control or limitation of strata displacements rather than support, the major function of some strata-control measures is support (Brady and Brown 2004).

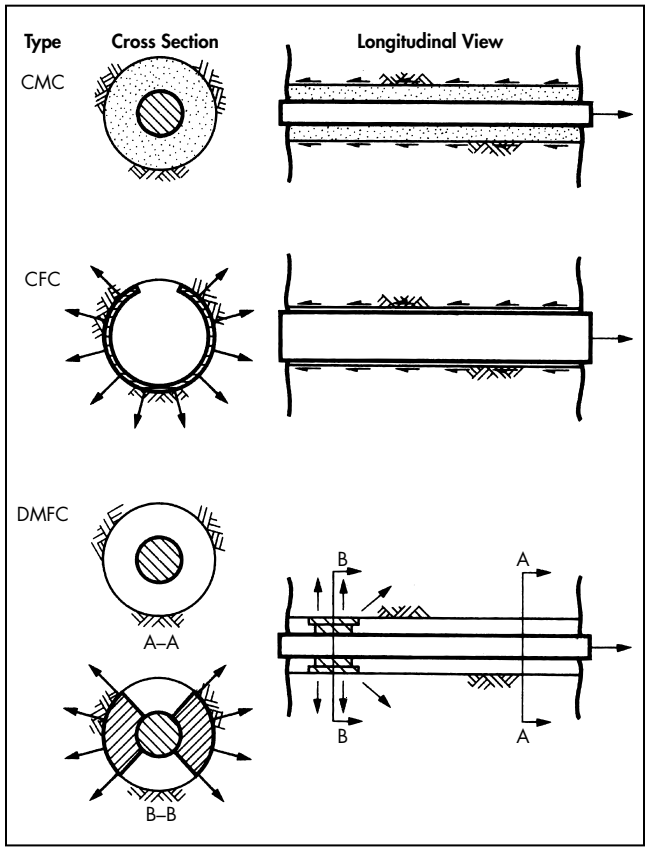
Figure 8.8-1 Reinforcement load transfer concept: (A) discrete load transfer and (B) continuous load transfer

Load Transfer Concepts for Reinforcement

Fundamental to the understanding of rock reinforcement behavior and the action of different elements and their effect on excavation stability is the load transfer concept. This is shown schematically in Figure 8.8-1 and is composed of three basic mechanisms:

1. Rock movement that requires load transfer from the unstable rock to the reinforcing element
2. Transfer of load via the reinforcing element from the unstable surface region to the stable interior region
3. Transfer of the reinforcing element load to the stable rock mass



Reinforcing element length can be considered in three general ranges associated with perceived unstable surface regions for different surface and underground excavations: near surface (1.5–3.0 m long), medium depth (3–15 m long), and deep seated (>15 m long) (Windsor and Thompson 1993).

Load transfer can occur by numerous methods, and many different reinforcing devices have been developed. In general, these devices are solid bar, hollow tube, or wire rope elements that are installed within boreholes drilled into the rock. A terminology has been proposed (Windsor and Thompson 1993) that places load-transfer mechanisms for these devices within one of three categories, as defined in Figure 8.8-2. These categories are

1. Continuously mechanically coupled (CMC),
2. Continuous frictionally coupled (CFC), and
3. Discrete mechanically and frictionally coupled (DMFC).

Continuous Mechanically Coupled Elements

These elements rely on a securing agent that fills the annulus between the element and the borehole wall. Generally known as grout, the agent is placed as a fluid and requires a finite setting time before the element is able to provide support. The setting time can vary from a few seconds to several hours

Source: Windsor and Thompson 1993.

Figure 8.8-2 Categories of element load transfer

depending on the type of grout used, which may well affect selection of the device. The major function of the grout is to provide a mechanism for load transfer between the rock and the reinforcing element (CMC in Figure 8.8-2). Reinforcing elements used with grouts are often manufactured with variable cross-sectional shapes. This variation causes a mechanical interlock between the element and the grout and strongly impacts the shear resistance, or bond strength, and the load-transfer stiffness that can develop at the element–grout interface.

Continuous Frictionally Coupled Elements

CFC elements behave similarly to CMC elements, except the CFC element is placed in direct contact with the rock (CFC in Figure 8.8-2). Load transfer results from friction between the element and the borehole and is limited by the radial prestress set up at installation. Any geometrical key that is present occurs by chance due to irregularities in the borehole wall.

Devices in this class consist either of expansion of an undersized section into a larger borehole or contraction of an oversized section into a smaller borehole (see "Frictional Support" section). Borehole size is critical to support performance in this class.

Discrete Mechanically and Frictionally Coupled Elements

DMFC elements tend to be simple bars with either a deformed end region or provision at one end for attaching an expanding anchor and provide either mechanical or frictional load transfer over this relatively short portion of the entire element

length (DMFC in Figure 8.8-2). This interval is commonly known as the anchorage length and is usually limited to less than 500 mm for grouted anchorages and 200 mm for expansion anchorages. The anchorage must have sufficient capacity to mobilize the full material strength of the element. Expansion shell bolts are the most common DMFC element (see the "Ungrouted Mechanically Anchored Rock Bolts" section). With these elements the anchor is expanded outward against the borehole wall because of tension in the element, and anchorage strength may be limited by the strength of the host rock. Grouted anchorages have a lower unit load transfer and offer advantages in weaker and softer rocks. In general, only resinous grout can provide the high-strength requirements for shorter anchorages.

Pre- and Postexcavation Reinforcement and Support Pre-tensioning

In certain applications it may be advantageous to install support elements prior to excavation (i.e., pre-reinforcement), while in other cases it may be better to install the support elements at some discrete time following excavation. In the former case, support elements may better restrain rock mass movements but may be required to sustain higher loads. In the latter case, ultimate support element loads can be controlled by allowing some initial rock movement. This is common in tunneling using concrete linings or shotcrete in weak strata, where one objective is to ensure the long-term integrity of the permanent support (e.g., the New Austrian Tunnelling Method). Rock-support interaction theory provides a framework for understanding the impact of pre- versus postexcavation practice and is covered in numerous standard rock mechanics textbooks (e.g., Brady and Brown 2004; Hoek et al. 1995). The limitations of rock-support interaction theory, however, must be clearly understood, particularly that subsequent extraction processes change the ground stresses, which therefore may require higher levels of support than development conditions.

In certain applications, it is also advantageous to provide the reinforcing element with an initial pre-tension. Posttensioning is the tensioning or retensioning of elements subsequent to installation. It is important to understand that additional tension is likely to develop in the element because of rock mass deformations in response to subsequent excavation, stress change, creep, and so forth, and to allow for this in order to avoid subsequent overstress and rupture of the support elements (Windsor and Thompson 1993).

Encapsulation Techniques

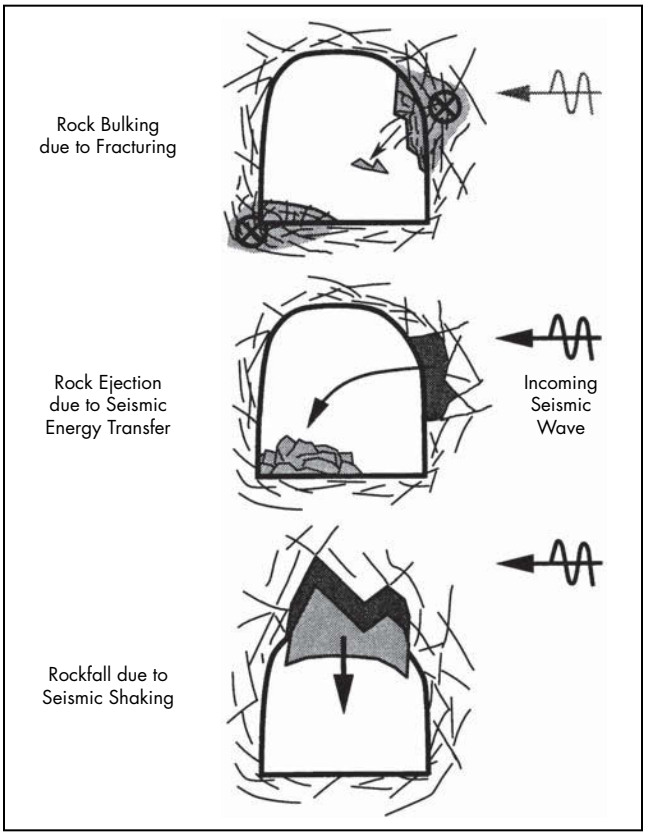
Encapsulation materials can generally be classified as cementitious, usually normal portland cement or resinous, with the latter generally being stronger. Cement grouts are suited to longer reinforcing elements because of availability, ease of mixing, and placement. Resins are restricted to shorter holes primarily because of difficulties in mixing resins at lengths exceeding 3–4 m. A benefit of encapsulation is increased resistance to corrosion, although in highly corrosive environments additional protection beyond simple encapsulation is required.

Resin-grouted reinforcement has found wide application in discrete load-transfer elements. Set times can be reduced to less than 10 seconds, which is particularly important for cyclic and fast advance mining methods where support installation is one of the controls on advance rate. It must be understood, however, that many other factors (e.g., machine availability, operator training, and cutting rates) also strongly influence advance rates. In addition, the anchors can supply design capacity within a few minutes of installation, which improves safety during advance. High early-strength grouts are also available in cartridges (Windsor and Thompson 1993).

Auxiliary Fittings

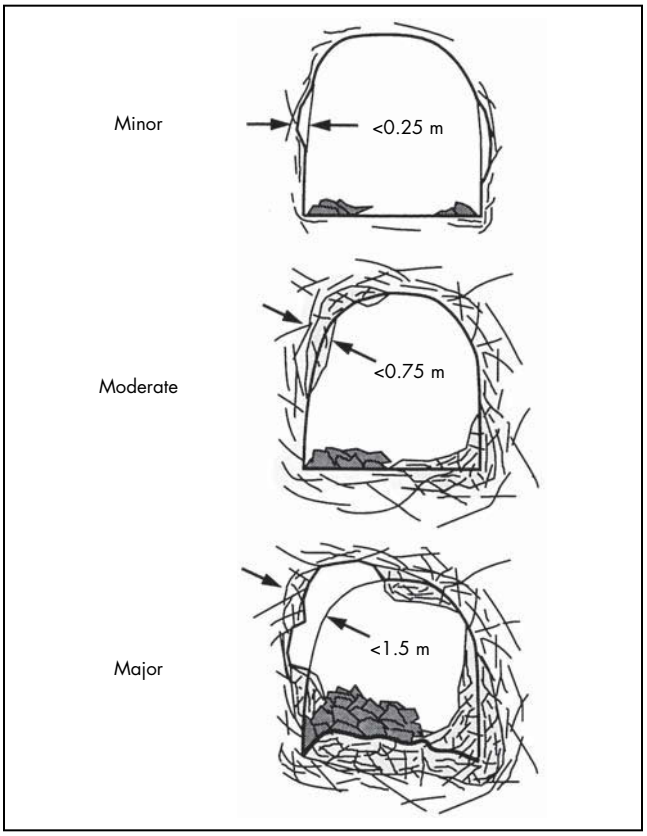
Various forms of auxiliary fittings have evolved for use with different reinforcing elements that cater to different geological conditions. The fittings are either attached to the reinforcing element at the rock surface or are used to modify the internal response of CMC elements. Special equipment and procedures are required for tensioned applications.

External fittings (e.g., plates, straps, mesh) can be attached to the reinforcing element to provide varying degrees of surface restraint to the rock mass. External fittings are mandatory for discrete coupled devices, while internal fittings are used primarily with CMC devices and may comprise intermittent anchors and/or decoupling sleeves. These combinations of devices can be used to engineer the stiffness of the reinforcing elements to match anticipated rock mass deformations based on predicted failure mechanisms.



In most applications the number of reinforcing elements in relation to the exposed excavation area is quite low. In closely jointed, fissile, or weathered rock masses where unraveling may be the dominant failure mode, stability can be improved by installing structural elements that span the reinforcing elements. Such support forms a surface retention system that restrains the movement of small blocks and provides a reactive stress to the free span area. This stress is usually low for mesh applications but will be higher for shotcrete. The concept of surface retention support on a larger scale using reinforcement as anchors is important and holds the key to supporting many of the larger, more complex failure modes, particularly for surface excavations (Windsor and Thompson 1993).

Static Versus Dynamic Support



The majority of ground support applications are designed for static rock mass conditions, which may include both simple gravity-driven (e.g., wedge failure and unraveling) and mine-induced stress-driven failure. In the latter case, a stable failure process occurs where most of the stored strain energy in the rock mass is consumed during the fracture and deformation process. Ground support must be designed with sufficient capacity for both anticipated loads and deformations; however, these will accumulate over time, and energy absorption will not be a concern.

Dynamic support elements are generally restricted to ground subject to rock-burst loading. First are some basic definitions (Kaiser et al. 1996):

- A seismic event is a transient earth motion caused by a sudden release of potential or stored strain energy in the rock. As a result, seismic energy is radiated in the form of strain waves. The magnitude of a seismic event is usually determined from the peak amplitude of the strain wave, using a logarithmic scale (e.g., Nuttli or Richter scale).
- A rock burst is a seismic event that causes injury to persons or damage to underground workings. The general and essential feature of rock bursts is their sudden, violent nature.

Source: Kaiser et al. 1996.
Figure 8.8-3 Rock burst damage mechanisms

Source: Kaiser et al. 1996.
Figure 8.8-4 Rock burst damage levels

Rock bursts are generally divided into three classifications:

1. **Strain bursts:** These are caused by high-stress concentrations at the edge of mine openings that exceed the strength of the rock. Events can range from small slivers of rock being ejected from the walls to the collapse of a complete wall as it tries to achieve a more stable shape.
2. **Pillar bursts:** Severe rock bursts, involving thousands of tons, have been caused by the complete collapse of support pillars. These tend to occur in extensively mined-out areas, and the resulting damage can be severe.
3. **Fault slip bursts:** Recognized in the 1980s, this type of rock burst occurs when slippage suddenly occurs along a geological weakness plane. This is the same mechanism as for an earthquake.

Rock-burst magnitude (and hence energy and damage potential) increases from classifications 1 to 3. The damage may occur as rock bulking due to fracturing, rock ejection by seismic energy, or rockfalls due to seismic shaking (Figure 8.8-3). Each mechanism may result in different levels of damage to an excavation and its support system. The damage severity depends on many factors, including

- Failure potential near the opening (i.e., the level of existing wall stress compared to the rock mass strength, which, in turn, depends on rock wall quality);
- Support effectiveness;
- Local rock stiffness;
- Magnitude of seismically induced stress, rock accelerations, or velocities;
- Opening geometry, size, and orientation; and
- Geological structure.

Three levels of rock burst damage severity are defined, as shown in Figure 8.8-4. Damage level determination is usually based on observations of previous damage, where such observations are available, plus analytical methods. The three severity levels are discussed later and are summarized in Table 8.8-1.

Only a limited number of ground support elements are suitable for dynamic loading conditions (see "Spiling" section), and under the most severe conditions even these are restricted by maximum practical support limitations.

ROCK REINFORCEMENT SUPPORT ELEMENTS

Rock reinforcement elements can be obtained in various lengths. The most common are near-surface support elements, generally ≤3 m long, that provide support to the inner shell of the opening and are commonly referred to as primary support. Deeper ground reinforcement can only be achieved either by using cable bolts or by connecting shorter, stiff bolt elements together as discussed later in this section. Such deep reinforcement is commonly referred to as secondary support.

Near-Surface Static Reinforcement (≤3 m depth)

Ungrouted Mechanically Anchored Rock Bolts

Mechanically anchored reinforcement elements, commonly referred to as point anchor bolts or expansion shell bolts, fall into the DMFC category and represent one of the earliest developments in rock mass reinforcement. These elements

Table 8.8-1 Rock-burst damage mechanisms and the nature of anticipated damage

Damage Mechanism	Cause of Rock-Burst Damage	Damage Severity	Thickness, m	Weight, kN/m²*	Closure,† mm	V_e,‡ m/s	Energy, kJ/m²
Bulking without ejection	Highly stressed rock with little excess stored strain energy	Minor	<0.25	<7	15	<1.5	Not critical
		Moderate	<0.75	<20	30	<1.5	Not critical
		Major	<1.5	<50	60	<1.5	Not critical
Bulking causing ejection	Highly stressed rock with significant excess strain energy	Minor	<0.25	<7	50	1.5–3	Not critical

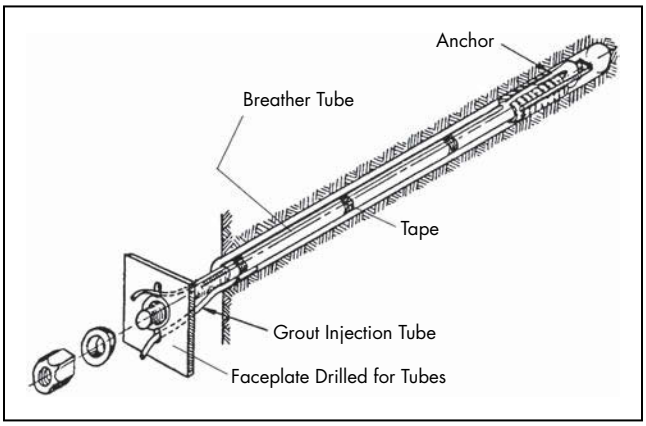
§NA = not applicable.

apply a positive force to the rock without requiring movement of the rock mass. They are composed of three elements: (1) an expansion shell anchor, (2) a faceplate assembly, and (3) a connecting steel bar.



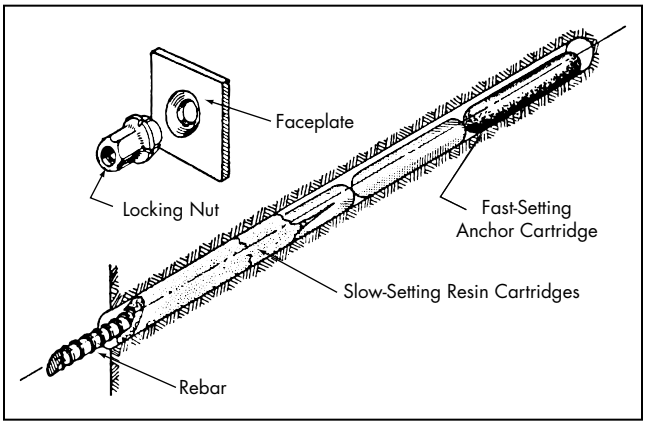
Expansion shell anchors consist of a tapered cone with internal thread plus a pair of wedges held with bail wire. The cone is screwed onto the threaded end of the bolt and the assembly is inserted into the borehole. The hole must be at least 100 mm longer than the bolt or the bail wire will be dislodged and the anchor will not set. Once in place, the anchor is seated with a sharp pull on the bar. Tightening the bolt forces the cone into the wedge, increasing the anchor force. Expansion shell anchors can work well in hard rock but are not good in closely jointed or soft rocks because of the potential for deformation and failure of the rock in contact with the grips.

At the bolt head, either a fixed head (forged head) or threaded end and nut system can be used. A faceplate is always required to distribute load from the bolt to the rock face. A tapered washer or conical seat is required to compensate for the rock surface not being perpendicular to the bolt (i.e., tightening the nut must place the bolt in direct axial tension). A wide variety of faceplates and domed or tapered washers are available. Details of these assemblies are available from the various bolt manufacturers.

The bar element in a mechanically anchored rock bolt is a smooth circular element. Steel grade and bar diameter can be varied to adjust reinforcement element capacity and stiffness.

Grouted Mechanically Anchored Rock Bolts

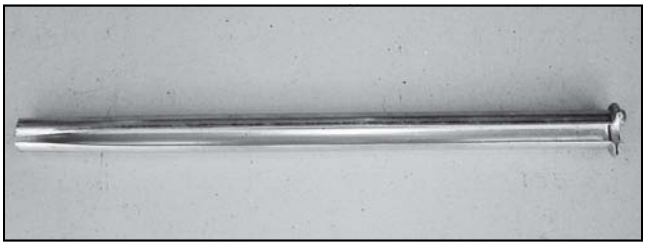
Mechanically anchored bolts can be changed from DMFC to a CMC category by filling the annulus between the steel element and the borehole wall with grout. Cement grout is used for this purpose and can be emplaced by the use of grout tubes inserted with the bolt (Figure 8.8-5) or through the use of a hollow stem bolt. Grout tubes are not commonly used with mechanically anchored bolts since space constraints restrict the grout tube diameter and therefore the water/cement (w/c) ratio of the grout that can be used (a w/c = 0.4 grout should be used). With a hollow stem bolt, grout is pumped through the hollow core of the bolt and is forced back through the annulus.



Source: Hoek et al. 1995.
Figure 8.8-5 Grout injection arrangements for mechanically anchored rock bolt

Grouting mechanically anchored bolts provides corrosion protection, stops anchor slip, and ensures that the full bolt capacity can be achieved. Hollow core bolts are available from a number of manufacturers.

Quality Assurance and Control



QA/QC is critical for all rock reinforcement elements. Tensioning of rock bolts is critical to ensure all components are in contact and that a positive force is applied to the bolt. Where bolts are required to carry significant load, they are generally tensioned to about 70% of yield. This provides a known load with reserve for additional load induced by rock movements.

Corrosion is one of the primary causes of bolt failure. This can be counteracted by grouting the bolts. The use of hollow stem bolts (e.g., Stelpipe bolt) makes this function simple to accomplish. It is nevertheless a two-stage process and therefore impacts cost. The primary purpose in grouting the bolts is corrosion protection and to lock the anchor in place to stop loosening from blasting. Grout strength is not too

Figure 8.8-7 Split Set friction stabilizer

important and higher w/c grout can be used (i.e., in the region of 0.4 w/c).

Ungrouted bolts must be retensioned after each blast for several rounds behind the face since blast vibration will cause anchor slip and loss of prestress. A torque wrench can be used to test bolt tension.

Beveled or conical seat washers must be used to ensure that tensioning of the bolt results in increased axial tension in the bar and subsequent seating of the anchor. Otherwise, for applications not perfectly perpendicular to the rock face, high torque on the nut will result from friction between the nut and the plate rather than tension in the bar.

Resin-Anchored Rebar Bolts

Pre-tensioned bolts. Ungrouted mechanically anchored bolts can work loose when subjected to blast vibrations or when anchored in weak rock. Additionally, they are subject to corrosion and provide only relatively soft reinforcement. Resin-anchored rebar overcomes these difficulties. Pre-tensioned rock bolt applications use two-component cartridges containing a resin and catalyst in separate compartments (Figure 8.8-6). The resin cartridges are inserted in the drill hole ahead of the bolt element, which is then spun into them, mixing the catalyst and the resin. Setting of the resin occurs in a few minutes (depending on mix specifications), and a strong anchor is created. The system works for most rock types, including weak rocks. Fully resin bonded bolts should be used for corrosion protection and long-term support.

Pre-tensioning of the reinforcing element is achieved by using a combination of slow- and fast-setting resins. In a pre-tensioning application, a fast-setting resin (~10-second set time) is inserted first, followed by slow-setting resin (e.g., 10 minutes) for the remainder of the hole. The bolt can be tensioned 2 to 3 minutes after installation. The bar element is a deformed reinforcing bar with the toe end cut at about 45 degrees so as to adequately puncture the resin cartridges. The high resin unit cost is offset by the installation speed of the tensioned, fully grouted bolt.

Dowels. Dowels are rock reinforcement elements installed passively in a borehole (i.e., no prestress). Such elements require movement of the rock mass in order to develop a restraining force. Dowels work well when applied close to the advancing face and/or where later mine-induced stress change will cause movement of the rock mass. The most common form is a resin-grouted dowel. In North America, this consists of a resin-grouted rebar dowel where single set time resin is used for full dowel encapsulation. Resin-grouted dowels and rock bolts are in the CMC category of support. Resin-grouted rebar forms a very stiff support, the capacity of which is dictated by the type of steel and the rebar diameter.

Quality assurance and control. Quality control issues with resin rebar support primarily revolve around problems with the resin. Resin QA/QC problems include the following:

- Shelf life is limited (may be as short as 6 months).
- Resins must be stored under conditions conforming to manufacturer's recommendations, including storage temperature and conditions. Freezing or excessive temperature may impact resin characteristics.
- Effective mixing of the resin can be a problem. Cutting the bolt rod at an angle to form a sharp point will help properly puncture the resin cartridges.
- The allowable length of time or number of rotations for spinning the resin is limited. Additional spinning destroys the resin structure and weakens the overall installation (follow the manufacturer instructions in this area).
- Hole diameter is critical, because it exerts a strong control on bond strength and load transfer stiffness.
- In some weak argillaceous rocks, the drill-hole surface can become clay coated and the resin will spin in the hole, causing incomplete mixing.
- The resin initially has a low viscosity, and in highly fractured rock the resin may seep into fractures, leaving voids in resin column.
- The reaction of resins with aggressive groundwater is not certain.

Frictional Support

Split Set bolts. Split Set stabilizers consist of a slotted, hollow high-strength steel tube and faceplate (Figure 8.8-7). The bolts are installed by pushing them into a slightly undersized hole. The radial spring force generated by compression of a C-shaped tube provides frictional anchorage along the complete length of tube. The toe end of the tube is beveled inward to facilitate installation, and the system is quick and easy to install. It can be particularly useful in mild rock-burst conditions where the bolt will slip and not break, and when used with mesh will retain broken rock generated by a mild burst. These bolts can also be used to pin up mesh in highly fractured and yielded ground prior to the application of shotcrete. Provided the load demand does not exceed capacity, this system can work well for short-term support. However, susceptibility to corrosion rules out this system for most long-term support requirements. The bolts are installed as dowels

and fall in the CMC category. Table 8.8-2 provides typical Split Set bolt specifications (these may vary for different manufacturers). Split Set bolt pull-out capacity is rated in metric tons per meter (t/m) and is derived from in-situ pull tests. Nominal pull-out strengths vary from 1 to 2 t/m.

Swellex bolts. The original Swellex dowel came in varying lengths and consisted of a 42-mm-diameter tube that is folded into a 25–28-mm diameter during manufacture. When the dowel is inserted into a 32–39-mm drill hole, no push force is required. The dowel is activated by injection of high-pressure water (about 30 MPa), which inflates the folded tube into intimate contact with the walls of the drill hole. In 1993, the original Swellex dowel was replaced with the EXL Swellex manufactured from high-strength but ductile steel. Present products consist of the Swellex premium (Pm) line (Table 8.8-3) and the Swellex manganese (Mn) line (Table 8.8-4) of bolts. The bolts are available in various lengths up to 7 m and in coated versions for corrosion protection. One of the most important features of the Swellex system is the high bolt ductility. The Pm line of bolts can withstand 10% strain while the Mn line can withstand 20% strain. This high ductility without loss of capacity makes the Swellex

bolt useful in rock-burst and high-closure applications. An additional advantage of this system is the speed of installation compared to conventional rock bolts and cement-grouted dowels.

Quality Assurance and Control

Split Set bolts. Corrosion is a potential problem with all Split Set bolts because of the thin steel section of the tube that is in direct contact with the rock. Although galvanizing the tube helps delay corrosion, much of the galvanizing may be scraped off during installation, and the impact of this on bolt life is uncertain. These bolts are generally not suitable for long-term support and should not be used in areas with aggressive groundwater. Split Set bolts have limited capacity and type SS 39 will only mobilize about 5 t on pullout. In many cases, actual field loading conditions will reduce active capacity to no more than 50% of the pullout load. The bolt capacity is sensitive to hole gauge, and the bolts have extremely low shear resistance due to the limited steel cross-sectional area.

Swellex bolts. Corrosion of Swellex dowels is of concern because the outer surface is in direct contact with rock and the steel section of the tube is thin. Coated Swellex bolts are now available that help to reduce corrosion susceptibility. The Swellex coatings should be less impacted by installation procedures than is the case with galvanized Split Set bolts. The long-term support characteristics of Swellex bolts, particularly in aggressive groundwater conditions, are nevertheless unknown. Swellex dowels can be tested for corrosion by repressurizing the bolts; if the bolt holds the pressure, it has not been perforated by corrosion. These bolts are also sensitive to hole gauge and are weak in shear due to the limited steel cross-sectional area.

Spiling

Spiling is a method of advancing a tunnel in collapsing soil or very loose rock (e.g., poor ground, fault gouge). Low-angle holes are drilled ahead of the face using a sacrificial drill bit and hollow rods that may be coupled to achieve the desired length. Grout is then injected through the hollow rods to consolidate the ground between the closely spaced anchors, forming a reinforced umbrella or diaphragm, and the next tunnel round is then advanced below this support. Following the advance, additional ground support is installed and another set of anchors is drilled and grouted, and the tunnel is again advanced. The self-drilling anchors are critical to this process. Numerous bit sizes and styles are available for varying conditions. Grout may be injected through perforations in the bit, or the hollow rods may also be perforated. There are numerous manufacturers of such systems.

Near-Surface Static Design Guidelines

Ground support design is a complex topic and a specialist area, the details of which are well beyond the scope of this chapter. At the simplest level, for static design, there are empirical design techniques that are relatively easy to apply (providing one fully understands the limitations of the supporting database and associated design methodology), and examples of these are provided in this section. The most basic design uses rules of thumb such as those provided by the U.S. Army Corps of Engineers (Table 8.8-5). Empirical ground support design charts have also been developed around rock mass classification charts (e.g., the rock mass rating system and tunnelling rock mass quality index [Q] system—see Chapter 8.4). Figure 8.8-8 shows the chart for estimating support categories based on tunneling quality index Q (Palmstrom and Broch 2006). More sophisticated support designs incorporate various numerical modeling techniques (e.g., Unwedge, Phase2, Flac3D). Discussion of these techniques is beyond the scope of this chapter.

Near-Surface Dynamic Reinforcement Elements

Near-surface reinforcement elements suitable for use under dynamic loading include cone bolts, Swellex bolts, and Split Set bolts:

- Cone bolts were originally developed in South Africa and were later modified by Noranda Technology for use in North America as a resin bolt. The MCB33 (Modified Cone Bolt for 33-mm holes) cone bolt is a smooth bar threaded at one end, with forged cone and mixing blade at the other end and is manufactured and distributed by Mansour Mining in Sudbury, Canada. It is installed in a specially formulated Coneloc or Fasloc resin and is mixed by the resin mixing blade. A plastic sleeve is installed over the shaft of the bolt to debond the resin from the bar, thus allowing the cone to yield or plough through the resin. The cone bolt load-displacement characteristic curve is shown in Figure 8.8-9. Cone bolts show high-ductility and energy absorption characteristics. Cone bolts should provide high-shear resistance.
- Swellex bolts have high-ductility (10%–20% strain, assuming they are anchored beyond the bulking zone) and high energy absorption characteristics. Swellex bolts are weak in shear and, if they become locked in the hole, the theoretical ductility may not be achieved.
- Split Set bolts show high ductility but low energy adsorption and low-load capacity (Figure 8.8-9). The bolts are weak in shear and if they become locked in the hole will rupture at low loads.

Medium-Depth Reinforcement Design (3–15 m)

Static Reinforcement Elements—Cable Bolt Support

A conventional cable bolt is a flexible tendon consisting of a number of steel wires wound into a strand, which is grouted into a borehole. Cable bolts are normally installed in regularly spaced boreholes to provide reinforcement and support for the walls, roof, and floor of underground or surface openings. Cable bolting is a versatile form of support, because strands can bend around fairly tight radii, making installation of long bolts from confined openings possible and, because they can be fabricated with a number of configurations of the steel wires (e.g., plain, bulb, nut case), a variety of performance characteristics can be achieved. In North American hard-rock mining, cable bolts are made from 15.6-mm, seven-wire reinforcing strand (manufactured to ASTM 416 standard), having a yield strength of about 20 t at 0.8% strain and an ultimate strength of 24 t at 3.5%–4% strain.

In theory, cable bolts can be placed to any depth but for pragmatic reasons are seldom installed to depths exceeding about 20 m. Multiple cables can be placed in the same hole to increase tensile capacity, if the borehole diameter is large enough. In addition, face restraint can be attached in the form of plates, straps, and mesh. Cable bolts are commonly used in combination with other support systems such as shotcrete, rock bolts, and mesh. Figure 8.8-10 shows twin-strand bulb cable bolts coiled to about 1 m in diameter. Plain-strand

Table 8.8-5 Typical rock-bolt rules of thumb

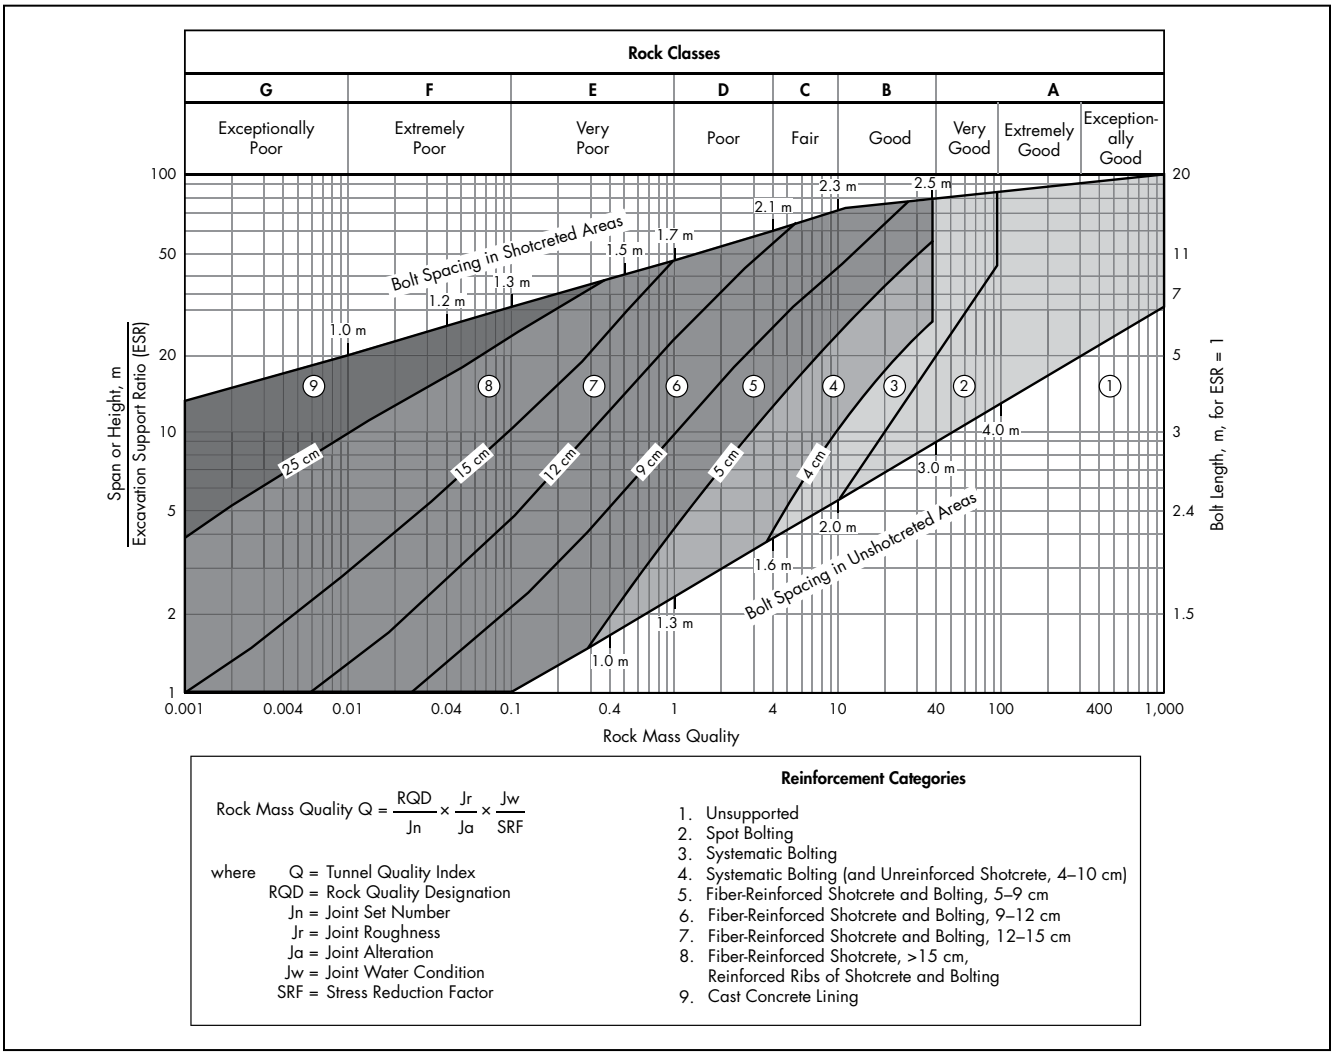
Parameter	Empirical Rule
Minimum length	Greatest of
	(a) 2 × bolt spacing
	(b) 3 × thickness of critical and potentially unstable rock blocks*
	(c) For elements above the spring line:
	Spans <6 m: 0.5 x span
	Spans between 18 and 30 m: 0.25 × span
	Spans between 6 and 18 m: interpolate between 3 and 4.5 m
	(d) For elements below the spring line:
	Height <18 m: as (c)
	Height >18 m: 0.2 x height
Maximum spacing	Least of
	(a) 0.5 x bolt length
	(b) 1.5 x width of critical and potentially unstable blocks*
	(c) 2.0 m†
Minimum spacing	0.9–1.2 m
Minimum average confining pressure at yield point of elements‡	Greatest of
	(a) Above spring line:
	Either pressure = vertical rock load of 0.2 x opening width or 40 kN/m^2
	(b) Below spring line:
	Either pressure = vertical rock load of 0.1 x opening height or 40 kN/m^2
	(c) At intersections: 2 x confining pressure determined in (a) and (b)§

Source: Adapted from U.S. Army Corps of Engineers 1980.
*Where joint spacing is close and span relatively large, the super-position of two reinforcement patterns may be appropriate (e.g., long heavy elements on wide centers to support the span, and shorter, lighter bolts on closer centers to stabilize the surface against raveling).
†Greater spacing than 2.0 m makes attachment of surface support elements (e.g., weld mesh or chain link mesh) difficult.
‡Assuming the elements behave in a ductile manner.
§This reinforcement should be installed from the first opening excavated prior to forming the intersection. Stress concentrations are generally higher at intersections, and rock blocks are free to move toward both openings.

and bulb-cable are the configurations most commonly used in North American hard-rock mining. Alternately, in the Australian coal industry, the standard long cable tendon has around 63 t capacity and the heaviest just over 80 t capacity.

Quality control issues with cable bolts deal with grout quality and cable cleanliness. Cables can be grouted either toe to collar using 0.35 w/c grout or collar to toe (i.e., breather tube method) using 0.4 w/c grout. High w/c grout reduces cement strength and stiffness and results in significant reduction of cable bond capacity, commonly resulting in stripping failure. The use of bulb cable helps overcome grout quality control to some degree. Plates are attached using a barrel-and-wedge assembly. The barrel and wedge are susceptible to rust, which causes the wedges to lock up and the assembly will slide off at the seating load (nominally 5 t). Copper coat grease (or equivalent) should be applied to the inner surface of the barrel and the outer surface of the wedges to prevent corrosion. A detailed coverage of all aspects of cable bolt practice is given in Hutchinson and Diederichs (1996).

Connectible Super Swellex. The Pm24C Swellex bolt can be used to achieve deep anchorage by connecting two or more threaded sections. The bolt has a 200-kN breaking load and achieves 10% strain. Swellex is commonly used in combination with other support systems such as shotcrete, rock bolts, mesh, and so forth. QA/QC issues are the same as for ordinary Swellex. Under static support conditions, these support elements may be too soft (i.e., may allow too much ground movement).



Static support design. For cable bolt support in hard-rock mining, static support design is generally done empirically using the Stability Graph Method (Hoek et al. 1995), which is widely used in North American and Australian hard rock mines. Numerical modeling can be used to help establish required support depth. Connectible Swellex can be used to replace cable bolts, but the Swellex density must be adjusted to achieve equivalent system capacity.

Dynamic Reinforcement Elements

Dynamic support elements suitable for medium depth conditions include debonded cable bolts and connectible super Swellex bolts.

Debonded cable bolts are created by placing a plastic sheath over a plain-strand section of the cable bolt. When the cable bolt is grouted in the borehole, the plastic sheath acts to debond the cable strand from the grout. The debonded section is then allowed to stretch freely, achieving 0.8% strain at yield and 3.5% strain at rupture. Each meter of debonded cable therefore permits ~8 mm of stretch at yield and 35 mm of stretch at rupture. Normally at least 2 m of cable is exposed at the toe, beyond the debond section. The cable may be secured at the collar by attaching a plate and barrel-and-wedge assembly. Alternately, a section of bulbed cable can also be left exposed at the collar. The use of debonded bulbed cable bolts under dynamic loading is discussed by Bawden and Jones (2002). QA/QC issues are the same as for static applications.

Pm24C Swellex bolts can be used to provide deep tendon support under dynamic loading.

Dynamic Support Design

Dynamic support design effectively implies rock-burst-resistant support design and is a function of the size of the seismic event and the location of the event hypocenter relative to the mine infrastructure in question (Figure 8.8-11). Local site factors such as the orientation of the infrastructure can also play a significant role in support and ground performance. Support ductility is required to achieve displacement capacity and energy absorption capacity (Figure 8.8-12). Tables 8.8-6 and 8.8-7 provide displacement and energy absorption criteria for most common support elements. Further coverage on this topic is beyond the scope of this chapter. A thorough coverage is provided in the *Canadian Rockburst Support Handbook* (Kaiser et al. 1996). Mesh is discussed in more detail later in this chapter.

Deep-Seated Ground Anchors (>15 m)

These long anchors tend to be arranged in larger cross-sectional areas to handle the greater volumes of unstable material. Used extensively in civil engineering and less so in mining, they are usually composed of a large number of individual elements that act together as a composite reinforcing element. To enable prestressing, they are usually discretely

coupled over a fairly long anchorage and may be used to impart considerable load to the surface of the rock mass by way of large, rigid, built-in stressing blocks situated at the free surface. These devices often play a critical role in maintaining stability and are subject to stringent installation quality assurance by proof testing programs.

High-shear-capacity elements (shear keys) may be in the form of universal steel sections, large diameter tubes, or commonly railway lines cast in concrete. These elements are most commonly used as pre-reinforcement in surface excavations. The large cross-sectional area of the steel elements provides high shear resistance to transverse displacements (Windsor and Thompson 1993).

GROUND SUPPORT

Screen or Mesh

Screen or mesh is used to form a surface retention support system to cover the rock mass between the reinforcing tendons that are usually spaced at 1 to 2 m centers. The mesh is attached to the reinforcing tendons by the plate assembly or by push plates installed after the reinforcing tendons have been installed. There are several types of mesh construction, including welded wire mesh, chain link mesh, and expanded metal mesh. The wire gauge and construction technique control the load capacity and stiffness of the mesh. The mechanical properties of several common mesh types are provided in Table 8.8-7. Mesh serves the additional purpose of providing reinforcement and ductility for plain shotcrete. Welded wire mesh with a minimum 100-mm hole size is recommended to ensure that the shotcrete can penetrate and bond to the rock.

Straps

Steel straps (6.35 × 100 mm) are sometimes attached between reinforcing tendons to increase the footprint of the plates and to help secure specific wedges. Hole locations are preformed in the straps, and it is often difficult to install bolts at the required location and to make the straps conform to irregular rock surfaces. This style of strap has largely been replaced with zero-gauge welded wire straps (Figure 8.8-13), which are easy to install and pull tight to the rock surface and have proven very effective.

Shotcrete

Shotcrete is the generic name for cement, sand, and fine aggregate concretes, which are applied pneumatically and compacted dynamically under high velocity. Shotcrete can be applied in either a dry or wet form. In the dry application, shotcrete components, which can be slightly predampened to reduce dust, are fed into a hopper with continuous agitation. Compressed air is introduced through a rotating barrel or feed bowl to convey the materials in a continuous stream through the delivery hose. Water is added to the mix at the nozzle. In underground mining, dry shotcrete components are normally purchased premixed in 1,000-kg bags for ease of material handling (Hoek et al. 1995).

In the case of wet mix, the shotcrete components and the water are mixed before delivery into a positive displacement pumping unit. Low-profile agitator trucks have been developed for underground mining applications. Shotcrete is usually mixed in a surface batch plant and delivered underground using either agitator trucks on a ramp system or by slick line down the shaft.

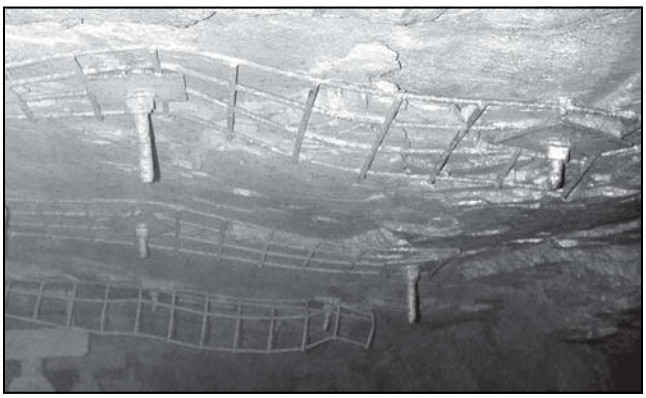

Figure 8.8-13 Zero-gauge straps

Shotcrete is normally applied in layers from about 50 mm to >100 mm thick. Because plain shotcrete is very brittle and will crack and spall off with small movement of the rock mass, it should always be reinforced. Welded wire mesh attached to the reinforcing tendons will provide reinforcement if plain shotcrete is placed over it. Alternately, fibers (steel or plastic) can be added to the mix to create what is normally called Fibercrete. The welded wire mesh and/or fibers provide tensile strength and ductility to the shotcrete to withstand movement of the rock mass. Shotcrete may be placed as an entire ring or only over selected sections of the excavation profile. A typical shotcrete application should achieve a uniaxial compressive strength of about 35 MPa after 28 days.

Wet-mix shotcrete is the most popular form because dry-mix shotcrete tends to have high rebound volumes, increasing unit costs, and usually results in inaccessibility of the area due to dust. However, wet-mix shotcrete has higher capital cost. QA/QC issues with shotcrete revolve primarily around preparation of the surface to be sprayed (the surface must be washed down clean in order to achieve proper bonding of the shotcrete) and control of the sprayed layer's thickness. Areas of active research with shotcrete today include the use of rapid curing shotcrete (via the addition of accelerators, etc.), deciding when it is safe to work under the shotcrete, and balancing the improvement in curing time against the inevitable loss of longer-term properties. Additional discussion of shotcrete design is provided by Hoek et al. 1995.

Concrete Liners

The three main types of concrete liners are poured, sprayed, and segmental:

1. Poured concrete liners are constructed by pumping concrete behind moveable forms (usually some type of slip from assembly). The poured concrete liner trails the advancing face by a discrete time/distance increment and is usually considered to be a secondary support system. Poured concrete liners are common in modern shaft-sinking operations and in some civil tunneling operations.
2. Sprayed concrete liners are created through the application of one or more shotcrete layers. Using a remote application arm, sprayed liners can be applied right up to the advancing face.
3. Segmental concrete liners are normally erected mechanically behind advancing tunnel boring machines and usually form the permanent liner for the excavation. This method is common in civil applications but is seldom used in mining.

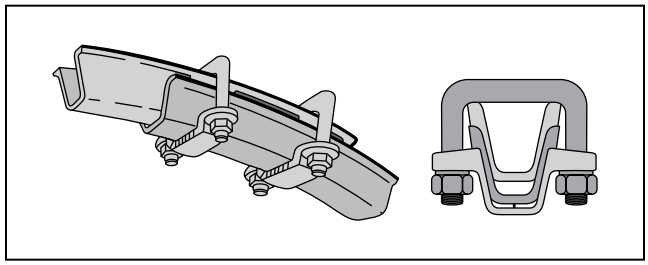

Figure 8.8-14 Steel arches with wooden lagging

Rigid Steel Sets

Steel arches or steel sets are used where high load-carrying elements are required to support tunnels or roadways. A wide range of rolled steel sections are available for this application. Where the rock is well jointed or becomes well fractured after the excavation is made, the spaces between the sets may be filled with steel mesh, steel, or timber lagging (Figure 8.8-14). Steel sets cannot be preloaded against the rock, and their efficacy depends on the quality of the blocking provided to transmit loads to the steel set. Improper blocking may lead to point loading of the set, often resulting in buckling failure of the legs. Today, steel sets are sometimes shotcreted in place, providing a more uniform loading and much stiffer response (Brady and Brown 2004). While steel sets give the impression of high load-carrying capacity due to their bulk, in terms of carrying capacity per weight of steel, they are often not that efficient. In most mining situations, they are an absolute last resort due to the difficulties involved in their erection, particularly under difficult ground conditions.

Yielding Steel Sets

Steel arches were widely used historically to support roadways in coal mines where they are often required to sustain large deformations. These deformations can be accommodated using yielding arches containing elements designed to slip at predetermined loads (Figure 8.8-15; Brady and Brown 2004). The modern U.S., South African, U.K., and Australian coal industries primarily use roof bolts and tendons, and this trend is continuing into other developing countries such as India and China. Steel sets present an impediment to efficient

Source: Hoek et al. 1995.

Figure 8.8-15 Assembly of a sliding joint is a top-hat section steel set

coal mining and are generally not considered as effective for ground control as reinforcing bolts and tendons. Hence they have been phased out over the past 30 years other than in arduous conditions around localized structures.

Shotcrete Pillar Support

Shotcrete pillars can be constructed by first forming a square cage of rebar anchored in boreholes in both the floor and the back of the opening. Each rebar should be 3 m long, with 1 m protruding from the hole. Additional rebar can be tie-wrapped to this rebar to complete the reinforcing cage. Steel half-culverts can be used to form the pillars, with angle iron tack welded so the half culverts can be bolted together. Shotcrete should be tremmied into the form, which should then be vibrated to remove air voids. Finally, the gap at the back is sprayed full of shotcrete. A 0.9-m-diameter shotcrete pillar using a 24-hour compressive strength of 15 MPa would carry a load of 1,200 t.

Timber and Steel Support

Timber support is no longer widely used in North America. The simplest form of timber support is the post and cap, or prop and lid, consisting of a single upright with a plate above. The post may be made of timber or steel, or may be a hydraulic prop. Timber posts, sometimes called sticks, are widely used to assist in supporting the mined-out area behind the stope face in the mining of narrow, reef-like metalliferous ore bodies. These sticks are usually 100 to 200 mm in diameter and are designed to support or help support the dead weight of the first 1 to 2 m of rock in the hanging wall. A typical 200-mm-diameter stick can have a short-term load-carrying capacity of 60 t (Korf 1978–1979), but for long-term use and low rates of load application, lower design capacities should be used.

Supports that are stiffer and have higher load-carrying capacities than timber posts or sticks of the same diameters are provided by pipe sticks in which a stick is press fitted into a steel pipe, typically 150 mm in diameter with a 4-mm-thick wall (Steinhobel and Klokow 1978–1979).

Sticks are passive support and require significant deformation to develop the full load-bearing capacity. They are also difficult to set properly, commonly leading to local falls of ground and increased loosening of the back. Their use is restricted to narrow openings or else they will act as slender columns and fail in buckling (Brady and Brown 2004).

In larger openings, timber cribs can be installed for local back support (Figure 8.8-16). Such timber cribs must be blocked against the back, and their effectiveness is highly dependent on the quality of the blocking. Timber

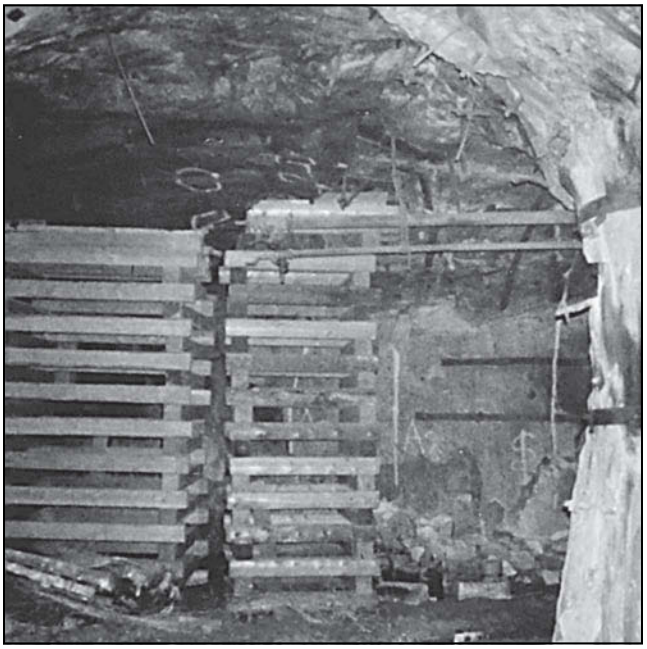

Figure 8.8-16 Timber crib

cribs can also be backfilled with waste rock to increase their load capacity. Timber cribs are a passive support and require significant ground movement in order to mobilize full load-bearing capacity. An issue not often discussed with timber support is shrinkage. If green timber is used, timber cribs can shrink from the roof by 100 mm over a relatively short period.

Hydraulic Props

Hydraulic props are set with a pre-load to provide active support and suffer from none of the disadvantages of sticks, although they are obviously much more expensive. The load bearing capacities of individual props may vary from as little as 5 t for a very light prop to more than 100 t for a 0.3-m-diameter prop. In the deep-level gold mines of South Africa, rapid-yielding hydraulic props are widely used to provide concentrated, active support of the hanging wall close to the face. Their rapid-yielding capability allows the energy released by rock bursts to be absorbed rapidly and safely, thereby minimizing the damage caused (Brady and Brown 1985).

A major risk with hydraulic props are leaks in the system, particularly longwall hydraulic supports, as mentioned earlier.

SAFETY

The majority of ground support is installed to ensure the safety of mine-operating personnel, and, where properly utilized, rock-fall-related injuries and fatalities have been dramatically reduced over the past 50 years. The statistics now indicate that most ground-control-related injuries occur during the installation of ground support (where workers are often in close proximity to unsupported ground) and are not due to subsequent ground instability. Today, it is common practice in many mines to use mechanized equipment to install primary support. In Australia, it is common practice in development headings to install Split Set bolts and screen using the jumbo on advance. In North America, it is more common to use mechanized bolters. In either case, the operator is protected by a steel canopy. In addition, mechanized scaling units can be used to scale the fresh heading prior to support installation. Another approach is to apply a flash coat of shotcrete (about 50 mm thick) and then to bolt through the shotcrete. Fiber-reinforced shotcrete can be used and may, in certain conditions, negate the need for screen.

WORK-FORCE TRAINING

At the end of the day, once all of the geotechnical design work is done and state-of-the-art products procured for use, it is all handed over to a group of miners to install. The quality of the final product is dependent on how well the work force is trained, how well the design is communicated, and on the quality of equipment provided. The importance of proper operator training cannot be overstated and in many areas the need for operator training in ground control principles is enshrined in the legislation.

MINING LEGISLATION AND DUTY OF CARE

In many areas of the world, and particularly in the developed world, the legislation pertaining to ground control has changed dramatically since about 1990. In most areas, a ground control management plan is mandatory and includes all manner of requirements above and beyond the type of ground support. A thorough discussion of this is beyond the scope of this chapter. Readers are encouraged to search out and carefully review the applicable local legislation.

CHAPTER 8.9

Mine Subsidence

John P. Harrison

INTRODUCTION

The phenomenon of subsidence is an inevitable consequence of the extraction from underground of any resource—be it solid, liquid, or gas. During recent years, with the trend toward larger mines and increasing requirements for environmental protection, it is no longer possible to ignore it. Worldwide, great attention is devoted to the subject and its methodical study, and strict regulations for its control have been introduced by government agencies in many regions to protect the public interest.

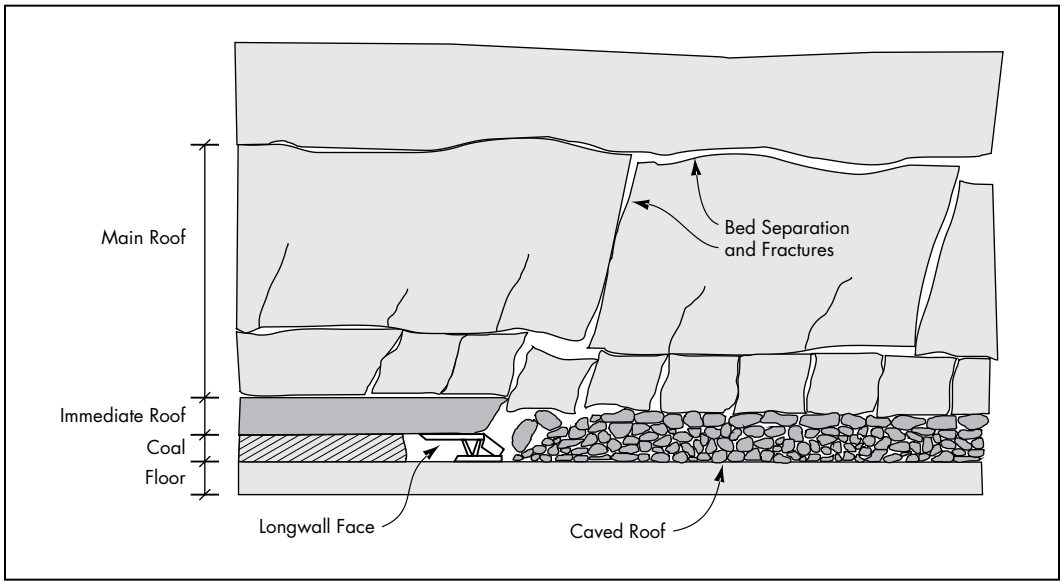
The problems associated with subsidence have been recognized since antiquity. Agricola's *De Re Metallica* of 1556 talks about "a mountain or hill…subsiding by its weight" as a result of mining (Agricola 1556). The early- to mid-20th century saw many developments in the understanding and prediction of subsidence, motivated by legal action resulting from severe damage to surface structures, communications, and agricultural resources caused by underground mining. It was the defense against unjustified claims that required improved understanding of subsidence phenomena. Thus, the major objectives of subsidence engineering are

- Prediction of ground movements,
- Determining the effects of such movements on structures and renewable resources, and
- Minimizing damage due to subsidence.

Consequently, subsidence engineering entails much more than the prediction of ground movements: It requires knowledge of geomechanics (both soil and rock mechanics), structural geology, hydrology and hydrogeology, mining methods and techniques, construction procedures, agriculture, socioeconomics, and mining and property law.

Although the effects of fluid extraction on subsidence have been widely investigated, they are beyond the scope of this chapter. Nevertheless, mining may lower the local water table, and this can induce ground movements that cause surface damage. This must not be overlooked.

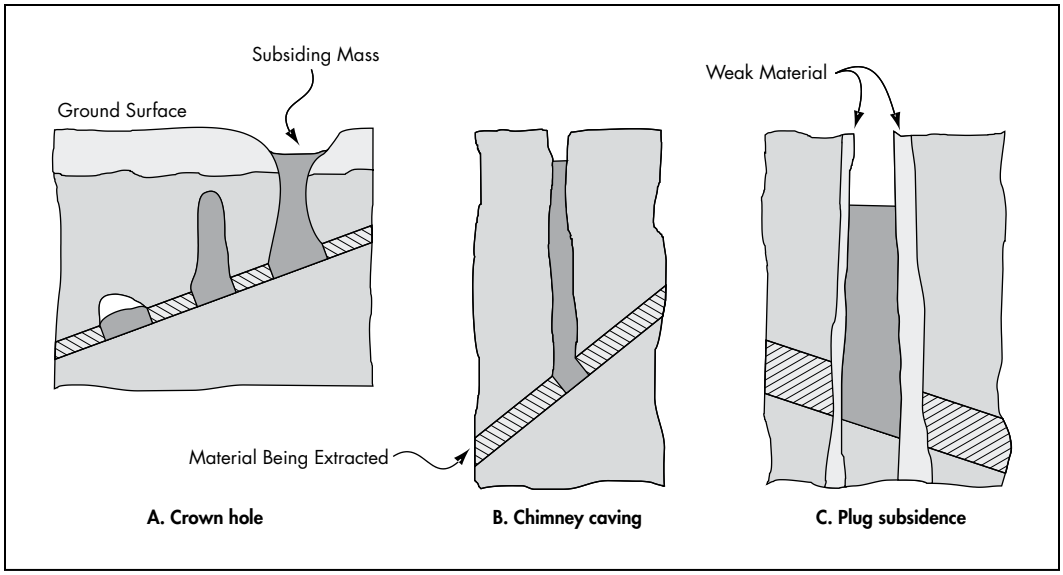
Finally, the term *subsidence,* as used in this chapter, encompasses the complete range of surface effects associated with the mining of minerals and not just the vertical displacement of the surface as is sometimes implied in the literature.



PRINCIPLES OF SUBSIDENCE

Development of Subsidence

The creation of any subsurface opening perturbs the stress state in the surrounding material. This perturbation produces deformations and displacements of the material, the magnitudes of which depend on the degree of the stress change, the spatial extent over which it occurs, and the nature of any rock support or reinforcement. If sufficiently large, these changes can cause the rock around a mine excavation to collapse into the mined void (Figure 8.9-1). The ground movements associated with such collapse tend to propagate to the ground surface, with the deformations and displacements experienced there being termed *subsidence*. Surface subsidence generally entails both vertical and lateral movements, and may be discontinuous (steps, cracks, or cavities form at the surface) or continuous (the surface deforms smoothly).



Discontinuous subsidence is generally of limited areal extent and is characterized by large vertical displacements. It occurs when material overlying an extraction zone collapses into the void, and its form depends on the mining method, the geometry of the extraction zone, and the geomechanical properties of the rock above the extraction zone (Figure 8.9-2). Crown holes may form because of roof or pillar collapse of shallow room-and-pillar (R&P) mines. A similar phenomenon is chimney caving (also known as piping or funneling), which occurs when a collapse at the mine level migrates upward (sometimes over distances of many hundreds of meters) through weak overlying materials. Both crown holes and chimney caving can occur above solution cavities, which themselves may be either a deliberate or inadvertent effect of solution mining. The presence of weak structural features (e.g., faults or boundaries between different geological materials) may lead to plug subsidence, in which a large plug of material falls suddenly and instantly downward into the mine void; the speed and suddenness of the process means this is particularly dangerous. Mining methods such as block caving

Source: Adapted from Brady and Brown 2004.

Figure 8.9-2 Forms of discontinuous subsidence

and sublevel caving also lead to discontinuous subsidence, but in these operations, use of and access to the surface area affected by the subsidence is generally prohibited.

In the case of continuous subsidence above laterally extensive extraction zones such as longwall coal mining operations, observations of subsidence profiles or troughs above the mined areas have shown they can be characterized on the basis of shape, in particular the absence or presence of an essentially horizontal central region. This leads to the concepts of subcritical, critical, and supercritical conditions (Figure 8.9-3), with the critical width being the minimum necessary to cause maximum surface subsidence. The position where the vertical displacement is effectively zero is known as the *limit of subsidence*, and the angle between a line joining this to the edge of the extraction zone and the vertical is termed the *angle of draw* or *limit angle*. The geometry shown in Figure 8.9-3 indicates that critical width is uniquely defined in terms of the mining depth and the angle of draw, and that the surface area affected by extraction is greater than the area of the workings themselves. The angle of draw has been found to be site-specific, as it depends on the geomechanical properties of the overlying materials; Table 8.9-1 gives various examples. In some areas, particularly those where the overlying rocks are particularly strong, a minimum extraction width has been found, below which no significant subsidence occurs (Sheorey et al. 2000); this is generally termed the *noneffective width*.

The minimum amount of mining required to lead to maximum subsidence of a point *P* is the extraction of a circular area whose diameter is equal to the critical width, and this circular

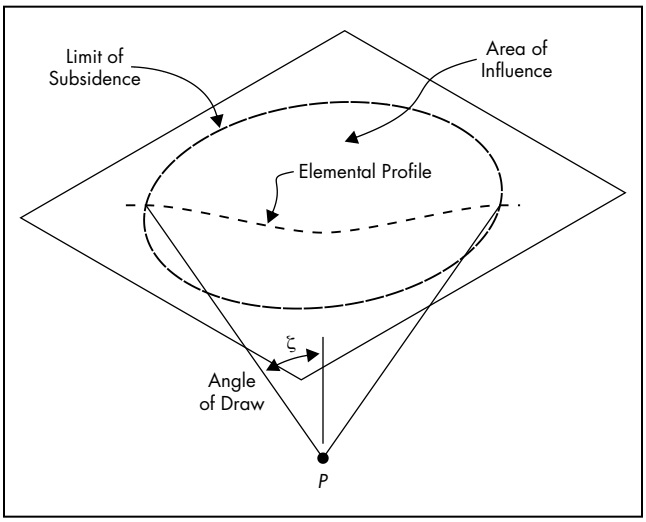

Figure 8.9-4 Concept of the area of influence

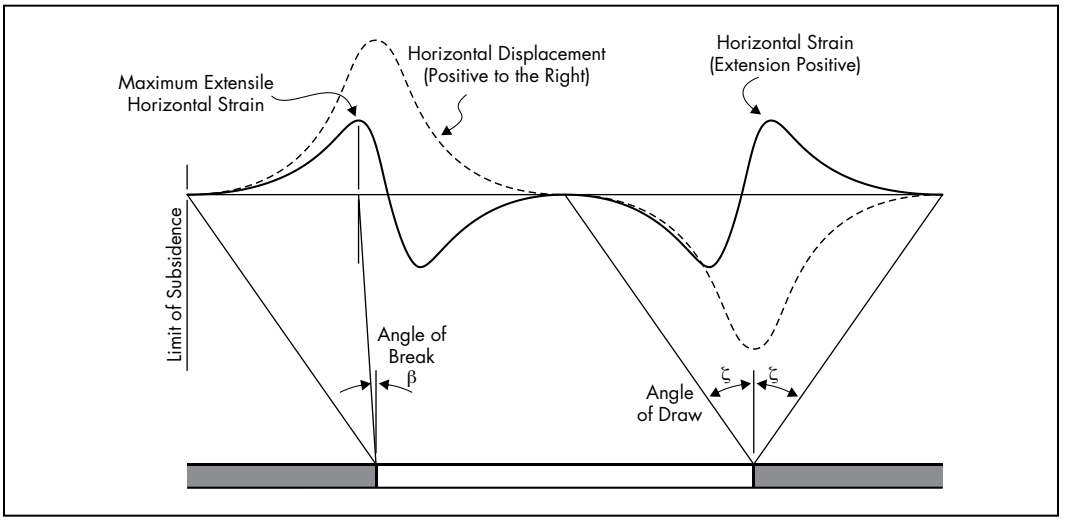
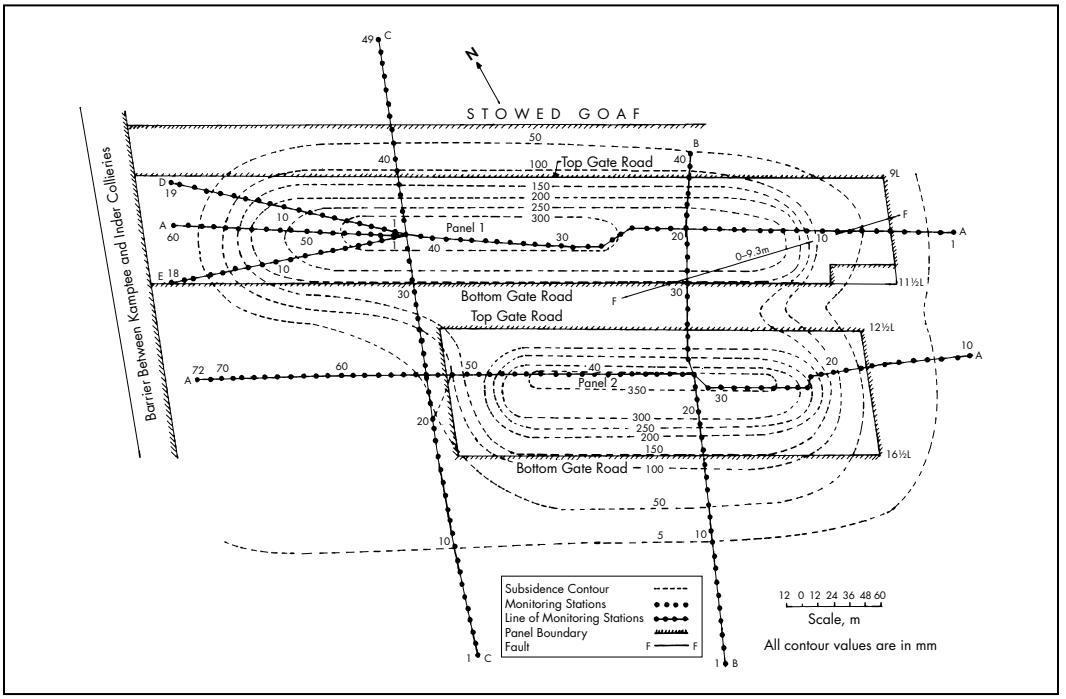


region is known as the area of influence. As every part of this area contributes in some way to the subsidence, extraction of material at a single point produces an elemental subsidence profile (Figure 8.9-4) that is circular in shape. The subsidence developed above any mining operation can be thought of as being formed by the summation of many such elemental profiles.

As subsidence occurs, points on the ground surface move horizontally toward the center of the mined area as well as vertically downward. Vertical displacement is greatest at the center of the mined area and zero at the limit of subsidence, with horizontal movement varying from a maximum almost vertically above the edge of the mined area to a minimum (essentially zero) at both the center of the mined area and the limit of subsidence. As the horizontal displacement is not constant, horizontal strain is induced at the ground surface. These strains are extensile (i.e., dilatant) outside of the boundaries of the mined area and contractile within them (Figure 8.9-5), although across the central region of the subsidence profile above critical- and supercritical-width workings the contractile strains are zero. Note that the terms *tensile* and *compressive* strictly refer to forces and stresses, and the terms *extensile* and *contractile* refer to strains. The inclination to the vertical of the line connecting the edge of the mined area to the surface point exhibiting the maximum extensile strain is called the *angle of break* or *angle of fracture*—not to be confused with the angle of draw defined earlier.

As a mine working is progressively extended, it begins at a subcritical width and, depending on the extent of the extraction, may pass into critical and supercritical widths. As the working face moves, so the horizontal extensile and contractile strain regions also move, meaning that a given point on the ground surface may experience different strain states as mining progresses. This is of critical concern for damage of surface structures. Finally, as Figure 8.9-6 indicates, the zone of subsidence reflects the shape of the extraction zone.



Factors Affecting Mine Subsidence

Experience has revealed that many geological and mining parameters besides the width of the extraction zone can affect the magnitude and extent of subsidence. The number

Figure 8.9-5 Horizontal displacement and strain profiles over a critical width opening

Source: Singh and Singh 1998; reprinted with permission from Elsevier.

Figure 8.9-6 Subsidence contours above longwall coal panels

and interrelation of these factors means that predicting in an accurate, quantitative manner the magnitude and time to subsidence onset is generally not straightforward.

Extraction Thickness

The thicker the material extracted, the larger the amount of possible surface subsidence. Note that it is the actual extracted thickness, not the in-situ thickness, that must be considered. Where mining takes place in several overlying mining horizons, subsidence is related to both the total extracted thickness and the sequence of horizon extraction.

Mining Depth

For supercritical longwall operations the maximum subsidence amount is unrelated to depth, but for other operations both the magnitude and time to onset of subsidence are dependent on depth.

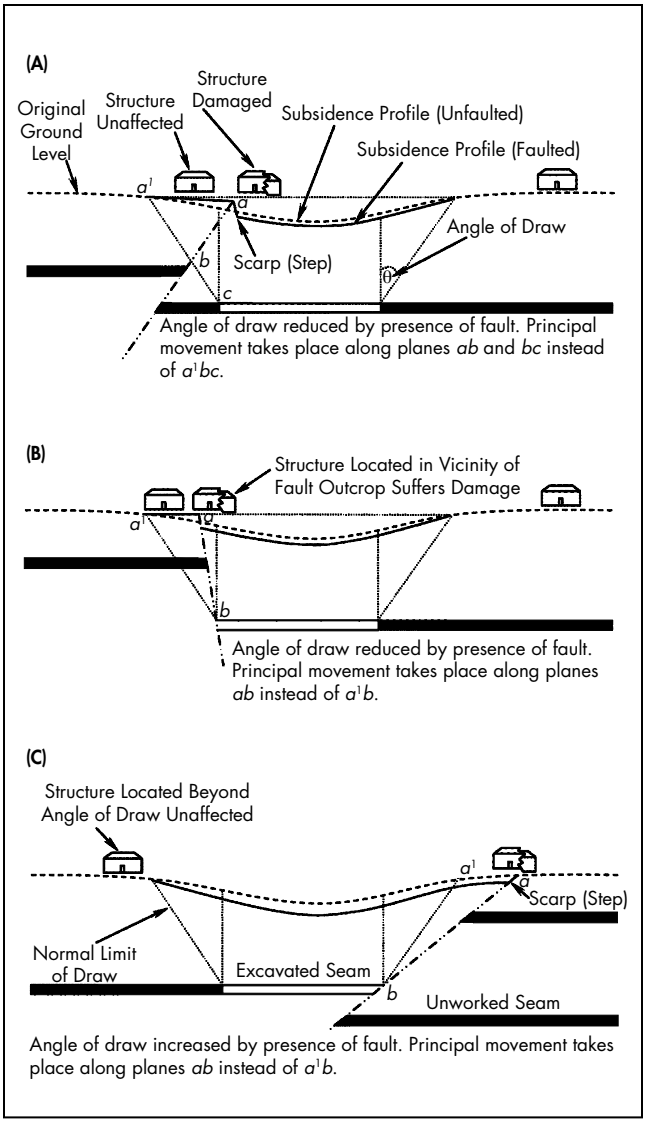
Inclination of Extraction Horizon

Asymmetric subsidence occurs when the zone being mined is inclined. The subsidence profile is translated in a downdip direction with both the limit angle and the horizontal strains increased downdip and reduced updip.

Degree of Extraction
Reducing the amount of material extracted will reduce the amount of subsidence. Thus, lower extraction ratios tend to both reduce and delay the onset of subsidence.

Mined Area
The critical width of a mined void must be exceeded in all directions if maximum subsidence is to develop. This is especially important if overlying competent materials are present, as these may tend to form bridges in the direction of subcritical width and thus decrease subsidence.

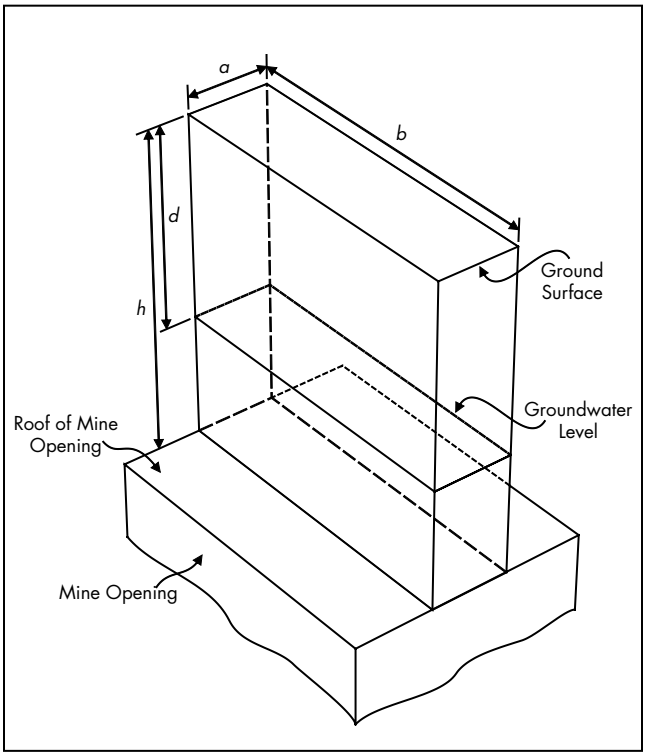
Method of Working
The amount of subsidence is largely controlled by the degree of caving induced by the mining method (e.g., complete subsidence for block caving and longwall mining, and zero for R&P) together with the amount of support offered by any backfilling. Nearly immediate, but predictable, subsidence occurs with longwall mining, whereas with R&P operations both the magnitude and onset of subsidence are largely unpredictable.



Extraction Rate
Surface subsidence follows the face as it progresses, and so to minimize the effect of strain and tilt on surface structures, a fairly rapid, constant face advance rate should be adopted (Legget 1972).

Competence of Surrounding Materials
Since subsidence propagates from the mine level, the mechanical behavior of the rock adjacent to the mined void directly affects the initiation of subsidence. Weak roofs and floors accentuate subsidence, whereas strong materials can delay or even prevent collapse and hence subsidence. Strong, massive materials above the mine level are able to withstand the effects of extraction for a prolonged period and hence defer the occurrence of subsidence.

In-Situ Stress State
High horizontal stresses may foster formation of an arch in the material overlying a mined void, thereby attenuating subsidence. However, arch formation is a complex phenomenon, depending on many geomechanical parameters: It cannot be guaranteed, and arches may fail suddenly and catastrophically.



Geological Discontinuities
The existence of faults, folds, and the like may increase and localize subsidence potential so strongly that in areas of adverse geological conditions the effects of the other parameters can be discounted. As mining perturbs the stress state in the ground, fault planes may become critically stressed and hence undergo shearing. The associated release of strain energy can be rapid and dramatic, producing seismic events, or can be more benign, resulting simply in the ground surface being displaced into a series of steps. Displacements will be concentrated toward faults, although horizontal strains may become negligible in their immediate vicinity. Structures that straddle faults may be severely damaged while nearby buildings remain relatively intact (Figure 8.9-7). Joints and fissures in the strata affect subsidence behavior in a manner similar to faults, but on a smaller scale.

Near-Surface Geology and Surface Topography
The nature of any near-surface soils and unconsolidated rocks affects subsidence development, with both the thickness and mechanical characteristics of these materials being important. For example, cracks and fissures may form in stiff clays, whereas soft clays may deform plastically and cohesionless sands may flow down into fractures in the underlying rocks. Specialist geotechnical advice may be needed in order to determine the behavior of structures in or on these materials. Sloping ground tends to emphasize downward movements because of gravity, and extensile strains may increase on hilltops and decrease in valleys, although there is evidence that the effect of topography on strain is unpredictable (Ewy and Hood 1984). Deeply incised valleys, particularly those in regions of high horizontal in-situ stress, may display valley bottom vertical subsidence that is markedly less than predicted for a horizontal ground surface, and horizontal closure greater than predictions of horizontal strain would suggest (Waddington and Kay 2003). These phenomena seem to be analogous to natural periglacial cambering and valley bulging in weak rocks.

Figure 8.9-8 Equilibrium analysis of chimney caving

Hydrogeology
Deformation of the strata around mined areas may alter hydraulic gradients, resulting in either the flooding or draining of surface areas and the formation or draining (in aquifers) of underground reservoirs (Booth 2002). Rocks may be weakened by changes in saturation, and, in carbonate (e.g., limestone) areas, caverns or karst may develop over a period of time. If surface runoff from precipitation or water from leaking pipes is allowed to percolate into ground fractured by mining, the increased groundwater pressure can reduce the effective stress, thereby inducing shear on faults.

Elapsed Time
Subsidence does not occur instantaneously but over a period of time. In R&P operations, subsidence may only develop a long time (possibly centuries) after the mining is complete, when pillar degradation leads to roof collapse. In caving operations, surface displacements may occur almost immediately after the face passes below an area. However, as noted, the presence of strong, competent layers overlying an opening can delay this.

Discontinuous Subsidence
The wide range of circumstances leading to discontinuous subsidence means that no generic method is available for predicting or analyzing the phenomenon. Instead, the principles of geomechanics must be applied on a case-by-case basis. As all discontinuous subsidence involves the movement of clearly defined bodies of rock or soil, it is often straightforward to develop a free body diagram of the system and examine its equilibrium.

Figure 8.9-8 represents an example of such an analysis for the case of a rigid prismatic block of rock whose vertical faces follow the Coulomb shear strength criterion. For a groundwater level of $0 \le d \le h$, the factor of safety, F, can be calculated as

$$F = \frac{2}{\gamma}\left[c' + kh\frac{\gamma}{2}\tan\phi' - \frac{\gamma_w \tan\phi'}{3h}(h-d)^2\right]\frac{a+b}{ab} \qquad (8.9\text{-}1)$$

where
a, b, d, and h = block geometry
c' and ϕ' = shear strength of the vertical faces
γ and γ_w = unit weight of the rock and water, respectively
k = ratio of horizontal to vertical in-situ stress in the block

By setting the factor of safety F to unity, these equations can be used to determine the critical value of the span b leading to caving.

Other analyses that are applicable in the context of discontinuous subsidence are pillar collapse and roof stability.

Continuous Subsidence

Subsidence Measurement and Monitoring
The differential settlement and horizontal strain developed during subsidence tend to be critical in terms of structural damage. As these are related to vertical displacement, measuring and monitoring subsidence displacements is of prime importance. To be of maximum benefit, monitoring should commence before any mining activity begins and be continued for as long as either ground movement is likely to occur or surface structures are liable to be affected by movement.

Traditionally, subsidence measurement and monitoring has been undertaken using customary precise leveling techniques. Measurements must be made on structures or markers that respond directly to the subsidence of the rock surface, and it is essential that all survey points are unaffected by surface movements (e.g., fluctuations in elevation due to freeze–thaw action or changes in saturation). Although many forms of survey marker have been devised, their essential characteristics are a long steel tube or bar topped with a disk or hemispherical dome of rust-resistant metal, grouted into the rock at a depth appropriate to the local conditions, and surrounded by concrete for protection.

Although the markers need to be sufficiently close to allow changes in the local subsidence gradient to be detected, economy of cost generally will require the spacing to be as large as possible. The U.K. National Coal Board recommended a spacing of $0.05D$, where D is the depth to the mine workings (National Coal Board 1975). In the United States, a spacing of $0.05D$ to $0.1D$ has been used. The accuracy of the measurements should be such as to detect horizontal strains of 1×10^{-4}, which is about one-tenth of the strain that causes structural damage. The measurement procedures may be obtained from any text on surveying, but attention needs to be paid to details such as the area to be covered, surface topography, labor requirements, and survey frequency.

Vertical displacements may be measured directly by trigonometric leveling (precision optical or laser), differential leveling, or tilt measurement. When using a theodolite, vertical angles must be measured correctly to one-half second of arc. With precise leveling, a micrometer direct reading to about 1.5 mm should be employed. An inclinometer with a sensitivity of 10 seconds of arc is generally adequate for subsidence measurements.

The increasing availability of high-resolution satellite imagery means that indirect measurement of vertical displacement using satellite interferometry is becoming more widespread as a subsidence monitoring tool (Wright and Stow 1999; Carnec and Delacourt 2000). Although displacements obtained in this manner currently have a resolution limited to the order of a few millimeters (Ge et al. 2007), the technique has many benefits, including removal of the need for surface surveys, regular automatic acquisition of data, and measurements not limited to specific profiles. For new mines it is also possible to use imagery obtained before mining in order to obtain baseline conditions. With the continual deployment of ever more powerful remote sensing satellites, it is reasonable to assume that interferometric techniques will become the future standard method of subsidence monitoring.

Subsidence Prediction

Subsidence prediction techniques may be characterized as either phenomenological or empirical, with phenomenological techniques using computer-based numerical modeling to reproduce subsidence by simulating the behavior (both continuous and discontinuous) of the rock around a mine, and empirical methods using various models and formulas based on observations and experience of actual mining subsidence. Empirical methods include influence functions, profile functions, and graphical techniques. Although empirical techniques have formed the basis of most subsidence predictions to date, continuing developments in numerical modeling and subsurface characterization using geophysics suggest that phenomenological techniques will become preeminent.

Phenomenological methods. Phenomenological methods are computational methods based on the principles of mechanics and assume some particular material model to be applicable to the rock. Initial work concentrated on elastic, viscoelastic, plastic, and elastoplastic continuum models (e.g., Marshall and Berry 1967; Crouch 1973), but recent work has moved toward discontinuum and hybrid continuum-discontinuum approaches (e.g., Wu et al. 2004; Zangerl et al. 2008). These are likely to develop further and become more prevalent because they more closely capture the fragmentation that occurs during subsidence than do continuum approaches.

Application of phenomenological methods requires sophisticated software (the complexity of the physical processes involved in subsidence means that simple numerical techniques are seldom appropriate) and suitably skilled analysts; although powerful and comprehensive, they cannot be used in an impromptu manner.

Influence functions. Influence functions apply the concept of the elementary cone (Figure 8.9-4), with the extraction zone being discretized as a large number of small elements of simple geometry and the subsidence at any point on the surface being obtained from the superposition of the influence of each extracted element. The functions themselves are empirical, and the method has achieved widespread application (Ren et al. 1987). It has been found to be particularly applicable to mine workings with irregular or complex geometries, but, as implementation of the method is reasonably straightforward, it is a pragmatic approach to predicting subsidence above any mining operation.

At their simplest, influence functions take the form

$$p(r) = k_1 S_{\max} f(B, r, k_2) \tag{8.9-2}$$

where

$p(r)$ = contribution made to the subsidence at some location on the surface by extraction of a small area located a horizontal radial distance r away
k_1 and k_2 = constants (Brady and Brown 2004)
S_{max} = maximum subsidence associated with critical width extraction (usually determined empirically)
B = critical width

In addition, as the subsidence over an element of extraction is assumed to follow an inverse square law (Kratzsch 1983), influence functions contain a term that is some function of r^2/h^2. The inclusion of the critical width in Equation 8.9-2 means that more complex functions are required when either the ground surface or the extraction zone is not horizontal. For the latter case, the use of an angle of draw that varies with orientation relative to the dip direction of the extraction zone has been proposed (Lin et al. 1992).

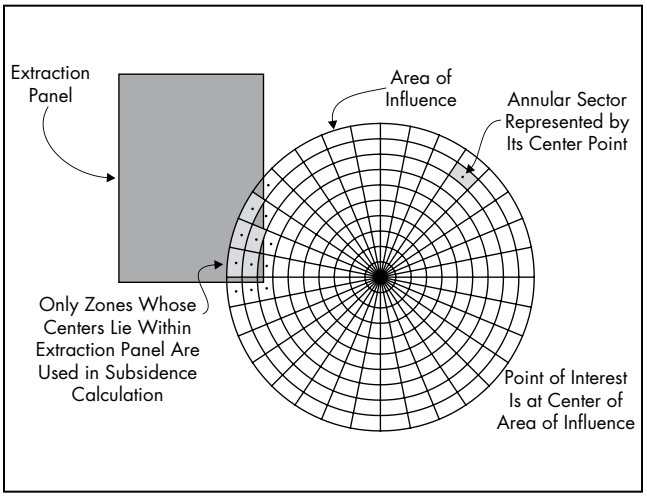
The complete subsidence s at a point on the surface is given by integrating Equation 8.9-2 over the entire extraction area A:

$$s = \int_A p(r)\,dA \tag{8.9-3}$$

Evaluating this integral is challenging for all but the simplest of influence functions and extraction geometries, and so a computer-based approach is usually used. One technique, illustrated in Figure 8.9-9, divides the area of influence of the function into a number of annular sectors and integrates the function over each sector to give an influence coefficient (Ren et al. 1987). Only those sectors that lie within the extraction area for a given point of interest are used in the calculation, and so determining subsidence becomes a case of simply summing the influence coefficients for each such sector. The calculation is repeated for a number of points of interest, and a contour map of subsidence determined. A major advantage of this approach is that the calculation is easily programmed and can readily be performed on a computer spreadsheet.

Calculation of the influence coefficients requires integration of the influence function over the area of each annulus. The influence of the ring between r_i and r_{i-1} is then

$$I(i) = 2\pi \int_{r_{i-1}}^{r_i} p(r) r\,dr \tag{8.9-4}$$



The sum of all *I(i)* is required to equal unity, and the results of Equation 8.9-4 must be scaled to ensure this is the case. As an example, take the case of the stochastic, or exponential, function (Ren et al. 1987):

$$p(r) = \frac{1}{R^2} \exp\left(-\pi \frac{r^2}{R^2}\right) \tag{8.9-5}$$

where R is the radius of the area of influence. Substitution of Equation 8.9-5 into Equation 8.9-4 yields

$$I(i) = \exp\left(-\pi r_{i-1}^2 / R^2\right) - \exp\left(-\pi r_i^2 / R^2\right) \tag{8.9-6}$$

and using this influence coefficients for a scheme using 10 annuli and 64 sectors are given in Table 8.9-2. With this scheme each annular sector contributes 1/640 to the overall subsidence

at a point, and so any errors associated with simplifying each sector to its center point is very small.

A related influence function that has found widespread application is

$$s(r) = \frac{n}{R^2}\exp\left[-n\pi\frac{r^2}{R^2}\right] \tag{8.9-7}$$

where n is a site-specific constant (Brady and Brown 2004). For any particular site, comparison of calculated and observed values of subsidence will allow determination of the appropriate value of the constant n.

A function proposed recently is

$$p(r) = \frac{1}{(1+4n)k^2h^2}\left[\begin{aligned}&\exp\left(-\frac{\pi}{k^2}\frac{r^2}{h^2}\right)\\&+n\exp\left(-\frac{\pi}{4k^2}\frac{r^2}{h^2}\right)\end{aligned}\right] \tag{8.9-8}$$

where

n and k = constants related to the maximum subsidence magnitude and the shape of the subsidence profile, respectively
h = mining depth (Álvarez-Fernández et al. 2005)

This latter function has been shown to be effective for very complex mining geometries (González-Nicieza et al. 2005; Díaz-Fernández et al. 2009).

Finally, as illustrated in Figure 8.9-10, the so-called focal point concept can be used to calculate the horizontal radial displacement (Ren et al. 1987) associated with each elemental value of vertical displacement. The resultant values of horizontal displacement at neighboring points of interest can then be used to calculate horizontal strain.

Profile functions. Profile functions are mathematical functions representing a complete subsidence profile at the surface along a traverse either parallel or perpendicular to the face of a longwall panel. Although they are, in effect, integration of an influence function along a particular traverse, profile functions are nonetheless selected empirically and the controlling constants determined from subsidence observations. Provided that sufficient suitable observation data exist to allow calculation of the constants, this method can be applied to a wide range of geological conditions, and profile functions have a history of application in several countries (Hood et al. 1983). A major limitation of profile functions is that they are applicable only to simple mine geometries, such as longwall panels.

Profile functions take the form

$$s(x) = S_{\max} f(B,x,c) \tag{8.9-9}$$

where

$s(x)$ = subsidence at position x
$S_{\max}$ = maximum subsidence associated with critical width extraction (usually determined empirically)
B = critical width (Brady and Brown 2004)
x = distance from the coordinate origin
c = site-specific empirical constant or function (Hood et al. 1983)

Differentiating such a function once with respect to x gives the surface slope and twice gives the curvature. It has been suggested that relating calculated curvature to structural damage is more valid than attempting to determine horizontal strain from a profile function (Whittaker and Reddish 1989).

Various exponential, trigonometric, hyperbolic, and error functions have been used as profile functions, but one that has been found to apply well to supercritical conditions in both the United Kingdom and United States is

$$s(x) = \frac{1}{2} S_{\max}\left[1 - \tanh\left(\frac{b}{h}x\right)\right] \quad (8.9\text{-}10)$$

where x is measured from the inflection point of the function (i.e., where $s = \frac{1}{2}S_{max}$), b is a constant, and h is mining depth.

Application of such a function requires values for S_{max}, b, and the location of the inflection point relative to the mined panel, and these can only be obtained from subsidence monitoring at either the mine to which they are to be applied or one in similar circumstances. For example, following extensive monitoring of a longwall coal panel in Illinois (United States), values of b of about 11 for transverse profiles and between 8 and 9 for longitudinal profiles have been reported (Hood et al. 1983). These values should be considered in the light of work that suggests $b = 5$ is appropriate for the United Kingdom (King et al. 1975); the disparity between the two sets of results confirms the need to obtain locally derived data.

Graphical methods. Graphical methods involve using previously obtained subsidence data, normalized with respect to one or two mining parameters, to develop charts from which subsidence associated with other mining operations can be predicted. These methods effectively entail graphical representation of a profile function but require considerable subsidence data and are generally restricted to similar areas and mining conditions from which the data were collected.

Probably the most comprehensive example of a graphical approach is that set out in the *Subsidence Engineers' Handbook* (National Coal Board 1975), which was developed for use in the coalfields of the United Kingdom. The basis of the approach is that strain and tilt were found to be related to maximum subsidence and mining depth in the following ways:

$$\begin{aligned} +E_{\max} &= 1{,}000 \times k_1 \times S_{\max}/h \\ -E_{\max} &= 1{,}000 \times k_2 \times S_{\max}/h \\ \omega_{\max} &= 1{,}000 \times k_2 \times S_{\max}/h \end{aligned} \quad (8.9\text{-}11)$$

where

$+E$ and $-E$ = extensile and contractile strains, respectively
k_1, k_2, and k_3 = constants of proportionality (Brady and Brown 2004)
h = mining depth
ω = tilt

The constants vary with the ratio of extraction width to mining depth and location relative to the center of the working face, and so the various charts presented in the handbook are effectively graphs of the constants in terms of these factors. The maximum subsidence is generally dependent on the mining depth and both the extraction thickness and width; Figure 8.9-11 shows the relation derived by simplifying to straight lines the comprehensive curves relating subsidence to extraction thickness given in the *Subsidence Engineers' Handbook*.

Because the charts used in this method are only applicable strictly to the area and conditions for which the source observations were obtained, they should not be applied to other circumstances. Instead, charts should be developed on an area-by-area basis (see, for example, the charts developed for use in New South Wales, Australia [Holla and Barclay 2000]).

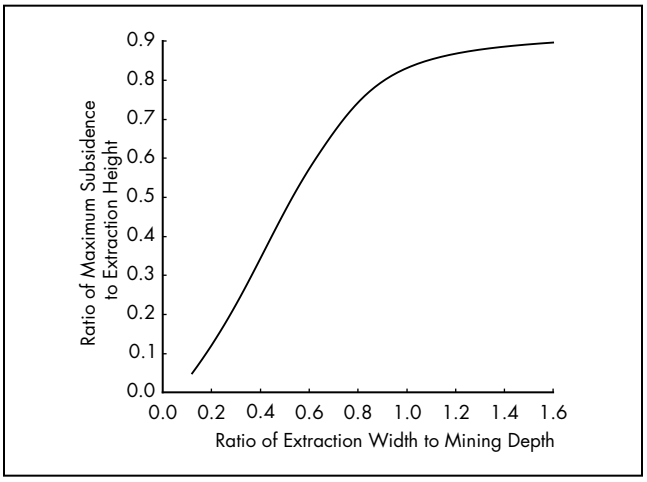

Figure 8.9-11 Simplified relation between maximum subsidence and extraction height, extraction width, and mining depth

Long-Term Effects

The duration of subsidence resulting from mining is composed of two distinct phases: active and residual. Active subsidence consists of those movements occurring contemporaneously with mining operations, while residual subsidence consists of those that occur later than this (either following the cessation of mining or the passing of a zone of influence). The magnitude and duration of residual subsidence has particular relevance to structural damage and legal obligations, but both of these vary markedly with the mining method and the geomechanical characteristics of the ground.

Numerous observations worldwide suggest that the magnitude of residual subsidence associated with longwall panels rarely exceeds about 10% of the total subsidence, with the duration of these movements typically varying from a few weeks to about 10 years (Table 8.9-3). Prediction of duration generally uses site-specific empirical relations; one such example from the United Kingdom is

$$t = \frac{2d\tan(\zeta)}{a} \quad (8.9\text{-}12)$$

where

t = time (years) for subsidence to complete
d = mining depth (m)
ζ = angle of draw
a = face advance (m/yr) (National Coal Board 1975)

However, further work is needed to fully understand time-dependent, or residual, subsidence over longwall panels (Goulty and Al-Rawahy 1996).

With R&P operations, most subsidence results from deterioration and collapse of either the support pillars or the roof between them, or punching of the pillars into the roof or floor. This may occur many years (decades or even centuries) after cessation of mining (Thorburn and Reid 1977; Ivey 1978; Dunrud and Osterwald 1980), and predicting the timing is difficult, as it depends on a large number of factors, including the strengths of pillars, roof, and floor; extent of fracturing;

Table 8.9-3 Duration of residual subsidence over longwall mines

Country/ Coalfield	Residual Subsidence Duration	Reference
United Kingdom	Several months to 3–6 years (strong overburden)	Orchard and Allen 1975
United Kingdom	2 to 4.5 years	Collins 1977
Germany	1 year (Cretaceous overburden), 2 years (sandstone overburden)	Brauner 1973a, 1973b
USSR	2 years (shallow mines), 4 to 5 years (deep mines, >400 m)	Brauner 1973a, 1973b
United States/ Illinois	12 months	Hood et al. 1983
India	16 months	Singh and Singh 1998

presence of water; depth of workings; pillar size; and extraction ratio.

The caving process associated with roof collapse will either migrate to the surface or become stable at depth, depending on the volume of the original void and the strength and bulking factor of the caving material. The surface expression of this subsidence is generally localized depressions or pits. Pillar failures result from either weathering or increased loading due to surface development (Piggott and Eynon 1978) or mining activity (e.g., pillar robbing, other nearby operations, or load transfer due to collapse of adjacent small pillars) and leads to trough-like subsidence. Punching failures (squeezes or crushes) occur when either the immediate roof or floor is weakened or altered by the action of water or other weathering processes and pillars are forced into them. Generally, the subsidence takes the form of a trough or basin. The failure mechanism in this case is similar to that of a structure exceeding the bearing capacity of its foundation. Factors that encourage punching failure include argillaceous materials in the roof or floor, high pillar stresses, and flooded conditions.

Of the wide range of factors that affect the duration of residual subsidence associated with R&P operations, the principal ones include depth of working; mine geometry; mine support and reinforcement; geomechanical properties of the overburden, roof, pillars, and floor (e.g., strength, stiffness, degree of fracturing); and groundwater and mine humidity. This wide variety of interrelated contributory factors means there is no comprehensive model for predicting the duration of residual subsidence over R&P workings. Many case histories are reported in the literature, a thorough review and understanding of which is likely to be more fruitful than attempts to develop predictive models for a particular operation.

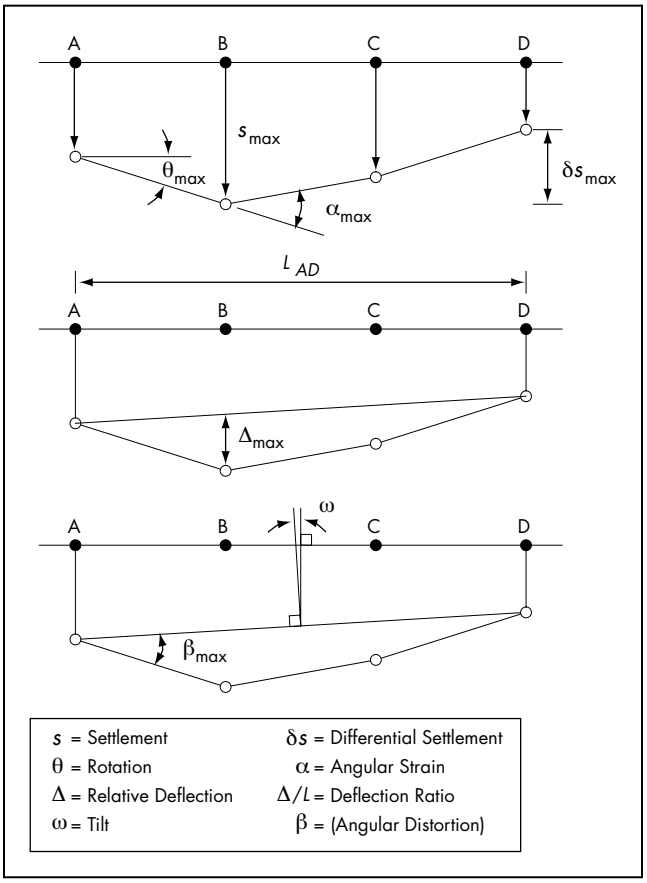
Subsidence-Induced Environmental Effects

The surface displacements and deformations characteristic of subsidence will affect any use made of the ground surface. This includes the ground as a foundation for buildings and structures, as well as a resource in its own right; subsidence affects both the built and the natural environment.

As previously outlined, subsidence comprises five major components:

1. Vertical displacement
2. Horizontal displacement
3. Slope (or tilt), the derivative of the vertical displacement with respect to the horizontal displacement
4. Horizontal strain, the derivative of the horizontal displacement with respect to location
5. Vertical curvature (or flexure), given approximately by either derivative of the slope

Vertical displacements alone cause little structural damage, although lowering of the land may adversely affect both urban and rural drainage systems, flow-through transport pipes, groundwater regimes, and vertical alignment of roads and railways. Similarly, uniform horizontal movements of the ground surface also cause little damage to structures. However, spatial variation in vertical displacement causes formation of slopes that can interfere with drainage systems and the vertical alignment of roads and railways, and can cause unacceptable tilt in tall structures such as chimneys. Surface horizontal strains cause most of the damage to structures located above mined areas. Extensile strains can lead to breaks in pipes, electricity or communications lines, and roads, and cracks in masonry or similar brittle structures. Contractile strains lead to distortion and buckling of steel structures, pipes, and railway tracks; damage to walls; and failure of the weaker parts of masonry structures (e.g., around door and window openings).



In most cases it is a serviceability, rather than an ultimate limit state, that governs whether or not subsidence damage is tolerable (Wahls 1994). Quoting other work, Wahls suggests that "movement is *not* tolerable if damage requires costly maintenance and/or repairs, *and* a more expensive construction to avoid this would have been preferable." The concept of *tolerable damage* is important. In general, it is related to the consequences of any damage and the ease and economics of repair, but in the context of mining it is also related to the cost and economics of changed or abandoned mining plans, if needed to reduce the effects of subsidence.

Work continues worldwide to codify the effects of deformation on structures. For example, European Standard EN 1997-1:2004 (i.e., Part 1, Geotechnical Design, of Eurocode 7, often referred to simply as EC7; CEN 2004) presents guidelines for limiting values of structural deformation and foundation movement. This code requires designers to consider overall settlement, relative (or differential) settlement, rotation, tilt, relative deflection, relative rotation, and horizontal displacement of structures (see Figure 8.9-12 for definitions), and gives guidelines for critical values for many of these parameters. Thus, the maximum acceptable relative rotations for open-framed structures, infilled frames, and load-bearing or continuous brick walls are likely to lie in the range from about 1/2,000 to about 1/300, with a maximum relative rotation of 1/500 being acceptable for many structures. As these ratios apply to sagging mode deformations, the code suggests that the values be halved for hogging modes (i.e., vertical displacement of the edges more than that of the parts between). Similarly, it is suggested that for normal structures with isolated foundations, total settlements up to 50 mm may be tolerable, with larger settlements being acceptable provided they do not cause excessive relative rotations, tilting, or other problems such as with the services entering the structure.

Finally, the code stresses that these guidelines "apply to normal, routine structures." For other structures, specialist advice should be sought.

Buildings and Structures

Although EC7 requires the effects of differential settlement, horizontal strain, angular distortion, and tilt to be recognized, it is the complex interaction between the magnitudes of these deformations and the characteristics of the

Source: Adapted from CEN 2004.

Figure 8.9-12 Definitions of structural deformation

structures themselves that determines the nature and amount of damage.

Extensile horizontal ground strain tends to produce vertical and step-like cracks in brick walls, generally of uniform aperture. Extension cracks in floor slabs usually occur at right angles to the direction of the extensile strain, with the sides of the cracks showing little or no shear offset. Contractile strains lead to bulging of walls and buckling and heaving of floor slabs and rigid coverings such as floor tiles. Angular distortion (or relative rotation) is a measure of shearing and leads to diagonal cracks in masonry and brick walls and their plaster coverings, and binding of doors and windows.

The concept of tolerable damage has led to the development of classification schemes such as that shown in Table 8.9-4. The information in this table has a history stretching back to the middle 20th century and is widely accepted. However, the tolerable damage concept means that this table and others like it should be considered as guidelines; for example, distorted window frames may be tolerable for some buildings, whereas even slight cracking may be intolerable for others.

These damage criteria are often embodied in various charts. As examples, Figure 8.9-13 shows how horizontal strain and angular distortion combine, and Figure 8.9-14 shows how horizontal strain and length of structure affect the damage classification.

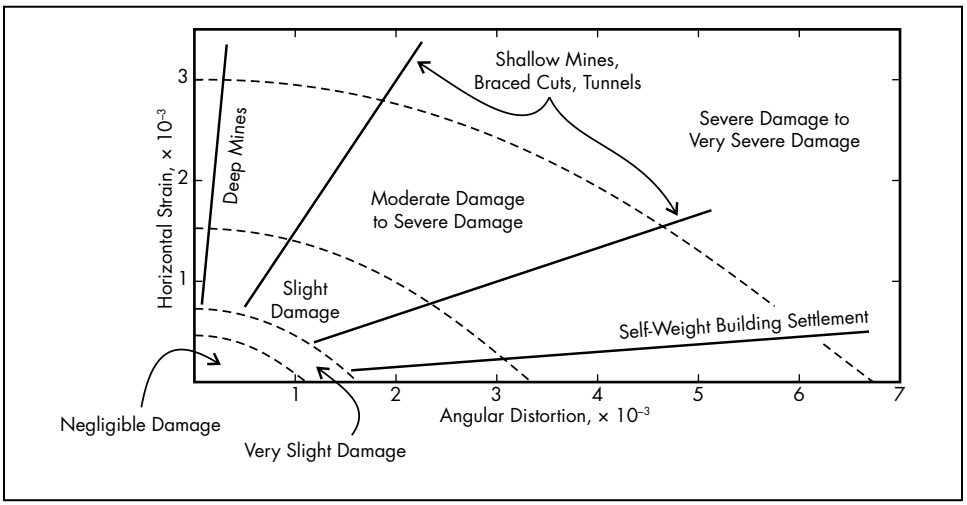
Damage may be caused to bridges by horizontal ground strain resulting in the movement of the supports of piers either toward or away from one another. Differential vertical settlement or distortions in the horizontal plane may bring about complex and often serious effects on the decking and arches (National Coal Board 1975). It is generally difficult to determine the location and nature of the ground movements based on visual observation of damage. Often compressive damage leads to crushing and spalling of concrete decks, with combined compression and extension due to bending causing opening and closing of construction joints in abutments. More substantial damage is characterized by distress in the superstructure, inward horizontal movement of abutments, jamming of beams and girders against the back wall of the abutments, and serious damage to the bearings (Moulton et al. 1985). These findings are summarized in Table 8.9-5.

Across a wide range of other structures, consensus seems to be converging on a value of 1.0×10^{-3} for tolerable horizontal strain (see, for example: Nishida and Goto 1970; Lackington and Robinson 1973; Lee 1977; Institution of Civil Engineers 1977; Kratzsch 1983). However, specialist advice should be sought for nonroutine structures.

Public Utilities and Communications

Roads and airport runways. Subsidence principally affects roads and roadways through formation of cracks and undulations in the surface; distortions to both horizontal and vertical alignment; damage to ancillary structures such as drains, fences, and curbs; deterioration of base courses and subgrade; and ponding of surface water. Structures used for high-speed operations (e.g., runways and motorways) are particularly vulnerable to such damage. The formation of tensile cracks on the pavement surface (usually coinciding with the position of the rib-sides in the mine workings) and compression ridges near panel centers (Donnelly and Melton 1995) are the most common forms of damage. As highway bridges are generally more susceptible to subsidence than the highways themselves, bridge damage criteria may be used to give conservative limits for highways.

Railways. Railway authorities are generally protective of railway infrastructure and will set quite prescriptive limits on subsidence effects. One of the first effects of subsidence on railways is rider discomfort, which may require the reduction of maximum permissible speeds. Changes in ground slope may adversely affect track performance by formation of localized depressions or creation of gradients greater than permissible for a given type of traffic. The reversals of surface horizontal strain (i.e., from zero to extensile strain initially, followed by contraction) observed over longwall panels as the working face progresses are particularly damaging (Institution of Civil Engineers 1977). At higher levels of contractile strain, rail tracks have a tendency to snake or bend, and in more extreme cases, the rails themselves may be forced from the track.



The extent to which a railway line is affected by ground movements is related to types of traffic involved, speed limits, types and construction of track, preventive and remedial works, and nature and magnitude of ground movements. Serviceability limits of 2.0×10^{-3} and 10.0×10^{-3} for horizontal strain and slope, respectively, have been suggested (Kratzsch 1983).

Pipelines. Generally, pipelines are laid below the ground surface and so deform in response to ground movements. If the magnitudes of these movements are such that either the pipeline or its joints or couplings are unable to accommodate the strains and rotations developed in them, the pipeline will fail. In the case of thin-wall welded steel pipe, this failure may

Table 8.9-4 Classification of building damage

Class of Damage	Description of Damage*	Repair	Approximate Width of Cracks, mm†
Negligible	Hairline cracks	None	<0.1
Very slight	Cracks in exterior brickwork visible upon close inspection; possible isolated slight fracture in building	Fine cracks easily treated during normal redecoration	<1
Slight	Several slight fractures inside building; visible external cracks; doors and windows may stick slightly	Cracks easily filled; redecoration probably required; some repointing may be required for weather tightness	<5
Moderate	Doors and windows sticking; weather tightness often impaired; utility service may be interrupted	Cracks may require cutting out and patching; recurrent cracks can be masked by suitable linings; repointing and possibly replacement of a small amount of exterior brickwork may be required.	5–15, or several cracks >3 mm
Severe	Windows and door frames distorted; floor slopes noticeably; walls lean or bulge noticeably; some loss of bearing in beams; utility service disrupted	Extensive work involving removal and replacement of sections of walls, especially over doors and windows	15–25, also depends on number of cracks
Very severe	Beams lose bearing, walls lean badly and require shoring; windows broken by distortion; danger of instability	Major work involving partial or complete reconstruction	Usually >25, depends on number of cracks

Source: Adapted from Wahls 1994.
*Location of damage in the building or structure affects assessment of degree of damage.
†Crack width is only one aspect of damage and should not be used solely as a measure of it.

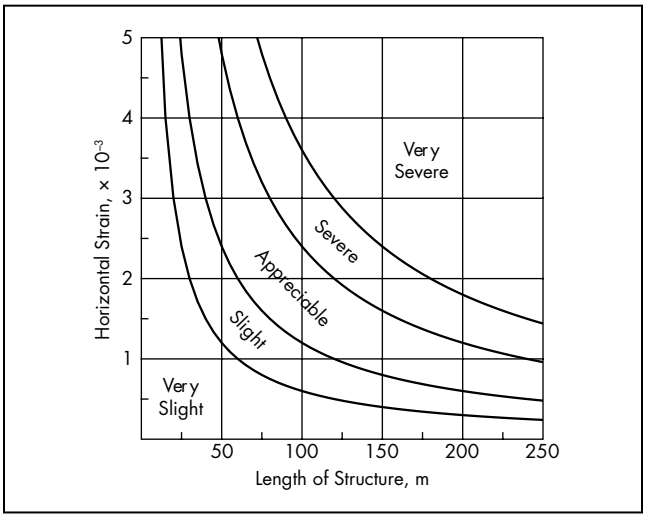
Figure 8.9-13 Building damage in terms of angular distortion and horizontal strain



be one of serviceability, in that the pipe undergoes local buckling; for other cases, it is likely to lead to either interruption or loss of service. The consequences of these depend on the contents of the pipeline and the nature of the service it provides.

The resistance a pipeline offers to ground movements is dependent upon such factors as the mechanical properties of the pipe material, the rotation and pull-out capacity of the couplings, connections to other structural elements, corrosion resistance of pipe and joints, state of repair, and installation technique (Trautmann and O'Rourke 1985; Abdoun et al. 2009). For pipelines constructed with flexible joints, the joints constitute the weakest component in a pipeline. Thus, the location of joints with respect to the subsidence profile together with the rigidity of the pipeline will significantly influence its susceptibility to damage, which is focused on whether subsidence-induced displacements can cause leakage at the joints (Luo et al. 1998). For pipelines constructed with welded, heat-fusion, or rigid bolted joints, the joints are as strong as the pipeline itself, and induced stress becomes the critical factor. Curvature and horizontal strain at the ground surface resulting from subsidence induce stress in a pipeline, and this must be added to the normal pipeline operating stresses.

To minimize subsidence effects, buried pipelines can be uncovered and actively releveled while subsidence is taking place. In all cases where substantial ground deformation is anticipated, suitable pipe layouts should be used to accommodate these; pipeline manufacturers supply standard details for such layouts.

Subsurface Structures

The deformations associated with mining occur at all depths within the rock above an extraction zone, as indicated in Figure 8.9-15, and so subsidence damage is liable to affect subsurface structures in addition to those at the ground surface. As Figure 8.9-15 suggests, the deformations and hence damage experienced by subsurface structures depend on their

Source: Adapted from National Coal Board 1975.

Figure 8.9-14 Structural damage in terms of length of structure and horizontal strain

locations relative to the extraction zone. Of course, mining operations may mean that such a zone will extend laterally, and in this case a subsurface structure may experience a range of strain regimes.

Shafts are the structures most critically affected by subsurface deformations. Although it is possible to locate shafts outside the area of influence of any workings—that is, within a protective shaft pillar—this may lead to uneconomic sterilization of resources for deep mines in laterally extensive deposits such as coal seams. In those cases where shafts cannot be protected within a pillar, it is important that they are designed and constructed to be serviceable under all of the vertical and horizontal deformations that the mining will induce. The tolerable deformations will depend on factors such as type of shaft lining, shaft use (i.e., ventilation or hoisting), and the presence of water-bearing zones.

The effect of subsidence on smaller mine structures, such as access drives and chambers for machinery and services, depends primarily on their position relative to the extraction zones. Below and at the level of extraction, the increased stress due to excavation rather than deformation is the most problematic. With appropriate design, all such structures should remain serviceable throughout mining. Structures within the caving material immediately above an extraction zone are unlikely to survive, regardless of their form of construction. At greater distances above the extraction zone, where the fracturing and deformation of the rock are more limited, it may be possible to design and construct structures that remain serviceable. The same holds true for structures in overlying soils.

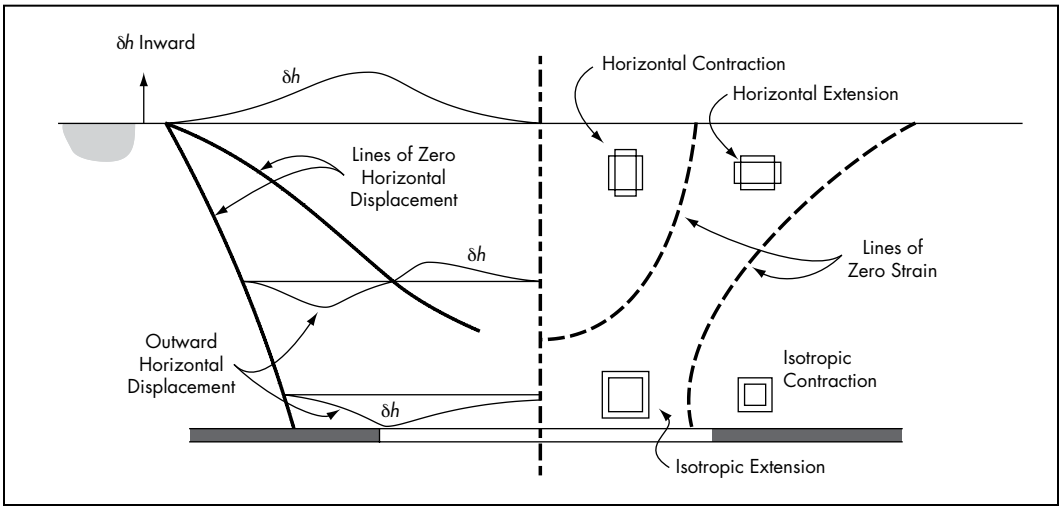
Agricultural Resources

Essentially, subsidence damage caused to agricultural resources is characterized by loss of use or reduced productivity. Subsidence generally affects agriculture through interference with the established hydrology, for example, formation of surface fissures in areas of extensile strain, leading to erosion and reduced water retention; changes to ground slope, leading to either increased runoff and erosion or reduced runoff and waterlogging; disruption of surface drainage patterns and systems; and contamination of groundwater with deleterious minerals such as sulfides and chlorides (Singh and Bhattacharya 1987). Subsidence features such as sinkholes can also affect the hydrology and in extreme cases can lead to sterilization of the resource or loss of livestock and equipment. Although forests and grazing lands are generally less susceptible to subsidence damage than are cultivated lands, the types of damage to which they are vulnerable are broadly similar.

Table 8.9-5 Tolerable deformations for bridges

Movement Type	Tolerable Magnitude	Source
Angular distortion	$4.0–5.0 \times 10^{-3}$	Moulton et al. 1985
Differential settlement	25 mm	DiMillio 1982
	25–50 mm	Moulton et al. 1985
Horizontal	35 mm	Moulton et al. 1985

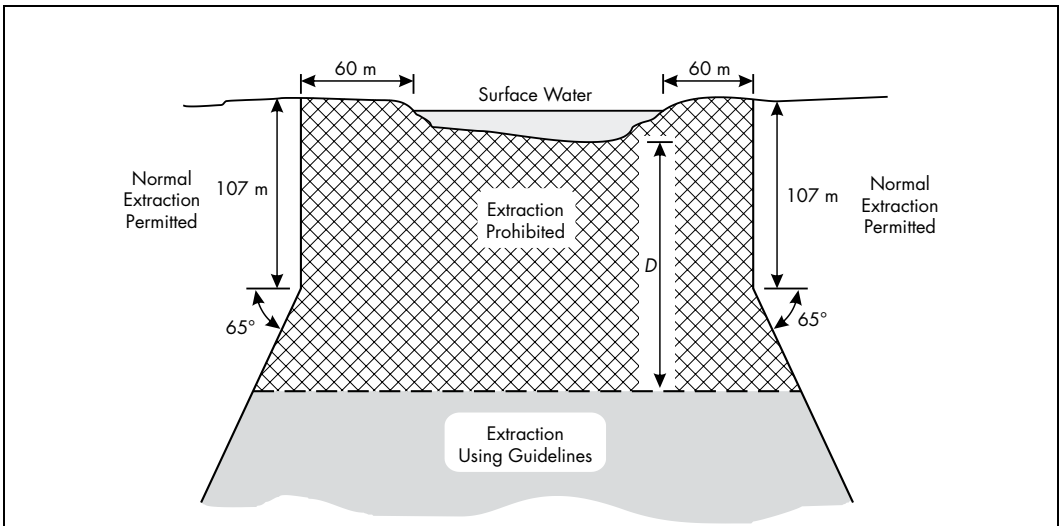
Hydrological Resources



If zones of extensile strain form beneath a body of surface water, there is the risk that fissures may develop in the underlying ground, leading to partial or total loss of water. If the body of water is extensive (e.g., a lake or the sea), then catastrophic inundation of the mine workings can occur. To prevent this latter occurrence, strict conditions are placed on working beneath water, and these can be used to offer conservative guidelines for prevention of subsidence damage. For example, the U.S. Bureau of Mines recommends a safety zone around and beneath any body of surface water, as shown in Figure 8.9-16, and gives guidelines for mining beneath such a safety zone (Babcock and Hooker 1977).

For the case of aquifers, subsidence-induced fissuring may significantly affect the hydrogeological and geochemical regime (Singh and Bhattacharya 1987; Booth 2002). Water table depression is common because all underground openings act as sinks, but the presence of impermeable materials in the overburden may inhibit this. Structural features such as faults and folds and the nature of the rocks themselves may have a significant influence on subsidence effects. Flow rates in surface streams may change, and the general loss of water can lead to reduced plant growth. The increased fracturing and changes in water flow paths can lead to oxidation of a number of minerals, leading to reductions in water quality and hence usability. This can be particularly important for potable water supplies. The limits set for undersea mining will probably lead to conservative conditions for mining beneath aquifers.

Pseudo-Mining Damage



Inhabitants of mining areas may blame mining activity for any damage observed in local structures or lands, especially if compensation is available for mining-related damage. Because damage may be due to effects other than mining, it is important that any other causes are recognized and the true source of the damage properly determined.

Differential settlement can occur in various ways. All foundations settle when first loaded, and so differential settlement can happen when old and new foundations are combined; this commonly occurs when old structures are extended laterally. Foundation settlement is particularly pronounced on clayey soils, and laterally varying soil properties can lead to differential settlement. Likewise, constructing a foundation on fill material, especially when the fill is improperly compacted or the fill only partially underlies the structure, can give the same effect.

Figure 8.9-16 Safety zone beneath a body of surface water

Some clayey soils change volume dramatically as their water content changes, shrinking as they dry and swelling as they become wet. Such changes can occur seasonally, can be the result of leaking water pipes and sewers, or can be due to planting or removal of nearby vegetation. Similar effects occur in fine-grained soils from freezing and thawing effects. As soil volume change by itself leads only to vertical strain, the absence of horizontal strain in a structure can be used to exclude mining as the cause of damage.

Changes to the hydrological regime can similarly lead to damage. Building activity, irrigation, or drainage associated with major excavations can all remove water from the ground. Inadequate or faulty drainage can lead to rising groundwater levels and saturation of the ground. Seepage into subsurface structures can result, as can deterioration of materials such as wood and plaster. However, hydrological changes resulting from mining activity are subsidence damage and must be recognized as such.

Poor-quality construction and building materials can increase the likelihood of damage to structures, as can natural wear and tear. Construction and maintenance records, together with an assessment of anticipated mining damage, can help identify these effects. Poor detailing whereby materials of widely different coefficients of thermal expansion are affixed to one another can lead to either cracking or buckling as the ambient temperature changes. Buckling in hot weather is particularly troublesome for poorly detailed, linearly extensive steel structures such as pipelines and railways.

Many components of buildings and structures are susceptible to chemical attack. In the case of ferrous components embedded in masonry or concrete, the volumetric expansion associated with the formation of rust can lead to tensile splitting and spalling of the host material. With steel window and door frames, cracked glazing may occur. Concrete is susceptible to a number of adverse chemical reactions. The presence of siliceous or carbonate aggregates in concrete can cause alkali–silica or alkali–carbonate reactions, whereby the reactive compounds swell due to absorption of water, and the swelling leads to formation of random patterns of cracking. Sulfate attack from either minerals in the ground or the aggregate, or ions dissolved in groundwater, can lead to similar swelling and cracking.

Dynamic loads from seismic events, machinery in industrial plants, or road and railway traffic can lead to cracking in brittle construction materials and differential settlement due to consolidation of foundation materials. Substantial surface movements on slopes can also be generated by various natural processes, such as freeze–thaw and solifluction (flow of saturated soil down a slope).

Extraction of fluids, particularly from aquifers and petroleum reservoirs, can also lead to substantial subsidence and damage. Such activities are usually licensed and highly regulated, and as such it will be straightforward to determine the degree of damage due to such operations.

Control and Prevention of Damage

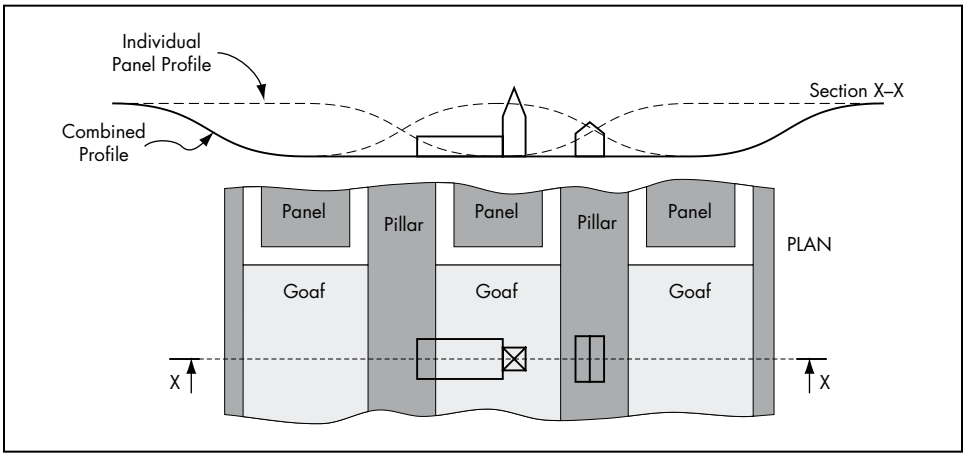
The measures that can be implemented to control and minimize subsidence damage fall into the categories of

- Adoption of particular mining techniques,
- Postmining stabilization,
- Architectural and structural design, and
- Comprehensive planning (Singh 1984).

Each of these comprises a number of devices. In all of these, comprehensive calculations are required to identify the economically optimal approach or combination of approaches.

Adoption of Particular Mining Techniques

The principal measures to consider are partial mining, changes to the mine layout, harmonic mining, backfilling, and changing the extraction rate.



Partial mining generally involves such measures as leaving protective pillars beneath critical surface infrastructure. As noted previously, with deep mines this is liable to lead to sterilization of substantial resources and hence be rendered uneconomic. Any structure supported by a protective zone will remain at its original elevation and thus end up at a higher level than the surrounding area once subsidence has taken place. This may lead to problems with transport links and utilities. In coal mining, partial mining can also involve extracting less than the full thickness of a seam. Apart from subsidence control, this can also be beneficial if either the immediate roof or floor is weak or susceptible to weathering.

Other partial mining techniques, such as electing to use an R&P operation or mining subcritical widths in order to reduce the maximum subsidence, are in some respects changes to the mining layout. Such changes involve locating and orienting extraction zones so as to limit deformations in surface structures to tolerable levels. For example, aligning the center line of a supercritical extraction zone with a surface structure will reduce the effects of changes in horizontal strain.

It is possible to adopt a mining layout whereby sized pillars separate adjacent and parallel extraction zones, so as to generate essentially uniform subsidence across the complete mining area (Figure 8.9-17). Clearly, for optimal benefit, this requires extraction of adjacent zones to proceed simultaneously. This is an example of harmonic mining, whereby extraction of adjacent zones is scheduled so as minimize changes or magnitudes of horizontal strain. As Figure 8.9-5 shows, regions of extensile and contractile strain exist above the rib-side of an extraction zone, and so by simultaneously mining two appropriately separated zones it is possible to substantially minimize the horizontal strain. However, harmonic mining severely constrains the mine operation and, in a mechanized environment, requires substantial investment in mining equipment. As a result, it is generally only applied where protection of surface facilities is paramount and mining costs can be disregarded.

Backfilling a mined void is well known to reduce subsidence. However, in mining operations that generate little waste material, the material for backfilling will need to be imported and the economics of this will need careful assessment. Where suitable material exists, separate infrastructure from that required for extraction may be needed for its emplacement. The reduction in subsidence damage brought about by backfilling benefits all surface facilities and may be particularly appropriate in areas where maintenance of surface drainage regimes is required.

Finally, subsidence development depends to some extent on extraction rate (Goulty and Al-Rawahy 1996). Thus, it is worthwhile to select an extraction rate that minimizes subsidence damage. Generally, higher rates are appropriate for unfractured rocks and lower rates for fractured rocks. However, after the equipment for a mechanized mine has been selected and commissioned, it is difficult to increase the extraction rate should that be found necessary.

Source: Adapted from Singh 1984.

Figure 8.9-17 Pillar widths between adjacent extraction zones sized to give uniform vertical movement

Postmining Stabilization

Stabilization of complete mine sites extending over many hectares may be achieved by backfilling (as previously outlined), grouting, or—in the case of shallow voids beneath derelict or unused land—complete excavation and backfilling. Grouting, which has found widespread application, involves pumping or injecting a cementitious material into the mine void using an array of boreholes drilled from the surface. High-pressure injection may be necessary if the grout is required to penetrate joints or fissures in order to stabilize a fragmented rock mass. Stabilization of individual structures generally involves either localized grouting of the mined void or, in the case of shallow workings, underpinning with new foundation structures, such as deep piles.

Architectural and Structural Considerations

When structures are to be built in areas of known or future mining activity, designs should be adopted that will tolerate the anticipated ground movements. This may include locating and orientating structures so they expose their shortest dimension to a subsidence trough (Figure 8.9-14 shows how damage decreases with decreasing length of structure) and avoiding the surface outcrop of any faults (Figure 8.9-7).

Many design techniques are available to produce structures tolerant of subsidence. For structures that are small in plan, it may be appropriate to adopt a rigid foundation and superstructure that is capable of withstanding differential settlement and horizontal strain. Such structures will tilt as a rigid body, which needs to be fully taken into consideration. In other cases, flexible structures are designed to ride over the subsidence wave associated with a mining face and do so by permitting free ground movement below the foundation, ensuring sufficient superstructure support and withstanding ground deformations without loss of structural stability. Concrete floor slabs no longer than about 18 m, which contain both top and bottom reinforcement and are founded on granular material, are characteristic of these designs. Trenches around the structures, backfilled with granular material, can be used to absorb horizontal strain. With utility buildings such as low-rise industrial units and warehouses, some minor damage may be tolerable. In these cases, it may be most economic to adopt a design that is a hybrid of the rigid and flexible approaches, and undertake minor repairs as required. For structures where avoidance of tilt is crucial, jacks or similar leveling devices may be necessary between the foundation and the superstructure.

Specific design details that are appropriate for domestic buildings include provision of movement joints and use of structural connections capable of withstanding both extensile and contractile strains; window and door frames positioned so as not to weaken the overall structure; internal walls finished with plasterboard rather than plaster; floors and roof secured to the walls; omission of bay windows, porches, and unreinforced masonry; outbuildings detached from main buildings; provision of increased falls to all gravity drainage systems, including gutters; no paving immediately adjacent to buildings; flexible paving materials; and light boundary fences rather than walls.

In the case of existing structures, overall repair expenses may sometimes be reduced if the structures are suitably modified prior to the commencement of subsidence (Kratzsch 1983). Measures that can be taken include provision of temporary supports and/or strengthening to parts susceptible to damage; supporting screens, partitions, and the like independent of the walls and floor; installing wall ties or temporary corbels to roof trusses likely to be pulled from their seats; taping windows, especially those with metal frames, to prevent flying glass; removing stained-glass windows to safe storage; temporarily installing pretensioned steel mesh around exterior walls; excavating trenches around buildings to below foundation level (without disturbing the foundations), backfilling with compressible material and, if required, covering with flexible paving; cutting slots in rigid pavements, floors, and superstructures to leave units about 18 m long; removing parts of structures (e.g., connecting corridors); and removing complete units from within rows of buildings.

In all cases where structures are damaged by subsidence, no repair work should take place until subsidence is complete. As Figure 8.9-5 shows, an approaching working face is preceded by a zone of extensile strain that quickly becomes one of contraction. As a result, cracks should not be filled until all movements have stopped and any debris that has fallen into cracks should be removed before the contractile strain develops.

Comprehensive Planning

Successful implementation of any surface land use or mine plans requires extensive knowledge of the requirements of each and complete collaboration between the various interested parties. It is essential that everyone (i.e., not only the general public but also mine personnel, developers, government and utility officials, and public interest groups) likely to be affected by subsidence is completely aware of all the issues.

Principles to be applied in the planning of development include the following:

- Avoid construction across faults.
- Construct only specially designed structures over shallow workings.
- Locate structures in areas where little strain is anticipated.
- Locate significant individual structures over areas that have either completely subsided or will not be mined.
- Locate linear structures such as canals, motorways, and railways so they can be uniformly lowered along substantial lengths.
- Avoid locating important structures near mine boundaries because coordination with several mine operators and surface landowners is onerous.

It may be necessary to bar construction from particularly risky areas, which should then be used for open spaces.

Development of areas likely to undergo subsidence must be socially and culturally acceptable as well as economically justifiable. This implies that the associated development plans must not only be agreed to by the mine owners and landowners but also be open to public comment prior to adoption. Any changes to such plans require the same public input.

Through a wide range of regulations—including environmental impact assessments, environmental protection, building regulations, safety requirements, and mining regulations—national, regional, and local government authorities exert considerable control over both subsidence and the development of land that is vulnerable to subsidence damage. In various places worldwide, mine owners have statutory obligations to prepare—and gain approval for—subsidence management plans that are circulated to all interested parties for comment and suggestion before being approved. It is likely that in the future this requirement will become universal.

CHAPTER 8.10

Tailings Impoundments and Dams

Thomas Kerr and Bryan Ulrich

INTRODUCTION

This chapter is an introduction to the techniques for and challenges associated with safe storage of waste residues from the mining industry, known as tailings. In most instances, tailings comprise crushed and ground rock and soil particles but in some cases may contain precipitates and/or residual metals or minerals from the ore or the process. Because they often form one of the largest volumes of waste from a mining and milling operation, together with their physical and chemical characteristics, tailings disposal is one of the largest elements of risk management and cost for a mine. Such risk is captured by the following quote: "The management of the disposal of mill tailings is of critical importance to the success of any mining project. Failures of tailings facilities have resulted in loss of life, devastating environmental damage, the closure of mining operations, dramatic declines in share value and, in some countries, the personal liability of the mine management" (Brown 2002).

In recognition of these consequences, the mining industry has, since 1980 or so, focused much attention on tailings management and improving the design, operation, surveillance, and closure of tailings facilities. Methods are now available to provide secure tailings storage over the full life cycle of a facility, but the main challenge is consistency in application. A second challenge is to maintain this momentum and continuously strive for improvement. Society will continue to demand more from the mining industry, and safe tailings management will be at the center of this demand.

The tailings characteristics are unique from mine to mine and are linked to the ore and the processes used to extract the mineral of value from the ore. Tailings produced at a phosphate mine, for example, will behave considerably differently than tailings produced at a gold mine. Similarly, uranium tailings will behave differently than those from an oil sands extraction operation. Each tailings facility is also unique because each site has different geological, hydrogeological, topographical, climatological, and seismological conditions that must be taken into account. The upshot therefore is that each tailings storage facility must be designed, operated, maintained, and ultimately closed in a project-specific manner. Although this requires dedicated resources and continuous planning and attention to detail, the business case for practicing sound tailings management is that a consistently well performing tailings facility adds considerable value to a mine in terms of reduced risk.

This chapter provides a summary of the key considerations related to present-day sound tailings management and is aimed chiefly at engineered, aboveground tailings storage facilities. Information on in-lake disposal, marine disposal, in-pit disposal, and tailings placement as underground backfill is largely beyond the scope of this chapter. The chapter discusses some of the risks associated with tailings storage facilities and their potential mitigation measures, and it presents some of the tools available to the mining industry to manage tailings responsibly through the full life cycle of a mine.

The design, construction, operation, and ultimate closure of a tailings facility can be complex, involving a broad spectrum of scientific and engineering specializations. This chapter does not attempt to cover these in detail. Rather, it should be considered as a starting point in gaining an understanding and appreciation for the types of issues that may need to be addressed in developing and managing a tailings facility. Specialist technical input is readily available from qualified people in the mining industry and companies that have assisted the mining industry with tailings management, and it is strongly recommended that these resources be utilized in any tailings facility project. Notwithstanding, it is important for nonspecialist individuals working with tailings facility design teams to have at least a basic understanding of the numerous considerations that must be adequately developed for proper design, and this chapter is intended to provide that knowledge.

The components of tailings facility design generally include

- Siting studies to select the most appropriate location and configuration;

Thomas Kerr, President, Knight Piésold and Company, Denver, Colorado, USA
Bryan Ulrich, Senior Vice President, Knight Piésold and Company, Elko, Nevada, USA

- Site geotechnical and geological investigations to characterize subsurface conditions and identify potential construction material borrow sources;
- Geochemical studies and modeling to estimate the tailings solids and water quality to assist in developing the environmental management plan;
- Hydrology and hydrogeologic studies to understand surface and groundwater flows, directions, quantities, and qualities to assist in developing the environmental management plan;
- Water balance calculations to define the logic for managing water within, to, and from the tailings facility and to estimate the associated flows and volumes;
- Environmental and social studies to define the prefacility or baseline conditions and estimate the changes or impacts (positive and negative) that may be expected when operations begin;
- Field and laboratory testing to develop engineering parameters to be used in analyses; and
- Engineering analyses to select the various components of the tailings facility, as well as their configurations and specifications, often including the following:
  - Embankments, including zonation;
  - Filters and drains;
  - Basin area lining system and underdrainage;
  - Tailings slurry rheology and dewatering to select an appropriate consistency for deposition;
  - Tailings delivery and deposition systems;
  - Fresh or nonimpacted water management systems, including perimeter diversions; and
  - Process water management systems, including tailings water recovery and reuse.

Often the design of each of these components is iterative with data collection and progresses in steps: from conceptual development to prefeasibility studies to feasibility design and final design. In addition, most tailings facilities are developed in stages and expanded throughout the life of the mine, and thus the design does not occur as a single step but is an ongoing process. These concepts are discussed in greater detail in the following sections.

TAILINGS MANAGEMENT PRINCIPLES

The consistent application of good practice and continuous improvement in tailings management over the life of a tailings facility (in some cases in perpetuity) requires the use of a comprehensive information and resources management system. Such a system, often referred to as a framework for tailings management, addresses the generation, organization, dissemination, documentation, implementation, and continuous upgrading of information, procedures, and policy matters related to a tailings facility over its life cycle. The life cycle of a tailings facility typically includes

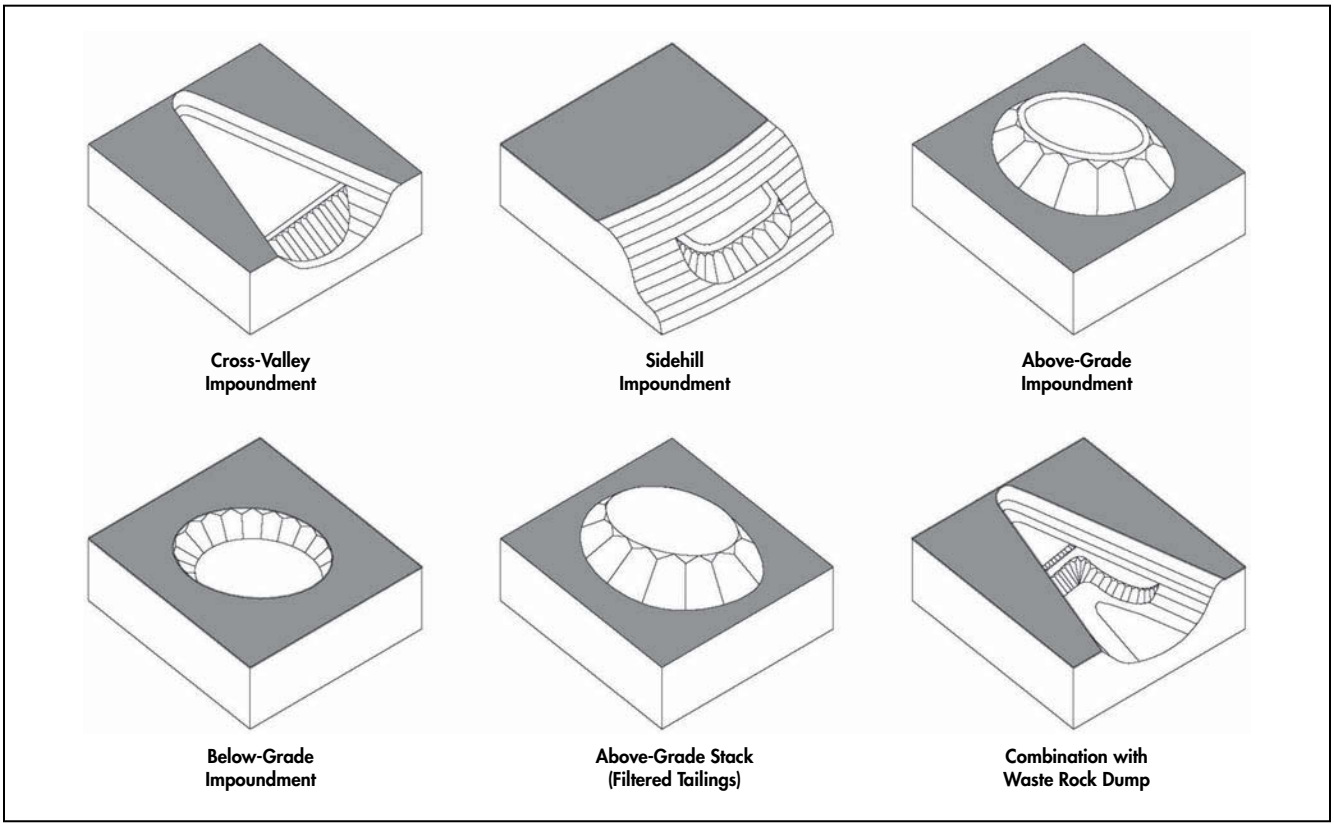
- Initial site selection, planning, and design;
- Construction of stage 1 or the starter facility;
- Operation and periodic construction of subsequent stages; and
- Decommissioning, closure, and postclosure.

A framework for tailings management not only defines the engineering, operation, maintenance, and surveillance activities for the facility, it defines the roles and responsibilities for the personnel involved. This includes management in terms of policy and procedural reviews and the provision of appropriate resources for completing the necessary tasks. The framework also addresses procedures for managing change in personnel, design, and operating criteria and emphasizes proper and consistent documentation through all stages of the life cycle. In addition, the framework discusses engagement and open communication with all identified stakeholders external to the mine.

A good overview of the need for a tailings management framework is provided with examples in the document by the International Council on Metals and the Environment (ICME 1998). The introductory chapter, titled "A Management Perspective," begins with the following statement:

> The challenge to the mining industry is to assure itself, governments, local communities, and other stakeholders that it is capable of meeting its responsibilities to manage tailings deposition in a manner which achieves the highest standards. It is not enough to rely on the fact that the technology is available to ensure all environmental objectives are met. The mining industry must go beyond technical excellence and demonstrate that it has the commitment, and the management systems and skills, to be able to manage tailings in keeping with the expectations of its stakeholders.

An excellent guideline for developing a tailings management system is provided by the Mining Association of Canada (MAC 1998), which describes the five principal elements of the MAC management system that are continuously evaluated throughout the life cycle of a tailings facility. The five elements are



1. Policy and commitment of the company,
2. Planning,
3. Implementing the plan,
4. Checking and corrective action, and
5. Management review for continuous improvement.

In keeping with the ICME statement, it is pertinent to note that two of the five components of the MAC guide are policy and commitment of the company, and management reviews. The MAC guide contains checklists of activities for each component under each life cycle stage to serve as a starting point in developing a framework.

Another guide for developing a tailings management system is provided by the Australian government's Department of Industry, Tourism and Resources (DITR 2007). Section 4.0 of the guide describes the components of a tailings management system, and Section 5.0 describes the guide's use in leading practice.

TYPES OF TAILINGS FACILITIES AND CONSIDERATIONS IN THEIR SELECTION

Because tailings characteristics vary from mine to mine and each site is different, tailings facilities can take a variety of configurations, with different operating principles, methods of delivery and deposition, solids management and facility development, solution management systems, and closure plans. The large majority consists of on-land impoundments developed behind berms, embankments, or dams. Figure 8.10-1 gives some examples.

Source: Adapted from Zahl et al. 1992.
Figure 8.10-1 Types of tailings facilities

In many facilities, the tailings are deposited in slurry form onto sloping beaches developed from previous deposition. Surface water drainage, consisting of tailings process water and precipitation falling on the tailings facility, runs down the slope to a low point on the beach where a surface water pond is maintained, typically at a safe, prescribed distance from the embankment. Water is often reclaimed from this pond for reuse in the mill, and, if the climate is wet, excess water may need to be released after any necessary treatment has been completed.

Control of the beach, including the slope angle, length, and direction, and thus control of the pond location, is accomplished in part by the slurry deposition system. Such systems may consist of a perimeter distribution pipe with numerous valve-controlled offtakes for a high level of control or a few single-point outlets if less control is required. Some facilities using thickened tailings to produce a slightly steeper beach slope may employ a central discharge point or series of points whereby the beach develops radially outward and storage is provided in a conical deposit contained behind a low-height perimeter berm. In some cases where the tailings contain sulfide minerals that may turn acidic if oxidized (common, for example, in porphyry-type ore deposits), the tailings facility must be designed to reduce the risk of acid generation. In such a case, there are two common approaches:

1. Develop the facility as a water impoundment and place the tailings under water (which has a low oxygen diffusion coefficient and thus reduces the risk of oxidizing the tailings). This can only be done in areas where rainfall runoff or other water supply is sufficient to maintain a water cover.
2. Utilize a multiple offtake or spigot-type of tailings deposition system that enables the points of slurry discharge to uniformly blanket each area of the beach and frequently rotate the points around the facility such that each area becomes covered with fresh tailings before the underlying tailings can turn acidic. Usually the tailings at the time of discharge from the mill contain excess alkalinity from the milling process, and the key is to cover the previous tailings layer with the next layer before this alkalinity is consumed.

Other more unique disposal methods may also be adopted depending on site-specific circumstances; some of these are described later in the "Unique Tailings Management Schemes" section.

Materials for Construction

Many types of structures are built to contain tailings (such as embankments) and to protect the surrounding environment (such as liners and drains). Often the embankments are classified by the materials used to construct them and by the shape of the cross section. Embankments may be earth fill or rock fill or both, and in some cases may be concrete- or membrane-faced. Roller-compacted concrete dams have also been used.

The use of waste products from the mining process, including waste rock from the mine and the tailings from the milling process, can be economically and environmentally beneficial in certain cases. For example, waste rock can

often be directly hauled from the mine to the embankment at a relatively low overhaul cost. Tailings can be processed using hydrocyclones or controlled deposition to separate the tailings into coarse and fine fractions, and the coarse fraction can be used for embankment construction. The use of mine waste products can reduce the need for excavating natural materials and thereby reduce the overall area of land disturbance. It is, however, necessary to fully characterize the waste materials before using them in embankment construction. Mineralized waste rock may be subject to oxidation and release of metals that could cause environmental impacts. Oxidation can also lead to mechanical breakdown of rock particles, which can result in a loss of strength. The coarse fraction of tailings can also be subject to oxidation, which would result in acid drainage and/or can be subject to water and wind erosion.

The alternative to using waste materials is the use of borrowed natural materials. The availability of different types of materials—for example, low-permeability soils, sand and gravel, and durable rock—may drive the design of the containment structures. However, excavation of these materials from within the facility's storage basin can have the added advantage of increasing the facility's storage capacity.

Staged Development

Because tailings are generated and deposited progressively over the life of a mine, the development of the storage facility can be sequenced and built in stages. These stages may include dam construction, basin raises, or lateral expansions. The advantages of staged development include

- Deferral of some of the capital costs over the life of the mine;
- Allowance for design adjustments in the latter stages as experience and knowledge are gained from the early stages;
- Allowance for adjustments to account for changing conditions, including hazard consequence, if the land use around the facility changes;
- Increased use of waste rock or drained or cycloned tailings produced over the life of the mine; and
- Facilitation of a slow loading rate to maintain stability in staged development at sites where soft soils form the embankment foundation.

Staged development also has some disadvantages:

- Over time, unless properly managed, some of the original design objectives and supporting information may become lost or unclear as personnel change.
- The quality of the construction may vary from stage to stage if different contractors, materials, and/or quality assurance and control procedures are used.
- These disadvantages can be countered with good documentation, adequate resources at all times through operations, and a commitment by management and the operating staff to continuous improvement. These are all aspects of a sound tailings management system.

The staging sequence and schedule for the facility's operation should be defined at the time of the initial design of the facility. They are usually connected to the mine plan because that determines the schedule of ore production and thus, by association, the schedule of tailings production. The mine plan also determines the waste rock production over the life of mine in case the waste rock is used for facility construction. However, most mine plans change frequently, and, thus, any change that could affect the tailings facility should trigger a review of the staged development and tailings deposition plans. However, care must be taken when making significant changes, because changing the construction materials schedule may affect the following:

- Elevations and alignments of tailings delivery and water reclaim systems
- Dam foundation stability (e.g., if the dam is on a soft clay foundation and its rate of rise increases, an undrained shear failure in the foundation may be triggered)
- Construction material properties for embankments, drainage layers, and so forth (by virtue of the reduced availability of the most suitable materials, which may result in performance changes that could detrimentally affect impoundment behavior)
- Tailings deposit stability (e.g., if the tailings are being relied upon for structural support of a perimeter slope and the rate of rise increases without adequate drainage, an undrained shear failure in the slope may occur)
- Tailings deposit density and compressibility (e.g., if the rate of rise of the tailings increases without adequate drainage, the degree of consolidation of the deposit could decrease as more pore water is trapped in the voids, resulting in a lower density and a longer period for the new rapidly placed tailings to consolidate)

Basin Liner Systems

The requirements for lining a tailings facility basin in part depend on the geochemical characterization of the tailings to be stored, the groundwater characteristics below the basin, and regulatory requirements. Regulatory requirements can be either performance driven or prescriptive in nature. Performance-driven regulations usually set limits on seepage rates or levels of impact on nearby groundwater, whereas prescriptive regulations mandate a specific liner design on the basis of the waste to be contained. In either case, the chemistry and rates of potential seepage from the tailings facility are the motivating criteria in liner design. Sites that may not require a liner, if the chemistry of the fluid is adequate and the regulations permit, will generally meet one or more of the following criteria:

- Low-permeability ground conditions cause the seepage rate into the ground to be low.
- Hydraulic containment is provided by the groundwater regime.
- Tailings are drained with minor or no pore pressures (i.e., filter stack or subaerially deposited tailings in a dry climate) such that the potential is low for seepage outflows.
- Groundwater is deep in the bedrock such that the seepage path length between the tailings deposit and groundwater is long enough to allow for attenuation of flow and elemental constituents.
- Groundwater is of naturally poor quality such that the seepage inflows will not significantly degrade existing conditions.

The difficulty in adopting either the first or second of these criteria is in conclusively demonstrating during the site investigation phase of the design that no discrete leakage pathways will exist (Brown 2002).

For protection of groundwater where tailings impoundments cannot meet one or more of these criteria, it is necessary to design and construct a liner over the impoundment base. Liners may be as simple as the selective placement of low-permeability soil to cover outcrops of pervious bedrock or granular soils. Alternatively, liners may consist of a multilayered system of low-permeability soil and/or geomembrane layers, in some cases with a drain between certain layers for seepage removal. In many cases, it is conventional practice to incorporate a drainage layer above the liner, which functions as an underdrain beneath the tailings to reduce the pressure head on the liner, reducing seepage through the liner. Another benefit of such underdrainage is that it provides bottom drainage for the tailings, promoting accelerated consolidation and ultimately a higher strength in a shorter period of time. However, in some cases the tailings immediately above the underdrain may consolidate to a low permeability, thereby restricting further drainage from the tailings mass. In this case, the benefit of the underdrain is to remove head on the liner only. The drainage layer typically consists of at least a 300-mm (12-in.) thickness of granular material, with perforated pipes at selected intervals within the drainage layer. The pipes are installed to increase the hydraulic flow-carrying capacity of the system. A filter layer, usually consisting of nonwoven filter fabric, is also used to prevent the ingress of tailings solids into the drain.

Low-permeability soil liners have some distinct advantages over geomembrane liners:

- Because of their thickness, the initial seepage front through the liner has significant time to travel.
- Concentration of solutes in the seepage water may be reduced as a result of dispersion, diffusion, and adsorption by the soil.
- The liner will consolidate under loading by the tailings deposit, resulting in further reductions in its permeability.

A disadvantage of soil liners is that seepage takes place through the entire area of the liner. For large facilities, even if the permeability of the soil liner is low, the overall seepage rate can still be significant. Other disadvantages are that soil liners are erodible and subject to desiccation cracking, frost heave, and osmotic consolidation (Brown 2002).

Geomembrane liners are formed of thin plastic membranes. Typical plastics used for these liners include high-density polyethylene (HDPE), linear low-density polyethylene, and polyvinyl chloride. The liners are placed in sheets, and the seams are welded or fused in the field to create a continuous membrane layer. Although the plastic materials are effectively impermeable, the liners invariably have a finite permeability due to leakage through pin holes, seaming defects, and water vapor permeation. Typical leakage rates for well-installed geomembrane liners are approximately 0.3 to 3 m^3/d/ha (30 to 300 gal/d/acre) of liner (Brown 2002).

A composite liner comprises a geomembrane liner placed in direct contact with an underlying soil liner. This combines the best of both liner types (a small unit leakage rate over a small area) and results in leakage rates substantially lower than either liner used individually. A main factor controlling the leakage rate through a liner is the hydraulic head on the liner. For a single liner without an underdrain between the tailings and liner, the head can be significant. The head on the overall liner system can be controlled by the installation of an inner liner separated from the outer or lower liner by a drainage layer. The drainage layer is designed to have sufficient capacity to remove leakage from the inner liner without significant buildup of hydraulic head on the outer liner. The drainage layer between liners may be used as a leak detection system to measure leakage through the upper liner (Brown 2002). In this application, the drainage layer is often termed a *leakage collection and recovery system*.

Embankment Types

Four basic configurations of embankments are used in tailings facilities: downstream, upstream, centerline, and modified centerline.

Downstream Embankment

The downstream embankment is constructed in stages so the centerline of the embankment crest moves downstream with each stage. Because this embankment type uses the largest amount of construction material, it is often the most expensive option. Its performance is completely independent of the physical properties of the tailings deposit, and for this reason in some jurisdictions (such as Chile) this is the only option available for a tailings embankment.

Upstream Embankment

The upstream embankment is constructed in stages with each stage constructed as a berm on the tailings beach immediately upstream of the previous stage. The centerline of the embankment crest therefore moves upstream with each stage. Because this embankment type uses the least amount of construction material, it is often the lowest-cost option. Upstream dams rely entirely on the strength of the tailings deposited upstream of the berm for support. A large proportion of tailings facilities constructed using the upstream method have utilized a spigoting method of deposition to produce a coarse fraction on the upper beach for strength. The spigoting method consists of numerous, closely spaced, and independently controlled offtakes that allow the tailings slurry to be deposited in a low-velocity manner over the beach for maximum segregation so that a free-draining, coarse sand deposit forms in the structural zone. Major failures of embankments constructed by the upstream method for the most part have been due to a lack of drainage in the structural zones and have led to the ban of upstream construction methods in some jurisdictions. Interestingly, no upstream dam has failed that has been rigorously designed using modern engineering principles to ensure that the embankment is adequately drained and the phreatic surface is controlled.

Centerline Embankment

The centerline embankment is constructed in stages so the location of the centerline of the embankment crest does not change with each stage. The upstream toe of each embankment stage is constructed slightly over the tailings beach, but the majority of each new stage is founded on the previous embankment stage. This method relies on some strength and structural support of the tailings for the upstream slope but does not rely on the tailings strength for overall stability. Liquefaction of the tailings as a result of earthquake loading could result in some localized instability of the upstream slope of the most recent stage, but this would not result in significant damage to the structure. The centerline method is a compromise between the higher-cost downstream embankment and the higher-risk upstream embankment.

Modified Centerline Embankment

A variation of the centerline embankment is the modified centerline embankment. In this method, the embankment crest centerline moves slightly upstream, thus reducing the quantity of construction materials required in the downstream shell zone of the embankment. Modern analytical techniques are used to determine how far the embankment crest centerline can be moved upstream with staged construction and still keep the embankment independent of the tailings' strength for overall stability. These techniques have resulted in significant cost savings without compromising embankment stability. Many modified centerline embankments have been designed, permitted, and constructed in Canada, South America, and the United States.

Liquid–Solid Separation in the Tailings Facility

A key factor in the selection and design of many tailings facilities over the last 20 to 30 years is liquid–solid separation, which has the benefits of

- Increasing the density of the deposit, thus increasing the storage efficiency and reducing the potential for liquefaction under static conditions and dynamic loading;
- Increasing the stability of the deposit because the shear strength of deposit tailings is derived from particle-to-particle contact of the solids (the liquid has no shear strength);
- Reducing the amount of long-term drainage from the deposit, which requires collection, monitoring, and release, possibly continuing well after the facility's closure (possibly requiring water treatment);
- Reducing the amount of long-term consolidation of the deposit, thus reducing the amount of settlement that the final surface may undergo, which can undermine the integrity of the cover; and
- Recovering as much of the liquid as possible from the tailings so that it can be recycled to the mill for reuse in the process, thus reducing the amount of water required to be added from an external supply. This is often the main factor in dry climates where outside water sources may be scarce.

In some cases, enhanced liquid–solid separation can also result in a slightly steeper slope angle on the deposit, which may improve storage efficiency, but caution should be exercised because the actual slope angle is affected by a number of factors and may be less steep than expected; and a steeper slope may be more susceptible to liquefaction.

Enhanced liquid–solid separation can be achieved in a few ways. One is a deposition method that discharges the slurry at a low velocity over the deposit, allowing the solid particles to drop out of suspension into the next layer while the liquid flows down the slope. In this approach, the tailings slurry is introduced at the top of the deposit through a number of adjacent but concurrently operated offtake points (often termed *spigots*) such that each point discharges a relatively small flow rate onto the deposit. By strategically relocating the points of active deposition, each newly deposited layer can be allowed to consolidate, and, in dry climates, to air dry, further enhancing liquid–solid separation while deposition is occurring elsewhere. This approach is sometimes referred to as the subaerial method. If a significant amount of clay is in the tailings, the addition of a flocculant to the slurry just before subaerial deposition may further enhance liquid–solid separation. Mechanical dewatering by thickeners (often in concert with flocculant addition) is another method. In recent years, significant advancements have been made in thickening technology and product development such that mechanically thickened tailings are becoming more common.

Maximizing liquid–solid separation may not always be the objective of a tailings facility design. For example, in wet environments where precipitation or run-on into the facility together with the separated liquid from the tailings produces an amount in excess of that needed for recycle, less emphasis may be placed on liquid–solid separation and more on securely storing the higher-moistures content tailings. In this case, the objective is to reduce the amount of excess water generated in the facility that requires releasing.

Tailings Continuum

The consistency of a tailings slurry has often been defined in terms of the weight of solids in the slurry as a percentage of the total weight of the slurry, which is termed the *slurry density* and expressed as percent solids. This convention is being amended, however, because the weight of solids is a function of the specific gravity of the parent material, and two slurries containing the same amount of water will have different solids contents if the specific gravities of the solids are different. The convention now being adopted is to use yield stress, a strength parameter, of the slurry as the indicator of its consistency. In rheological terms, *yield stress* can be defined as the shear stress that must be applied to the slurry in order to initiate its movement, which is applicable to the design of a transport system. In geotechnical terms, yield stress can be defined as the undrained shear strength of the slurry at rest, which is relevant to the slope of a beach on which a fresh layer of tailings will cease flowing.

In any tailings slurry, as water is removed progressively and the percent solids increases, the yield stress will also increase in a nonlinear relationship. Tailings in the higher-water-content region consist of conventional (low density), thickened (moderate density), and heavily thickened (high density) slurries, and have yielded stresses that are generally between 0 and 200 Pa. As the degree of thickening increases progressively across this region, the propensity for sedimentation and segregation of the solid particles from the slurry reduces. These tailings can typically be transported by centrifugal-type slurry pumps, although at the top end of the range, positive displacement pumps may be necessary.

Tailings with higher solids concentrations have a paste consistency, which is sometimes defined as nonsegregating. Typical yield stresses for paste are often up to several hundred Pascals, and these tailings typically require positive displacement–type pumps for transport. The liquid limit of the tailings is often in the paste region.

Tailings with consistencies greater than heavily thickened consist of filter cake material and are typically placed and compacted into the tailings facility by mechanical instead of hydraulic methods. Dewatering to a cake consistency requires filters, typically vacuum or press-type filters.

The broad spectrum of tailings consistencies, from low to high density, is termed the *continuum* because the boundaries are not well defined. Historically, tailings have been produced and disposed at the low-density end of the continuum. However, over the last 10 to 20 years there has been an increasing move toward thickened and paste disposal in concert with a significant advancement in the technology to dewater tailings. The key advantage of thickening

is increased water recovery for reuse, although reduced long-term consolidation of the deposit and/or higher storage densities may also occur. But on a case-by-case basis, these factors need to be weighed against the cost of thickening, transporting a higher-yield stress material, and managing additional recovered water. Thus the selection of any tailings methodology on the tailings continuum is the subject of trade-offs.

One challenge in the design of a tailings facility and delivery system is that the rheological properties of the tailings can change between the plant and disposal facility. Thus, it is important to begin the design at the point of deposition into the tailings facility and design the tailings facility using criteria consistent with the desired point on the continuum and then work upstream to the plant. The effects of shear thinning of the slurry or paste in the pipe and pumps must then be accounted for when designing the thickener.

SITE CHARACTERIZATION

Climate and Hydrology

The climate and hydrology of a region are influenced by patterns of temperature, wind, and atmospheric moisture, and patterns of surface runoff, respectively. The total amount and timing of runoff dictate many aspects of a tailings facility, ranging from environmental concerns (such as what level of impact the facility might have on water quality) to engineering concerns (such as how much storage is required for temporary storage of seasonal or storm runoff, or whether stormwater diversions or a spillway are needed, and, if so, how large they should be).

Typically, little or no site-specific climatic and hydrologic data are available for most development sites at the time of initial design. In most instances, a data collection program is initiated during project feasibility and environmental impact studies, but, to a large degree, these data are for short-term periods and of limited use at the time of project design. As a result, the climatic characterization of a project area is generally conducted on the basis of regional data, which may be extrapolated to the project site according to known or suspected weather patterns, similarities of watershed characteristics, and an understanding of the fundamentals of hydrometeorologic systems, including lapse rates, orographic effects, and rainfall/runoff mechanisms. A correlation of the regional data to the short-term site-specific data is often attempted to support the extrapolation.

The hydrometeorologic characterization of a site typically involves estimates of temperature, evaporation, precipitation (rain and snow), and runoff on both average monthly and annual bases, including some measure of variation. Also required are values of extreme precipitation and flow, usually on a daily basis and usually presented in terms of likelihood of occurrence. In addition, in colder climates, patterns of snow accumulation and melt are needed, often with depths of frost penetration and ice accumulation.

Geology

The regional geology typically defines bedrock types (lithology and alteration) and structure (faults and locations, unconformities, and fracture types and their frequencies, orientations, and strengths) in the site vicinity. Specific site investigations should then be carried out to investigate and accurately map these features on a more concentrated scale. Their location and characteristics can be important to the site characterization and type and configuration of tailings facility to be built. Regional geology maps can usually be obtained from various government agencies. Generally, smaller-scale maps in the order of 1:1,000,000 are easily obtained. The availability of larger-scale maps (i.e., more highly detailed maps), such as 1:250,000 or 1:100,000, is more variable because of the economical, political, and geological characteristics of the area. Many industrialized countries have government geology departments at the federal and provincial or state level, although many developing countries only have limited geological data at the federal level. In addition, the size and population of the country, state, or province may dictate the map scale. Another source useful for gathering regional information is the Internet. Many countries have maps in digital form for viewing and printing.

After regional maps have been obtained, it is recommended that a qualified person carry out a field reconnaissance to verify the mapping. Larger-scale mapping should be carried out if these maps do not exist or the geological or structural setting at the proposed site is complicated. It is important at this stage to identify weak or otherwise unfavorable bedrock units or active faults. These identifications will aid designers and form the framework for detailed site investigations.

Terrain Analysis

Terrain analysis assists in characterizing the origins of and landforms associated with the surficial or near-surficial materials (soils and rocks) in the vicinity of the tailings facility. This analysis is designed to identify and classify material types (potentially for construction) and to identify potential natural hazards that could impact the tailings facility. The terrain analysis will not necessarily determine accurate characteristics of the materials but is a useful tool for defining where detailed site investigations are required.

There are two levels of terrain analysis. The first is at a desktop level and comprises aerial photography. The second involves ground reconnaissance and mapping to verify or modify the observations made from the air photos. The objectives of these two levels are to define as many of the following attributes as possible: bedrock geology, quaternary geology, landforms and geomorphology, soil types, weathering, erosion and deposition modes, slope instability, climate effects, vegetation, hydrogeology, geotechnics, volcanic activity, seismicity, natural dams, human activity, and land use. This list is quite exhaustive, and many of these attributes will not be present at a given tailings facility site. However, it is prudent to initially check for all of them.

In areas of steep, wet terrain, it is recommended that 1:15,000-scale air photographs be used for the first level of reconnaissance. Steep terrain is generally characterized as having significant portions of the area with slopes greater than 50% or 27°. If drier, flatter terrain is present in the site vicinity, 1:40,000-scale air photographs are adequate. If reconnaissance flights and air photo production can be acquired, this exercise can be completed in conjunction with topographic surveys.

The second level of terrain analysis comprises ground verification of the air photo interpretation. The requirements for ground reconnaissance are based on the terrain attributes identified in the first stage. Generally, areas where the slopes are greater than 50% require foot traverses, while areas of flatter terrain can be completed by ground checks supported by helicopter or vehicle. Unstable or potentially unstable areas

identified during the air photo interpretation must be checked in detail by foot traverses and 1:5,000-scale mapping.

The results of the terrain assessment should be made into a terrain hazard map, outlining areas of potential natural hazards or geological risks, construction materials, and targeted dam sites.

Geotechnical Site Investigation

Geotechnical site investigations for a tailings facility need to be carefully planned with an initial design concept in mind and should be conducted to an increasing level of detail as the facility moves from scoping level to preliminary and on to detailed design. Further, site investigations should investigate the geologic interpretation of the site developed during the previous site-characterization exercises. The key objectives of site investigations for tailings facilities are to

- Confirm potential natural hazards identified during the terrain analysis phase;
- Characterize foundation materials through sampling and laboratory index tests, such as particle size distribution and plasticity;
- Characterize existing groundwater conditions through drilling investigations, including in-situ hydrogeologic properties of the foundation soils such as permeability;
- Determine geotechnical properties of the foundation soils, such as shear strength, compressibility, and permeability; and
- Confirm availability and characteristics of the earth-fill or rock-fill materials required to construct the facility according to the proposed design concept, including mine waste materials from open-pit development.

Typically, test pits, drill holes, and seismic refraction (in some cases, electrical conductivity or gravity) surveys are sufficient tools for site investigations for detailed design of a tailings facility. Test pits are used to investigate potential construction material borrow sources and the shallow foundation conditions for the tailings dam or basin. Test pits alone may be sufficient for scoping level designs. To excavate test pits, hydraulic excavators with minimum 5-m (16.5-ft) depth of excavation are typically used. Drilling investigations of the foundation are required for the feasibility and detailed design of a tailings dam.

A properly planned and executed site investigation includes careful selection of the drilling method(s) to ensure the necessary data are collected. It is strongly recommended that a qualified geotechnical engineer supervises all drilling activities to ensure sampling and testing are completed at appropriate locations and following appropriate methods, and that appropriate information is being collected.

Electronic cone penetrometer testing (CPT) is now commonly used to gain continuous profiles of in-situ soil properties in sands, silts, clays, and tailings deposits. Often these tests are carried out using a tip fitted with a water pressure transducer to record pore pressures (CPTu) and in some cases the CPTu can be equipped to carry out in-situ seismic tests in which the cone is equipped with a geophone to record the arrival of shear waves from a surface source. CPTu is an excellent method to extend the data and fill in gaps from more traditional drilling, sampling, and standard penetration testing (SPT). For gravelly materials, the Becker drill is a common method that provides samples and penetration data that can be correlated to the SPT.

Samples collected from the investigations are tested in a soils laboratory for index, strength, compressibility, and permeability characteristics. For the latter two types of tests, undisturbed samples of foundation materials are recommended. For materials from potential borrow areas, index tests will likely include moisture density or compaction testing to confirm their suitability for placement in the tailings dam, basin liners, or drainage systems. Strength and compressibility tests are also required for fill materials and should be performed on remolded samples compacted to the density criteria that will be required by the construction specifications. Permeability tests are required for materials to be used in high- or low-flow applications such as filter drains or core and liner zones, respectively.

Seismicity

In regions of high or even moderate seismicity, often the seismic loading controls the stability and thus design of a tailings dam. Consequently, a seismicity review of the region where the project is located should be carried out during the initial stages of project planning. Initial studies at the conceptual or prefeasibility level may be limited to a review of existing information or maps regarding the regional seismicity, and preliminary seismic design parameters may be obtained from seismic hazard maps for the region, if available. In some areas of the world these are available through the U.S. Geological Survey and/or the Global Seismic Hazard Assessment Program, both of which have Web sites. However, for feasibility and final design stages of a tailings facility, more sophisticated methods of analysis are typically required, including both deterministic and probabilistic methods of seismic risk analysis.

A probabilistic analysis defines a unique probability of occurrence for each possible level of ground acceleration experienced at a site, using methodology based on Cornell's probabilistic analysis (Cornell 1968). The likelihood of earthquake occurrence within defined seismic source zones is determined by examining seismicity data. Using historical earthquake records for the region, magnitude–frequency recurrence relationships are established for each potential earthquake source or fault zone.

Unlike the probabilistic analysis, the deterministic method does not account for the likelihood of a predicted ground acceleration occurrence. Seismic source zones or fault systems in the region are defined, and maximum earthquake magnitudes are assigned to each source based on the characteristics of the fault, including type and length. Expected ground motions, including acceleration, are then transmitted to the site using attenuation relationships. The maximum acceleration produced by this procedure is referred to as the maximum credible acceleration and the corresponding earthquake as the maximum credible earthquake (MCE). The MCE is defined as "the largest reasonably conceivable earthquake that appears possible along a recognized fault or within a geographically defined tectonic province under the presently known or presumed tectonic framework" (ICOLD 1989).

The seismic design parameters selected for the design of a tailings facility are dependent on the seismicity level in the region and the geologic and tectonic conditions at and in the vicinity of the site. They are also dependent on the hazard consequence classification of the dam or facility. For high or very high consequence facilities, the MCE may be adopted as the maximum design earthquake (MDE), which is often defined as the earthquake that a facility must be able to withstand

without catastrophic failure. For lower-consequence facilities, a lesser earthquake from the probabilistic analysis may be selected for the MDE. Another design earthquake is the operational basis earthquake, which the facility must be able to withstand without impeding its operation and is usually selected from the probabilistic analysis.

ALTERNATIVES ANALYSIS AND SELECTION

The selection of a site, configuration, and in some cases the design basis for a tailings facility requires a systematic and defensible method to properly account for the pertinent factors that apply. These often span a wide range of subjects and in some cases may conflict with each other. Usually a few steps are involved. The first is the identification of potential facility sites and configurations on topographical maps. Preconcept level sizing is based on the anticipated tonnage of tailings to be stored and an estimate of the in-storage density. The second step is often a fatal-flaw assessment of the identified options to eliminate those that for one reason or another could not be developed. Fatal flaws may include

- A site on land that cannot be acquired or developed (possibly because of land status or ownership, restricted areas, an ecosystem or water resource that cannot be affected, a community on or adjacent to the site that cannot be relocated, or utilities that cannot be moved); and
- A site at risk of being affected by a natural hazard, such as a major active fault, unstable ground, or a major avalanche or flow debris chute.

The third step in an alternatives analysis is to compare and rank the options remaining after the fatal flaw assessment by scoring them against appropriate comparative criteria in a structured matrix. Depending on the level of detail required, the matrix may be relatively simple or complex. In the early stage of planning, a simple approach may be warranted if the list of comparative criteria is short (due to limited information on the project) or if the initial number of options is large. A more detailed comparison of a few selected options can then follow.

A more detailed comparison uses a tiered multiple-accounts matrix method, often utilizing a three-tiered structure for grouping similar or related criteria together (Robertson 2004; Kerr et al. 2003). The first tier consists of the major account headings, such as technical, economic, environmental, or social. The second tier consists of subaccount headings, which are grouped under each of the account headings; for example, "capital cost of the initial stage of the tailings facility," which would be positioned under the economics account. The third tier drills down further under the subaccounts level and contains the specific comparative criteria that will be used to score and rank the options; for example, "capital cost of the initial stage dam" under the "capital cost of the initial stage of the tailings facility" subaccount. Numerical weights are applied at the three levels of the matrix to reflect the relative importance of one criterion, subaccount, or account to another criterion, subaccount, or account at the same level but not across levels. Individual scores are then assigned to each option at the criteria level, and the results are calculated as weighted output scores for each option at the subaccounts, accounts, and overall levels.

At the overall (or upper tier) level, a comparison of the weighted output scores gives the overall ranking of the options. At the accounts and subaccounts levels, the comparison gives the ranking of facilities for each account or subaccount. Understanding which options are considered better or worse at these levels may be just as important as at the overall level. The multiple accounts matrix approach also allows for the calculation of *discriminatory values* at the subaccounts and accounts levels, which define the accounts or subaccounts that had a greater or lesser influence on the weighted scores at these levels.

One of the greatest advantages of the multiple-accounts approach is that by applying the weights in the manner described, experts in different fields can provide input to only their appropriate accounts or subaccounts, with others providing input elsewhere while not biasing the overall results.

In many regulatory environments, it is now often mandatory to demonstrate that a program of options identification, analysis, and appropriate ranking was adopted to support the selection of the site and design basis for a tailings facility. The multiple-accounts matrix approach, if used properly, can serve as a thorough, transparent, and defensible tool for this.

Table 8.10-1 Terms and definitions associated with the solid, liquid, and air phases

Solid	Liquid	Air
V_s = volume of solid particles	V_w = volume of water	V_a = volume of air
W_s = weight (mass) of solid particles	W_w = weight (mass) of water	W_a = weight (mass) of air (negligible, taken as zero)

CHARACTERISTICS OF TAILINGS

Tailings are often composed of solid, liquid (usually water), and gas (usually air) phases in various relative volumes or masses. The liquid and air phases occupy *voids* between the solid particles. If air is absent, the voids consist only of liquid, and the tailings are said to be *saturated*. Some useful terms and definitions related to these phases are shown in Table 8.10-1.

The total weight or mass of tailings is composed of the W_s and W_w components, while the total volume of tailings is made up of V_s, V_w, and V_a components.

The water or moisture content of tailings is defined as the ratio of the weight or mass of water to the weight or mass of solids and is usually expressed as a percentage. It can be defined as

$$\text{moisture content (mc)\%} = (W_w/W_s) \times 100\%$$

The bulk density of tailings at a point in a deposit is defined as the total weight or mass of the tailings in a unit volume and can be expressed as

$$\text{bulk density } (\rho_b) = (W_s + W_w)/(V_s + V_w + V_a)$$

The dry density of tailings at a point in a deposit is defined as the weight or mass of solids in the tailings in a unit volume and can be expressed as

$$\text{dry density } (\rho_d) = W_s\,(V_s + V_w + V_a)$$

Dry density is a commonly used parameter in the design and monitoring of a tailings deposit because the quantity of tailings produced from the mill is usually defined in dry tons (or metric tons) and is derived from the dry weight of the ore feed after the mineral of interest is removed.

Bulk and dry density can be related to each other by the moisture content using the relationship

$$\rho_b = \rho_d * (1 + (mc/100))$$

The void ratio of tailings is defined as the ratio of the voids volume in the tailings to the solids volume and can be expressed as

$$\text{void ratio (e)} = (V_w + V_a)/V_s$$

The degree of tailings saturation is defined as the ratio of the water volume in the tailings to the voids volume and is usually expressed as a percentage. It can be expressed as

$$\text{degree of saturation } (S) = [V_w/(V_w + V_a)] \times 100\%$$

wherein saturated tailings ($S = 100\%$) have no air in the voids and thus $V_a = 0$.

The specific gravity of tailings solid particles is defined as the ratio of the weight of solid particles in the tailings to the volume of the solid particles and can be expressed as

$$G_s = W_s/V_s$$

where G_s is specific gravity.

The terms previously described can be interrelated using the following equations:

$$(e) = (G_s * \rho_w/\rho_d) - 1$$
$$\rho_d = (G_s * \rho_w)/(1 + e)$$
$$\rho_b = (G_s * \rho_w) * (1 + mc)/(1 + e)$$
$$S = mc * G_s/e$$

where ρ_w is the density of water (1 t/m^3).

Plasticity and Related Issues

The tailings continuum described previously was based on rheology. From a geotechnical point of view, tailings are generally considered to exist in four states of consistency (from high to low moisture content): viscous fluid, plastic, semisolid, and solid. If the tailings contain clay minerals, the plastic range is significant. A property associated with the clay minerals, *plasticity* can be defined as the ability of the clay to deform without cracking. Plasticity results from the electrochemical behavior of the clay particles and the attractive bonds that remain between them even after relatively large deformations. It is often quantified by the plasticity index (PI), which is the difference between the boundaries of the following consistency states:

- Liquid limit (LL) is the moisture content of the clay at the high end of the plastic range, at the boundary between the plastic and viscous liquid states. Remolded clayey materials at this boundary have a low, undrained shear strength, often in the 1-to-2-kPa range.
- Plastic limit (PL) is the moisture content of the clay at the low end of the plastic range, below which the clay changes from a plastic consistency to a moist semisolid material or cake. Remolded clayey materials at this boundary often have an undrained shear strength in the order of 100 kPa (or possibly higher).

The PL and LL values are termed the *Atterberg limits* and are determined from tests in which samples of the material are remolded (deformed plastically) under defined procedures. Given the correlations with remolded strength, the Atterberg limits define the range of moisture contents over which the strength of the material increases by approximately 100 times. Most tailings of hard-rock origin have a low clay content and thus low plasticity. In terms of moisture content change, the difference between the higher and lower end of the plasticity range is low. In some cases the difference between the PL and LL is zero, and these tailings are termed *nonplastic*.

From a tailings engineering perspective, the important considerations related to PL, LL, and PI are

- Tailings with a low PI (e.g., of hard rock or low clay content) can gain significant strength with only a minor reduction in moisture content; and
- Tailings with a high PI require a significant amount of water to be removed, usually under load or evaporation (the process of consolidation), to gain significant strength.

The boundary between the semisolid and solid states is defined as the shrinkage limit, which is important because it defines the moisture content below which no further volume reduction or shrinkage will occur with additional drying or moisture loss. At this point the particles have reached such a dense packing that any further moisture loss results without a further reduction in void ratio. The result is a reduction in saturation as air enters the voids to replace the ongoing water loss.

Permeability and Drainage

Basic Principles for Flow

The amount of flow that can pass through saturated porous media such as tailings is dependent on

- Permeability coefficient of the tailings, which is defined as the amount of flow that can pass through a unit cross-sectional area of the tailings under a unit hydraulic gradient; and
- Hydraulic gradient, which is the amount of head loss that takes place along the flow path divided by the length of the flow path.

Darcy's equation defines this relationship:

$$Q = k * i * A$$

where

Q = volumetric amount of flow per unit of time (m^3/s)
k = coefficient of permeability of the tailings (m/s)
i = hydraulic gradient, which is equal to the change in head or the head loss divided by the flow path length, or $\Delta h/\Delta l$
A = cross-sectional area of flow (m^2)

The permeability coefficient of tailings is influenced by the particle sizes and their distribution, density (or void ratio), and degree of saturation of the material.

Shear Strength

Loading Cases

The proper analysis of stability of a tailings facility structure requires use of the most suitable loading case(s), shear strength parameters, and drainage conditions. The loading cases may include

- Long-term, steady-state conditions;
- End of construction conditions;

- Rapid loading (or unloading);
- Staged construction conditions;
- Earthquake loading;
- Postearthquake conditions;
- Rapid drawdown; or
- Hybrid cases.

Not all of these cases are addressed in this text, and the reader is directed elsewhere for further reading.

Total and Effective Stress Shear Strength Parameters

Total stress is defined as the total amount of force applied to an area of material divided by the area, whereas effective stress is the portion of the total stress that is taken up in particle-to-particle contacts. The difference between the two is the pore water pressure. Thus, total stress is defined without regard to the portion of the stress that is carried by the soil particles and the portion carried by the water. It is the same for the undrained and drained conditions.

The shear strength of soils or tailings is controlled by effective stress, whether failure occurs under drained or undrained conditions. The relationship between shear strength, or fully mobilized stress (S), and effective stress (σ') can be represented by a Mohr–Coulomb strength envelope. The relationship can be expressed as

$$S = c' + \sigma' \tan \theta'$$

where

c' = effective cohesion
σ' = effective stress
θ' = effective stress angle of internal friction, typically referred to as the effective stress friction angle

Strength envelopes for soils or tailings are established by performing shearing tests on samples consolidated to a range of effective confining stresses, and if the tests are triaxial, the results can be plotted on a Mohr stress diagram. Effective stress and total stress envelopes can be established.

Seismic and Liquefaction Considerations

Tailings liquefaction is a major challenge in the design of tailings facilities and can be triggered by both cyclic and static shear stresses. Liquefaction occurs when a soil loses a significant portion of its strength or stiffness for a relatively short time but long enough for slope-stability or bearing capacity failures to occur. Because it is unpredictable and occurs under various conditions, liquefaction has been viewed as a difficult problem. There are many recorded cases of liquefaction failure of mine waste and quite likely many more undocumented cases (Been and Li 2009).

Liquefaction, including occurrences due to earthquake loading or from static causes, requires close assessment, typically by specialist practitioners. Various methodologies assess the liquefaction potential of mine tailings. In-situ methods are often employed for such an assessment, using applications such as the SPT, CPTu, seismic CPTu, field vane shear test, Becker hammer test, or self-boring pressure meter. Various laboratory approaches also assess the liquefaction potential of soils, such as cyclic simple shear and cyclic triaxial testing.

Typically, a tailings facility designer will assess the likelihood of liquefaction due to earthquake shaking and static loading. For earthquake-induced liquefaction, laboratory or in-situ testing results are typically required, with in-situ testing often the preferred method. An example approach for assessing earthquake-induced liquefaction is the use of the CPT piezocone, a tapered electronic probe that is advanced into a soil deposit typically using a hydraulic ram, such as a geotechnical drill rig. The piezocone is equipped with load cells and transducers to measure the device's penetration resistance at its tip, friction along its side shaft, and pore pressures that develop during penetration. This pore pressure has been termed *dynamic pore pressure* by some practitioners, but the authors suggest it should be termed *quasi-static pore pressure*, because the piezocone is a quasi-static test. By pausing the penetration, the quasi-static pore pressure is allowed to dissipate to reestablish the equilibrium pore pressure, which represents the in-situ pore pressure at that point in the deposit.

By conducting several of these dissipation tests, it is possible to develop a pore pressure profile throughout the deposit's depth. This profile is useful in understanding the effective stresses in the vicinity of the probe and helps assist to establish whether the material is contractive or dilative. Data from the piezocone tests are combined with parameters pertaining to the design earthquake event (i.e., earthquake magnitude and ground acceleration) to complete the analysis. Procedures for completing an earthquake-induced liquefaction analysis use piezocone, seismic CPTu, SPT, and Becker hammer (Harder and Boulanger 1997). The art and science of liquefaction assessment is continually developing, and the National Center for Earthquake Engineering Research (NCEER) report has been updated several times (Robertson and Wride 1998; Robertson 2004; Arango 1996).

Once the likelihood of the occurrence of earthquake-induced liquefaction is established, it is necessary to develop strength properties for the soil zones that are predicted to liquefy (Yoshimine et al. 1999; Olsen and Stark 2002). The Yoshimine method produces a more conservative analysis (Robertson 2004).

Geochemistry

Characterization of both the solid and solution portion of the mill tailings is an essential step in the development of the tailings management plan. The acid-generating potential and metal-leaching characteristics of the solid tailings mass and the chemistry of the liquid effluent will affect the design of the tailings containment facility and be important considerations in solution management and reclamation planning. Acid rock drainage (ARD), metal leaching, and contaminant/metal release from mine tailings facilities are recognized environmental concerns. To ensure that natural aquatic systems are not significantly degraded or that human or other receptors are not impacted, it is important to fully understand the tailings material by conducting a thorough waste characterization program.

A phased approach to waste characterization is often a prudent way to proceed. The relatively inexpensive static tests can be performed on a large number of tailings solids samples, using the results of the initial testing to plan for additional, more detailed testing requirements. This stage of the characterization program will include acid–base accounting (ABA) or equivalent to determine the relative balance of potentially acid-generating and potentially acid-consuming minerals; leach extraction testing to measure the soluble components of the samples; and other testing to determine trace element content of the waste. Whole rock analysis and mineralogical descriptions may also be conducted. Trace element

testing will usually consist of a full suite of metal analyses (inductively coupled plasma–mass spectrometry [ICP-MS]/inductively coupled plasma emission spectrometer). Trace element concentrations will indicate which constituents are naturally high in the waste and may be a concern for future leaching. A comprehensive list of testing methods can be found in the Canadian Mine Environment Neutral Drainage documentation (MEND 1991).

ABA, or the determination of the relative amounts of acid-generating and acid-neutralizing minerals in a sample, can be accomplished through a number of test procedures, with the Sobek acid–base account test and the modified acid–base account test being the most common. These tests measure the acid potential (AP), also called the maximum potential acidity, of the sample based on its sulfur or sulfide content. The sample's neutralizing potential (NP) is determined by titrating a pulverized sample of the material with an acid, with the resulting NP representing the acid-neutralizing capacity of the sample. The sample's net neutralizing potential (NNP = NP – AP), ratio of NP to AP, and paste pH are also determined. The results of the ABA testing are compared to general guidelines to assess whether the samples are likely to generate acid. Guidelines may vary for different areas but are generally based on the NNP and the ratio between NP and AP (NP/AP).

Static testing provides valuable insight into the acid-generating and metal-leaching potential of the waste. It does not, however, provide information about the rate of acid generation or neutralization and should not be used to predict drainage water quality in the field. In addition to static testing, simple leaching tests such as synthetic precipitation leaching procedure, meteoric water mobility procedure, or net acid-generating leachate analyses will provide preliminary data on potential contaminants of concern.

The next step in the characterization process for the tailings solids is kinetic testing. If static testing results show high variability between samples, a relatively high number of samples should be considered for kinetic testing. If the static testing results are largely consistent, fewer samples are needed for the kinetic testing phase, because similar results indicate less variability in the samples. Kinetic testing is used to confirm the samples' acid-generating or acid-neutralizing characteristics while determining the reaction rates for acid generation and neutralization. Kinetic tests are most often conducted in a laboratory, where chemical weathering is simulated over time in cells or columns. The composition of the leachate collected from kinetic testing can be used to predict drainage water quality in the field if concentrations are corrected for the effects of climate and particle size. The leachate should be analyzed for total and dissolved metals (ICP-MS), conductivity, total dissolved solids (TDS), a full set of anions and cations, and pH. Kinetic testing procedures include humidity cell, humidity column, column leach, Soxhlet extraction, and field plot tests.

It is equally important to characterize the tailings solution or the aqueous portion of the tailings slurry. A sample of the tailings solution from the pilot test work should be analyzed for a range of parameters, including total and dissolved metals (ICP-MS), nutrients, and reagents and reagent by-products used in the process, TDS, and turbidity. For example, if cyanide is used in the process, the effluent should be tested for the full range of cyanide species (total cyanide, free cyanide, weak acid dissociable cyanide, strong acid dissociable cyanide, cyanate, and thiocyanate). If warranted, speciation of metals of concern should be determined because the species of metal present significantly affects the availability and toxicity of the metal. Effluent concentrations are compared to in-country effluent guidelines or the World Bank effluent guidelines. A toxicity test of the effluent is also often required to ensure that the effluent is not acutely toxic to aquatic life. If discharge to nearby waterways is considered, effluent concentrations, coupled with the site hydrology, can also be used to perform water quality modeling exercises. Predicted water quality concentrations are then compared to in-country/international water quality guidelines or criteria for aquatic life protection (Brown 2002).

WATER MANAGEMENT

A key part of the tailings facility operations is the management of water in the facility. Water enters the tailings facility as process water in the tailings slurry, direct precipitation, and runoff from surrounding undiverted catchments. It is lost in the tailings deposit as pore water in the voids and to evaporation and seepage. In almost all cases, water is recycled to the mill for reuse in the process. Generally, if the total quantity of the water lost to permanent storage in the voids, evaporation, and seepage is greater than the quantity of water entering the facility from precipitation and runoff, the facility is considered to be in deficit, and makeup water is required to sustain the milling operation. If the opposite applies, the facility is in surplus, and excess water may need to be treated and released or adequate storage provided to contain it.

Precipitation and evaporation usually vary seasonally, which results in water surpluses some months and required makeup water in other months. Water can be stored in the surface water pond in the tailings facility during the wetter months and used as makeup water in the drier months. A detailed water balance that accounts for the water inflows and losses on a monthly basis is required for a tailings facility. It should consider climatic variations to ensure that makeup capacity for dry periods and treatment or storage capacity for wet periods are sufficient. The water balance is used to predict the variation in size of the surface water pond in the tailings facility pond on a seasonal basis as the facility is filled.

A further aspect of water management is to ensure that the tailings facility has adequate capacity at all times to store, route, or otherwise handle runoff from extreme precipitation events. Overtopping as a result of storm runoff is one of the most common causes of tailings facility failure. It is imperative that adequate storage is provided to safely contain the surface water pond within the tailings facility at all times. Particular focus should be on the wet season, with the addition of the design storm plus required freeboard for wave run-up. If sufficient temporary storage cannot be provided, it is often prudent to include an emergency spillway, although in a stage-developed facility, constructing a spillway for each stage may be complex.

Water Balance

The general hydrologic equation describing the water balance of a typical tailings management facility (concentrator, tailings, supernatant pond, other storage ponds, piping, and pump back) is given by

$$P + Q - E \pm \Delta S - D = 0$$

where

P = precipitation on the tailings facility and contributing catchment area

Q = runoff inflows to the tailings facility, including runoff and water liberated from the tailings slurry minus outflows from the tailings surface water pond, consisting of reclaim water to the plant and excess water discharges to treatment (if necessary)
E = evapotranspiration (evaporation plus transpiration)
ΔS = change in storage in the tailings facility and associated ponds
D = deep percolation (unrecoverable by drains and/or plants at closure)

Water balances are used to evaluate the size and configuration of the components for either water storage or flow discharge as well as to quantify the design water supply and evaluate environmental issues (Fenn et al. 1975; van Zyl et al. 1988; Tindall and Kunkel 1999; Kunkel and Lishnevsky 2009). Water balance calculations can be made using simple spreadsheets or can be quite complex in nature and must consider plant operations, potential power outages, and extreme storm events to ensure the development of a complete assessment.

Water Storage

The average and maximum monthly design sizes of the tailings surface water pond throughout the mine life can be determined by various calculations. The authors prefer the following two methods: (1) average monthly pond volume plus a design storm event, and (2) monthly percentage chance of exceedance analysis. For providing adequate pond storage capacity, the larger result of the two should be considered. However, the largest monthly pond size from either method may vary from year to year throughout the operating life of the mine, and this should be accounted for in the staged expansion plans for the tailings storage facility.

In the first method, the averages of the monthly tailings pond volumes are calculated for each of the 12 months of the year and combined with the volume contributed by the selected design storm event. The design storm volume may vary throughout the months of the year, so the maximum of these two components is sought.

In the second method, a frequency analysis is performed on the various January-to-December pond volumes, often to define the 0.001% (representing a 100,000-year storm event), 0.01% (a 10,000-year storm event), 10% (a 10-year storm event), and 50% (a 2-year storm event) chance of exceeding pond volumes.

Water Removal Systems

The control of the supernatant pond is probably one of the most important procedures in managing a tailings system. Inadequate pond control can result in overtopping, increase in pore pressures, reduction of freeboard, high seepage rates, and embankment settlement (Engels and Dixon-Hardy 2009). These conditions can lead to instability and a high risk of problematic situations. For a conventional impoundment (particularly upstream and centerline embankments), it is essential that the ponded water be kept to a minimum volume, well back from the embankment crest, and the freeboard be sufficiently high all along the tailings embankment. Suitable monitoring and management of the supernatant pond are required to safely manage the tailings.

Decant systems for tailings management should be designed for daily management of the supernatant pond as well as storm event surges. The design of the decant system should allow for a high surge capacity of stormwater to compensate for near future storm events. If the pond cannot drain fast enough (typically within weeks), then the freeboard of the embankment may be lost if a near future storm occurs.

The three most common methods of water control within a tailings management facility are (1) drains associated with subaerial deposition, (2) free-standing or sidehill riser decant towers, and (3) decant barges. Each of these water removal systems is briefly discussed in the following subsections.

Drains (Subaerial Deposition)

In subaerial tailings deposition, the slurry typically discharges out of drop bar just ahead of a rising tailings beach. This leads to some dissipation of energy as the tailings slurry exits the drop bar onto the beach. The tailings then flow at a relatively low velocity over the beach, which allows for liquid–solid separation. The points of active discharge are frequently alternated around the sides of the tailings management facility to form a thin-layered, drained, and stable tailings deposit against the embankment.

For this type of facility, the beach is sloped into the central area of the facility so that surface water draining from the tailings and runoff from precipitation are displaced away from the embankment. A small surface water pond is maintained in the central area directly against a blanket underdrain that covers the lined base of the facility, which slopes down to a low point in the facility. The underdrain comprises a layer of free-draining gravel within which a network of perforated, corrugated polyethylene tubing pipes is installed, and this layer is sometimes covered with a geotextile to filter the tailings solids. The geotextile is covered with another layer of gravel and cobbles for erosion and protection of the geotextile from ultraviolet radiation exposure.

A reclaim pond (or return water pond) stores the water being decanted from the facility. The pond is situated outside the confining walls of the tailings storage area a short distance from the embankment toe. The water in the reclaim pond is either sent to treatment/polishing ponds for discharge to the environment or pumped back to the plant for use in the processing operation. If the climate is suitable, some reclaim water can be sent to evaporation ponds or sprays.

Decant Tower Systems

A decant tower is an intake structure consisting of a hollow tower (riser) that is connected to a horizontal conduit or pipe that normally travels beneath the impoundment and through/under the tailings facility embankment. The riser is extended as the level of tailings in the impoundment rises. The decant tower skims off the clear water from the surface of the supernatant pond and carries it away by gravity through the underlying conduit (European Commission 2004).

Decant towers can be effective at removing ponded water from a tailings facility but can be difficult to operate. As more tailings are disposed of in an impoundment, decant tower systems come under increasing stress. The ever increasing weight of the tailings can crack and damage a decant conduit that flows underneath and through an impoundment facility (Engels and Dixon-Hardy 2009). Sidehill decant systems utilizing stop logs are less likely to have operational problems because the decant tower is always accessible from shore, and the placement of stop logs is relatively easy.

One major disadvantage is that the water has to be continuously positioned around the decant tower; unlike a decant

barge, a tower cannot be relocated. If a decant tower becomes inoperative, emergency pumping or spillways need to be implemented. Any tailings facility operating plan should have precise contingency plans documented in case a decant tower becomes inoperative either by isolation, blockage, or failure.

Decant Barges

A decant barge consists of a floating platform that houses pumps used to reclaim water from the supernatant pond to the processing plant or reclaim pond. Unlike decant towers that are gravity fed, a decant barge requires electrical power to operate the pumps that decant the water from the supernatant pond. This increases operating costs because a constant and reliable power source is required to ensure the pumps operate, as a power failure results in no water being decanted. It is good practice to have standby pumps and diesel generators to use in an emergency or when a decant barge cannot cope with rapid inflows during storm conditions or when process water is required in large quantities. Before power or equipment failures occur, there should be emergency procedures and response plans that can be implemented in both normal and storm conditions in order to rapidly mitigate any decant problems (Engels and Dixon-Hardy 2009).

The capacity of the decant barge should be adequate to remove day-to-day decant demands as well as stormwater accumulation. The barge should also be situated in an easily accessible location for maintenance and inspection purposes, ideally against the side of a valley wall (for a valley impoundment) or against the side of a jetty wall in an impoundment area where ponded water is the deepest. The water depth below the barge can influence the clarity of the decant water being extracted by the barge.

As the supernatant pond location changes and/or the tailings volume increases, a decant barge or submersible pump can be moved. For valley impoundments or in-pit disposal, the decant barge or pump is generally retracted to keep the equipment close to the valley or pit walls. This makes it easier to access and prevents the use of heavy anchoring to control varied movement, which can be expected the farther away the equipment is from surface anchoring points. Each time a barge is moved to other cells, the plant water demand should be recalculated to ensure the barge is capable of meeting the water demand in the new cell (Engels and Dixon-Hardy 2009).

TAILINGS DELIVERY AND DEPOSITION

Tailings are transported from the mill to the tailings management facility using any of the following methods:

- Pump and pipeline systems
- Gravity flow in open channels and pipelines (widely used in Chile and Peru for large-tonnage systems)
- Belt conveyor and trucks (limited to low-tonnage filtered tailings operations)

The following points should be considered for the design of a pump and pipeline tailings delivery system:

- Ideally the tailings facility should be located in relatively close proximity to the mill to minimize capital and operating costs.
- The elevation difference between the mill and tailings facility has an important bearing on the operating complexity and cost of the delivery system. If the tailings are transported uphill, the additional elevation change increases the pumping requirements and may lead to greater capital and operating costs. For tailings facilities located downslope of the mill, the pumping requirements can be considerably reduced. However, if the elevation difference exceeds the pipeline friction losses, choke stations or drop boxes are required to dissipate the excess energy, which can complicate the system operation.
- For thickened tailings systems where the tailings facility is some distance from the mill and/or at a higher elevation, locating the thickeners adjacent to the tailings facility rather than at the mill may have cost advantages.
- Centrifugal pumps are suitable for most tailings applications. High concentration non-Newtonian tailings applications may require the use of positive displacement pumps. Typically the capital costs of the systems will be greater than comparable centrifugal pump systems, although the operating costs may be reduced because of the increased pump efficiency and lower maintenance costs.
- Tailings delivery pipelines are generally constructed aboveground using HDPE (low-pressure applications) or unlined carbon steel piping. For especially corrosive or abrasive tailings, lining steel pipe with HDPE, rubber, or polyurethane has cost benefits. In certain applications, cementitious type pipes are sometimes used.
- Provision must be made along the tailings pipeline corridor for the containment of possible spillages associated with blockage clearance or pipeline failure; this is especially important near water features such as lakes and rivers. Some applications may require the use of double contained piping. To minimize the likelihood of pipeline failures, the pipeline condition must be regularly monitored.
- In cold climates provision must be made for draining the pipeline to prevent freezing during pipeline or pumping system shutdowns.

CONSTRUCTION CONSIDERATIONS

Detailed designs for construction of tailings management facilities comprise technical specifications for the work and detailed drawings issued for construction. These documents can be included in a contract for facility construction by a third-party contractor or can be used by the mine to carry out the construction using its own equipment and staff. The design of a tailings facility, like that of most large civil structures, is based on the available topographic and geologic mapping and information generated by the site investigation into soil and rock, groundwater, and surface water conditions. It is inevitable that conditions encountered in the field during construction will differ to some degree from those assumed or estimated in the design, and thus it is good practice that a representative of the design engineer be on-site to provide technical direction for construction. This will ensure that variations in site conditions are recognized and that the design is modified as required to meet the design intent. This service can be and often is integrated with the quality assurance/quality control (QA/QC) role. QA/QC is required during the construction of a tailings facility so that conformance of the work with the technical specifications and construction drawings is measured and recorded. This continuity from the design through construction is also important from a liability perspective. A designer that has no involvement with the construction can take the position that any shortcoming is a result

of the construction or changed conditions that were evident only during construction, while the constructor conversely can take the position that the design had shortcomings.

Continuity of qualified outside consultants over the life of a facility can also be important as, by its nature, the mine may have a high staff turnover. Often the design engineer provides the only continuous presence on a tailings facility over the mine life.

An important but sometimes overlooked aspect, tailings facility construction is the preparation of detailed as-built drawings and a record of construction for the completed facility. The preparation of these important items takes place at the end of the project when budgets may be nearly exhausted. They are invaluable however, as the basis for ongoing staged construction and if any problems arise with the facility's performance.

MONITORING

Operation, Maintenance, and Surveillance

Operation, maintenance, and surveillance (OMS) are critical aspects of any successful tailings management facility. The procedures should be documented in an OMS manual, and regular checks or audits made to confirm they are being followed. The procedures should be modified and the OMS manual revised as necessary.

An OMS manual should be in place upon commissioning and maintained through closure. It should provide a clear, documented framework for actions to be taken for a wide variety of occurrences. The OMS manual should also provide a reliable basis for measuring the facility's performance and for demonstrating due diligence of the operating team. The detail level of an OMS manual should reflect site-specific requirements. The need for revision may be triggered by changes in such matters as

- Hazard classification of the dam,
- Operational performance of the facility,
- Project personnel or the company organizational structure,
- Regulatory or social considerations,
- Life cycle and/or design philosophy (MAC 2002),
- Geology, and
- Climate.

An excellent guideline on tailings facilities OMS is available through MAC (MAC 2002). An OMS manual should provide the user with information in a clear, logical format that is easy to read and implement, and supporting documents should be clearly identified and referenced. The user should be able to easily identify what is required and how to access the needed information. The manual should allow the facility's performance to be compared to expectations, design criteria, and operating intent, particularly in the event of significant incidents.

Confirmation That Design Objectives Are Being Met

Initial designs for tailings facilities are established on the basis of engineering estimates about the behavior of the embankments, the deposited tailings, seepage and groundwater conditions, and overall water management. It is essential that sufficient instrumentation is installed and that a comprehensive monitoring and surveillance program is implemented to measure actual performance against the design objectives. The monitoring program should include a formal inspection carried out at least annually by a senior engineer with full knowledge of the design and operational criteria for the facility. The results from the monitoring program should be reviewed on a regular basis, preferably by the design engineer, to assess whether the design requirements are being met. A regular review of monitoring data can provide early warning of developing problems and allow remedial action to be taken before problems develop into a major concern, or worse, a failure. Many regulatory jurisdictions require that monitoring reports be prepared on a regular basis, which fully describe the tailings facility operation over the reporting period and record the volumes and types of tailings that have been deposited, the formal inspections findings and resulting recommendations, and the data from instrumentation and their interpretations (Brown 2002).

Monitoring may consist of visual observation of the embankment and an assessment of data from piezometers and other instrumentation. Preventive maintenance, based on the timely observation of potential problems, can help maintain the stability of the structure, control seepage, and contain costs. Distress signals, such as cracking, sloughing, saturated areas on the downstream face, unusual plant growth, and settlement, indicate potential deficiencies in the structure, but without proper instrumentation it may be difficult to accurately interpret the extent of the problem. Piezometers, pressure gauges, survey monuments, and borehole slope inclinometers can be used to indicate developing trends in the facility's behavior. Observations made from these instruments, combined with daily operators' logs, which show dates and locations of deposition, meteorological conditions, and so forth, can help in the analysis of the facility's condition (Vick 1990).

Instrumentation

Visual observations alone are an insufficient means of monitoring the safety of a tailings facility. Instrumentation should be installed in the embankment and/or its foundation to monitor changes that may be critical to stability and to help predict unstable conditions. Instruments can be installed to measure pore water pressures, seepage flows, embankment movements, and earth pressures (EPA 1994).

Pore water pressures are measured with piezometers, which encompass several types used to monitor pore pressures, such as standpipes (isolated tip and fully slotted) or pneumatic, vibrating wire, or silicon strain gauge ceramic tip. They may be installed during the construction of a tailings facility or later in a borehole. Each type of piezometer has various advantages and disadvantages, a full discussion of which is beyond the scope of this chapter. Piezometers should be installed in the structural zone of embankments, in drains, and in the tailings deposit. A well-conceived installation of piezometers can play a crucial role in understanding the pore pressure distributions in a tailings facility, and care should be taken to install this equipment to provide information on critical sections of the facility for use in slope-stability analyses.

Measuring slope movements can also play a critical role in facility monitoring. Simple methods for measuring embankment deformations can be easily employed. Markers can be installed on the surface aligned in a straight line-of-sight to permit rapid detection of movement during periodic observations. Survey methods may be used to enhance monitoring of tailings facilities especially if visual observations indicate possible slope instability. The simplest example of a survey method consists of a line of survey points installed along the embankment, slope, or toe of the slope. These markers

are surveyed shortly following installation and periodically thereafter.

A more advanced device for assessing deformations within an embankment is a borehole inclinometer, which consists of a cased borehole in which the lining is equipped with two sets of orthogonal longitudinal guiding tracks. A slope indicator device is lowered into the borehole and records the verticality of the lining in two directions at right angles to each other and at constant depth increments. These directions are usually parallel to and at right angles to the slope. By integrating the recorded slopes of the borehole lining, the deformation throughout the casing can be assessed.

Slope cross sections and available freeboard for pond water levels may also be important aspects of the monitoring program, especially for upstream or cycloned facilities and for traditional paddock dams. Flows from drains should also be measured and samples tested periodically for water quality.

Safety Audits

The operator of a tailings facility should implement an annual audit and review of the facility to help assess whether the operations remain consistent with the design criteria. The annual audit should be undertaken by a suitably qualified and experienced person, preferably the original designer or an independent third-party individual.

Periodic operational audits provide a valuable status report of actual facility performance compared to the design parameters, expectations, and assumptions. The records provide an ongoing history of the facility and can be vital for sites with frequent personnel changes. An audit can assist with tailings management planning, dam construction scheduling, and improvements to the overall operation.

A comprehensive periodic audit and review report should include the following:

- Updated site plan
- Updated survey plan of the facility including cross sections and contours of the embankment and tailings beach
- Certification from a qualified and experienced person that any construction (since the previous report) meets appropriate engineering and safety standards
- Data about the engineering properties of construction materials and comparisons of those properties with the design criteria
- Updated data on the properties of the tailings stored in the facility
- Reconciliation of the stored volume and densities of the tailings with the design values
- Calculations of the deposition rate against capacity and of the remaining facility capacity in terms of time and volume
- Water balance data
- Climatic conditions over the period between reports
- Data from daily inspections and periodic monitoring during facility operation
- Review of the safety and stability monitoring results
- Review of the environmental monitoring results
- Information on the operation of diversion channels, drains, and freeboard
- Information on the location and depth of boreholes and their proposed monitoring program
- Inspection and maintenance schedules for tailings pipelines and other pertinent equipment
- Information on the operations in terms of risk assessment
- Planned operations for the next reconciliation period

UNIQUE TAILINGS MANAGEMENT SCHEMES

Owing to the wide variety of tailings types, sites, settings and environments, and operational requirements, each tailings facility is unique. This has prompted the development of some unique schemes to enhance the performance and/or reduce a specific facility's risk and cost. A few examples are given.

- **Disposal of tailings within other mining facilities.** At the La Quinua mine, which forms part of the Yanacocha complex in Peru, a new, thickened tailings management facility has been commissioned within an active heap leach pad where the heap leach ore pile is used to provide full containment of the tailings (Kerr et al. 2009).
- **Mud farming.** Fine tailings placed in large paddocks in a dry environment often form significant surface crusts from evaporative forces, which reduce subsequent evaporation and thus densification and stiffening of the underlying tailings. The surface may be *farmed* using a modified bulldozer equipped with long floats and Archimedes screws. This practice is used at the Wagerup alumina refinery in Western Australia.
- **Pit tailings disposal.** Tailings are placed in mined-out open pits for cost-effective storage and to limit the overall footprint of the mine. In some cases, to limit oxidation, operations place potentially acid-generating tailings in a reducing environment below the groundwater level. Care must be taken to determine that the tailings will not contaminate the groundwater, which is often accomplished by establishing and maintaining a flow gradient into the pit. This is practiced at various operations worldwide, including some of the uranium mines in northern Saskatchewan.
- **Algae introduction into the tailings stream.** This method promotes algae growth on the surface of the tailings deposit to suppress dust generation. It is being investigated at the Sierrita mine in Arizona (United States).

Research is also being carried out on a number of potential tailings improvement initiatives that have not yet made it to full-scale implementation. These include

- Use of foam to transport filtered tailings in a pipeline instead of conveyors or truck haulage, in an effort to reduce cost;
- Addition of fibers into a tailings stream that will become integrated into the deposited mass and provide added strength in the structural zone; and
- Mixed disposal of tailings and mine waste rock in a single mass such that the rock component provides strength, and the tailings, if maintained saturated, reduce the oxygen diffusion into the mass, thus reducing the potential for acidic conditions to develop if the rock or tailings have significant sulfides.

LESSONS LEARNED

Although mining and tailings disposal have been part of human history for thousands of years, the disposal of tailings into dedicated facilities has been practiced only since the early 1900s. Initially the construction of these facilities was by hand, due to a lack of earthmoving equipment, which prompted the

use of upstream techniques for most dams. By the 1940s and 1950s, the availability of large earthmoving equipment and engineering principles for water storage dams, in terms of placing selected materials in certain zones in compacted horizontal lifts, began to be applied to mine tailings facilities. In the 1960s, largely as a result of a few earthquake-induced failures of tailings dams, the phenomenon of liquefaction began to be understood and accounted for in design, although it is only now that a related phenomenon, static liquefaction, is becoming well understood. Planning for the safe management and containment of water in tailings facilities is also relatively new, having become a specific design and monitoring subject in the 1960s and 1970s. More recent is the recognition that chemical stability is a crucial aspect of tailings management, and over the last 20 years much research has been carried out to, among other things, control acid drainage from sulfide tailings deposits.

Notwithstanding the relatively rapid advancement in tailings management engineering, the mining industry has been saddled with a somewhat checkered history, in part due to tailings facility failures and incidents. Like any other field of human endeavor, learning from its mistakes is vital. It has been reported that "there have been no unexplained failure events" and concluded that "In all cases over the past thirty years, the necessary knowledge existed to prevent the failure at both the design and operating stage, but that knowledge was not used" (Martin et al. 2002). This position was updated in 1998: "The mining industry has the technology to safely design, build, operate and decommission tailings facilities. This technology must be consistently applied for the safe and environmentally responsible management of tailings" (MAC 1998).

With those statements as a backdrop, it is worth investigating the lessons learned from past incidents. The following trends are reported for tailings facility incidents (Martin et al. 2002):

- Active impoundments are more susceptible to tailings dam failure than inactive facilities.
- The correlation between upstream constructed dams and the likelihood of incidents is strong, although the large number of upstream dams in the database must be recognized.
- Seepage-related phenomena are the main failure mode for non-upstream tailings dams.
- Earthquakes are of little consequence for most non-upstream dams.
- For inactive impoundments, overtopping is the primary failure mode.

The International Commission on Large Dams Bulletin 121 (ICOLD 2001) provides a comprehensive report of these lessons, drawing from a range of tailings management facility failures and incidents. The main causes of failures and incidents identified were

- Lack of water control in the facility leading to overtopping and/or seepage erosion (piping),
- Lack of construction control, and
- General lack of understanding of the features that control safe operations.

Tailings facility failures were due to (in order of prevalence)

- Slope instability,
- Earthquake loading on upstream dams,
- Overtopping,
- Inadequate foundations, and
- Seepage.

Successful planning and management of tailings facilities could benefit greatly from involvement of stakeholders; thorough investigations and risk assessments; comprehensive documentation; and tailings management integrated into mine planning, operations, and closure (ICOLD 2001). It is also suggested that benefits can be realized by adoption of a comprehensive tailings management system and maintaining continuity of staff, including consultants, to the greatest extent possible.

Specific examples of tailings facility failures where lessons can be learned include the Stava tailings facility in Italy (Ulrich 1996) and the Merriespruit tailings facility in South Africa (Fourie et al. 2001).

Stava Dam Incident

On July 19, 1985, two tailings dams near Stava, Italy, catastrophically failed, resulting in the destruction of two villages and causing extensive property damage. Two hundred and sixty-nine lvives were lost (Genevois and Tecca 1993). A total of 190,000 m^3 (154 acre-ft) of liquefied tailings flowed down the Stava valley. The flow reached the village of Tesero, a distance of 4 km (2.5 mi) from the mine, in only minutes. The failures occurred without any warning (Berti et al. 1988) and are not attributed to earthquake shaking or stormwater flooding.

These dams were never engineered, at least not in the conventional use of the term; however, the initial construction of the upper dam was based on the successful operation of the lower dam. The dams were constructed with minimal design effort. Site investigations were never carried out in any form until after the failure, lab testing was never conducted, and design drawings were never made. Surveying was never attempted at the site, and no instrumentation of any kind was ever installed.

The failure of the upper dam was caused by the presence of a high phreatic surface within the sand shell leading to the initial failure, which strained sufficiently to produce liquefaction of the sandy materials. "The critical factor was direct ingress of water into the sand shell of the embankment and subsequent saturation of a portion of it" (D'Appolonia and Morgenstern 1988).

When the saturated zone had incorporated a region of the sand shell approximately 7.5 m (24.6 ft) wide, failure was incited under drained conditions. Because the sand shell was in a loose state, the straining that took place generated positive pore pressures, sufficient to induce liquefaction under static loading conditions (i.e., static liquefaction), and the sand shell began to flow. A condition of undrained loading of the slimes resulted from this loss of confinement, and the slimes deformed in an undrained manner (D'Appolonia and Morgenstern 1988).

The relationship between the stability of a dam and the location of the phreatic surface within a dam has been well recognized by the geotechnical community for a considerable time. Records of pond water level indicate that the pond was at its historic maximum elevation at the time of failure. In addition, there is ample evidence that appreciable seepage existed in the sand shell just prior to failure. Given such information, it would appear that the dominating factor causing the failure was related to the location of the phreatic surface (D'Appolonia and Morgenstern 1988).

The failure of the Stava dam stands as a grim reminder to the mining industry of the need for proper design, operations, and monitoring of tailings facilities, and as an important reminder to the geotechnical community of the need to understand the possibility of failure mechanisms such as static liquefaction and how subtle changes in operation practices may lead to significant changes in important characteristics such as seepage patterns within a tailings facility.

Merriespruit Tailings Failure

Failure of the 31-m- (100-ft-) high gold tailings facility just outside of the village of Merriespruit, South Africa, in February 1994 resulted in the death of 17 people and widespread damage to the village and the surrounding environment. The failure occurred shortly after a 50-mm (2-in.) rainfall event. Approximately 600,000 m^3 (21.2 million ft^3) of liquid tailings flowed from the facility, through the village of Merriespruit, stopping about 3 km (1.9 miles) downgradient.

It is accepted that the primary cause of the failure was overtopping, which resulted in large-scale removal of tailings from the slope face (Wagener et al. 1998). The post-failure investigations found that the dam overtopped at the breach location and water flowed over the crest of the dam for 1 to 2 hours. Removal of tailings from the outer slope would have exposed tailings inside the facility that had previously been confined. Conventionally, however, gold tailings produced from Witwatersrand quartzites are considered to be strongly dilatant (Blight 1998), and thus even if confinement were removed, the tailings should not have moved for any significant distance, because for a strain-hardening soil the resistance increases continuously during undrained loading (Zhang and Garga 1997). In addition, the outer zone of the tailings dam was considered to be well consolidated due to the thin layer deposition procedure wherein layers of tailings are placed sequentially around the perimeter and allowed to drain, desiccate, and consolidate (Blight and Steffen 1979). Undoubtedly, it came as a surprise to the geotechnical community in South Africa that 600,000 m^3 (21.3 million ft^3) of gold tailings would liquefy and flow as far as 3 km (1.9 mi) (Wagener et al. 1998).

The fact that no gold tailings dam in South Africa had previously failed with such devastating consequences probably contributed to the complacent response to the excessive seepage and toe sloughing that occurred prior to the dam's catastrophic failure. Conventional stability analyses carried out a few months prior to the failure indicated a satisfactory factor of safety against slope instability. Based on a traditional geotechnical engineering approach to slope stability, perhaps the perception that the facility was inherently safe can to some degree be excused. Many practicing geotechnical engineers today, if presented with the information available at the beginning of February 1994, might also come to the conclusion that the tailings impoundment, although not in a completely satisfactory state, was not intrinsically unsafe. It is only when the concepts of static liquefaction are invoked that incipient instability might have been predicted. Such a prediction would have been difficult, if not impossible, without either piezocone profiles or information regarding the in-situ void ratios and knowledge of steady-state soil mechanics.

The failure of the Merriespruit tailings dam caused a major reconsideration of operating procedures of tailings dams in South Africa and contributed in some measure to the development and publication of a Code of Practice for Mine Residue Deposits (South African Bureau of Standards 1998). Although such improvements are commendable, it is important not to lose sight of the fact that the Merriespruit failure was a single, isolated incident and that many dozens of gold tailings dams in South Africa have been successfully and safely operated for nearly 100 years. The stark lessons learned from Merriespruit should not be forgotten: Poor pool control, subaqueous tailings deposition, and inadequate freeboard are all well-known sources of operational difficulties on tailings dams. The Merriespruit failure simply emphasized this point, with tragic consequences.

CURRENT AND FUTURE TRENDS

The mining industry has made, and continues to make, many significant improvements to tailings management. Such changes come under the following categories (Martin et al. 2002):

- Management practices
  - Creation of guidance documents
  - Initiatives by the mining companies
  - Use of qualified engineering consultants
  - Response to regulatory trends
- Tailings management technologies
  - Improved geotechnical designs
  - Designing for geochemical issues
- Metallurgical improvements
  - Control of ARD (when applicable)
  - Management of cyanide (when applicable) and other chemical reagents

Increasingly, guidance documents are being prepared by the mining industry and other stakeholders including regulatory authorities, as described previously in the "Tailings Management Principles" section. Such documents provide guidelines for a wide variety of topics ranging from nontechnical issues, such as the development of management frameworks and identification of management responsibilities, to more technical matters, such as OMS of tailings facilities.

International standards are frequently mentioned yet they are not well defined. In general, they consist of a compendium of standards and guidelines by lending agencies such as the World Bank and its International Finance Corporation (IFC), mining industry initiatives, and regulatory agencies. The IFC has recently produced an environment, health, and safety guidance document for mining (IFC 2007) that includes tailings and water management. The Mining, Minerals and Sustainable Development (MMSD) project of the International Institute for Environment and Development (IIED) produced its report "Breaking New Ground" (IIED 2002), which includes a section on large-volume wastes, including tailings. The United Nations under its United Nations Environment Programme (UNEP), the International Council on Metals and the Environment (ICME), and more recently the International Council on Mining and Metals (ICMM) have also produced case study and risk management guideline documents for tailings. The broad objectives of these documents are generally to

- Monitor, interpret, communicate, and implement improvement trends in mining and the environment;

- Provide direction and influence to international and national government polices and company practices related to improving environmental management, regulations, and practice; and
- Seek cost-effective solutions to environmental challenges in mining.

Mining companies themselves are also producing several initiatives to improve mining operations globally. In addition to the MAC initiatives described earlier, one other such initiative is the International Cyanide Management Code that is administered by the International Cyanide Management Institute (ICMI) for the manufacture, transport, and use of cyanide in the production of gold (ICMI 2009). This code is typically referred to simply as the cyanide code. The cyanide code is a voluntary program for the gold mining industry, illustrating the commitment of mining companies to, among other things, improve tailings facility design and operation, and promote

- Responsible management of cyanide used in gold mining,
- Enhance the protection of human health, and
- Reduce the potential for environmental impacts.

Companies that become signatories to the cyanide code must have their operations audited by an independent third party to demonstrate their compliance with the code, the results of which are published and divulged to the public. In addition, many international mining companies have written their own in-house guidelines, much of which can be found on their company Web sites. Several companies have promulgated such undertakings as internal audits of their procedures and management systems, forming review boards with industry experts from internal and external sources, especially for significant, high-profile undertakings. Probably the biggest current initiatives are improved designs of tailings facilities, including the use of thickened, paste, and filtered tailings, and incorporating closure and reclamation objectives into the design.

The practice of tailings management has come a long way in a relatively short period thanks to (1) its establishment as a dedicated topic of engineering and environmental science, and (2) the commitment made by many mining companies, industry associations, and regulatory bodies for improvement. However, continuous improvement must be sought. The following topics warrant attention in the near future.

Improved Consistency of Good Tailings Management Practices Across the Industry

It is now accepted that the technology exists to address all currently contemplated engineering and environmental science issues related to safe and secure tailings disposal (although it is also accepted that technology improvements will continue to be made). However, it is also recognized that the technology is not always used or used adequately. The industry is working to put tools in place that will help rectify these gaps but is not yet at the finish line. Widespread adoption of full life-cycle tailings management systems, as outlined in the "Tailings Management Principles" section, will help, as will acceptance by all mine owners that a well-developed and safely operating tailings facility has value and is not simply a cost. Good documentation is fundamental to this endeavor because, over the life of many tailings facilities, key people come and go and the current people must be aware of the thinking to date.

Improved Recognition of the Uniqueness of Each Tailings Facility and the Need for Appropriate Expertise

Because each tailings facility is unique, an off-the-shelf or cookie-cutter approach to design is not acceptable. This is why mining industry guidelines are just that—guidelines. They do not and must not replace sound project-specific engineering and environmental science provided by appropriately qualified firms or individuals. Knowledge and experience are fundamental to take advantage of the lessons learned and to fully understand and appreciate the nuances associated with the site conditions, tailings properties, and the facility's operating principles.

Improved Recognition That Tailings Facilities Are Permanent Features with an Indefinite Life

Tailings dams differ in many ways from water dams in that they are generally permanent structures unless the tailings deposit is subsequently removed (which can happen if the tailings are reprocessed or the area is evacuated for mine expansion). Thus, indefinite time frames may need to be contemplated when designing and operating a facility. Planning from the beginning for closure and a postclosure period is gaining acceptance, but planning for indefinite closure may be more appropriate. Although peak deterministic (equivalent to a very long return period) earthquake and storm events are now being used, the long-term durability and potential degradation of materials for seepage barriers, drains, and structural zones are not always contemplated. In addition, the implications of future land-use changes that could increase the hazard classification of the facility should be appreciated.

Increased Application of Dewatered Tailings in Appropriate Circumstances

The technology associated with dewatering tailings for bulk surface disposal is improving rapidly in response to demand by the industry. The most pressing need is in dry climates where the value of water is high and thus the benefit of recovering and recycling water is also high. This is particularly true at the large copper mines in Chile where significant volumes of water are lost to evaporation from the tailings facility. The biggest challenge is associated with the large tonnages of tailings produced and thus the large dewatering capacity required.

A second challenge is the cost. In recent years substantial advancements have been made to reduce capital (equipment) and operating (power) costs, and, as further experience is gained, additional capacity expansions and unit cost reductions can be expected. Understanding the behavior of thickened, paste, or filtered tailings when deposited is also a key challenge, particularly in terms of predicting shear strength and liquefaction potential, and beach slope angles for high-density tailings. Often the decision to use thickened or paste tailings, in addition to increased water recovery, is because development of more steeply sloped deposits reduces the height required for containment structures. Care must be taken, however, to avoid overpredicting the slope if the beach length is large, because this may result in the need for subsequently constructing an unexpected rise to the structure.

Dust Control

Dust generation has become a problem for some tailings facilities with large exposed beaches in windy environments. Often the dust is generated from sandy tailings in the upper portion

of a segregated beach because the sandy tailings are unable to retain the capillary moisture that finer tailings can, which helps to hold the particles on the beach. However, in areas where freeze–thaw cycles are significant, both sandy and finer tailings can be dewatered and loosened from the beach, creating a dust concern. Current methods for controlling dust include the installation of snow fences in strategic high-impact locations, application of water to moisten the dry and dust-prone areas, or the application of tackifiers to adhere the loose particles to the beach. A more innovative approach involves the injection of algae into the tailings stream to produce a biological cover on the exposed beach surface. Thickened tailings can help in areas where freeze–thaw is not an issue because the degree of particle segregation is reduced.

Placing Greater Emphasis on Integrating a Tailings Facility with Other Mining and Mine Waste Facilities

Placement of tailings underground in mined-out workings as backfill has been successfully done in numerous mines worldwide and is partly responsible for the origins of the tailings dewatering industry because dewatering was required to give the tailings substantial strength and stiffness. However, the disposal of tailings in combined surface facilities with other mine wastes, such as waste rock from the pit or heap leach pads, is less common. The La Quinua thickened tailings management facility previously described is unique because it is the only one in which the tailings are fully contained within an active heap leach ore pile. Combining these facilities requires careful consideration of the design and operating principles of each and achieving compatibility. This may not always be possible. However, if compatibility can be reached, the benefits are large and include cost, land-use, and closure efficiencies. Extrapolation of this example to tailings within waste rock storage facilities may hold similar promise of successful applications.

CHAPTER 8.11

Waste Piles and Dumps

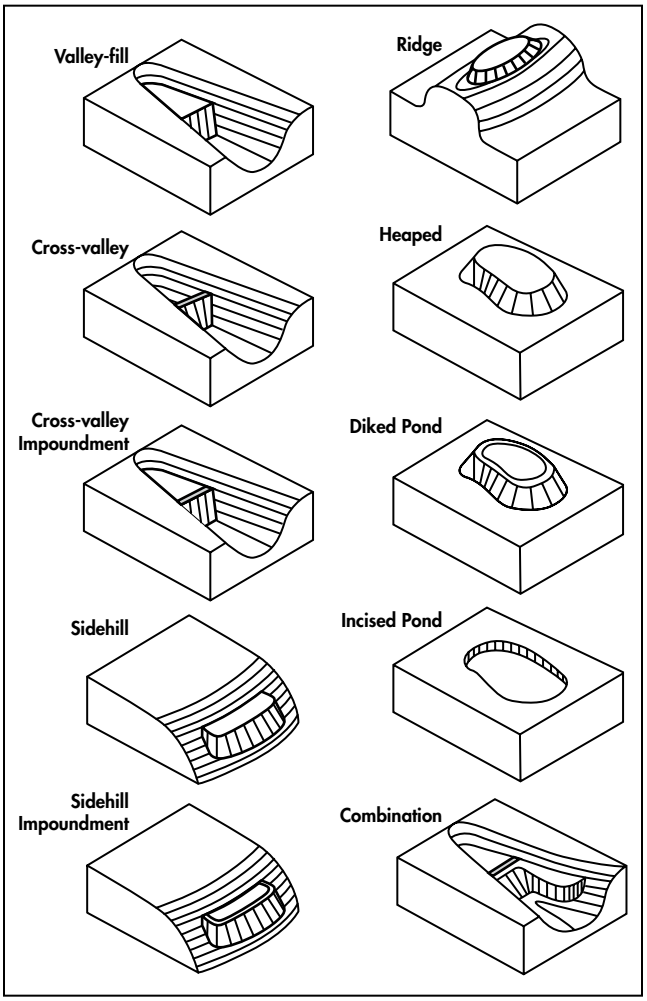
Marc Orman, Rich Peevers, and Kristin Sample

The terms *mine waste piles* and *dumps* refer to piles of waste rock or leached ore that carry little or no economic value at the time they are placed. As commodity values rise and process methods gain efficiency, waste piles and dumps may be reclassified as ore and gain value. Also, the waste material may be valuable at some future time as an aggregate source, for use in riprap, drain material, or other process method that recovers the commodity at lower grades or has lower acceptable rates of return. Heaps are ore piles that are amenable to a leaching process, both with and without the use of liners, and share physical characteristics with piles and dumps.

HISTORIC PERSPECTIVE

Ever since humans began to extract materials of value from rocks, waste or other lesser-valued material has been left behind after the extraction process. For early miners, waste dumping was simply a matter of pushing the waste out of the way, either down a slope or to any other available area. Frequently, these waste materials ended up in drainage basins, rivers, and lakes where they caused environmental harm. In 1884 in California (United States), hydraulic mining was essentially outlawed by the Sawyer decision because the mine waste in the rivers had led to flooding after streams and rivers became choked with solids. This law, handed down by the Ninth Circuit Court in the case of *Woodruff v. North Bloomfield Gravel Mining Company*, became one of the first environmental decisions in the United States (U.S. Circuit Court 1884).

Over time, other regulations and laws have emerged, and standard practices have evolved to minimize the environmental damage and potential hazards associated with the disposal of mining waste. Enlightened mining companies now deal with their waste products in a responsible manner, especially when negative impacts on the public may result because of improper disposal. Nevertheless, improper disposal and handling of mine waste continue to pose environmental hazards across the world. While the hazards associated with mine waste disposal have decreased in most developed countries, it continues to be problematic in regions where regulations and environmental laws are not strict and enforcement is lax.



A significant contributor to mine waste dumps is heap leaching, which is a relatively new form of mining where low-grade ore is piled over large surface areas and irrigated with solutions. The resulting pregnant solution is then processed to recover the desired commodity. After the leaching is completed, the leached ore becomes a waste product. On a permanent pad, the ore material is stacked and leached in lifts until the pile reaches the final design height. Modern leach pad facilities can be hundreds of meters high and cover thousands of square meters in area. Alternatively, on a dynamic pad, a single thin lift (5 to 10 m [16.4 to 32.8 ft]) of ore is stacked and leached on the pad at any one time, after which the leached ore is removed and stored in a waste dump. In the past, environmental issues were not a main consideration for heap leaching. However, in response to environmental regulation, facilities have evolved, and many now utilize geosynthetic liners incorporating a leak-detection provision.

The earliest full-size leaching projects in the United States were for copper in the form of dump leaching with natural containment. Subsequently, with the introduction of cyanide for leaching gold and silver, soil liners came in vogue in the late 1970s to the mid-1980s (Breitenbach and Smith 2007b). Since then, use of geosynthetic clay liner, high-density polyethylene (HDPE), low-density polyethylene (LDPE), linear low-density polyethylene (LLDPE), and polyvinyl chloride (PVC), as well as asphalt impregnated geotextiles and a few others, have become the standard liner materials for heap leaching.

TYPES OF WASTE PILES, DUMPS, AND HEAPS

This section provides a description of waste piles, waste dumps, and heap leach pads (both lined and unlined). Although these types of facilities are similar, the liner aspect introduces an additional potential for failure along the liner as part of design. On the other hand, for unlined facilities it is important to consider the materials' geochemistry (both the ore as well

Figure 8.11-1 Mine dump configurations

as the resulting pregnant solutions) and the site's hydrology to ensure that natural water resources are adequately protected.

Configurations

Collectively, waste pile, dump, stockpile, or a leach heap can be referred to as waste structures. As such, their layout generally falls into the following categories, depending on the type of waste, the purpose of the waste structure, and the physical constraints at the site. Each of the configurations is shown in Figure 8.11-1 and discussed in further detail in the following paragraphs.

A *valley-fill* waste structure, as the name indicates, fills a valley. Many of the lined valley-fill leach pads require some type of stability berm at their toes. Construction of a lined valley-fill leach pad would begin at the toe berm and progress up the valley. Construction of a waste dump (not a leach pad) usually begins at the upstream end of the valley, and dumping proceeds along the downstream face (as shown in Figure 8.11-1). For a heap leach facility, stacking should begin at the toe and proceed up the valley to avoid slope-stability problems.

The top surface is usually sloped to prevent water ponding. Stormwater run-on can be controlled by constructing diversion channels up-gradient of the facility. In steep terrain, where the facility is going to take a long time to fill, it may be more economic to construct a rock drain below the facility to pass stormwater. Subdrains may also be needed below the structure to control seepage from natural springs and material drainage.

A *cross-valley* structure crosses the valley, but the valley is not completely filled up-gradient. The structure is usually designed with a rock drain at the bottom of the valley to control the storage and/or discharge of stormwater flows, or a water diversion system must be installed up-gradient to provide drainage around it. This type of structure could also be used as a retention dam for fine coal or waste slurries, in which case the design must conform to applicable regulations for dams and impoundments.

A *sidehill structure* lies along the side of a slope but does not cross the valley bottom. This structure may be constructed to impound either water or mine waste slurries (and therefore would need to conform to applicable dam regulations). As with a cross-valley structure, a sidehill embankment should also be designed and constructed with either stormwater diversion channels or rock drains to control the storage and/or discharge of flood flows. In some cases, the hillside may require benching and/or a keyway at the toe to increase the stability of the facility.

A *ridge embankment* straddles the crest of a ridge, and waste material is placed along both sides. Unlike the cross-valley or sidehill configurations, this type of structure is typically not used to impound fine-grained material or water. In some cases, one or both sides of the ridge may require benching and/or a keyway at the toe to increase stability.

A *diked embankment* is constructed on nearly level terrain and can either impound fine-grained or coarse-grained mine waste. By definition, this type of embankment is composed of two parts: a down-gradient containment dike and the embankment or dump itself. These two parts may or may not be isolated from one another by liners. If fine wastes are impounded by coarser waste, the structure is considered a *dike*. If the embankment is homogeneous and coarse, the embankment is termed a *heap*, such as a heap leach pad.

Leach Dumps or Heaps

Leach heaps consist of low-grade ores spread or stacked on large platforms where the pile is irrigated with leaching solution to leach out the recoverable product of value. Although heap leaching has been used mostly for precious metal and copper ores in the past, it is now also being used for other products, such as uranium and nickel. In recent times, even municipal wastes have been leached using similar methods to accelerate the decomposition of waste and add capacity to the facility. Heaps are normally placed on impermeable liners of natural and synthetic materials (discussed in more detail later in this chapter).

Dumps usually refer to material piles created by end dumping. Run-of-mine ore is sometimes simply dumped instead of being stacked on a leach pad and leached for economic recovery of the contained commodity (a process known as *dump leaching*). The same procedure is often used for secondary recovery from leached ores. Dumps are generally placed on natural soil or rock subgrade surfaces that have been demonstrated to have some degree of natural solution containment and are normally located on sloping ground or in a valley to promote drainage to the toe.

Stockpiles

The term *stockpile* refers to any pile of material that is placed for future use. This can include material with either proven or potential value, material for structural fill, or other materials obtained from borrow pits or removed from stripping projects. Waste rock or processed material to be used as backfill can also be categorized as a stockpile. These materials, which are stored for processing or future use, appear much the same as waste rock except they are normally isolated from waste materials so they may be recovered at some later time as economically as possible and without being contaminated with waste. Stockpiled material, such as the ore itself, may be chemically unstable, and the stockpile may require liners, caps, and/or stormwater diversion structures to prevent water infiltrating the pile and causing water contamination.

Placer Waste and Tailings Deposits

During placer mining for gold or aggregates, the practice of washing sand and gravel to recover minerals can produce tailings with particle sizes ranging from coarse to fine (<75 μm) and wash water, which should be treated. The coarse waste fraction can be disposed of using one of the methods previously described; however, the fines portion is similar to the tailings from a milling operation. Considerations for these types of wastes include the placement and storage of the tailings and treatment of the wash water to meet discharge requirements.

With physical constraints of space limitation and the rising cost of conventional impoundment methods for tailings storage, the use of process items such as thickeners and filter presses to put tailings in piles or mounds has become more common. With the removal of additional moisture, alternative disposal methods such as thickened tailings, paste backfill, treated paste backfill, and dry stacking become viable options, which can add capacity to the facility.

IMPACTS OF WASTE DUMPS

Waste dumps and heaps have several (actual and potential) impacts on the environment, which must be considered as part of their permitting and design. These impacts include disturbance of the land, water quality issues, slope stability, and visual effects. In the past, waste dump disasters have led to the contamination of surface and groundwater, as well as massive slides, which have buried communities.

Planning waste disposal facilities requires evaluating the regulatory constraints, identifying an appropriate site, designing the structural and environmental integrity of the facility, developing an operating and maintenance plan, and developing a reclamation plan for future land use (Center and Zlaten 1982, and Ritcey 1989, as cited in Zahl et al. 1992). From the design point of view, the specific issues to be considered are the contamination potential of the waste, slope stability, the condition of the waste structure's formation under normal and seismic loading, and ways to control water (both internal and external) to the dump.

Water Quality

Water quality impact issues associated with waste, unlined dumps, or poorly constructed heap leach facilities can be a major environmental concern. Waste rock should be thoroughly tested at the design stage for acid-generating and metals-leaching potential to ensure that water resources are adequately protected.

To provide background information on flows and water quality, groundwater and surface water samples should be collected before construction begins. These measurements and samples should be collected throughout the year so that seasonal fluctuations can also be monitored and effectively evaluated. All drainages and aquifers in the vicinity of the project should be tested to ensure that water quality for the entire project area is well understood before the project begins.

Initial testing of the water samples should include major cations and anions, metals, nitrates, dissolved and suspended solids, salts, and organic compounds, as well as other constituents that may emerge as relevant during the process and involve potential changes to water chemistry. Samples should be collected from dedicated monitoring wells and surface sampling locations, both up- and down-gradient of the project site.

A water quality monitoring plan should be prepared to document sample locations, sampling frequencies, and protocol for collecting the samples. At a minimum, the plan should contain the following items:

- Identification of the surface and groundwater sources
- Monitoring objectives
- Description of water quality parameters
- Sampling point descriptions and a map of their locations
- Analytical procedures
- Data quality control objectives
- Data management and quality control details
- Sampling equipment to be used
- Sample preparation and handling procedures
- Chain of custody and data sheets to be used
- Reporting requirements

Land Disturbance

Wherever mine waste is placed, the natural environment is changed, and the process is therefore classified as land disturbance. The initial disturbance creates the potential for sedimentation of natural waterways caused by erosion and water quality degradation, which are among the major potential impacts of waste dump construction. Although waste dumps can be designed to minimize the impacts of land disturbance and blend in with natural surroundings as part of reclamation in some locations, these disturbances have been perceived by some as highly destructive to the environment. Specifically, in California, all metallic mines are now required to use waste rock to backfill all open pits as part of the state's mine reclamation requirements. The U.S. Office of Surface Mining requires restoration to approximate original contours for surface coal mining. These requirements can add considerable cost to final closure.

Since most waste structures are not compacted, the volume of a pile or a dump can be much greater than the volume of the pit, which adds further to the issues of how to hide, or at least reduce, their impact.

Visual Impacts

Visual impacts from mine waste dumps and leach pads can be a major concern for mines located in the vicinity of populated areas or where the facilities will be visible from roads and highways. Visual impact and viewshed studies are now performed routinely in many areas of the world as part of initial mine permitting.

In areas where the color of the rock blends with the natural color of the terrain, visual impacts will be less than in areas

with sharp color contrasts. In flat areas, hills develop, and, in mountainous terrain, ridge tops appear and grow, and drainages are filled. By maintaining slope angles that are similar to natural slopes, visual impacts may be reduced, and many companies are now designing dump surfaces to simulate the original topography. However, contrasts in colors from the natural vegetation to rock and topsoil can take several years to blend together as the revegetated slopes take hold following reclamation.

A visual impact study may include the following components, as described by the Federal Highway Administration (FHA 1981):

- Description of the project setting and the major viewsheds
- Photographic study of the project from the major views
- Description and analyses of the existing visual resources and responses from people in the area
- Renderings of the project alternatives' views
- Assessment of the visual impacts of the project alternatives
- Possible methods to mitigate the adverse visual impacts

As part of the visual impact study, maps are usually produced and show the areas from which the project would be visible according to different design options. The design options typically include several different ultimate elevations and possible configurations of the waste dump or heap.

DESIGN OF WASTE DUMPS

This section provides an overview of waste dump design. Further details regarding the design of waste dumps may be obtained from the following recommended SME-AIME publications and from several other references cited throughout this chapter: McCarter 1985a, 1990; and Hustrulid et al. 2000.

Proper planning and design require a thorough understanding of the material properties of the waste rock or ore, liner interface strengths in the case of a lined facility, and foundation conditions. In the case of a dump or heap leach, groundwater and seepage properties of the ore must also be understood in order to properly design these types of facilities. Studies would include a field investigation consisting of mapping of soils and rock; drilling boreholes; monitoring well installation; excavating a test pit; sampling waste rock, ore, and foundation materials; laboratory testing; and analyses.

Slope Stability

Slope instability and failure are major issues for all types of mine waste dumps and heap leach operations. The risks and environmental impacts of waste dump instability are a major concern for both mine operators and regulators. A slope failure in a waste structure could cause injuries and disruption of operations because of equipment burial or closure of an access or haul road. Slope failure in a heap leach pile can lead to a liner failure and the potential release of pregnant solution, which may result in contamination of groundwater resources, as well as a loss of revenue. In either case, there are clean-up and remediation costs. Proper preplanning and design are imperative to avoid these types of costs.

Numerous factors affect waste dump or pile stability, including site topography, dump geometry, rate of stacking and lift thickness, geotechnical properties, method of construction, equipment loads, phreatic surface, and seismic forces—all of which must be considered in the evaluation of the waste structure's stability over its design life. Generally, limit equilibrium analysis using one of the several prevalent approaches is considered adequate to evaluate slope stability of waste dumps.

Failure Modes

The basic failure modes of waste dumps must be considered during the stability evaluation and design. Detailed descriptions of identifiable waste dump failure modes and appropriate analyses are described by many in the literature (e.g., BCMDC 1991; Caldwell and Moss 1985). Each of the main failure modes are shown in Figure 8.11-2.

Surface or edge slumping. The most common failure mode is edge slumping (crest slumping), where a thin wedge of material translates down the slope, parallel to the dump face. This shallow failure typically originates near the crest of the dump because of oversteepening. Cohesive or low-permeability waste materials allow the development of oversteepened slopes. End dumping the waste in thick lifts or pushing material over the dump crest also leads to a higher risk of over-steepening and edge slumping. Edge-slumping failures often occur after heavy precipitation, which leads to increased pore pressures in the low-permeability waste. In coarse rock-fill dumps, oversteepening of the crest may develop due to initial interlocking of the blocks (BCMDC 1991).

Plane failure similar to edge slumping may occur deeper within the waste dump materials. In this case, sliding occurs along a single plane of weakness within the dump, which may have been created because of a zone of poor quality waste or from dumping waste on top of snow or ice. The plane of weakness parallels the dump slope or daylights at the dump face.

Shallow flow slides. Flow slides are shallow slumping failures of saturated or partially saturated waste. Typically triggered by rain or snowmelt, they result in material flowing down the slopes due to shear failure or collapse of the soil structure.

Rotational circular failures. Rotational circular failure (mass failure along a curved failure surface) may occur within the waste as a result of excessive dump height, additional loading induced during an earthquake, weak or fine-grained waste materials, reduction in toe support, and/or high pore-water pressures. Rotational failure surfaces may also extend into the foundation if the soil is weak or high pore pressures develop, such as within a deep fine-grained soil deposit. Creep failure is also a type of rotational failure, with widespread rotational shearing characterized by bulging at the dump toe (BCMDC 1991).

Base failure (spreading). Base failure may occur if a thin, weak base layer is placed over the foundation, especially if the foundation is inclined. If a slope wedge of the waste dump translates laterally along a shear surface, the foundation soils may spread and be squeezed ahead of the advancing dump toe. This phenomenon, known as foundation spreading, may result in progressive failure of the overall dump (Vandre 1980; BCMDC 1991).

Block translation. Block translation (planar sliding) may result from any of the inducing factors mentioned for rotational failure and is favored by steep foundation slopes and a thin, weak soil cover or lined surface. The bulk of the dump slides as a rigid block along a plane of weakness. This weak plane may be within the foundation soil, along the interface between the dump and the foundation, or along a liner interface.

Liquefaction. If the soil foundation or the waste dump itself is composed of liquefiable materials, and high pore-water

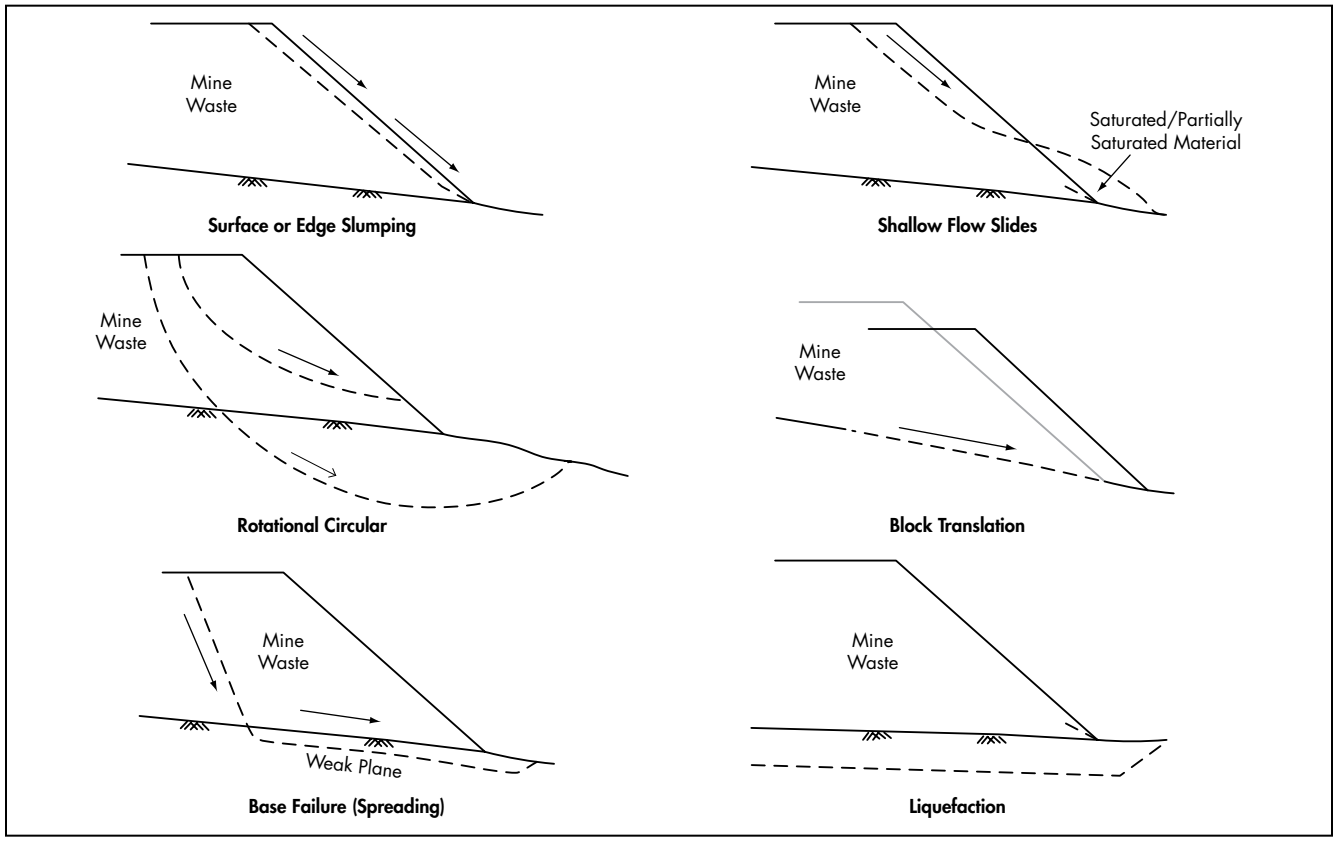

Figure 8.11-2 Failure modes

pressures exits, then liquefaction may pose a significant stability risk. If liquefaction occurs in the foundation, the entire dump may be translated or there may be progressive failure (BCMDC 1991).

Factors Affecting Slope Stability

To properly design a mine waste dump for stability, the following details should be considered:

- Site topography and location
- Dump geometry, rate of stacking, and lift thickness
- Geotechnical properties of the waste, liner system (if applicable), and foundation
- Methods of construction and equipment loading
- Seepage, phreatic surface level within the dump, and the solution collection system
- Seismic forces and liquefaction potential

The size and complexity of the project, as well as the consequences of dump failure, will typically control the extent of the investigation performed to obtain this information. The investigation should be thorough enough to identify all adverse conditions and to provide reasonable certainty that the parameters used in the design are appropriate (Vandre 1980).

Site topography. Based on economics, dump-site locations are typically selected to minimize the distance between the waste source and the disposal area. The waste may be disposed of in an area completely outside of the pit, or in-pit dumping may be preferred.

During the investigation stage of design, the topographic information gathered should include the entire drainage area that may affect the dump, as well as identifying those areas that would be affected should a dump failure actually occur. Should a failure occur, the inclination of the dump foundation will be an important factor in the dump stability as well as run-out distance. Experience shows that foundation slopes steeper than 25° typically result in lower factors of safety for slope stability. On the other hand, topographical features providing lateral support or toe buttressing will improve the stability of the waste dump.

Dump geometry and stacking method. The geometry of the waste dump depends largely on the dumping method, as well as the topography of the site. The two common construction methods for waste dumps include end dumping and stacking material in lifts or layers. If the material is end-dumped from the crest of the waste dump, the material will flow down the slope and rest at or near the angle of repose, with the larger particles rolling down to the toe of the dump (Couzens 1985). The angle of repose for mine waste rock typically falls within the 35°-to-40° range, leading to steep side slopes. The factor of safety for the slope of an end-dumped waste pile is close to 1.0. The slopes are generally not flattened or compacted until closure of the waste dump.

In comparison, layered or stacked dumps allow for a higher factor of safety to be maintained, because they are constructed in a more controlled manner from the bottom up. The layers can be placed and compacted to increase the density and strength of the material. However, except for the heap

leach piles, layered waste dumps are not always feasible, as they require relatively flat topography (Vandre 1980).

Waste dumps constructed from end dumping are more likely to have a loose, collapsible particle structure within the dump than those constructed from the layered method. Collapse will result in localized *arching*, which leads to reduced normal pressures and shear strengths (Vandre 1980).

The exterior slopes of heap leach pads and waste dumps are typically constructed as steep as practical during mining operations to maximize the tonnage contained in the dump. Slope-stability analyses are used to determine the maximum allowable overall slope angle, including benches, for maintaining stable slope conditions to the planned ultimate dump height (Breitenbach 2004).

Smith and Giroud (2000) examined the effect of ore placement direction on the stability of a geomembrane-lined heap leach pad and concluded that stacking ore in the down-gradient direction results in a less stable structure than stacking in the up-gradient direction typically would.

Geotechnical properties—mine waste. The geotechnical properties of mine waste materials vary significantly between projects and even between different phases of the same project. The density, saturation, and shear-strength parameters of the materials forming the dump slope affect the failure mode and the calculated factor of safety (FS) against sliding. Other useful information for design includes the particle size distribution, specific gravity, permeability, compression index, soils classification, and degradation behavior of the waste materials. These parameters are generally based on laboratory tests. However, field practices and construction procedures are often not completely simulated in the laboratory for various reasons (e.g., equipment limits, time and budget restraints), and therefore engineering judgment is required in selecting properties for stability analyses. Verification testing is often required during construction to ensure that the parameters used during the design were reasonable, accurate, and appropriate.

Waste rock is coarse material typically classified as cobbles, rocks, or boulders with some fines. As previously stated, the angle of repose for mine waste rock typically ranges from 35° to 40° and is based on factors such as particle size and shape, fall height, specific gravity, and amount of water present. The density of waste rock materials typically ranges between 1.6 and 2.2 t/m^3 (100–137 lb/ft^3), depending on whether the material is loose or compacted (Williams 2000). In heap leach pads, for example, the ore is purposely stacked in a loose state to maintain a high permeability, as required by the leaching process. As subsequent lifts are placed, the density of the lower lifts increases as they are compacted by material placed on top, and therefore the shear strength of the lower lifts typically increase (Smith and Giroud 2000). Stacking or dumping mine waste in thick lifts results in significant variability of the in-place density within each of these lifts.

Understanding the shear-strength behavior of the waste material is important for evaluating the slope stability of the waste dump. Waste density and gradation variability, along with differences in normal and confining stresses (e.g., inside the pile versus at the toe or on the slope face), result in heterogeneous shear strength throughout the pile. Generally, a linear-strength envelope with a single friction-angle value over the entire range of stresses may be assumed for the stability analysis. However, dump heights achieved these days result in a much wider range of normal stresses in the pile, over which the strength envelope does not necessarily remain linear, and this nonlinearity of the strength envelope must be considered in the stability analysis.

The dominance of cobble- and boulder-sized rock fragments in typical waste rock imparts a dilatant behavior under low effective normal stresses and significant crushing of contact points at high stresses, as demonstrated in the case of rock fill (Barton and Kjaernsli 1981). The friction angle of the rock fill is strongly stress dependent and will be significantly lower for material at the base of the dump (due to higher normal loads) than for material near the toe of the dump (under low loads). Barton and Kjaernsli (1981) estimated that the effective friction angle of rock fill increases by between 4° and 8° for every 10-fold decrease in effective normal stress. The shear strength of rock fill is also influenced by the rock-fill dry density, void ratio, unconfined compressive strength, uniformity coefficient, maximum grain size, fines content, and particle shape.

Laboratory testing of the mine waste is often too limited to accurately represent the potential material variability of a large volume of waste under various loading conditions. Therefore, the shear strength of the mine waste for design and analysis purposes must often be estimated based on various inputs, including current laboratory test results, previous experience, the behavior of similar materials, and published literature (Vandre 1980; K.P. Sinha, personal communication).

Another aspect to consider during design is the effect of weathering on geotechnical properties. Waste materials that were assumed to be durable may weather or be altered in some other way, which decreases slope stability. For example, weathering of feldspar-rich rock may result in formation of clay, decreasing the effective friction angle and inhibiting rapid drainage.

Geotechnical properties—foundation. The foundation is a critical factor in the overall stability of the waste dump. The dump-site investigation should identify the general geology of the site and any adverse geologic and soil conditions. The soil cover and rock weathering depths should be determined and the materials should be classified for design. Particular attention should be paid to the presence of shallow groundwater, discharge areas, landslides, creeping slopes, organic soils, clays, and dip slope bedrock structures (Vandre 1980). The subsurface exploration may include sampling, in-situ testing, and borehole geophysics, and should cater to obtaining the critical parameters for design.

After soil and rock samples have been obtained during the investigation, laboratory testing should be performed to identify the pertinent geotechnical properties of the materials. The classification, strength, permeability, and consolidation properties of the foundation materials, and how these properties are affected by time or saturation, should be determined. The shear strength and thickness of the foundation soil is an important parameter for slope stability and the dump failure mode. Permeability of the foundation material will affect the generation of pore water pressures in the foundation, affecting the dump stability and limiting the permissible dumping rate. Foundations consisting of low-plasticity silts and clay soils have been blamed for forming shear failure surfaces of several large (>10 Mt [11 million st]) dump failures (Zavodni et al. 1981). Consolidation parameters are used for calculating expected settlement of the foundation; excessive settlement could have serious implications in terms of the liner and collection system in case of heap leach piles and dump failure in general.

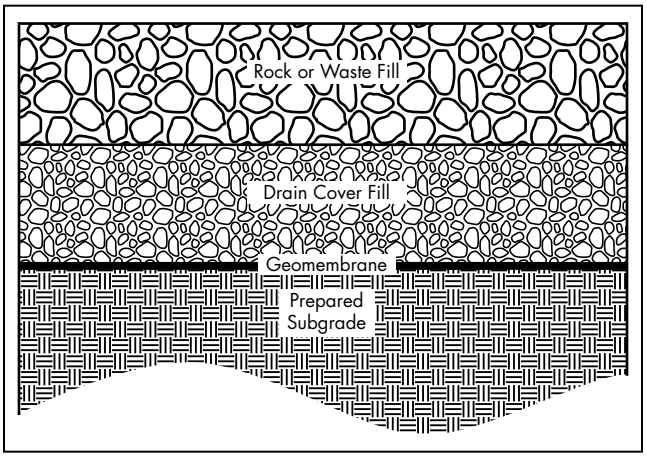

Figure 8.11-3 Example of heap leach pad liner system

Geotechnical properties—geosynthetics. Within the last 20 years, gold, silver, and, more recently, copper leach pads have been constructed with geomembrane-lined foundations (Breitenbach 2004). Typically, LLDPE or HDPE is used as the base liner. The decision is based on the elongation, strength, and other requirements of the application, as well as economic reasons. PVC liners have been provided in specific cases, mainly for economic considerations. The liner interfaces with the overliner (the drainage material), the subgrade, or the ore material itself (in case of interlift liners) create planes of weakness in the leach pile. An example of a geomembrane-liner system for a heap leach pad is shown in Figure 8.11-3. Slides in lined facilities usually occur by wedge failure along the geomembrane interface with geotextile or low-permeability subgrade (Breitenbach 2004), this being the weakest link in the chain. Thus, the soil–liner interface strength parameters may become the most critical data for evaluating heap leach stability. The soil–liner interface strength depends on several factors, including normal load, rate of applied shear, soil type, density, water content, and drainage conditions, as well as liner thickness, flexibility, and texture (Sample et al. 2009).

Just as with the waste and ore material, soil–liner interface strengths may also exhibit a nonlinear strength envelope, with the friction angle generally decreasing as the normal stress increases. Thus, as heap leach piles are extended to greater heights, decreases in the interface friction angle used for the stability analysis should be considered for the liner interface.

To select an appropriate minimum FS against slope failure, the designer must consider whether peak or post-peak (residual) strengths were used for the liner interface in the stability analysis. One method to ensure conservative design for wedge failure of a heap leach pad is to assume post-peak (residual) strengths for the liner system. Numerous studies of shear stresses for geomembrane–soil interfaces based on direct shear testing have been published, and the conclusions regarding peak versus post-peak strengths have been mixed. Post-peak strengths as low as 50% of peak strength have been observed for geomembrane–clay interfaces (Byrne 1994; Stark and Poeppel 1994), while other studies indicated that no strain-softening (i.e., reduction in strength with straining) behavior occurred (Koerner et al. 1986; Masada et al. 1994). Valera and Ulrich (2000) recommend the use of post-peak shear strength for soil–liner interfaces in stability analyses of heap leach pads, because the interface may reach residual strengths because of minor strains caused by installation and initial loading. Residual strength conditions may also be reached because of cyclic loading during an earthquake (K.P. Sinha, personal communication). Sharma et al. (1997) observed that the reduction in HDPE–soil interface strength after peak stress was greater when the plasticity index of the soil was more than 30.

Groundwater and phreatic surface. The effects of water on the stability of mine waste dumps can be difficult to evaluate, and measures should be taken to prevent excess water from entering the dump. In order to accurately assess the stability of the waste dump, a seepage analysis should be performed to establish flows through the dump and the height of the phreatic surface. Water pressure buildup within the dump will lower the FS for slope stability, and the potential for increases in the phreatic surface should be considered.

Within heap leach pads, the phreatic surface is often assumed to be some height above the base liner (e.g., 1 to 3 m [3.3 to 9.8 ft]), based on the design of the collection system. Because of the leaching process, leach pads present a combination of extreme base pressures and high moisture conditions not present in other lined facilities, such as landfills (Thiel and Smith 2004). In addition, leach pads are sometimes located in highly seismic areas, raising concerns about liquefaction due to sudden pore-pressure buildup.

An increase in the foundation water table may significantly decrease the FS for a deep failure through the foundation material, while perched water within the dump may lead to surface failures. Flow parallel to the surface of the slope may also decrease the FS significantly.

Seismic forces. In seismically active regions, the slope stability of the waste structure is also evaluated for seismic loading conditions. The seismic loading, although dynamic and cyclic in nature, is generally treated as a superimposed equivalent set of static loads, and the stability analysis for this case is referred to as the pseudostatic analysis. For these analyses, the two-dimensional mass in the limit equilibrium slope-stability model is subjected to a horizontal acceleration, which represents inertia forces due to earthquake shaking and is equal to an earthquake coefficient multiplied by the acceleration of gravity. The earthquake coefficient, or pseudostatic coefficient, is selected based on a specified design earthquake. Often a percentage of the maximum design acceleration in bedrock may be used for the pseudostatic analysis. However, selection of an appropriate pseudostatic coefficient may rely heavily on engineering judgment and is often debatable. Also, materials within the waste dump may undergo a significant loss of strength during earthquake shaking, which may not be entirely understood or defined from the laboratory testing. Therefore, while pseudostatic analyses are a simple and convenient tool, they should serve primarily as a screening method as to whether significant displacement may occur during the design earthquake. If a low FS is calculated in the pseudostatic analysis (e.g., <1.0), then significant displacements may occur, and displacement (deformation) analyses should be performed.

Dynamic analyses with numerical tools provide a more sophisticated alternative to pseudostatic analyses. Analyses may be performed with tools such as the finite difference program FLAC, and available finite element method and boundary element method programs. Use of these tools during design may depend on project budget, design requirements, and available resources.

For waste dumps, the greatest stability risk posed by earthquakes is typically liquefaction of foundation materials, although liquefaction may occur in susceptible waste materials as well. If liquefaction occurs in the foundation, the entire dump may be translated or there may be progressive failure (BCMDC 1991). Liquefaction due to seismic events is typically limited to 20 m (66 ft) in depth or shallower, due to the beneficial effects of confining pressure against liquefaction susceptibility (Thiel and Smith 2004). Simplified procedures to evaluate liquefaction resistance in soils have been widely discussed in the literature (e.g., Seed and Idriss 1971; Seed 1979; Ambraseys 1988; Suzuki et al. 1995; Arango 1996; Andrus and Stokoe 1997; Olsen 1997; Youd and Noble 1997; Robertson and Wride 1998; Youd and Idriss 2001). The paper by Youd and Idriss (2001) is a summary of commonly used procedures and provides recommendations for design.

General Design Considerations

All waste dumps have some risk of instability, whether due to an inadequate design process or unforeseen variability of assumed parameters. The issue of addressing uncertainty in geotechnical design has been discussed in depth by numerous authors (Duncan 2000; Christian 2004; Whitman 1984; Christian et al. 1993). The trade-off between the costs of a thorough geotechnical investigation versus the risks of design uncertainty has long been a challenging management decision in geotechnical projects. For mine sites, significant investment is typically made in exploration and estimating mineral resources, and the geology of a mine site is often more thoroughly documented than other types of geotechnical projects. Nevertheless, the engineering properties of the soil and rocks relevant to slope stability receive less emphasis. Baecher and Christian (2003) observed that the areas of geotechnical concern, such as slopes and waste disposal facilities, are usually associated with mine costs rather than revenue, and, therefore, significantly less money is devoted to their site characterization and laboratory testing.

One may ignore the uncertainties involved in a design, take a conservative approach, rely on observational methods (Peck 1969), or attempt to quantify the uncertainty. Geotechnical projects, in general, may include a combination of these methods.

Factor of safety. The most common way to take the conservative design approach is to require a minimum calculated FS for slope failure. The methods used to calculate the FS are described in detail in Chapter 8.3. The minimum FS selected for design allows for some margin of error between the assumed conditions and those that actually exist in the field, and should consider the following, as outlined by Vandre (1980):

- Consequences of instability
- Thoroughness of the geotechnical investigation
- Reliability of the design assumptions
- Ability to predict adverse conditions
- Possible construction deviations from design
- Engineering judgment based on past experience

The FS is calculated for normal loading conditions, as well as for seismic loading when the project is located in a seismically active area. In general, a minimum FS of 1.3 (for shallow failures) to 1.5 (for more significant failures) is considered acceptable for long-term (static) conditions (NAVFAC 1982; Vandre 1980). The FS required for extreme adverse conditions, such as the design seismic event or temporary slopes, is typically lower than that required for long-term stability of final waste slopes, and a range of 1.1 to 1.3 is generally accepted.

Reliability. For significant structures, such as waste dumps and heap leach pads, it is critical that sources of uncertainty in the stability analysis be acknowledged early on and considered in the overall design approach. As with any project, economics and other physical constraints such as space limitation do not always allow for an overly robust design. In an effort to quantify uncertainty and provide a level of confidence in the safety and reliability of a design, probabilistic methods have been developed and implemented in many slope-stability software packages. Reliability methods are often used in the design of open-pit mine slopes but not as commonly in designing heap leach pads and waste dumps. When selecting appropriate values for the input parameters of the stability analysis, the level of uncertainty in the data and the assumptions that are made must be clearly identified and considered in the design.

Simplified deformation analyses. Analyses may also be performed to evaluate seismically induced deformations. The pseudostatic analysis method can be used to calculate the yield acceleration of the sliding mass. This yield acceleration may then be used in simplified procedures for estimating earthquake-induced deformations, such as those provided by Makdisi and Seed (1978) and Bray et al. (1998). Determination of acceptable deformation limits may depend on several factors, such as regulations, engineering judgment and previous experience, and acceptable risk.

In summary, slope failure may occur in waste dumps by a variety of failure modes, which include surface slumping, shallow flow slides, rotational circular failures, base spreading, block translation, and liquefaction. In geomembrane-lined heap leach pads, slides typically occur by wedge failure along the critical interface of the liner system. Engineering judgment and experience must be used when selecting the appropriate analysis method for these potential failure modes, as well as when selecting input parameters for the dump materials and foundation. The reliability of the stability analysis results depends on whether the design assumptions are representative of the actual waste dump conditions.

Settlement

Waste rock settlement occurs because of particle reorientation, weathering of high clay-content materials, weakening of inter-particle bonding due to water, and transport of fine particles through the dump (Williams 2000). The rate of settlement is affected by dump height, loading rate, location within the dump, and material type (Zavodni et al. 1981). Settlement is more predictable and usually less in layered dumps than in end-dumped embankments.

During placement of the waste material, initially self-weight settlement may occur or crest settlement may happen because of compaction or surface sloughing from oversteepening (Zavodni et al. 1981). After waste placement, primary settlement and creep settlement occur at a decreasing rate with time and have been shown to continue for more than 10 years after dump construction (Williams 2000). The majority of the settlement, however, occurs within the first months after construction (Zavodni et al. 1981).

As the dump materials become saturated, there is a reduction in strength, and collapse settlement may occur (Williams 2000), especially in loose, end-dumped waste piles. The potential for collapse can be minimized with adequate compaction (Vandre 1980).

Under dry conditions, settlements of 0.3% to 7% of the waste dump height have typically been reported (Naderian and Williams 1996). However, settlements of more than 20% of the total dump height have also been documented (Zavodni et al. 1981).

Various techniques can be used to monitor deformations of waste dumps with time. These methods include onsite inspections, surveying, photogrammetry, extensometers, inclinometers, settlement cells, and laser beacons (McCarter 1985b). The appropriate monitoring methods are selected based on the waste dump height, material, and method of construction. Robertson (1982) describes the development and operation of effective waste dump monitoring systems.

Seepage and Drainage

The same fundamental seepage principles used in the design of earth dams and levees should be considered in the design of waste piles and tailings storage facilities (Cedergren 1989). Understanding fluid flow through waste dumps is important for evaluating both stability and environmental risks. Most mine waste dumps and leach piles are usually unsaturated, and accurate seepage and contaminant transport modeling requires determining unsaturated soil properties (Fredlund et al. 2003). However, unsaturated soil behavior is less understood than saturated behavior, and unsaturated properties and flow modeling are not always included as part of the waste dump and heap leach design. In fact, most geotechnical seepage calculations are based on saturated soils. The fundamentals of seepage through porous media are explained in detail in Chapter 8.2. The soil properties used in unsaturated flow modeling are briefly introduced here.

The soil parameters used in unsaturated flow modeling are derived from nonlinear equations using laboratory test data and are generally referred to as the hydraulic conductivity function and the water storage function. To model seepage through an unsaturated pile, these functions are required for each material in the flow path (Fredlund et al. 2003). Various methods of determining unsaturated soil parameters for input in waste dump models are described in detail in Fredlund et al. (2003). Some of these methods are also summarized here.

The hydraulic conductivity function (HCF) represents the conductivity of the unsaturated material at various water contents. The HCF can be measured in the laboratory or estimated using the methods of Brooks and Corey (1964), van Genuchten (1980), Campbell (1973), and Fredlund and Xing (1994). Many software packages allow users to select one of these methods when entering input parameters into the seepage model. Soil–water characteristic curves (SWCCs) represent the relationship between the water content of the soil and the soil suction, and can be measured in the laboratory using a variety of devices. The SWCC is also used to determine the water storage function, which relates the change in water content to the change in soil suction. This relationship becomes highly nonlinear as the soil desaturates (Fredlund et al. 2001).

The saturated hydraulic conductivity represents the limiting condition for unsaturated flow and is generally measured as such in the laboratory. However, if laboratory data are not available, there are multiple methods for estimating the saturated hydraulic conductivity of a material indirectly. The formulas typically relate the hydraulic conductivity to the grain size distribution of the material. Some of the available methods include those by Hazen (1892), Kozeny (1927), Carman (1938, 1956), Rawls and Brakensiek (1989), Alyamani and Sen (1993), and Sperry and Pierce (1995).

Design and construction elements can significantly affect seepage and drainage through waste dumps. The top surface of the waste dump should be graded to prevent surface water from flowing onto the slopes. Since the 1990s, geosynthetic *raincoats* have been used on heap leach pads in high-rainfall areas to minimize storm runoff flows into the collection ponds (Breitenbach 2004; Smith 2008). These raincoats also serve as protection against erosion and damage to the agglomerates (Breitenbach and Smith 2007a).

When waste rock is dumped, the coarsest fraction often ends up at the bottom of the dump, creating a *rock drain* at the base. Depending on topographic details, such rock-fill drain sections can be significantly large and a useful tool for controlling flow, especially in places such as valley bottoms where a watercourse already passes. If the flow capacity of the rock drain is exceeded, the phreatic surface may rise, lowering the stability of the waste dump. Therefore, understanding the hydraulic behavior of rock drains is important for waste dump design. Hansen et al. (2005) have provided some insight into this issue. Additionally, the Rock Drain Research Program was completed in Canada to study the characteristics of rock drains and their environmental effects (Fitch et al. 1998).

In heap leach pads, a properly designed and operating solution collection and liner system is critical for retrieving pregnant leach solution, as well as for controlling phreatic surface levels within the heap. The most versatile and preferred liner system currently used for heap leach pads consists of a low-permeability soil layer overlain by a geomembrane with a drainage layer of crushed rock (overliner) on top of it (Breitenbach 2000). However, in the drier and remote areas of South America, the geomembrane with the overliner is generally considered adequate. The geomembrane liners are specified by their material type, thickness, and surface roughness, and are designed on the basis of initial and final loading conditions and the expected strains produced in the liner. A properly selected overliner or drainage material and a stringent construction quality-assurance program during installation are crucial to performance of a liner system. The overliner material is specified in terms of gradation, or maximum and minimum particle size, in order to avoid puncturing the geomembrane, provide adequate support to the leachate collection pipes, and facilitate adequate drainage. Key concerns for liner system selections are summarized in Table 8.11-1.

Erosion

Erosion is a natural process that cannot be stopped, only controlled. Erosion on material stacked at the angle of repose can be hazardous, because of the risk of material failure and catastrophic movement downslope, as well as sedimentation and contamination of downstream waters. Reclamation and closure of waste dumps or piles usually requires regrading for reduction in slope and seeding of vegetation. Both of these efforts will dramatically reduce erosion. Large dumps, mounds, or piles are designed to control and collect runoff and prevent material failure. The final reclaimed landform is also an important element in long-term erosion control.

It is much easier and less costly to avoid contamination before it occurs than to clean up after the fact. Because of this, regulators and industry are designing facilities that, from their inception, reduce the potential for harmful effects to the environment.

Table 8.11-1 Key concerns for liner system selection

Engineering and Design Concerns	Construction Concerns
• Liquid containment: liner integrity • Operational and closure stability: interface friction strength, flexibility, nonplanar anchorage • Chemical and temperature compatibility • Subgrade and overliner: gradation, permeability, lift placement, compaction, surface preparation • Long-term exposure: ultraviolet (UV), oxidation/aging, animals, and other biological attack • Puncture resistance: subgrade and overliner fill type • Flexibility: differential foundation settlement, installation, puncturing • Tensile, tear, and seam strength: liner uniformity, thickness • Contact between composite geomembrane liner and low-permeability clayey soil subgrade	• Shipping to site: container rolls versus boxes • Installation, deployment, and seaming • Ease of repair: local liner expertise, equipment • Site access: storage area, perimeter access, slopes • Dynamic and static loading conditions: cover fill, roads, traffic, ultimate load • Weather and climate: UV, wind, rain, ice, temperature changes, stress cracking, expansion/contraction • Cold weather installation and cover: frozen subgrade, safety • Grade change adaptability: steep grade gravitational forces, corners, benches, pipe boots • Tie-ins for expansion facilities • Overall cost to construct: materials, labor, schedule

Source: Mark E. Smith and RRD International (Adapted from Smith 2008).

The erosion potential of the waste needs to be characterized, and, where possible, higher erosion-potential material should be capped with a material that has lower erosion potential. An example is the sodic waste rocks in Australia.

Rock Dumps

Rock dumps are generally designed with a slight grade on the top deck to allow rainfall to flow to a collection system and be conveyed to a collection pond. A similar system is placed at the toe of the dump as well. The water in the ponds is tested regularly and treated if required. The collection systems are normally part of the larger mine-wide stormwater control plan. A good stormwater management plan, which will prevent ponding of water against the safety berm at the crest of the dump, helps avoid washouts of the slide slopes on active rock dumps. Generally, the operational toe of a dump will be offset to accommodate the ultimate toe of the reclaimed dump, at a 2:1 (horizontal to vertical) or 3:1 slope, allowing room for minor ravel and washouts on the side slopes.

Another important erosion consideration for slopes is their shape. Concave slopes can reduce erosion (McPhail and van Koersveld 2006). Naturally eroded features are concave in shape, and by emulating this with wider catch benches on the lower elevations of the dump or pile, eroded material from the upper levels is slowed and deposited on the lower levels.

The configuration of the dump design is an important consideration in stormwater management planning. The run-on controls for a valley fill are much more complicated than for a ridge crest or heaped dump, as the entire design storm flow of the drainage needs to be conveyed around the dump or pile. In all cases it is important to keep rainfall from native ground separate from what falls on the dump, as the latter may be contaminated, whereas the former should not be.

Erosion has typically been modeled in civil applications using the U.S. Department of Agriculture Universal Soil Loss Equation, of which there are several variations, including the original Universal Soil Loss Equation (USLE), the Modified USLE, and the Revised USLE. However, this model is for agricultural situations where the slopes are much flatter than those used for waste rocks dumps. Several computer codes such as SIBERIA and CEASAR are being used that utilize digital terrain models and mathematical algorithms to predict both erosion and deposition. The various versions of the USLE calculate erosion loss only. These codes have their own disadvantages as well, such as the need for rigorous calibration (Hancock 2009).

Leach Pads

Leach pads are designed to allow leaching solution to pass through the stacked material, which is then collected on a liner system with collection pipes to be conveyed to the process facility. These systems catch and collect all meteoric water as well, and the ponds must be sized to capture a design storm. A detailed *water balance* is usually calculated to size the ponds and to understand the water needs of the pad and the process facility. In a properly designed leach pile, the material stacked on the pad should have a high enough infiltration rate to prevent excessive solution flowing on the surface and on the side slopes. Any such flow is captured in lined trenches around the pad.

ACID ROCK DRAINAGE

Acid rock drainage (ARD) occurs whenever unoxidized sulfide material is exposed to the atmosphere and water. Dumps, piles, or stacks of material are particularly susceptible to ARD due to the permeability of the material, availability of atmospheric oxygen, and amount of material that can come in contact with meteoric and surface water flow. This topic is covered in detail in Chapter 16.5 and is briefly touched upon here.

Design criteria for ARD prevention for large dumps or mounds include chemical characterization of the material, acid–base accounting (ABA), compartmentalizing the dump/pile into discrete cells for material buffering control, and run-on/runoff control.

Chemical Characterization

Some large mines in Nevada (United States) use ABA and build the waste rock facility to confine potentially acid-generating material in cells composed of acid-consuming material. This creates a net acid-neutralizing environment. In order to do this, good characterization of the material needs to be completed. With modern production analytical capability and mine dispatch systems, material that is not ore can be characterized and routed to a specific location on the dump. If the material balance is not net acid neutralizing based on the ABA, the dumps may need to be placed on a low-permeability layer and capped upon closure.

Waste characterization can also include tests for total and soluble metals, such as the U.S. Environmental Protection Agency's (EPA's) toxicity characteristic leaching procedure and the State of California's waste extraction test. Testing for pH in water flowing from dumps is important, because lower-pH water is more likely to contain metals that have been leached out of the waste rock.

Run-On and Runoff

The run-on component of meteoric water is controlled based on a stormwater management plan. Stormwater collection systems need to be well thought out and based on the mine plan, topography, and required maintenance. A mine-wide

stormwater management plan is required for mines in the United States, and these plans are site specific.

The runoff component of meteoric water is controlled by the waste facility's design and may be included in the overall stormwater plan. Important considerations for the runoff plan include material classification, treatment requirements, and appropriate sizing of ponds and catchments. In the case of a waste rock dump, water that infiltrates the dump will be contained at the toe of the dump. Only the surface flow will be contained on the top.

CLOSURE AND RECLAMATION

Closure and reclamation of heaps and piles are necessary for environmental, ecological, and health and safety reasons, and in some instances for economic reasons such as to recover bonds posted during the permitting or construction phase.

The closure process typically requires detoxification of heap leach facilities, and reclamation usually means decreasing the slopes of heaps and dumps, covering the area with growth media, and reseeding vegetation where appropriate. Rock dumps that have acid drainage issues require ongoing treatment of the water flowing from these facilities. Detoxification of leach pads is required in the United States and typically involves lengthy periods of rinsing to reduce the cyanide or other toxic content of solutions circulating in the heap.

Sloping the waste facility to moderate slopes of 3:1 (horizontal/vertical) or flatter is typically required. Capping of dumps and leach facilities with semipermeable capping material allows for the establishment of a growth medium for planting vegetation, which is the best way to prevent erosion. As discussed previously, the final landform should be concave if possible, with shallower slopes at the base of the facility. In addition, many agencies are requiring certain randomness to the final landform, avoiding stretches of linear slopes and ridges. Many operations do concurrent reclamation, where they slope and plant segments of their facilities to reduce the overall operating footprint and possibly to recover a portion of their bond.

An important factor to consider is the longevity of the closure system. Many waste facilities are looking at closure periods in hundreds of years, and waste facilities containing radon or other radioactive material are looking at thousands of years of containment. Natural material will last longer than synthetic materials, and this must be considered in the design of a facility handling radioactive material.

RADIOACTIVE WASTE ROCK

Some waste rock can be radioactive and may require special design considerations. Uranium mill tailings have received a lot of attention because of their radioactive properties and as a result are designed for long-term disposal. Phosphate mining and processing produce phosphogypsum tailings, which may also contain trace levels of radioactive material (FIPR 2010).

Phosphogypsum tailings have been used as fertilizers and for other uses. However the EPA has banned the use of phosphogypsum with an average radium-226 concentration of >10 pCi/g (picocuries/gram) for agricultural application (FIPR 2010). As a result of phosphate mining, currently 0.909 billion t (1 billion st) of phosphogypsum waste materials are stacked in the state of Florida, and about 27.3 million new metric tons (30 million short tons) are generated each year.

Uranium tailings contain low levels of radioactive radium-226. Ra-226 has a half life of 1,620 years and decays into the odorless and colorless gas radon-222, which has a half life of 3.8 days. Inhalation of Ra-226 is known to lead to lung cancer. Because of the radioactive properties of uranium tailings, the standard practice is to design the impoundments for long-term disposal, typically 1,000 years. To avoid erosion over this type of time frame, slopes of the piles need to be minimized, and natural forms of containment should be utilized.

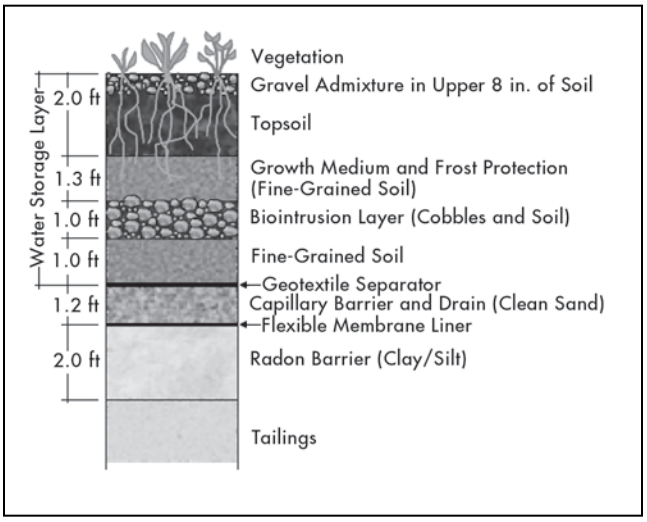

Figure 8.11-4 Typical cover for uranium mill tailings

In the United States, the design of uranium tailings impoundments and covers falls under regulations in the Uranium Mill Tailings Radiation Control Act of 1978. These regulations require that a cover be designed to produce reasonable assurance that the radon-222 release rate does not exceed 20 $pCi/m^2/s$ for a period of 1,000 years to the extent reasonably achievable, and in any case for at least 200 years when averaged over the disposal area for at least a 1-year period. In some cases at inactive sites, the regulations allow for a radon concentration of <0.5 pCi/L above the background concentration. The regulations also state that the tailings should be disposed of in a manner that no active maintenance is required to preserve the conditions of the site.

The typical cover includes, from bottom to top, the following layers (thicknesses are variable):

- 0.61-m (2-ft) radon/infiltration barrier consisting of clay
- 0.15-m- (0.5-ft-) thick capillary break layer consisting of coarse sand/fine gravel
- 1.07-m- (3.5-ft-) thick water storage soil layer consisting of fine-grained soil
- 0.15-m- (0.5-ft-) thick surface erosion protection layer (soil/rock mixture) consisting of 80% soil, 20% riprap boulders
- Vegetated surface for water balance control

The actual thickness of the radon/infiltration barrier in a specific case would be based on calculations of radon flux at the surface of the compacted soil layer. An example design is shown in Figure 8.11-4. The soil type would be selected from available borrow sources that can satisfy performance requirements for permeability and radon attenuation. The compaction requirements would be determined with tests and calculations of saturated hydraulic conductivity and radon attenuation.

A uranium mill tailings cover calculator is available on-line at www.wise-uranium.org/ctch.html. This calculator

determines the radon fluxes and concentrations in multilayer uranium mill tailings and cover systems, and optimizes the cover thickness to satisfy a given flux constraint. The calculator is a clone of the RAECOM (Radiation Attenuation Effectiveness and Cover Optimization with Moisture Effects) code (Rogers and Nielson 1984). The input data include

- Radium-226 activity concentration (if the value is unknown, it can be estimated from the grade of ore processed in the uranium mill);
- Radon-222 emanation fraction (the fraction of the total amount of Rn-222 produced by radium decay that escapes from the soil particles and gets into the pores of the soil);
- Radon-222 effective diffusion coefficient;
- Porosity;
- Moisture content; and
- Minus #200 sieve fraction.

Typically, the effective diffusion coefficient of radon in unconsolidated soil material with low moisture content is in the order of 1.0^{-6} m^2/s (1.08^{-5} ft^2/s). The upper limit is represented by the radon diffusion coefficient in open air, which is approximately 1.1×10^{-5} m^2/s (1.18^{-4} ft^2/s). At the lower extreme, in a fully saturated soil material, the radon diffusion coefficient may be as low as 1.0^{-10} m^2/s (1.08^{-9} ft^2/s).

ACKNOWLEDGMENTS

The authors thank the following for their assistance in preparing this chapter: Krishna Sinha, corporate technical director, who acted as technical reviewer; and Peter Holland, senior geologist, for the uranium section.

Infrastructure and Services

CHAPTER 9.1

Electric Power Distribution and Utilization

Reinhold A. Errath

POWER DISTRIBUTION IN MINING

This chapter introduces the engineer to electrical power use in mining and concentrator plants, drawing upon mining equipment designs of the last decade.

Today's mine power systems are complex and subject to numerous technological and environmental constraints. It is no longer possible to treat the subject with the indifference shown in the past. Power distribution equipment is partly stationary and partly mobile, and subject to extreme levels of dust, moisture, and vibration. Mining and concentrator machinery create electrical loading that is often cyclic and variable. Designing and maintaining such an electrical distribution system is challenging and demanding, and requires specialist knowledge of both mining and electrical engineering. Effective mine management requires that those who are responsible for production and safety be familiar with the mine's electrical distribution system.

Typical mining and concentrator-plant power requirements today are ~120 MW for a 100,000-t/d (metric tons per day) plant. In the utility substation, power is transformed from transmission distribution voltage to commonly 22 to 33 kV, and then carried to major load areas to supply large industrial consumers directly or to power distribution substations that step the voltage down.

It is the responsibility of the mining company to select the voltage best suited to its needs. The choice depends primarily on the amount of power purchased. It is not safe to assume that a power company can serve a large mine complex from existing primary distribution lines or even from the transmission system. The problem stems from the fluctuating nature of mine loads. For example, large excavators in surface mines can require high peak power for a short time, followed by regenerative peak power, all cycling within a span of 45 seconds. Fluctuating loads can create voltage and frequency variations beyond the limit set for other utility customers. Similarly, most large draglines and shovels require 4.16 to 30 kV to start up.

History of Electrical Use in Mines

In the late 1800s, electricity was introduced into mines in the form of direct current (DC) for rail haulage. Direct current was used because most systems at that time were powered by DC generators. Direct current has a number of advantages for haulage, the most outstanding of which is that series-wound DC motors have excellent traction capabilities.

In the early 1920s, the first electrically driven mining machine for underground use, the coal cutter, was introduced. This was followed almost immediately by the loader, also driven by DC motors. In mines with rail haulage, trailing cables supplied power to the machines from trolley wires and rails.

In the late 1930s, the next significant increase in power consumption came with the introduction of the shuttle car. The car was battery powered at first. Later, an automatic reeling device to handle a trailing cable was added to overcome the deficiencies of batteries; the cable was connected to the haulage power system. This equipment, when combined with the cutters and loaders, placed additional demands on the DC distribution system.

In the late 1940s, DC was again expected to provide the power as continuous mining machines began to be used extensively in coal mines. However, continuous mining equipment typically consumed more energy than did the various conventional mining machines that they replaced. Consequently DC now proved unsatisfactory in most cases, and the high current demand created enormous voltage drops in the distribution system. The DC supply system was therefore separated from the haulage system, but even this proved inadequate. Voltages at the machines were so far below rated values during peak operating periods that even moderate efficiency was unachievable. The increasingly large cable sizes required to supply the needed power were difficult to handle. The use of three-phase alternating current (AC) motors and distribution was the obvious answer.

Mines quickly converted from DC to AC for both distribution and high-horsepower loads in mines when higher voltages were permitted by the authorities. As a result of these conversions, mine power systems generally now have two voltage levels: distribution and utilization. The substation transforms the utility voltage down to distribution levels. Power is distributed through conductors from the substation to the power center (sometimes called the load center). The

Reinhold A. Errath, Technology Manager for Drives, ABB Switzerland Ltd., Baden, Switzerland

power center is either a portable switch room or fixed installed "e-rooms" where voltage is transformed to low-voltage utilization levels: today typically 660 or even 480 V. However, despite this reference to voltage levels, the terms *distribution* and *utilization* describe functions of the power system, not specific voltage ranges.

Originally, primary AC distribution was made at 2,300 or 4,160 V. In most mines, these levels were later increased to 7,200 or 13,200 V. The principal reason for the increase was that, at higher voltages, the same load draws correspondingly less current. Cables can thus be smaller, which reduces costs and also distribution losses. From the beginning, 480 V AC was most popular for utilization, despite the fact that drive powers progressively increased as continuous mining proved successful. The downside was that additional drive power required larger trailing cables. Most operations compensated by raising the rated motor voltages to 550 V. Recently, manufacturers have produced machines with 950-, 2,400-, and 4,160-V motors to further overcome problems with trailing cables.

Whereas series-wound DC motors were universally used for underground rail haulage, the first large motors used for surface mining were shunt-wound DC because of their constant-speed characteristics. Initial distribution for electric shovels was also DC.

Technological advances soon made AC power systems superior and AC motors were tried with some success. However, by 1927, AC/DC motor–generator (MG) sets and the invention of the Ward–Leonard (W-L) control concept caused these efforts to be abandoned. The new control system enabled motor speed to be varied by altering the armature voltage while maintaining a constant voltage across the shunt field. The MG sets functioned as onboard power-conversion units, thereby establishing the use of AC distribution in surface mines. Sets driven by synchronous or induction AC motors, W-L control, and DC motors established the standard, and even now the combination is still used on older mining excavators.

The W-L concept is no longer used for new installations. Rather, the standard today is the frequency converter and the AC motor. The multiple-drive (sometimes called multidrive) configuration, which is standard now for shovels with more than one motor, is a fully 4Q operating system, where 4Q signifies four quadrants—that is, motor and generator modes in both directions of rotation.

Power Terminology

Several terms are used to describe the operation of a power system. These terms are applicable not only in system design, operation, and maintenance but also in utility company billing.

The sum of the electrical ratings for all equipment in an electrical operation gives the total connected load, expressed in kilowatts (kW), kiloamperes (kA), kilovolt-amperes (kVA), or amperes (A). Many loads operate intermittently, especially for mining equipment, with varying load conditions. Accordingly, power demand is frequently less than the connected load. This fact is important in the design of a mine power system. The system should be designed for what the connected load actually uses, rather than the total connected load. Obviously, these considerations have great impact on power system investment.

IEEE has standard definitions for load combinations and their ratios because of the importance of assessing equipment power demands. The most important definitions are the following (IEEE 141-1986):

- **Demand:** Electrical load for an entire complex or a single piece of equipment averaged over a specified time interval. The time or demand interval is generally 15 minutes, 30 minutes, or 1.0 hour. Demand is generally expressed in kilowatts, kilovolt-amperes, or amperes.
- **Peak load:** Maximum load consumed or produced by one piece or a group of equipment in a stated time period. It can be the maximum instantaneous load, the maximum average load, or (loosely) the maximum connected load over the time period.
- **Maximum demand:** Largest demand that occurs during a specified time period.
- **Demand factor:** Ratio of the maximum demand to the total connected load.
- **Diversity factor:** Ratio of the sum of the individual maximum demands for each system part or subdivision to the complete system maximum demand.
- **Load factor:** Ratio of the average load to the peak load, both occurring in the same designated time period. This can be implied to be equal to the ratio of the actual power consumed to the total connected load in the same time period.

For example, consider a power cable supplying several mining sections in a mine or concentrator plant. The sum of the connected loads on the cable, multiplied by the demand factor for these loads, yields the maximum demand that the cable must carry. When applied to current, this is the maximum amperage. Good demand factors for mine power systems are in the range 0.7–0.8, depending on the number of operating sections; the lower value is used when there are fewer producing units.

The demand factor can be extended to include estimates of average load. For instance, the sum of the average loads on a cable multiplied by the demand factor provides the average load on the cable. A prime application here is for approximating the current that a conductor is expected to carry. The demand factor and the diversity factor can be applied to many other electrical applications, such as estimating transformer capacities, protective circuitry continuous ratings, and the load that a utility company must supply.

The load factor can be used to estimate the actual loads required by equipment. Here the total connected load multiplied by the load factor yields an approximation of the actual power consumed. The average load factor in underground mining tends to be low, due mainly to the cyclic nature of machine operation but also to the use of high-horsepower motors for performing specific functions, sometimes for only a small fraction of the possible running time.

The peak load is normally one basis that utility companies use to determine power bills. Most often, one month is the specified time period. Demand meters are often installed at the utility company's metering point.

Design Criteria

The goal of the engineer is to provide an efficient, reliable electrical system at maximum safety and for the lowest possible cost. The types of information made available to the engineer include the following:

- Expected size of the mine
- Anticipated potential expansion
- Types of equipment to be used
- Haulage methods to be used

- Available power from the utility company
- Amount of capital assigned for the electrical system

Designing a safe, reliable electrical power distribution network for an industrial plant requires detailed planning to avoid installation, commissioning, and operational problems and limitations of future plant expansions. Basic questions regarding mine operation scenarios need to be answered, and careful attention must be paid to the following:

- Location of equipment, altitude, and earthquake zone (for installations at >1,000 m above sea level, design must be suitable for operation at higher altitudes; in earthquake-prone areas, design must be as specified in the *International Building Code* [ICC 2009], which replaced the older Uniform Building Code)
- Safety of electrical technicians and other personnel, reliability of operation, simplicity, maintainability, and selective system operation
- Voltage regulation (to handle fluctuations in voltage resulting from changes in electrical load), high/medium/low voltage levels (designated HV/MV/LV) and breaker technology, transformer sizes and impedances, protection monitoring, and control philosophy
- Load flow and network harmonic studies, harmonic distortion levels at the point of common coupling (PCC), electromagnetic compatibility (EMC) issues, and power factors
- System efficiency, grounding and lightening, and potential for expansion

Of these, safety, reliability, and simplicity are closely related, depend on good preventive maintenance, and are of vital concern in the cramped, inhospitable environment of a mine operation, especially in underground mines. Routine and dedicated maintenance should be performed only by electrically trained personal, and training for these tasks must be provided.

Importance must be paid to the mean time between failures (MTBF). The failure rate increases as the number of installed components in a system increases. Similarly, the mean time to repair (MTTR) must also be carefully considered. Safety is enhanced with reliability measures such as adequate interrupting capacity, current-limiting capability, and selective system operation. Adequate interrupting capacity and current-limiting capability ensure protection during a disturbance. Current limiting, when applied to grounding, is perhaps the most significant personnel safety feature of mine electrical systems. Selective system operation is a design concept that minimizes the effect of system disturbances.

Although initial cost is important, it should never be the determining factor in the design of a mine's power system. High-cost equipment can easily offset first costs by reducing operating costs when designs maximize safety and reliability.

Using the data available, the task of the mine electrical engineer is to

- Select one combination of power equipment;
- Provide power or circuit diagrams;
- Estimate equipment, operating, and maintenance costs;
- Set system specifications; and
- Receive and assess proposals from suppliers.

The engineer must possess a firm knowledge of mine power systems and operating plans. No two mines are exactly alike, so there can be no standard mine electrical system. The engineer must resort to fundamental concepts, an awareness of what has worked in the past, and a clear understanding of technological, operational, environmental, and safety constraints.

Power Supply and Distribution Equipment Solutions

The increase in power plant size in the last decade has been accompanied by an evolution in mine power systems toward higher complexity. Key aspects of concern must now include the following:

- Overhead power transmission
- Voltage level
- HV substation
- HV, MV, and LV technologies

Overhead Power Transmission

Power requirements for a 100,000-t/d plant can typically reach 120 MW as a consequence of almost yearly increases in grinding-equipment size involving, for example, huge mine hoists, transport belts, and pumps. In addition, concentrator plants are usually built in remote areas where power supply and network conditions are not always adequate. The trend in load-behavior characteristics over the last few years, from network linear loads to nonlinear loads, requires sufficient network short-circuit power capability to operate the electrical equipment correctly. Adjustable-speed drives constitute 80% of the total installed power in today's modern mine operations, resulting in 70–90-MW nonlinear loads from 120 MW of installed power.

The short-circuit power at the PCC defines whether a plant is normally operable or special measures must be taken. The best engineering practices specify the following:

- If the short-circuit power at the PCC, in megavolt-amperes, is a factor of >6 times the total nonlinear installed power in megawatts, no special measures need be taken. If the factor is <6, consideration must be given to implementing special filter and compensation units, voltage compensators, or, in the worst case, rotating synchronous condensers.
- The minimum short-circuit power at the PCC must be ≥400 MVA for a 100,000-t/d plant. The maximum short-circuit level must be kept within the breaker-protection capability.

There are in principle four remedial approaches.

Approach 1: Replace single lines with two parallel lines. For plants in remote areas, overhead power-line lengths from the next power station can easily be up to 400 km. The transportability of electrical energy is reduced significantly in such cases because of the inductive resistance of the line. A solution is to run not just single lines but two parallel lines (Figure 9.1-1A). For example, a single overhead line whose short-circuit power is 700 MVA at the beginning of the line furnishes, at 300 km, only 40% of its original value (280 MVA); two parallel lines furnish 60% of their original value (420 MVA).

Approach 2: Increase voltage in the lines. An alternative method of boosting short-circuit power in overhead lines is to increase the line transmission voltage (Figure 9.1-1B). For example, a 230-kV overhead line whose short-circuit power is 700 MVA at the beginning of the line furnishes, at 300 km, only 40% of its original value (280 MVA); a 400-kV line furnishes 70% of its original value (490 MVA).

Approach 3: Use direct current. Another solution, for distances of >600 km, is to use DC transmission (Figure 9.1-2).

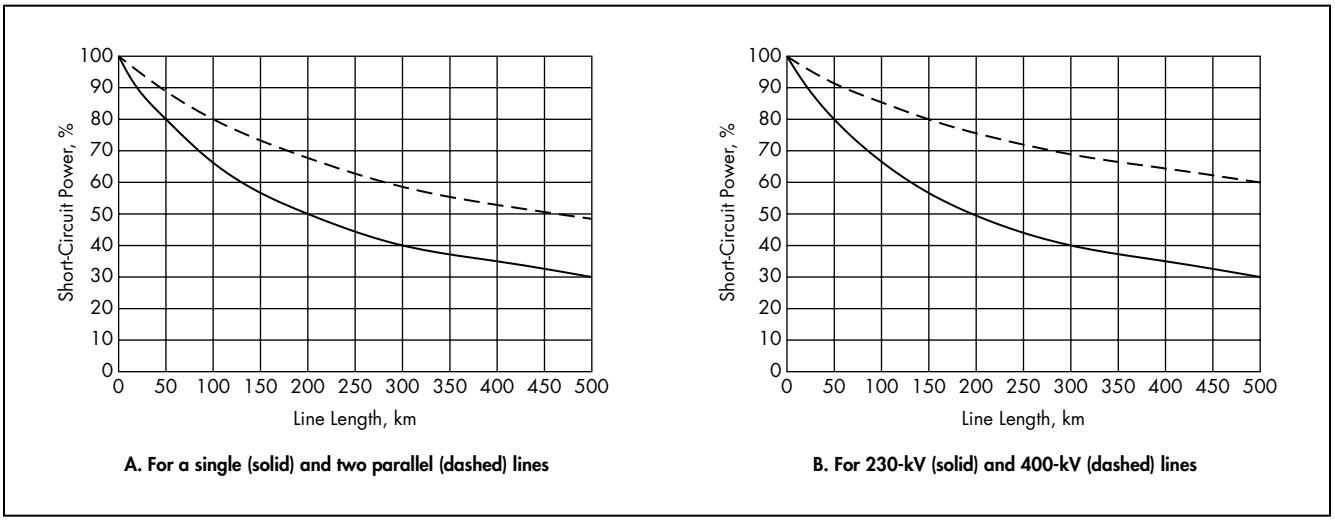

Figure 9.1-1 Short-circuit power as a function of overhead line length

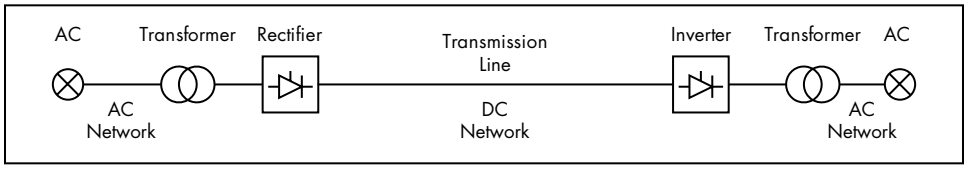

Figure 9.1-2 DC transmission

DC transmission by overhead line or by cable at high voltage (750–1,000 kV) is an alternative at these distances. Relevant factors are the voltage drop from the beginning to the end of the line and the ohm resistance (there is no inductive line resistance). A significant advantage over AC transmission is the nonattenuation of short-circuit power along the line.

Approach 4: Produce supporting power directly at the plant. Power production directly at the plant is technically advantageous. First, there is no attenuation; full power is available at the plant. Second, network short-circuit power on the PCC is improved. This approach makes sense for plants located in remote areas. For example, an additional on-site power generator of 50 MVA increases network short-circuit power to ~350 MVA and solves many problems that are characteristic of weak networks. However, the advantages of this solution are largely outweighed by the disadvantages, including the need to transport fuel to remote areas and the logistical and technical problems at high altitudes.

Voltage Level

The network connection voltage is generally determined by the power utility and depends on the required power of the new facility, capacity of the local network, location of utility substations, and utility network voltages. Typical loads that utility authorities allow for connection to their system are listed in Table 9.1-1.

Utility planning authorities dictate their requirements and rules in most cases when permitting connection to their electrical grid. Typical considerations include the following:

- Ownership of the substation
- Total harmonic distortion limits (set by the authorities to typically <5%)

Table 9.1-1 Typical loads allowed by utility authorities

IEC* Connection Voltage, kV	NEMA† Connection Voltage, kV	Load, MW
11	13.8	20
22	24	20
33	38	40
66	72	60
132	145	150
220	260	200
500	550	500

*IEC = International Electrotechnical Commission.
†NEMA = National Electrical Manufacturers Association.

- Power factor requirements (set by the authorities to typically >0.9)
- Maximum power drawn
- Short-circuit contribution from plant to grid
- Equipment and installation standards that must be fulfilled
- Protection and metering requirements
- Load-shedding systems

HV Substation

After the coupling voltage has been determined with the utility, the HV substation can be considered. Factors to consider include the following:

- Current requirements
- Lighting and voltage insulation levels
- Short-circuit levels
- Environment

Table 9.1-2 Typical loads allowed by utility authorities for HV switchgear and associated equipment

Connection Voltage, kV	Load, A	Short-Circuit Level, kA
66	3,150	40
132	3,150	40
220	3,150	40
500	3,150	40

- Site conditions (potential pollution, earthquake, and atmospheric conditions)

Common engineering practice in the last two decades is to indicate the most-used configuration in terms of load and short-circuit levels for HV switchgear and associated equipment, as shown in Table 9.1-2.

The substation should be located as close as practical to the load without compromising safety and access to the site and plant during construction and future expansions. The location should be chosen so as to minimize contamination from dust sources such as stockpiles and from airborne chemicals. To minimize power outages, redundant incoming power supplies should be considered.

Use of underground cables and surge arrestors rather than overhead line construction should be considered when designing the substation. This solution minimizes exposure to lighting strikes and provides a good safety margin for inadvertent accidental contact with live HV connections by heavy machinery or personnel.

Depending on the configuration from the overhead line (i.e., whether there is one line or two lines from different sources), often multiple HV/MV transformers, 50 to 80 MVA each, are installed. On the MV side, the transformers also feed three or four distribution systems that are connected by selectable tie breakers. This configuration covers all plant operational conditions including failure of one of the transformers. Because of the operational flexibility with this configuration, it is essential that a switching concept for the tie breakers be implemented. The concept must respect not only the plant load but also power factors and network harmonics.

Usually automatically operated tap changers are installed on the primary side of the transformers. Tap changers provide the correct voltage to the plant and mine consumers, and compensate for voltage variations in the HV feeder line or voltage changes due to varying load requirements in the plant. Tap changers are usually switchable in ±2.5% and 5% steps. It is critical that the function of the tap changers be coordinated as soon as the distribution bars on the secondary side are connected (i.e., the tie breaker is closed). One tap changer must be designated master and the others slaves. Later, if more plant loads are added, it can be relatively simple to boost the transformers for more power with forced cooling.

A delta primary connection and wye (Y-shaped) secondary connections are preferred for standard two-winding power transformers, and are commonly used in mine power centers. The wye secondary connection provides an easy means for resistance grounding. The delta primary connection isolates the distribution circuit from the utilization circuit with respect to ground currents. The delta–wye connection stabilizes the secondary neutral point and minimizes production of harmonic voltages. In certain situations, a delta secondary connection may be specified and the primary connection may be a delta or a wye. If neutral grounding is desired or required, a grounding transformer is needed to derive a neutral grounding point.

The point of common coupling (PCC) is the point where the utility ends and the plant starts. This point defines the following:

- Level of voltage distortion from the utility to the plant and contribution from the plant to the utility, needed to design the harmonic filters. The most frequently used standard is IEEE 519-1992.
- Power factor from the plant to the utility, needed to design power factor correction equipment. A value of >0.95 is generally required.
- Allowable voltage fluctuations, needed to design equipment for the rated load and to protect it from over- and undervoltages.
- Network short-circuit power, in megavolt-amperes, needed to design harmonic filters and converter transformer impedances.

A typical power distribution configuration for a mine and plant operating at >100,000 t/d is shown in Figure 9.1-3.

HV and MV Technologies

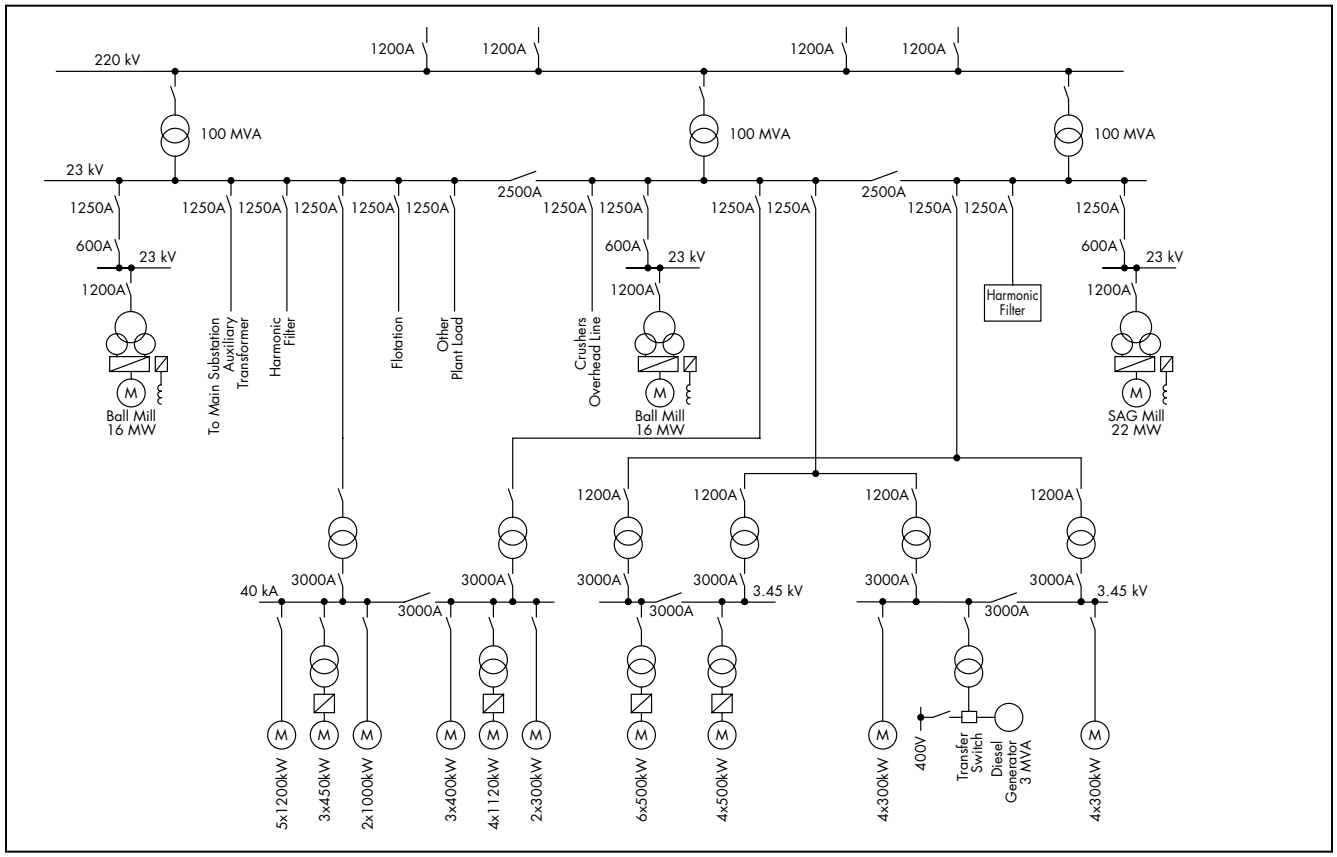
HV and MV technologies relate primarily to the types of switchgear system used. Switchgear systems are of two types: air-insulated switchgear (AIS) and gas-insulated switchgear (GIS) (Figures 9.1-4 and 9.1-5).

Conventional metal-clad AIS systems fully fitted with draw-out circuit breakers (CBs) are in common use. For primary distribution circuits, either vacuum or sulfur hexafluoride (SF6) circuit breakers can be used. Both provide similar operating and technical characteristics. Vacuum circuit breakers are lower in cost but can expose electrical distribution systems to overvoltages from motors during the switching-off cycle. This problem can be eliminated by using fused vacuum contactors (FVCs) rather than circuit breakers. FVCs should be considered for high short-circuit levels or high MV-motor switching cycles. Their use provides MV motor protection, reduces required cable sizes and thus costs, and prolongs device life by reducing the amount of let-through energy incurred.

These relative performances of these three AIS technologies are compared in Table 9.1-3. The cable sizes required for use with various FVC and CB configurations are listed in Table 9.1-4.

GIS systems offer several advantages over AIS systems. They are much more compact (20 × 15 m, as compared with 75 × 75 m). They are available up to 500 kV and are minimally affected by power derating factors. They can easily accommodate a duplicate bus-bar system. They are suitable for use in site conditions that are arduous with high contamination, high altitude, or extreme climatic conditions. They can become cost-effective when consideration is given to substation real estate, civil works excavations, and geographical location. Systems are available that provide visible isolation and equipment grounding facilities for operator verification, thus ensuring safe and practical isolation of the electrical plant.

Primary distribution network voltage should be determined according to a site's distribution distances and power-flow requirements, which depend in turn on site size, location, and conditions. Current requirements, lighting, voltage insulation levels, and short-circuit levels are all important.



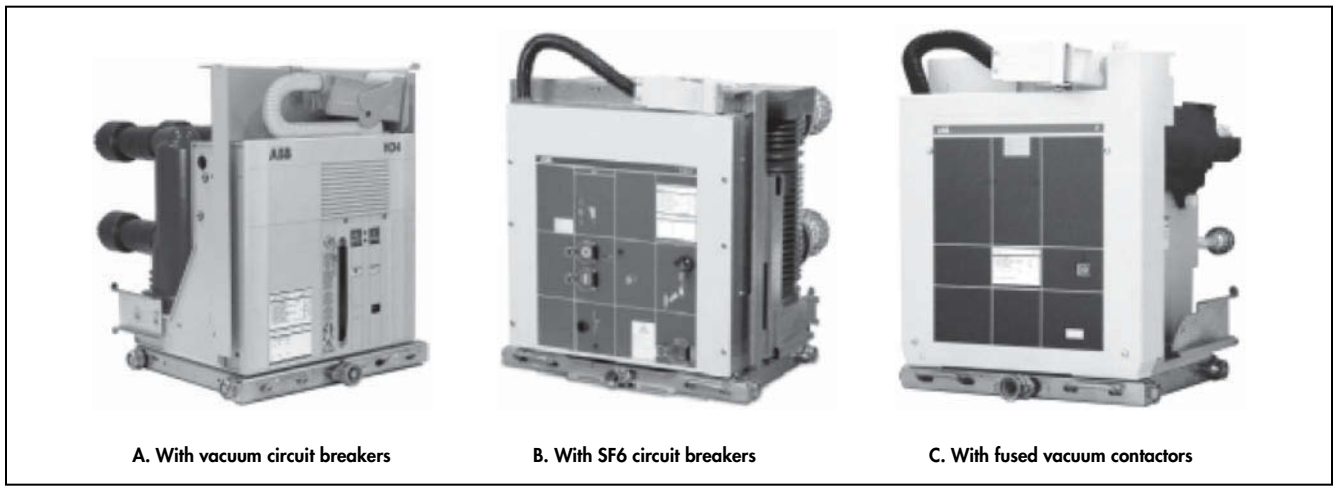


Figure 9.1-3 Typical power distribution configuration for a mine and plant

A. With vacuum circuit breakers **B. With SF6 circuit breakers** **C. With fused vacuum contactors**

Figure 9.1-4 Air-insulated switchgear systems

The cost of cabling between substations should be a determining factor in distribution voltage selection. Substation and associated equipment for MV installations should be designed for full arc fault containment to provide maximum operator safety during installation or in the event of an internal switchgear fault. Consideration should be given as to how to increase distribution voltage when current and short-circuit values rise above the typical values shown in Table 9.1-5.

When supply outages cannot be tolerated, duplicate bus-bar systems should be considered for switchgear. Such systems give additional flexibility to the power distribution system. However, they are relatively costly. Consideration should also be given to emergency power feeds for critical areas of the process.

LV Technologies

Civil installation and transformer costs can be minimized by careful grouping and positioning of motor control centers (MCCs). Redundant or standby drives and feeders should be positioned within the MCC so as to avoid common modes of failure such as cubicle faults and loss of control supplies.

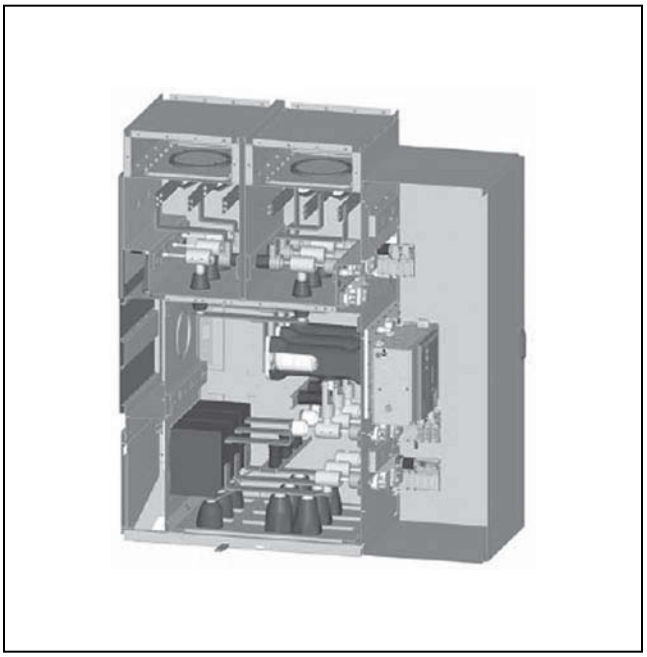

Figure 9.1-5 Gas-insulated switchgear system

Cabling and hardware costs for connecting the electrical and control systems are simplified with the advent of intelligent switchgear systems with electronic protection and monitoring and with control devices with communication facilities.

Larger MCC installations can be accommodated with appropriately large switching-hardware current ratings and short-circuit clearing capacities. Large industrial projects increasingly use 690-V rather than 400-V systems; the relative capabilities of the two systems are shown in Table 9.1-6. Single loads, for instance for a motor, are limited to the values shown in the table due to the need to limit the thermal loading of the connected MCC module.

MCC packing density should also be confirmed to avoid excessive temperatures in the MCC and associated components. As with MV gear, the cost of cabling between areas should be a determining factor in the selection of operating voltage. Substation and associated equipment for LV installations should be designed for full arc fault containment.

For weak networks, any voltage drop upon motor start-up must be considered, as well as the cable length and size between the MCC and the motor. If the voltage drop is outside limits, the motor may not start at all, because the start-up torque capability of a squirrel-cage induction motor is proportional to the square of the voltage drop. In such cases a better solution is to use frequency converters for assisted start-up.

Table 9.1-3 Relative performances of three AIS technologies

	Switchgear Technology		
Performance Criteria	**Vacuum CB**	**SF6 CB**	**FVC**
Mechanical endurance	10,000 operations	10,000 operations	500,000 operations
Electrical endurance	30,000 operations	30,000 operations	500,000 operations
Short-circuit let-through energy	Full short-circuit current	Full short-circuit current	Limited by fuse

33	3,150	40

Soft starters are applicable only in certain cases, mainly for limiting network start-up current.

Power Quality Support Equipment

Power quality support equipment includes filter and compensation units, static-voltage compensators, active filters, and synchronous condensers.

Filter and Compensation Units

Filter and compensation (F&C) units must be applied in most cases to comply with IEEE 519-1992 for network quality. F&C units are ideally positioned at the MV level and cover all harmonic-producing loads.

All electrical equipment that consumes nonsinusoidal current from the supplying line must be considered to be a source of harmonic current, and all other equipment such as transformers and AC motors must be considered to contribute to harmonic pollution of the network. Equipment impact can be more or less severe depending on the amplitude and frequency of the harmonic currents. Network impedance also has a significant influence on the magnitude of harmonics.

Frequencies in the spectra of harmonic-generating loads can arise from both constant-frequency and variable-frequency sources.

Cycloconverters and frequency converters clearly produce harmonic-producing loads. Beyond these, the inrush current effects of switching on converter transformers must be taken into account. The magnitude of the inrush current is based on the saturation inductances of the transformer and can reach 6 to 7 times the nominal current. The inrush current contains all integer low-order (including zero-order) harmonics for DC components. Harmonic components decay with a time constant ranging from several seconds for low-power transformers to a few minutes for high-power transformers.

Second-order harmonics are not normally expected in plants, but their presence causes heavy distortion of the network, so their potential to cause negative effects is rated as high. It is therefore necessary to damp second-order harmonics with a filter, even though it is expensive to do so. This is especially important for weak networks with consequently low network natural parallel resonance, because the potential danger of hitting the network with low parallel resonance during transformer switch-on is high and therefore equipment damage is likely.

Cycloconverter input current distorts the supply voltage to an extent that depends on supply system impedance. For strong supply systems with high fault levels, the effect on the supply voltage is minimal. However, for weak supply systems or low fault levels, the supply voltage becomes highly distorted. A highly distorted voltage can disturb the operation of sensitive devices connected to the system or simply increase their losses.

A typical filter configuration for a plant contains groups of switchable passive filters starting with F2 for the second harmonic and continuing with F3, F4, F5, F7, and F11 (Figure 9.1-6). The total filter configuration for a 100,000-t/d plant is ~70 MVAr (megavolt-amperes reactive, the unit of reactive power in an AC power system).

All of the following additional technologies are implemented today in different configurations that support but do not replace F&C systems (Errath et al. 2001a, 2001b). A breakthrough with active filters will be realized only if the switching frequency of the elements increases by a factor of ~10 and prices decrease by a factor of ~5.

Table 9.1-6 Loads and short-circuit levels for LV 400- and 690-V motor control centers

Voltage, V	Load, A	Short-Circuit Level, kA	Single Loads, kW
400	5,000	≤80	≤315
690	5,000	≤65	≤500

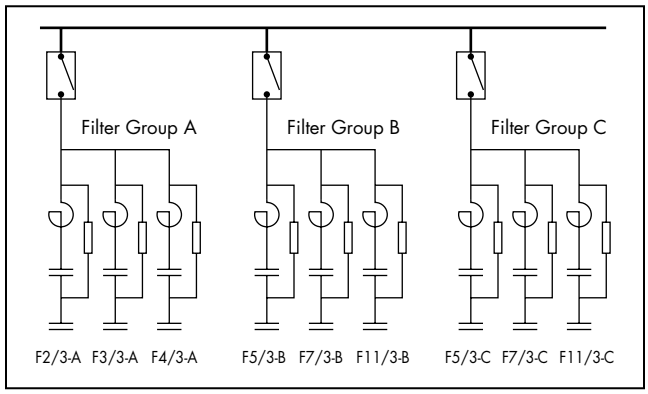

Figure 9.1-6 Typical filter configuration for a plant

Static VAR Compensators

Static VAR compensators (SVCs) control the reactive power (VAR) and are used mainly in weak utility networks (Figure 9.1-7). An SVC holds line voltage at a constant level. Most power systems can be represented by a simple model showing source voltage, bus short-circuit capacity, impedance from the source, feed line to the plant, and plant load characteristics. However, loads are never constant. In the milling part of a mine where the largest single loads are incurred, starting or stopping one drive can affect total plant load by 10% to 20% and change plant bus voltages by 5% or even 10%. To compensate for changes in line voltage, SVCs can be used as switched capacitors to produce stepped increases or decreases in voltage.

SVCs control VAR steplessly (without voltage jumps) within small tolerances (~1% reaction in three sinusoidal cycle times). They raise voltage by adding VARs (adding capacitive VARs) and lower voltage by subtracting VARs (adding inductive VARs), thus enabling the voltage on a bus to be kept constant.

The information needed for regulation is the bus line voltage and the line current. The regulator defines the firing-pulse angle from the SVC. Some SVC layouts are of mixed configuration, in which some capacitors are switched in and out and the rest are regulated by the SVC. This configuration minimizes SVC size, although total capacitive power remains the same. When using an SVC in a utility supply system as a voltage stabilizer, it is advisable to position it as close as possible to the plant, because SVC function must be electrically coordinated with the F&C unit in the plant.

An important consideration when using an SVC is that its large reactive power (~50–100 MVAr for a 100,000-t/d plant) causes network parallel resonance to decrease. What constitutes a reasonable amount of harmonic contribution in the network must also be considered.

Active Filters

In the mineral industry, the use of active filters is still restricted to smaller units of ~4 MVA or multiples of that value connected

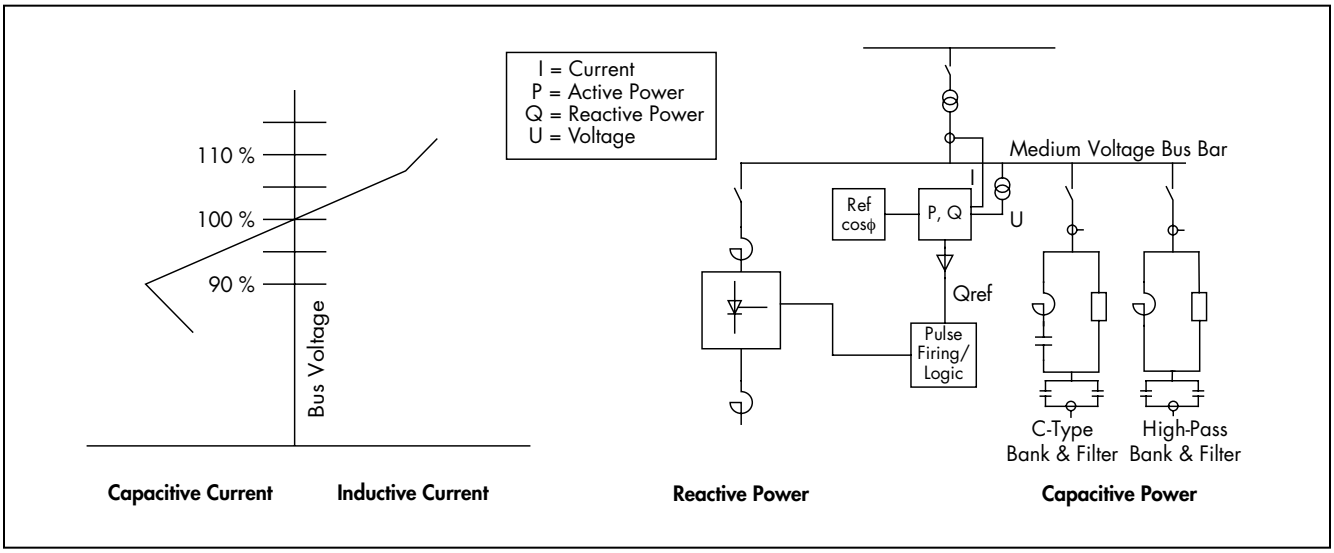

Figure 9.1-7 Static voltage compensator

in parallel. This restriction is due mainly to the actual high investment cost of the active filters and the inability of this technology to cope with higher harmonics.

Synchronous Condensers

Synchronous condensers have played a major role in voltage and reactive power control for many years (Figure 9.1-8). A synchronous condenser rotates or spins freely, unconnected to the network. Its relatively small frequency-controlled motor rotates increasingly faster until it reaches the synchronous speed.

Synchronous condensers have been connected at both subtransmission and transmission voltage levels to improve stability and maintain the voltage within desired limits under varying load conditions. However, they are used mainly to supply a portion of the required converter reactive power and to provide system reinforcement as needed. They are a proven solution for increasing short-circuit power in plants and also increasing the network's parallel resonance.

Synchronous condensers have an inherent advantage over capacitors in that they are functionally synchronized with the power system. Their field is controlled so as to induce them to either generate or absorb reactive power. A further strong advantage is their ability to ride through small network disturbances because of their large accelerated masses.

The short-circuit improvement at the point where a synchronous condenser connects with a 15-MVA condenser is ~100 MVA. This performance efficiency is considered good in that total full-load losses are <1% of the condenser rating.

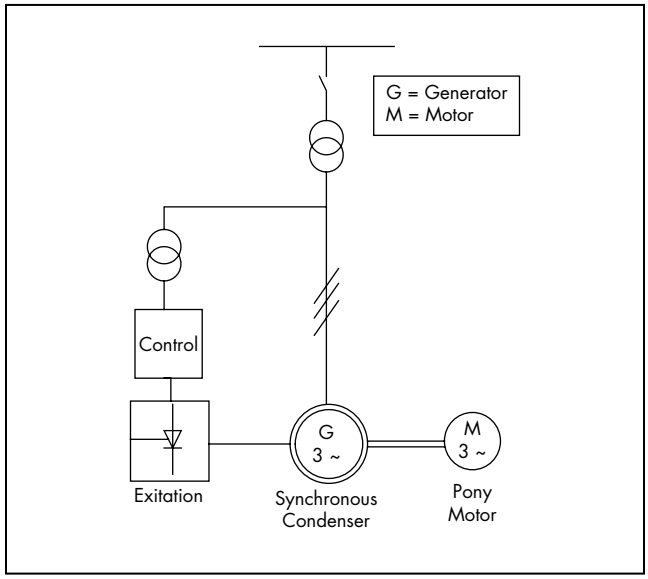

Figure 9.1-8 Synchronous condenser

Drives and Motors

Almost all relevant process drives today are adjustable-speed drives. Traditional power distribution for fixed-speed drives applies now only to smaller motors. Adjustable-speed drives usually have their own distribution philosophy.

SAG Mill Drives

Large autogenous grinding (AG) and semiautogenous grinding (SAG) mills are usually powered by adjustable-speed drives—either gearless mill drives (GMDs) or geared single- or twin-pinion drives. SAG mill drives are larger than AG mill drives in both size and power. In new installations, power ratings for SAG mill drives can range up to 28 MW.

Adjustable-speed drives are always coupled by converter transformers that are connected to the MV distribution system. The transformer is a *converter transformer*, not a distribution transformer. The converter transformer must handle current harmonics and nonstandard secondary voltages produced by the drive.

A general rule for sizing converter transformers is that the sum of their power ratings in megavolt-amperes should be ~1.9 times the power of the drive in megawatts. For example, the 21-MW drive shown in Figure 9.1-9 requires converter transformers with a total power rating of ~40 MVA (= 3 × ~14 MVA). Normally, three converter transformers are connected by one MV breaker to the MV bus distribution system. The secondary voltage of the transformers is relatively low—depending on the cycloconverter configuration, in the

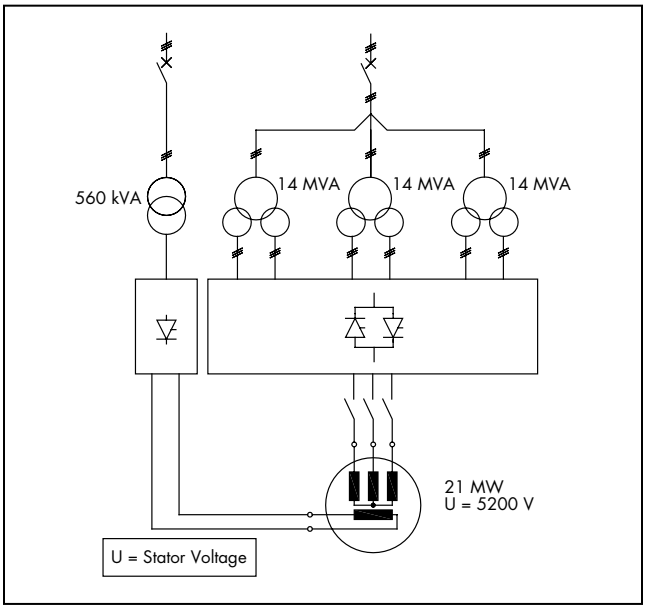

Figure 9.1-9 Converter transformer in a 12-pulse configuration for a 21-MW gearless mill drive powering a SAG or ball mill

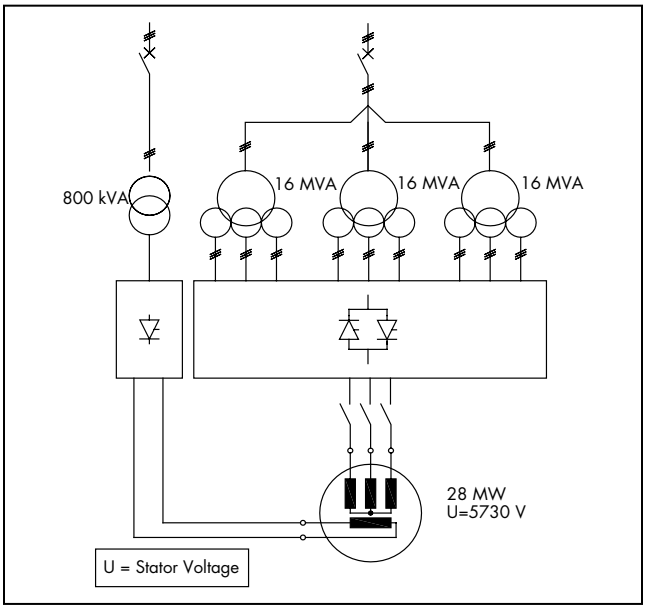

Figure 9.1-10 Converter transformer in an 18-pulse configuration for a 28-MW gearless mill drive powering a SAG mill

range 1,000–1,800 V. An isolation switch is mounted for safety reasons between the cycloconverter and the motor. A controlled rectifier unit is used for excitation and connected by a converter transformer to the MV bus bar with a voltage of <22 kV.

For average-size-drive motors, converter transformers are typically triple-wound. If the primary winding is in a delta configuration and one of the two secondary windings is in a star configuration with a phase shift of 30°, a 12-pulse configuration is possible on the transformer (Figure 9.1-9). Typical start-up torque is up to 130% of the nominal network current. Start-up current is very soft and is not a problem in terms of power distribution. Maximum power is achieved only with the rated torque at the rated speed. Thus adjustable-speed drives are generally considered electrical-network-friendly in comparison with fixed-speed drives, which can draw start-up currents of 600% of the nominal network current.

For >25-MW-drive motors, converter transformers should be quadruple-wound in an 18-pulse configuration because of the physical limits of the semiconductor (Figure 9.1-10) and to minimize creation of harmonics.

Cycloconverters are fuseless. In the event of a short-circuit in the motor or the cycloconverter, current is limited only by the impedance of the converter transformers. Cycloconverters are designed to survive short-circuit currents for 200 ms, which is longer than an MV breaker normally takes to trip (40–80 ms). Normally, three transformers are connected by one MV breaker to the MV bus distribution system. As an example, the motor in cycloconverter operation is designed for 5,730 V.

Ball Mill Drives

For ≤7-MW ball mills, drives are usually fixed-speed and geared. Wound-rotor induction motors with secondary starter or synchronous motors are usually used with adequate start-up equipment to limit the start-up current to the network. In terms of power distribution, drives with fixed-speed motors are more challenging to use than are those with adjustable-speed motors because of their high start-up currents. The first harmonic created is the 5th in the six-pulse configuration, except for interharmonics, followed by the 7th, 11th, 13th, and so on.

For >7-MW ball mills, drives are usually adjustable-speed GMDs. Adjustable-speed geared single- or twin-pinion drives are also used. For adjustable-speed drives in the range 7–22 MW, the primary converter transformer is connected in the same manner as for a SAG mill directly to 13.8, 22, 33 kV on the MV bus. The converter transformer winding vectors are similar to those for the SAG configuration.

For small GMDs, converter transformers are often in a six-pulse configuration (Figure 9.1-11). The primary transformer can be connected to the MV distribution bus to 4.16, 13.8, or 22 kV (maximum).

High-Pressure Grinding Rolls

High-pressure grinding rolls (HPGRs) are another option for grinding or milling (Figure 9.1-12). HPGRs were first used in the minerals industry in the 1990s and are known for their high material-breaking efficiency. Their main application is for hard-rock gold and copper ore. They have twin drives in a typical power range of 2 × 2 MW. A grinding circuit usually consists of two to four HPGR sets followed by two or three ball mills.

HPGRs have standard 2,300-, 3,300-, or 4,160-V motors with reinforced bearings. The drives are mainly frequency converters. One drive receives power from a single triple-wound 5–6-MVA transformer. The other drive handles high-load peaks up to 200% of the nominal torque and must be able to share the load between the two rolls in a fast, controlled manner. This load behavior must be taken into consideration in the power distribution.

Conveyor Belts

Conveyor belts today are equipped, depending on the application, with direct on-line motors and hydraulic or gearbox slip-ring motors with resistor starters or variable-frequency

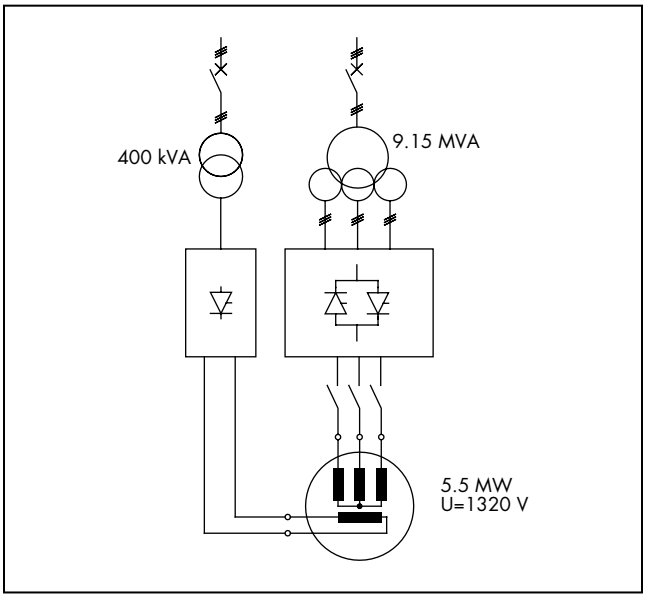

Figure 9.1-11 Converter transformer in a six-pulse configuration for a 5.5-MW gearless mill drive powering a ball mill

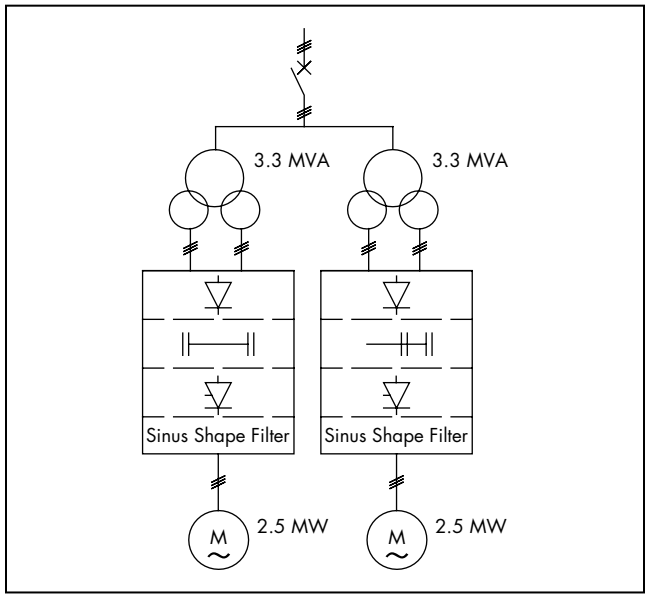

Figure 9.1-12 Single line of an HPGR set

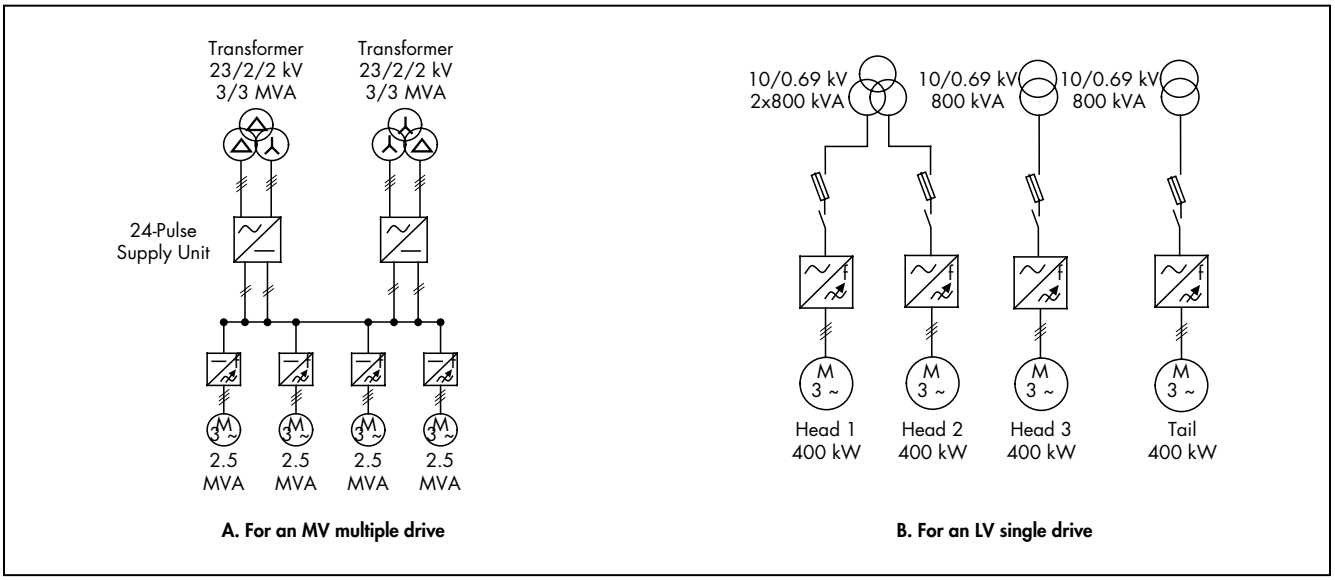

Figure 9.1-13 Conveyor-belt drive systems

drives (Figure 9.1-13). Larger conveyor systems are driven by several motors in the power range from hundreds of kilowatts up to 2 MW at the head and tail end, depending on belt width and length and on conveyor profile.

Overland conveyor belts can curve with uphill and downhill sections of many kilometers, and are controlled mainly by variable-frequency drives (VFDs). Downhill applications use mainly active front-end (regenerative) drives where the drive electrically breaks the belt and braking energy is supplied back to the grid (Lüchinger et al. 2006).

VFD supply voltages are as follows: for LV drives, 500 or 690 V; for MV drives, 3.3, 4.16, or 6 kV. The load behavior is a constant torque load with a relatively low dynamic for start-up and braking. Typical start-up or braking torque is between 1.15 and 1.5 times nominal torque. The supply power range for one conveyor can vary from several hundred kilovolt-amperes to ~15 MVA.

Cyclone Feed Pumps

The drives of cyclone feed pumps have recently undergone significant performance changes. A large plant typically has two to four ~1,500-kW pumps. Pumps are usually controlled by frequency converters and operated at low speed. The pump motor is a scalar-controlled induction motor and often does not have a gearbox but is coupled directly to the pump. To achieve low-speed (600–200-rpm) operation, the motors are designed with 16 to 30 poles. Operation with a frequency converter guarantees a soft start with low network load. The supply voltage of the frequency-converter transformer is from 4,160 V to 22 kV. Advantages of this configuration are that

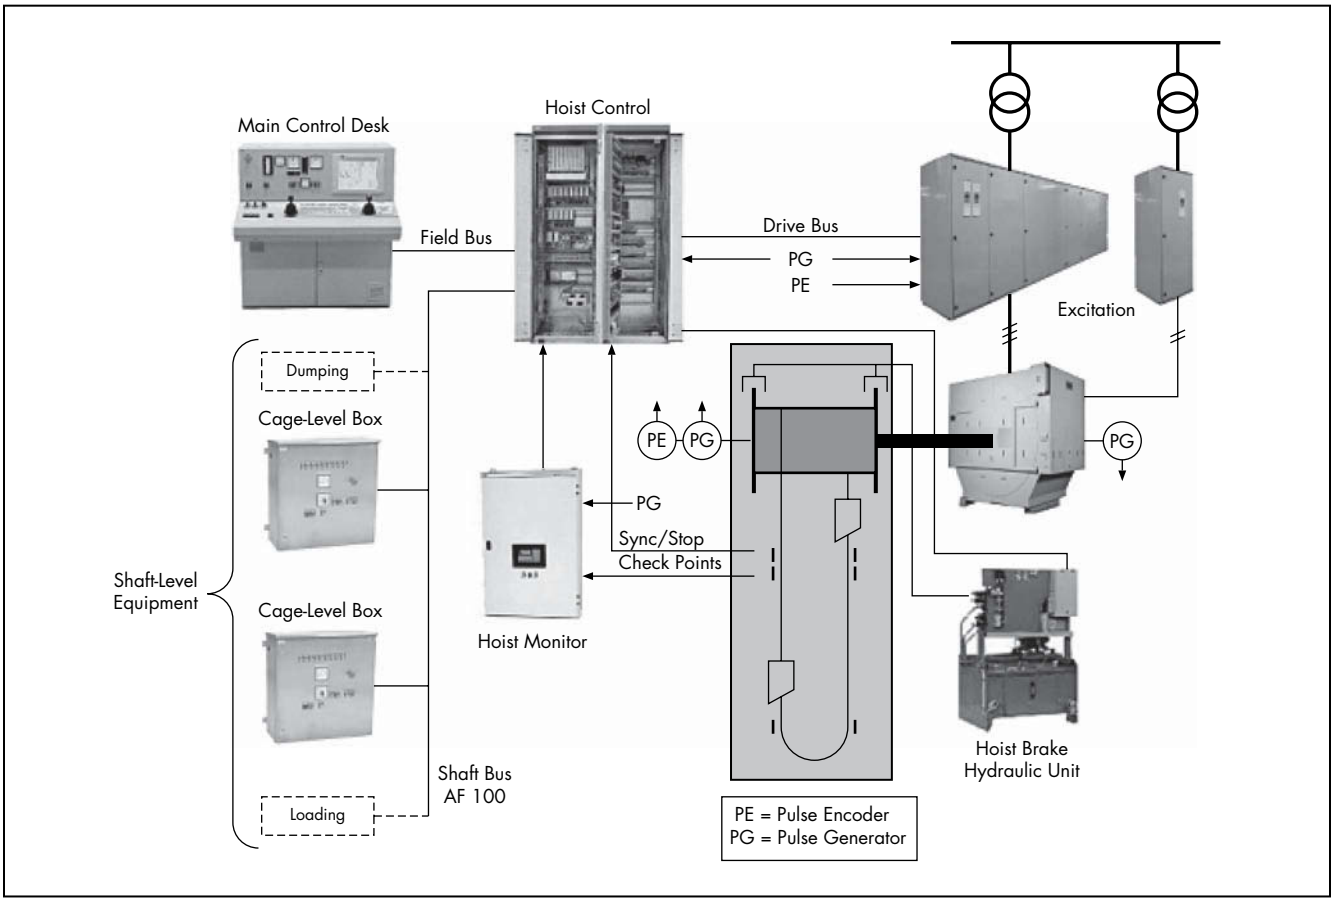

Figure 9.1-14 Friction-type mine hoist

it is adaptable to process requirements, energy savings, lack of energy-wasting throttle valves and maintenance-intensive gearbox, and the high efficiency of the drive system. A disadvantage is the higher investment cost for the motor.

Mine Hoists

Underground mining relies on hoists to transport people, equipment, and ore between the mining zone and the surface. In many mines, vertical shafts are combined with a ramp. However, ramps are not technically or economically viable in mines that are deep or have poor rock stability. In such mines it is common to sink both a production and a service shaft. The shafts can also be used for ventilation purposes. The main considerations for a mine hoist are absolute operational safety, reliability, energy efficiency, and productivity. Grid stability must be considered because of changing load cycles during hoist operation.

Mine hoists are of two types: friction and drum (Figure 9.1-14). Modern hoists are powered by AC motors. Smaller hoists with power requirements of ~1,500 kW normally use a gearbox with high-speed induction motors. Larger hoists use a direct drive with an overhung synchronous motor. Speed control is achieved by a voltage-source-inverter (VSI) frequency converter.

Modern hoists are direct-drive systems; that is, the motor is coupled directly, without the use of a gearbox, to the single- or double-drum hoist. The power of a friction-type hoist system is in the range of 5 to 10 MW. The main components of a hoist system include a synchronous motor, 4Q frequency-converter drive (motoric and generatoric), hydraulic brake system, control system for friction, rope oscillation, and so on. Figure 9.1-15 shows the electrical design for the friction-type mine hoist shown in Figure 9.1-14.

Dragline Excavators

Dragline excavators are one of the largest mining machines for overburden removal in strip mines. They can have any of three major drive systems:

1. MG sets with digital field excitation
2. Conventional AC drives, LV or MV variable-speed with squirrel-cage AC motors and gears
3. Gearless AC drives with gearless ring motors for hoist and drag drums

Most draglines built between 1960 and 1990 use Ward–Leonard MG sets and DC motors. Draglines built today use conventional or gearless AC motors. The new systems are almost maintenance free, more efficient overall, and contain better drive controls.

Supply power usually varies from 4 MVA for small draglines up to 25 MVA for large draglines. Higher voltage and short-circuit capacity are desired for better performance. Standard dragline supply is typically ≥22 kV. Drive-system voltage is typically 6 kV for the synchronous motors of an MG set and 1,400 or 690 V for AC drives.

Draglines with MG-set drive systems usually have two to four sets; some larger draglines even have six sets (two extra

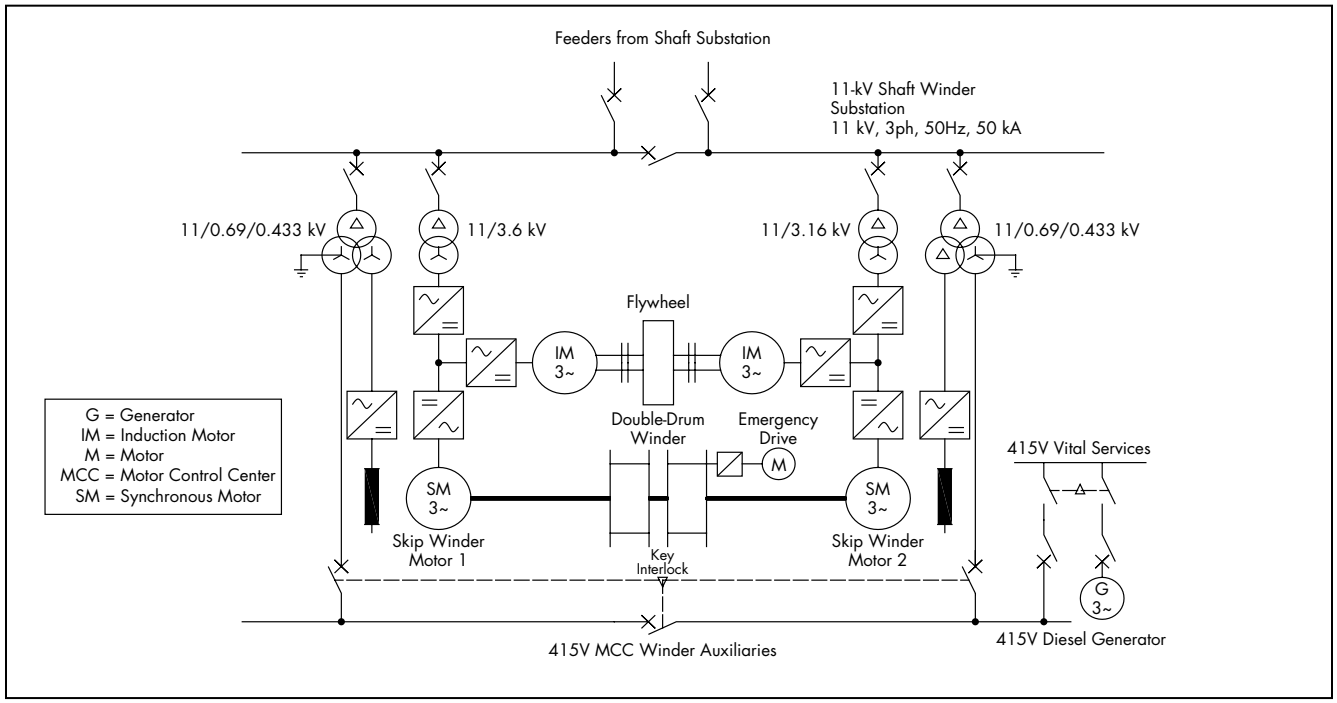

Figure 9.1-15 Friction-type mine hoist system, generic single-line configuration

sets for the walking mechanism). Older systems are commonly upgraded with programmable logic controllers (PLCs) and digitally controlled field-excitation modules. Conventional AC drives have been successfully installed on smaller and even a few larger draglines.

A typical application is a multiple-drive dragline (Figure 9.1-16), where one supply unit feeds several motor inverters over a common DC bus bar. The system shown in the figure has two hoist motors, two swing motors, and two drag motors. Typically two to four such sets are installed on a dragline. The common DC bus allows energy sharing among the motors (some motors run in motor mode, some in generating mode).

Usually a regenerative insulated-gate-bipolar-transistor-(IGBT-) based supply unit is used to feed excessive braking energy back into the grid. These units usually have better power factors (~1) and low total harmonic distortion levels. For weak grids, they protect the drive against voltage dips or even short blackouts. Modern units have an adjustable leading or lagging power factor and can be used for reactive power compensation. The duty cycle of dragline motion is complex and demands high drive dynamics, fast controls, and high overload ability on the part of the motors.

Gearless drive systems are currently state of the art for draglines. Gearless technology has emerged from mill and mine hoist applications where gearless ring motors, integrated into a drum, have proven to be reliable and efficient. The AC ring motors, integrated into hoist and drag drums, are powered by MV variable-speed drives.

Primary Crushers

Main crushing motors can be across-the-line starting, soft-starting, or variable-speed, depending on crusher size, type, and application. For hard-rock crushing, typically one motor is MV across-the-line starting. For applications where speed regulation is necessary, VFDs are the best choice, because they can maintain constant-speed seizer rotation regardless of the type or size of material fed into them. Such drives adjust torque on the shaft to maintain speed and a continuous quality of crushed material. The crusher can also be used for mass-flow control, depending on the type of crusher and the motor's type and speed range. Crusher sizes are in the lower megawatt range.

Shovels

Today most shovels have static DC drives with digital field control. Since the 1980s, AC shovels have been used increasingly. Small electric rope shovels with MG sets are still available but are becoming obsolete. Most shovel suppliers now promote AC technology.

Bucket-Wheel and Bucket-Chain Excavators

Bucket-wheel and bucket-chain excavators are used in continuous mining applications where trucks are not used (Figures 9.1-17 through 9.1-19 show three of many possible configurations). Overburden and ore are transported by conveyor belts. Spreaders are used to spread the overburden on the reclamation side of the pit. Continuous mining is efficient for thick, homogeneous seams of ore (generally lignite).

Excavators are complex systems. A bucket-wheel excavator typically has three or four conveyor belts, a propel system with 3 to 12 crawlers, multiple winches for hoisting, a bucket wheel, and swing drives. The supply power of an excavator can reach 16 MVA. The total drive power depends on the size of the excavator and can be ~10 MVA. The supply voltage is usually 4.16, 13.8, 22, or 30 kV. VSDs are used for propel, swing, hoist, belt, bucket-wheel, or bucket-chain drives. Excavators are custom-built according to the geological situation. The drives and power distribution systems for spreaders and reclaimers are similar.

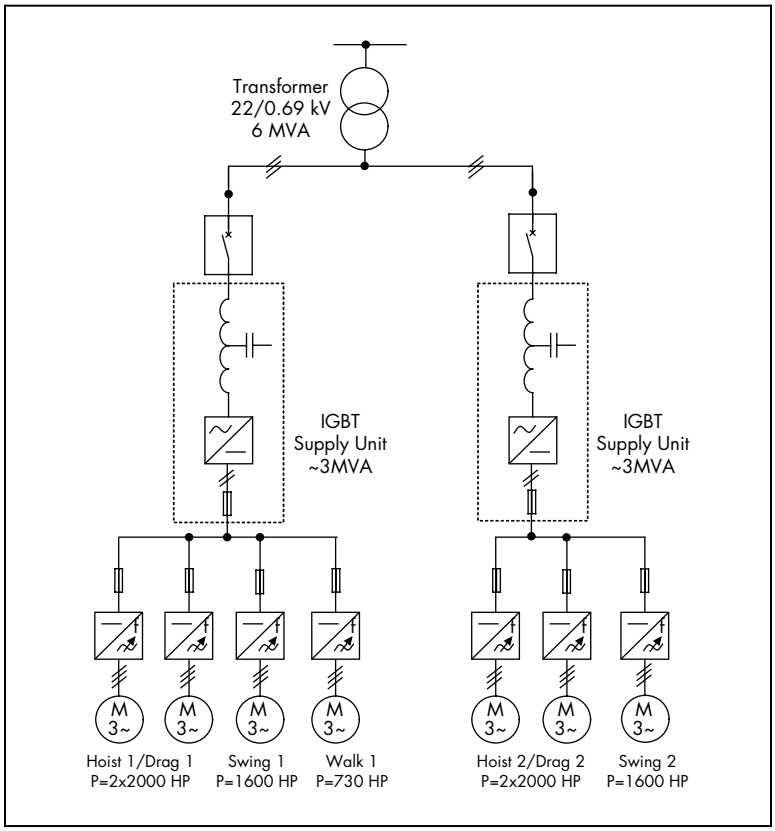

Figure 9.1-16 Multiple-drive AC dragline, single-line configuration

A bucket-chain excavator differs slightly from a bucket-wheel excavator in that it drives on rails, and the propel mechanism usually has about 60 motors. The bucket chain is driven by two large gearless ring motors supplied by a cycloconverter whose supply power is ~2 MVA and motor speed is ~13 rpm. The voltage for the bucket-chain drive is ~1,400 V.

Stackers and reclaimers move on a well-defined path and handle stockpiles of defined size, and so can usually be completely automated for unstaffed operation. Automation is accomplished by means of VFDs, PLC systems, and Global Positioning Systems or laser-positioning systems for collision protection, stockpile scanning, and ore handling. When combined with automated ore-quality detection systems, stackers and reclaimers can significantly increase the overall efficiency of a material-handling plant.

Other Design Considerations

Since the 1990s, plants are often installed at high altitudes in the range 3,000–4,600 m. Installation at high altitude requires special attention in dimensioning and design. In addition, many such places are in active earthquake zones and tend to have high snow loads, low temperatures, high wind speeds, and other harsh environmental conditions. All such factors must be considered in the design of a power distribution system.

Design for High Altitude

Four principal aspects must be considered when dimensioning equipment for high altitude: cooling, insulation, heat radiation, and utilization.

Cooling. At increasing altitude, the density of air decreases and therefore also does its cooling capability. This situation can be remedied by two measures: (1) increase or adjust airflow to obtain the desired cooling effect, or (2) install larger equipment with lower output power.

Insulation. At increasing altitude, the density of air decreases and therefore also does its insulation capability. Factors to use in correcting voltage ratings for reduced insulation capability due to altitude are listed in Table 9.1-7. For example, at 4,000 m, a unit of equipment rated at 690 V can be used at only 500 V (690 V $\times$ 0.73); for MV distribution, a unit of equipment rated at 33 kV can be used only on a 22-kV bus.

Heat radiation. At increasing altitude, copper bars tend to heat up progressively more. Cables and copper bars from the power distribution must be dimensioned accordingly, and this effect must be considered in the design of power distribution.

Utilization. How standard motors can be used depends on altitude. For ambient temperatures in the range 30°–40°C, the maximum design temperature at sea level is reduced by the following amounts:

- Insulation class B motor: 0.8°C for each 100 m above 1,000 m
- Insulation class F motor: 1.0°C for each 100 m above 1,000 m

Design for Earthquakes

Shock waves radiate from fault fracture zones and arrive at the earth's surface as complex multifrequency vibratory ground motion with both horizontal and vertical components. The

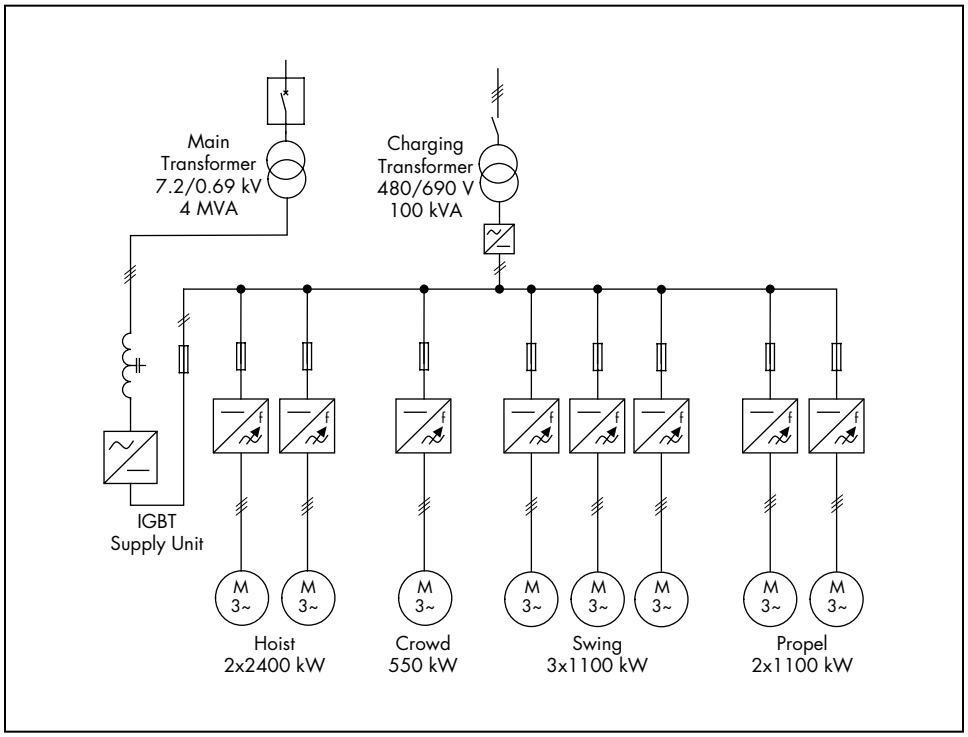

Figure 9.1-17 Bucket-wheel and bucket-chain excavators with spreaders, stackers, and reclaimers

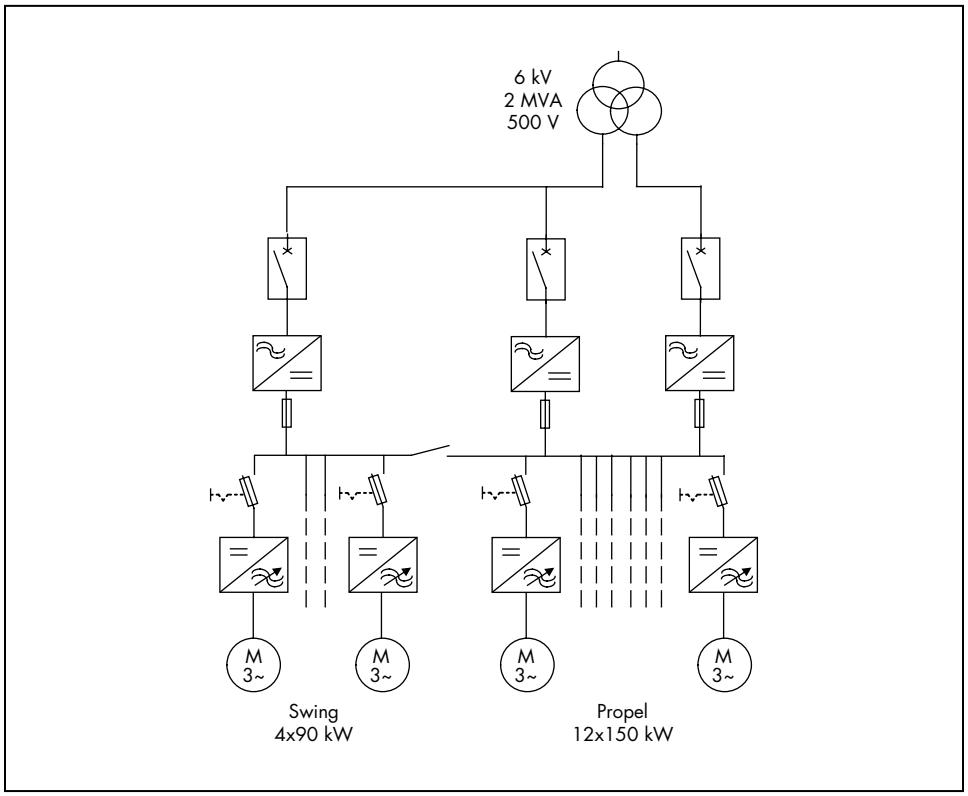

Figure 9.1-18 Bucket-wheel and bucket-chain excavators with stackers and reclaimers (dashed lines)

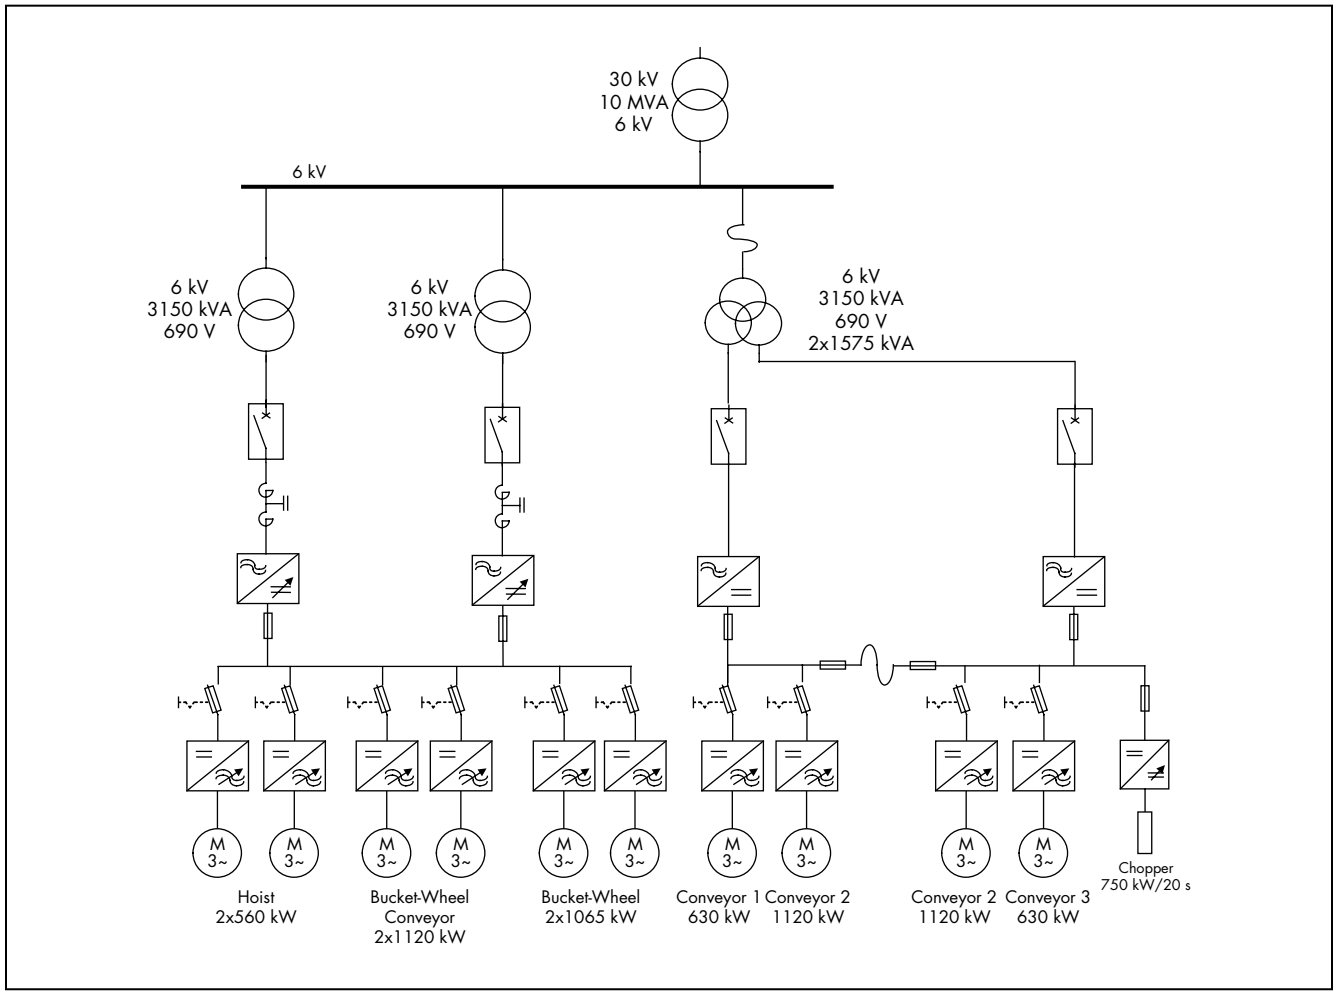

Figure 9.1-19 Bucket-wheel and bucket-chain excavators (multiple-drive) with stackers and reclaimers

response of buildings and mechanical constructions to earthquake ground motion depends on their strength of construction, ductility, and dynamic properties.

The basis for design and construction in areas of intense seismic activity is defined in the standards of the *International Building Code* (ICC 2009). The code standardizes magnitudes of seismic activity and catalogs areas of known activity into defined earthquake zones. For example, most mines in Chile and Peru are situated in IBC zone 4.

Distribution and process equipment such as drives, converter-power-distribution buildings, and switchhouses are required to withstand the expected magnitude of excitation in a defined earthquake zone. Equipment configuration is also relevant. In general, taller and heavier constructions are larger in mass and have lower natural resonance frequencies that can be close to typical earthquake frequencies.

Design for Power Self-Generation

It is generally less expensive and more reliable to purchase electric power from a utility company than to operate one's own generating plant. However, a mine may be located in a remote area, far from a utility transmission or distribution system, making self-generated electric power the only feasible alternative.

Generating plants for mines are typically powered by diesel engines or by coal-, oil-, or gas-fired boilers or even water power. Some mines purchase electric power but also use diesel-powered generators for standby electric power. If the primary source of power is lost, a generator can be started quickly and used to supply standby power to critical equipment such as ventilation fans and personnel or elevator hoists and sensitive process parts. Special attention must be paid to overvoltage (and also undervoltage) conditions that might result from power self-generation.

Network voltage is generally less stable for self-generated power than for interconnected networks. Single-load units can easily use up to 20% of the total installed power. SAG mills can use 20–30 MW, ball mills can use 12–18 MW, mine hoists can use 10 MW, and draglines can also have high power demands in concentrator and mining areas. Not using one or two mills can reduce system load by up to 50%.

A generator does not adapt to new load conditions nearly as quickly or stably as does the utility company. Power can take up to 10 seconds, possibly more, to stabilize, during which time the system voltage and frequency fluctuate with potentially dangerous consequences. Various scenarios must be studied in detail, and the consequences of the scenarios must be considered in system design. Installed equipment

Table 9.1-7 Insulation-capability correction factors for various altitudes

Altitude Above Sea Level, m	Insulation-Capability Correction Factor
1,000	1.0
2,000	0.9
3,000	0.8
4,000	0.73
5,000	0.66

Table 9.1-8 Cable voltage rating required for various distribution voltages

Distribution Voltage	Cable Voltage Rating Required
440 V	600 V or 2 kV
550 V	600 V or 2 kV
4.16 kV	5 kV
7.2 kV	8 kV
12.47 kV	15 kV
13.2 kV	15 kV

must be capable of coping with those conditions. The protection and destruction level of the equipment must be known and designed for accordingly.

CABLES

Cables carry electricity from the substation where power is taken from the utility-company lines to the point of utilization by a mining machine, pump, conveyor belt, or other equipment unit. Many variations in mine distribution are possible, and several types of cables can be put to similar use.

The cable type recommended depends on the application. Some cables remain stationary for years; others are moved frequently. Cables that are connected to mining machines are called *portable cables*. U.S. federal regulations use the term *trailing cables* for the specific type of portable cable that is used in mines (MSHA 1981). Trailing cables are flame-resistant and flexible.

In underground mines, cables that feed the power center or are attached to the high-voltage side must be moved when the power center is moved, which generally is not often. Similarly, in surface mines, cables that feed from switchhouses or unit substations to mobile equipment are moved only occasionally and are not connected directly to a machine. Stationary cables can be feeder or portable cables.

Cable moving is a recurring task both underground and aboveground. Trailing cables can be placed on reels or spools to facilitate moving. Reeled cables are often used on shuttle cars, as are mobile cable reels on surface excavators.

Cable selection is based on a number of parameters including current-carrying ability, voltage rating, and configuration. The basic components of a cable are its conductor, insulation, and jacket; there may also be fillers, binding, shielding, and armor. The conductor is surrounded by insulation and covered by a jacket.

For optimal flexibility, cable conductors are composed of many wires combined into strands, and a number of strands combined to form the conductor. Conductors are either copper or aluminum; the latter is cheaper and lighter but lower in conductivity. The cross-sectional area of a conductor is important for mechanical strength and is closely related to current-carrying capacity.

Insulation is required to withstand stress from heat, voltage, and physical abuse. It must be specially designed not only to protect mine personnel from electric shock but also to separate power and grounding circuits effectively. Excessive heat is particularly destructive to insulating compounds. The main sources of heat are ambient temperature and power loss in cable-conductor resistance.

The maximum, normal, continuous current that a conductor can carry safely is directly related to cable heating, and the term *ampacity* is often used to describe this current level. The ampacity rating is usually based on the maximum rise in conductor temperature, with the temperature limit chosen on the basis of the specified life expectancy of the cable insulation. The *temperature class* (always given in degrees Celsius) describes the maximum allowable sustained conductor temperature at an ambient temperature of 40°C. Cable used in a confined space can overheat with continuous current at the cable's ampacity rating. This is especially true for cable wound on a reel, either for storage or for mobility. The cable's ampacity must be derated in these cases; ampacity and derating-factor tables are available in regulations from various governing bodies.

The most common insulating compounds for cable are neoprene, styrene butadiene rubber (SBR), ethylene propylene rubber (EPR), and cross-linked polyethylene (XLP). SBR is used in 600-V trailing cables. It has good elasticity and flexibility, a 75°C temperature rating, and good resistance to damage by crushing from runovers and rockfalls. EPR has replaced SBR in many trailing cables because, for the same insulation thickness, it has a higher voltage rating (2,000 V) and higher temperature rating (90°C). XLP is also rated at 90°C and is used in HV mine-feeder and portable strip-mining cables. However, it is stiff and therefore not recommended for reeling applications. Typical cable voltage ratings are listed in Table 9.1-8.

The main purpose of the cable jacket is to protect the inner components and hold the assembly in the designed configuration. Common jacket materials are neoprene, nitrile butadiene rubber plus polyvinyl chloride (NBR/PVC), and chlorosulfonated polyethylene (CSPE, also called Hypalon). Armored cables are used in some borehole applications; the heavy metallic jacket affords extra protection to the conductors and insulation.

Flat cables are commonly used on mining machinery such as shuttle cars that have cable-reeling devices. The flat shape allows increased length on a cable reel and is less susceptible to run-over damage. Round cables are typical on all other mining equipment. Low-voltage AC mining machines commonly use unshielded Type G or Type G-GC cables.

Current and voltage regulation are the major concerns in sizing cable power conductors for an application. The effective continuous current through a cable power conductor must be less than the cable ampacity, with correct derating factors applied. The voltage drop across the distribution and utilization systems must be such that voltages at load are within allowable tolerances. For trailing cables to machines, current is often the determining factor, because these cables are almost always relatively short. For feeder cables that serve many loads, however, lengths are often so great that voltage drop becomes a principal concern. Even though cable size may be adequate in terms of ampacity and voltage drop, other factors can affect decisions about conductor size, including tensile

load, weight, and available short-circuit current. Of these, weight can be particularly important, because cable should not be too heavy for miners to handle. The maximum conductor size is usually considered to be 4/0 AWG (American Wire Gauge) for three-conductor cables.

Several methods can be used to determine cable current, including full-load current, effective current demand, and application of a load factor. Regardless of the method used, typical current requirements for mining machinery change continuously over time. The extremely wide variability of mining conditions makes it difficult to define current levels for any part of a given duty cycle with precision. Thus, the use of full-load current is recommended.

The primary concern for voltage conditions is that satisfactory voltage must be at the machine terminals for proper start-up and operation. The allowable voltage tolerance on machine motors is usually ±10% of the rated voltage. Maintaining adequate voltage is one of the more difficult problems in mining and is often the main constraint on mine expansion.

For a thorough voltage study of a mine and its concentrator plant, all impedances and all loads in the power system must be known. A circuit diagram must then be prepared and calculations performed to determine whether voltage levels at the machines are satisfactory. Analyses must be performed not only for normal load conditions but also for start-up of critical motors. If calculated voltages are below those tolerated, system impedance must be reduced. The most convenient way to do so is to increase cable conductor sizes.

Cable couplers are complex plugs and sockets used throughout a mine distribution system to connect mobile machinery to trailing cables, to connect cables with one another, and to connect cables to power centers, switchhouses, and substations. Their complexity is directly related to the mine environment in which they are used; they must resist damage, be sturdy enough to withstand repeated use, prevent electrical hazards, be watertight and dustproof, and withstand heat and cold. Some models are rated explosion-proof. The coupling mechanism must be easy to use yet secure. HV couplers, sized at ~15 kV/500 A, are used to connect switchhouses and mine power centers, to join HV cables, and for HV machines. They accommodate three power conductors, one or more grounding conductors, and one or more ground-check conductors. LV and MV couplers, sized at 225, 400, 600, 800, and 1,200 A, are used primarily to connect mobile equipment to power centers and junction boxes and to connect 600–1,000-V cables. They are sturdy in construction but less complex than are HV couplers.

POWER DISTRIBUTION ARRANGEMENTS

Power distribution arrangements can involve surface overhead-line distributions, back distributions, surface mine distributions, and underground mine distributions.

Surface Overhead-Line Distribution Arrangements

Surface transmission and distribution of electric power is most commonly achieved by means of overhead conductors. The conductors use air space for insulation over most of their length. Their elevation protects them from contact with personnel and equipment.

Overhead conductors are arranged in various configurations to reduce line-to-line contact due to wind, ice loading, or sudden loss of ice load, and may include different combinations of power, neutral, and static conductors. Aluminum conductors with steel reinforcement are commonly used because of their strength and relatively low price, but special applications may call for other materials such as copper.

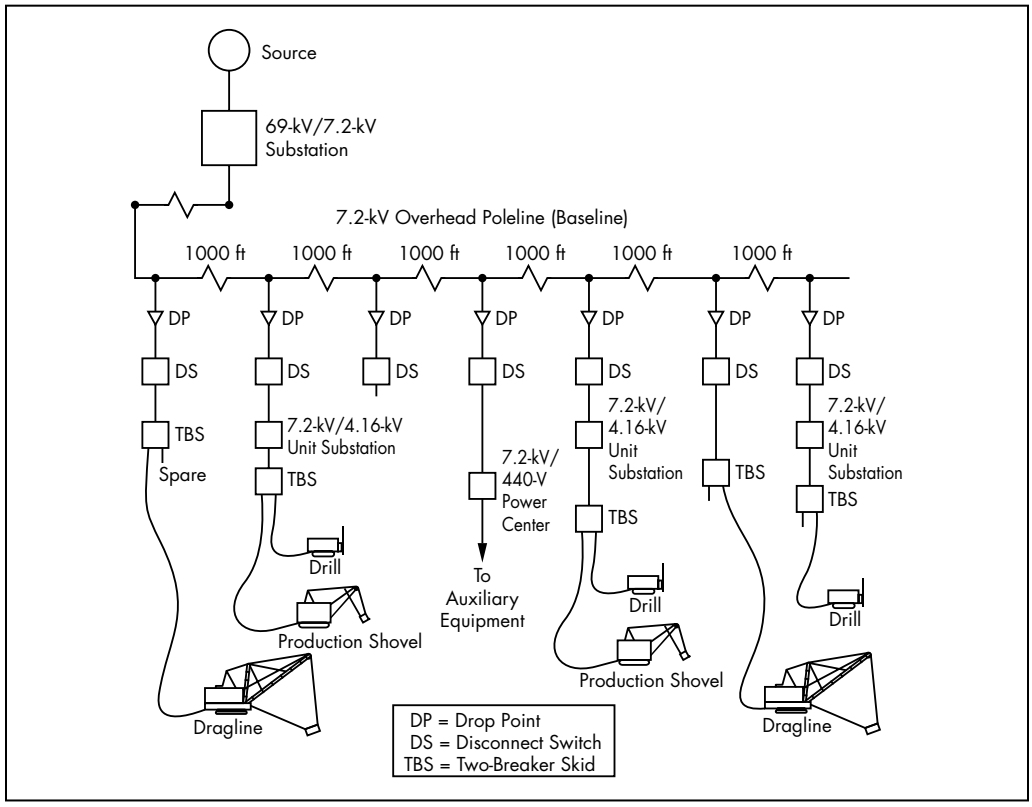
The types of overhead-line installation used for mining are similar to those used in utility distribution systems. Pole lines are typically used to supply equipment in surface mining and to feed surface facilities related to mining. The lines are normally installed on single wooden poles that can carry up to six conductors, including three for power, one for grounding, one ground check (pilot), and one static. Pole lines can be relatively permanent installations such as those feeding plants, shops, and other surface facilities and long-term pit baselines or ring mains. Temporary poles mounted in portable bases (such as concrete-filled tires) are commonly used in surface mining operations to carry power into the pit.

Basic Distribution Arrangements

Basic distribution systems for industrial applications are radial, secondary-selective, primary-selective, primary-loop, or secondary-spot configurations (IEEE 141-1986). Radial configurations are the most popular in mining, although other configurations are used where special circumstances call for greater system reliability. Surface mines have, of course, greater flexibility than do underground mines and use a wider range of configurations. Secondary-spot configurations, which are the most popular for large facilities in other industries, are uncommon but can be suitable for preparation and milling plants.

A radial distribution system in its simplest form consists of a single power source and substation supplying all equipment. Radial systems are relatively inexpensive to install because equipment is not duplicated. They can be expanded easily by extending the primary feeders.

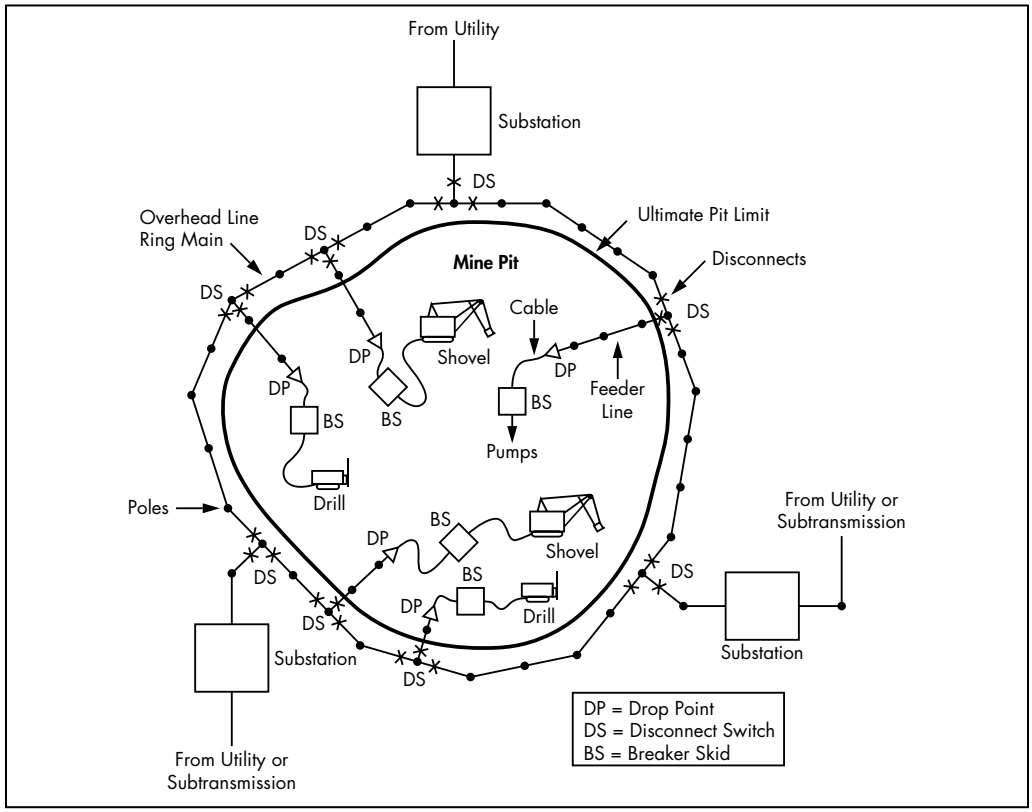
A secondary-selective distribution system consists of a pair of secondary substations connected through a normally open tie breaker. It is both flexible and reliable; if a primary feeder or substation fails, the bad circuit can be removed from service and the tie breaker can be closed automatically or manually. Maintenance and repair of either primary circuit is possible, without incurring a power outage, by shedding nonessential loads for the period of reduced-capacity operation. If substation requirements are greater than 5,000 kVA, economics often justify this double-ended arrangement.



Surface Mine Distribution Arrangements

Mine power systems are of three types: transmission or subtransmission, distribution, and utilization.

Distribution and utilization systems can vary greatly, but in some mines, both functions can be handled on the same system. The location of the mine substation is usually an economic compromise between the cost of running transmission lines and power losses in primary distribution. From the main substation, power is distributed to the various load centers in the operation. Incoming utility transmission should be extended to as close to the load as practical.



Subtransmission circuits, primary switchyards, and main substations are almost always located in areas unaffected by the mining operation. Surface mine power distribution, in its simplest radial form, consists of a substation, distribution, and a power center feeding the mining equipment (Figures 9.1-20 and 9.1-21). This arrangement is common in small surface operations where the distribution voltage is commonly 15,000 or 4,160 V but can be as low as 2,300 V in older equipment.

Although most strip mines use radial distribution, secondary-selective distribution is also used (Figure 9.1-22).

Figure 9.1-22 Strip mine all-cable secondary-selective distribution system

Source: Morley and Novak 1992.

Figure 9.1-23 Strip mine all-cable radial distribution system

In this configuration, a portion of the primary distribution is established as a baseline or bus, usually located on the high wall paralleling the pit for the entire length of the cut. It is typically located ahead of the pit and moved as the pit advances. As machines move along the pit, their baseline connections are changed to other convenient locations.

The baseline usually consists of overhead pole lines as shown in Figure 9.1-20. The arrangement of overhead pole lines plus cables is common in older mining operations. Typical spacing between poles, or line span, is 60 m. Drop points, denoted in the figure by triangles, are terminations between the overhead conductors and the cables, mounted about 2.4 m above the ground on poles and spaced at regular intervals in the range ~305–457 m. Cables connected to the drop points deliver power to skid-mounted switchhouses located on the high wall or in the pit. Cable couplers are commonly used for both feeder- and trailing-cable connections. Disconnect and circuit-protection functions are required for each distribution load.

Layouts for all-cable mine distributions (Figures 9.1-22 and 9.1-23) are similar to those just described. In this case; however, the baseline is assembled using cable-interconnected switchhouses. A common approach is to use disconnect skids with three internal switches in the baseline and have separate breaker skids in line with the cables feeding the machinery. Another approach is to combine the single breaker skids into the baseline switchhouses.

Open-pit power systems are similar to those for strip mines with one main exception: distribution typically establishes a ring bus or main that partially or completely encloses the pit. Radial ties to the bus complete the circuit to switchhouses located in the pit, and portable equipment again uses shielded trailing cables.

For secondary-selective distribution (Figure 9.1-22), a normally open tie breaker is placed in the baseline. In some operations, the two substations and the tie breaker are in the same location with two feeders running from the substation area to the baseline. Distribution voltage for the surface mine can be 8, 15, 25, or 34.5 kV, and less commonly 4.16 kV. The primary purpose of any distribution scheme in a surface mine is to provide a flexible, easily moved or modified power source for the highly mobile mining equipment.

Underground Mine Distribution Arrangements

Underground mine power systems are more complicated than surface power systems. Consider, for example, the situation for a coal mine. The nature of the mine and its service requirements dictate that distribution must almost always be radial; the freedom in routing distribution enjoyed by surface mines is not available underground. For increased reliability, secondary-selective main substations are used. Distribution voltage is usually 8 kV, although older 5-kV systems can still be found and 15 kV has increased in popularity in recent years.

Power and mine grounding are fed underground in insulated cables through a shaft, borehole, or intake entry. In coal mines, these cables are required to terminate in disconnect switches within 152 m of the point of power entry into the coal seam. The switches allow total removal of underground power in an emergency. Power is distributed from the disconnect switches, which may be part of a switchhouse, through cables to power centers or rectifiers located as close to the machinery as practical. All cables on HV circuits, usually involving only distribution, have shielding around each power conductor. The prime load concentrations in underground mines are created by the mining sections. Distribution terminates at the section power center, which is a transformer combined with a utilization bus and protective circuitry. From this, several face machines are powered through couplers and trailing cables.

With rail haulage, distribution terminates at rectifiers that contain a transformer and rectifier combination. The rectifiers are located in an entry or crosscut just off the railway. DC power is supplied through circuit breakers to an overhead conductor or trolley wire and to the rail, with additional rectifiers located at regular intervals along the rail system. For further protection, the trolley wire is divided into electrically isolated segments. The typical rectifier supplies the ends of two segments of trolley wire, and each feeder has its own protective circuitry to detect malfunctions. In some mines, DC face equipment and small DC motors are powered from the trolley system through a fused connection (or nip) to the trolley conductor and rail.

All power equipment used underground must be rugged, portable, self-contained, and specifically designed for installation and operation in limited spaces. In addition, all equipment and connecting cables must be protected against failures that could cause electrical hazards to personnel, primarily by protective relaying built into each system part, with redundancy to maximize safety.

CHAPTER 9.2

Compressed Air

John Hooper

THEORY OF COMPRESSED AIR

Compressed air is used extensively in mining and is often referred to as the "fourth utility," behind water, electricity, and diesel. In essence, compressed air is stored energy and, when controlled, it can be used for production purposes. Energy from compressed air is used to drive pneumatic equipment such as air motors, actuators, instrumentation, and pneumatic tools. It can also be used to cool and clean components or parts and to blow off waste material—a particularly valuable application in mines.

Industry also uses compressed air as an active part of processes that require a supply of clean, dry air, for example, in cleaning the finished product. The effects of compression are a decrease in gas volume, increases in gas pressure and temperature, and an increase in the concentration of contaminants.

HISTORY AND LANDMARKS

Compressed air has been used for as long as people have built fires, as blowing on cinders to make them flare up uses air that has been compressed in the lungs. The first mechanical compressors were hand-operated bellows, with the more-efficient foot bellows coming into use in about 1,500 BC to produce bronze. Bellows and other early blowing machines were primarily used to supply a combustion blast to furnaces and to ventilate underground workings. Use of compressed air as a means of energy transmission began to be discussed in the early 19th century when it was established that the rapid cooling and condensation of steam limited its use to very short distances.

Large-scale application of compressed air to transmit energy began at the Mont Cenis tunnel in the Swiss Alps in 1861 (Peele 1920). Tests with compressed-air-powered drills tripled the daily rate of advance of the tunnel, so the decision was taken to use pneumatic rock drilling and compressors operating at 600 kPa (87 psi). There were problems, including constant repairs, as the materials of the day could not cope with the tremendous stresses. But the tunneling was completed successfully, and it was demonstrated that compressed air could be transmitted over long distances.

The use of compressed air became firmly established with the installation of a compressed air distribution network in the Paris sewer system. The 586-kPa (85-psi) network was immediately successful, and patents were developed for all kinds of equipment, including a clock that kept the correct time thanks to timed pulses from the compressor plant, pneumatic message dispatch systems, passenger lifts, drink dispensers, and air motors of up to 70 kW (95 hp) to operate machine tools, looms, presses, and so on. Air was also used for the pneumatic drive of direct current generators for lighting. Many saw it as the energy distribution method of the future, superior to the emerging electrical distribution system.

Today, the use of compressed air complements that of electricity. Pneumatic tools and apparatus have augmented the power of the human hand, while allowing it to retain the control that is vital for precision work. Air-powered tools are durable and safe, and their light weight avoids operator fatigue. Applications of compressed air also include monitoring, control, and regulation of equipment, often in combination with electric and hydraulic systems. In terms of overall economy, compressed air competes with electric power in many fields and is used in conjunction with electricity in many others.

Compressed air–powered rock drills began to be used in U.S. copper mines in Ducktown, Tennessee, in 1872 and in the copper and iron mines in Upper Michigan in 1878—before then the only method was to drill by hand. Hammer-type rock drills were developed towards the end of the 19th century. At that time, air compressors were primarily steam driven and relatively inefficient. Consequently, mines employing large numbers of drills and other air-powered equipment sought other means of air compression. Several mines located in areas of varying topography installed hydraulic air compressors to solve the problem (Peele 1920). The best-known system was built in 1910 at Ragged Chute on the Montreal River to serve the mines in Cobalt, Ontario, Canada, and is still operating. The development of the electric-powered compressor made hydraulic compressors, which required large vertical shafts to channel potential energy, obsolete by 1939.

John Hooper, Managing Director, Joem Promotions, Deal, Kent, UK

The Swedish method, which was introduced toward the end of the 19th century, was developed to provide a one-person face-drilling operation, whereby the rock drill and "pusher leg" were powered by a new source of energy—compressed air. This accelerated the need for efficient sources of compressed air. By the mid-1940s, the forged tips of drill steels had been replaced by tungsten carbide inserts. Further developments included large crawler drills, which combine a percussive hammer with a separate high-torque rotation device for trouble-free drilling in even difficult rock.

COST AND PRODUCTIVITY COMPARISONS

Compressed air is a form of energy that provides beneficial features such as being safer to use in particular situations, allowing the use of lightweight power tools, being more economical to use and convey, being cleaner than some other forms of energy, and being easier to work with.

Although electricity per kilowatt-hour may cost less than compressed air, it is safer and more convenient to work with compressed air, particularly underground. Compressed air is widely used underground because of the safe nature of pneumatic motors compared to electrically driven tools, especially in areas where there may be flammable gases and sparks that would pose a risk.

A primary use underground tends to be in driving pneumatic tools such as drills. Large quantities of air are also used in removing dust. The air could be supplied by piping networks, or in the case of mobile equipment, by onboard compressors.

The energy savings from the use of compressed-air systems and air compressors could be 20% or more, particularly if variable-speed compressors are used to tailor consumption to current demand.

APPLICATIONS AND AIR-DRIVEN EQUIPMENT

Compressed air is used widely in mines, both in powering equipment and in providing air under pressure for operations such as clearing debris. It is used both in the handheld tools of semimechanized tunneling and with larger equipment for fully mechanized work.

Uses include hammer drills, where the air both powers the hammer and clears away the broken rock. The air may be supplied either by portable compressors or through lines fed from large static compressors at a central location, usually on the surface in the case of an underground mine.

Compressed air can be used at almost every step of a mine's production process. For instance, a copper mine could use it in the extraction, screening, crushing, milling, mechanical sorting, flotation, filtering, and drying operations.

Typical surface applications for air in mining include service air to operate tools, bagging operations, dust removal, and mineral filtration systems to remove buildups. Underground uses include handheld drills, operation of pneumatic tools and water pumps, and power machinery.

The amount of flow required is related to the application. Medium pressure in the range of 350 to 1,400 kPa (50 to 200 psi) will cover 90% of the applications, which vary from pneumatic conveying to pneumatic actuators and tools to auxiliary ventilation fans. The air can be used to operate machinery or pneumatic tools such as the wrenches and tools used in cutting and grinding. Other applications include cleaning.

Processing areas also benefit from dry air and the pressure required is typically in the range of 480 to 690 kPa (70 to 100 psi). Mineral filtration and separation operations on the other hand require higher pressures, typically 1,380 to 1,590 kPa (200 to 230 psi).

A term that is often used is *free air delivery* or *FAD*, which is the volume of air exiting the compressor expressed in terms of the inlet pressure and temperature conditions using the ideal gas law. (*Free air* is defined as air at normal atmospheric conditions [O'Neil 1939].) The difference between the FAD and the actual intake volume represents losses within the compressor. Thus, when comparing models, it is important to be aware that some manufacturers measure the air exiting the compression element rather than the intake volume.

Drilling, cleaning, and ventilation are key applications for compressed air in mining work. Developments in performance and reliability have been very important, as have improvements in the mobility and maneuverability of the equipment. Today's smaller and lighter compressors can be moved more easily to the next location, without the need for additional equipment to carry out the move.

Drilling Using Air-Driven Equipment

Compressed air plays an important role in the drilling of blastholes using techniques that combine the rotary action of drilling with the impact of a hammer. Injected air is used both in driving the hammer that is used to break up the rock and in blowing the debris out of the hole.

The air is used in techniques involving top hammer drilling, where the hammer is mounted at the top of the drill shaft, and in down-the-hole (DTH) drilling, where the intensity of the hammer action is increased by locating it on top of the drill bit rather than at the top of the drill string. Part of the volume of air is used to power the hammer, and the rest is used to flush the hole by removing the material that has been broken apart.

Demand for increased productivity in the benching at open-pit mines has spurred the use of hole diameters larger than 127 mm (5 in.) in diameter.

DTH drills can produce large-diameter holes, with straighter alignments than could be achieved with a top hammer.

Top hammer drilling is, however, a particularly economical method that is ideal for use in good, competent rock for holes of short to medium depth, with little if any deviation and no requirement for large-diameter holes. It gives a good penetration rate for high production capacity and its energy costs are low.

The hydraulic rock drill delivers the impact energy through a string of sectional drill steel to the drill bit. This method is fast, though achieving a straight hole can be more difficult in certain drilling conditions. There is an approximately 10% energy loss in each coupling joint.

The DTH method is also commonly used and comes into its own for drilling holes that go deeper, have large diameters, and where hole straightness has a higher priority than penetration rate. It is also chosen when drilling in extremely broken and fractured rock, where the flushing requirements are very high.

The rock hammer is positioned directly behind the drill bit, ensuring minimal power losses. High-pressure air is used for impact and as exhaust air for flushing the hole.

DTH drilling is a highly reliable method of producing clean, straight holes in a variety of drilling conditions. However, this method gives slower penetration rates than top hammer drilling.

DTH drilling applications include blastholes in production drilling, drop-raise cut holes and pilot holes in raise driving, and ventilation and communications holes for drainage.

Atlas Copco also developed the COPROD system for use where drilling conditions are difficult, where there is broken rock or where higher capacity/productivity is required. It combines the straight-hole drilling accuracy of DTH drilling with a speed superior to top hammer drilling. The system consists of impact rods combined with drill tubes to produce high penetration rates and longer drill steel life. Rotation and percussion are separated, optimizing the drill string for each function. The impact rods are stacked so that they are flush, which transmits percussion without the loss of energy that occurs in the coupling joints of conventional drilling methods.

The main difference between pneumatic and hydraulic drill rigs is simply whether the rock drill's hitting and rotating mechanism is driven by compressed air or by hydraulic oil. The track movement can also be propelled by compressed air.

Increasing Drilling Efficiency

The use of compressed air is vital in the creation of the deep, large-diameter holes that are essential for achieving optimum blast economy in open-pit mines and quarries. The burden between the free face and the drill hole is dependent on the hole diameter, spacing, and depth. Being able to create larger-diameter holes can significantly reduce the number of feet to be drilled, hence, increasing productivity.

Air Flushing

Increasing power output from rock drills leads to higher penetration rates so that efficient flushing of the cuttings becomes increasingly important. The flushing medium is normally air for surface drilling and water for underground drilling. The flushing air comes from a pressure tank supplied by one or more compressors, where the compressor is regulated to maintain the required supply.

Air is blown down through the drill bit, and the cuttings are removed via the annulus surrounding the drill shaft. The cuttings can be bound by a flushing additive added to the working air or can be removed using a dust collector.

Flushing is used to clean the bottom of the hole to prepare it for the next blow and to carry the cuttings out of the hole. The first of these tasks usually gives no trouble, although it is necessary to ensure that the passageways for the cuttings on the sides of the drill bit are sufficiently large and that the flushing holes in the drill bit are directed so that effective cleaning of the bottom of the hole is ensured.

The second task is, however, more demanding. The ability of air to carry the cuttings away will depend on the nature of the particles. To carry cuttings out of the hole, the carrying velocity must be greater than the settling velocity of the material. The settling velocity is calculated using the Newton–Rittinger equation, as the flow of the cuttings will generally be turbulent:

$$v_s = (4gd(\rho_s - \rho_a)/(3C_d\rho_a))^{0.5} \qquad (9.2\text{-}1)$$

where

v_s = settling velocity
g = gravitational acceleration
d = particle diameter
ρ_s = specific gravity of solid particle
ρ_a = specific gravity of air

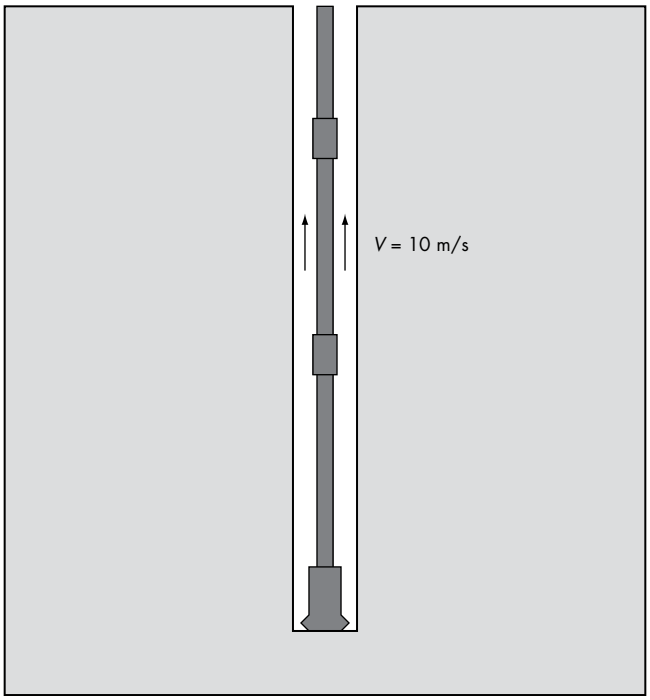

Figure 9.2-1 Flushing velocity in a drill hole

C_d = drag coefficient (usually taken as 0.43)

Equation 9.2-1 shows that the flushing velocity is proportional to the density and diameter of the solid particle. Although not represented in Equation 9.2-1, particle shape also has an effect—it is easier to carry away a particle in the shape of a leaf than one of the same weight that is spherical.

Using Equation 9.2-1, one finds that for a 2-mm- (0.08-in.-) diameter particle with a density of 2.0 g/cm^3 (125 lb/ft^3), the air velocity up in the drill hole must be at least 10 m/s (32 ft/s). A velocity of 10 m/s is considered the minimum required for rock particles of normal density (see Figure 9.2-1).

The flushing air requirements depend on the drill bit size, the rod size, the rock type, and the condition. The necessary air volume can be calculated, as the bit diameter and the rod diameter are known. A 76-mm- (3-in.-) diameter drill bit and 38-mm- (1.5-in.-) diameter rod would require 35 L/s (74 cfm) at an air velocity of 10 m/s (33 ft/s). The same rod in a 102-mm- (4-in.-) diameter hole would require 70 L/s (148.5 cfm) of air.

$$\text{area of annulus} = \pi(76^2\ \text{mm}^2 - 38^2\ \text{mm}^2)/4 = 3{,}400\ \text{mm}^2$$

With an air velocity of 10 m/s, the airflow rate is given by

$$V = 10\ \text{m/s} \times 3{,}400\ \text{mm}^2 = 34\ \text{L/s (72 cfm)}$$

If, on the other hand, one wants to drill holes with a diameter of 102 mm (4 in.) (using FI38 equipment), the annular cross-sectional area is given by

$$\text{area of annulus} = \pi(102^2\ \text{mm}^2 - 38^2\ \text{mm}^2)/4 = 7{,}040\ \text{mm}^2$$

With an air velocity of 10 m/s, the volume is given by

$$V = 10\ \text{m/s} \times 7{,}040\ \text{mm}^2 = 70\ \text{L/s (148 cfm)}$$

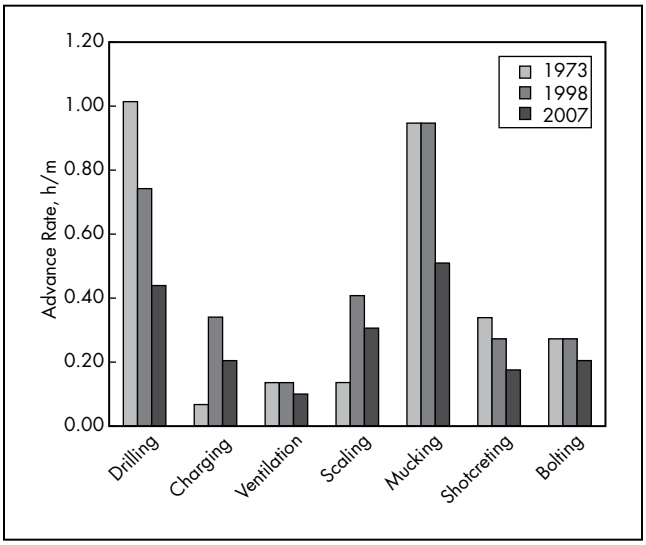

Figure 9.2-2 Relative costs over time of different production activities

Determining Air Pressure and Flows

The air required to clear holes depends on factors including the material to be removed, the drill method, and the hole dimensions.

The amount of air required depends on the equipment and the compressed air pressure chosen. The total air requirement for a typical Atlas Copco 89-mm- (3.5-in.-) DTH hammer at 586 kPa (85 psi) would be 46 L/s (97 cfm). This rises to 200 L/s (425 cfm) at 2,480 kPa (360 psi). For a 150-mm (6-in.) hammer, the airflow required for the hammer would range from 84 L/s (178 cfm) at 85 psi to 480 L/s (1,015 cfm) at 360 psi.

Planning for the total compressed airflow required also requires other aspects to be taken into account. The total air requirement for a drilling task is built up from the demands of the various operations involved, which can include the use of hammers, rotation units, feed motors, dust collectors, and air flushing.

A rig fitted with a 102-mm (4-in.) hammer operating at 2,000 kPa (290 psi) might require 205 L/s (434 cfm) for the hammer itself, but the operation would require twice this amount when the air for the feed motor, rotation unit, and dust collector are taken into account.

Similarly, a 586-kPa (85-psi) operation involving a mid-sized rock drill could require 268 L/s (568 cfm) to operate the drill, but it would require a further 25 L/s (53 cfm) for the feed motor, 70 L/s (148 cfm) for the flushing, and 65 L/s (138 cfm) for the dust collection.

Falling Costs

Time spent per foot of advance at a tunnel face has fallen markedly in recent decades for the sequential operations of drilling, charging, ventilation, scaling, mucking, shotcreting, and bolting (see Figure 9.2-2).

TYPES OF COMPRESSORS

The many types of compressors are divided broadly into two families: positive displacement and dynamic (or centrifugal) types. The most common type of dynamic air compressor is the rotary screw, which is available in oil-lubricated or oil-free versions. Piston compressors have been around since compressors were first invented, but advances continue to be made to create high-pressure models with advantages in efficiency, ease of maintenance, and reduced life-cycle costs.

In an oil-lubricated screw compressor, air passes through the air inlet filter where dust particles are separated. Inside the screw element, air is mixed with the injected oil and compressed. The oil is used to seal the clearance between the rotors and the casing of the element, and it ensures friction of the elements and cools the output air and screw elements. A separator removes the oil from the air, first through centrifugal force and then through filtration.

In oil-free screw compressors, the gap between the rotor elements is minimal. There is no oil injected in the screw element. The male and female rotors receive a special coating, and, as they do not touch, there is no friction and less heat production. The jacket of the element is cooled. The air then passes through an aftercooler, where it is cooled. The condensate is then separated and drained away.

A dryer cools the air through a refrigeration cycle to 14.8°C (5.4°F), and the further condensate that is generated is removed. The air then flows through the integrated dryer heat exchanger, where it is warmed by the incoming warm, humid air coming from the compressor's aftercooler.

The final step on leaving the dryer is to filter the compressed air.

Quality/reliability is generally seen as the most important factor behind the choice of a compressor model.

Portable and Stationary Systems

Having determined the use of rotary, oil-injected air compressors, the mine can decide on the use for an electric-powered stationary installation or diesel-powered portable units.

If a ready and stable electrical supply is available, it might appear that the stationary installation is the preferred option. But it is never that easy, so additional factors to be taken into consideration include

- Cost of diesel versus electricity,
- Stage of development (is the site a greenfield or a brownfield, or is it at the mining setup stage?),
- Distance of the infrastructure and place of work,
- Logistics (complexity of transporting pylons or diesel to the site, plus criteria of storing the diesel on-site), and
- Life expectancy of the mining operation.

Many underground mines today have less need for compressed air circuits than in the past, thanks to the growing use of portable compressors or compressors built into mobile equipment. Portable air-driven equipment such as drills have become increasingly efficient, and they provide great flexibility in their ability to be moved to wherever required.

Another factor has been the advent of load-haul-dump vehicles. Their use has diminished the need for the slushers (double-drum hoists), which were commonly used to move ore and had compressed air motors.

Some underground mines have dispensed completely with a stationary compressed air plant, though most still have a compressed air network. Its uses are varied. It can be used, for instance, to blow away dirt and pipe blockages, apply sprayed concrete, clean tools, clear or cool the air, and power hand tools such as drills. It can also be used as a hazard-warning system if stench gas is added.

Typical compressed air requirements in an underground mine will be for air at 7.8 to 9.2 bar (100 to 120 psig).

Where static compressors are being used, the typical solution will involve using a combination of fixed compressors—which are always either simply loaded or unloaded—and ones with a variable-speed drive (VSD) that cater for the peaks and troughs of the load cycle. Standby compression capacity would also be installed for wherever maintenance is required or in case of failure.

Use of VSDs minimizes the energy required to maintain the required pressure. Precise control of the pressure can be achieved through an external regulating system. This can be preprogrammed with all the required criteria for system operation using rules to ensure optimum efficiency, including factors such as ensuring that operational hours are shared between main and standby machines. This external regulating system is able to obtain substantial energy savings.

Fixed static compressors are generally sited on the surface, with only the piping taken belowground. This ensures sufficient air for the cooling of the compressors, as well as avoiding the harsh underground environment and the difficulties of delivering such large pieces of equipment underground.

Some stationary compressors are available that are built into standard 6-m- (20-ft-) high cube freight containers to allow outdoor use, saving the need for a separate container room.

Applications for small portable compressors, which deliver from 30 to 88 L/s (67 to 187 cfm) in the 8 to 12.5 bar (100 to 170 psig) range, include driving pneumatic tools such as chipping hammers, jackhammers, grinding tools, and rammers. They are also suitable for uses that require high FAD, such as sandblasting. More powerful models provide higher free air delivery while still remaining small enough for ease of transport and maneuvering.

Today's small, light equipment means that the operator can move to the next work point easily, without needing additional equipment to transport the compressor.

The next tier includes heavy-duty models designed for environments such as quarries. These models deliver about 165 to 183 L/s (350 to 388 cfm) at 8 to 12.5 bar (100 to 170 psig). Typical uses include rock drilling.

Where higher pressures between 9.5 and 14.6 bar (125 and 200 psig) are needed, there is a choice of models catering for flow rates between 233 and 400 L/s (494 and 847 cfm). Higher pressures can be achieved through the use of two-stage portable compressors capable of delivering up to 31 bar (440 psig).

The ability to deliver ever-higher pressures has resulted in productivity gains in mines. Changing from a regular-sized 26-bar (365-psig) machine to a 31-bar (440-psig) machine brings considerable benefits. Most machines are built for 26-bar (365-psig) pressures.

Altough it may be possible for the compressor element itself to produce 31 bar (440 psig) or more, other components such as seals and pressure vessels must be able to operate at the higher nominal pressure. Because most components may need changing to achieve such an upgrade, the resulting machine will inevitably be more expensive—the increased capital cost must be balanced against the reduced operating costs due to the productivity gain.

Operations that require a high volume of air include rock drilling. For this application, the compressor needs to be easy to operate as well as easy to relocate for quick start-up in quarries and maximum productivity.

Compressors can also be built into vehicles to suit a customer's needs and provide air power at remote locations—for instance, using a truck that has a power take-off from the drive train. From the power take-off, a belt drive or drive shaft can be used to take power from the engine. The engine is used to power the vehicle when it is driving and to power up the compressor when the vehicle is stationary at the site where the compressor is needed.

Oil-Lubricated Versus Oil-Free Compressors

Stationary compressors come into two broad categories: oil-lubricated and oil-free. In oil-lubricated compressors, the lubricating oil serves a number of purposes:

- It seals the clearance gaps between the screws and the casing.
- It lubricates the drive between the male and female screws.
- It assists in extraction of the heat generated during compression.

After the compression phase, a mixture of compressed air and lubricant (oil) leaves the air end and is passed to an oil separator, where the lubricant is removed. But part of the oil is exhausted from the compressor, usually as an aerosol or in a mist form.

In mining, compressed air is sometimes used to supplement ventilation air through the use of Venturi blowers. The presence of oil could be an issue in these circumstances, although the amount of air supplied in this manner is generally small. The air quality would generally only be an issue if a compressor were being used to supply a majority of the air in long-dead headings with little other air supply.

If oil-free air is required, filters are necessary on oil-lubricated compressors. The costs for maintaining and replacing the filters must be balanced against the smaller capital cost for the compressor compared to an oil-free compressor.

Another aspect in choosing between oil-lubricated and oil-free air compressors is the total power requirements for the compressor. Oil-lubricated compressors are not available beyond 500 kW (680 hp), limited by physics and economics, whereas oil-free compressors can be obtained in megawatt sizes.

Atlas Copco has an installation in an underground Turkish mine where about 8 MW of oil-free compressors are in use. This application would require 16 of the biggest oil-lubricated machines, but significantly fewer oil-free machines. More machines also mean greater maintenance costs. The compressors are installed on the surface, with tubing and pipes to transport the air underground.

Oil-lubricated compressors tend to be chosen when compressors need to be installed underground, as they are less sensitive to the local environment as well as being easier to transport.

Boosters

Today there is a growing demand in mining for much higher pressures that cannot be met by an air compressor alone. Typically, for example, a portable oil-injected screw compressor delivers air at pressures between 7.8 and 31 bar (100 and 440 psig). Compressed air at pressures between 51 and 346 bar (735 and 5,075 psig) requires a booster to increase the pressure.

The outlet of the feed-air compressor is fed into the booster as its inlet. Single-stage booster compressors therefore take in air at perhaps 26 bar (360 psig)—instead of atmospheric

pressure—compressing the air further to achieve the desired pressure up to 70 bar (1,015 psig). Multistage boosters are used to take the pressure up to a maximum pressure of 346 bar (5,070 psig).

Booster applications include minerals exploration drilling using reverse circulation techniques and coal-bed methane, where drilling very deep holes, up to several miles deep, can be demanded. Other applications for boosters include nitrogen injection for mine fire suppression, eliminating the risk of explosion and the risk of oxidation on valves, pipes, and drill bits.

The booster is built on a modified engine block—typically a John Deere or Cummins equipped with booster pistons mounted on modified engine pistons and using different sizes depending on pressure/flow. The capacity of the booster is determined by the inlet pressure and the speed of the driver engine. The higher the revolutions per minute, the more FAD the booster will displace.

ECONOMIES OF DRILLING

In making a purchase decision, people often only consider the purchase price, but it is important to obtain information from suppliers about the actual operating costs of the equipment. This ensures that allowance is made for hidden costs such as preventive maintenance.

Life-Cycle Costs

Manufacturers of compressors continue to carry out development work to optimize the production of air. The aim is to maximize FAD for the lowest power consumption, as this is the main factor in driving down energy costs.

The purchase price is only a small part of the cost of providing compressed air. The quality and service life of the compressor and its components, costs of energy (70%) and maintenance, and the indirect costs of downtime are among other factors to take into account.

Accurate calculation of the total cost of ownership is a complex matter, and some manufacturers produce calculators to help would-be purchasers of pneumatic drilling equipment take into account all the variables, including factors such as annual operating hours for the equipment, depreciation costs, interest on financing, and fuel and operator costs to arrive at total hourly costs.

Two other key elements influencing system operating costs are operating pressure and air leakage. Reductions in either can result in considerable savings. Air leaks have been estimated to waste as much as 30% of many systems' output, and most compressed air systems that are more than 5 years old are estimated to have a leakage rate of about 20% of the total volume consumed. Even a 3-mm (0.12-in.) air leak is estimated to represent almost 42,000 kW·h of wasted energy per year.

As little as 1% moisture in the oil can reduce the life of the compressor's bearings by 40%. Today's compressor designs avoid this through electronic control of the oil-temperature system.

Automatic control systems also play an important role in ensuring efficient operation, for instance, by matching use of VSDs to fluctuations in flow.

Manufacturers develop systems to improve the efficiency of air production and the quality of the compressed air. Recent electronic developments regulate the engine speed and the inlet air to optimize fuel consumption.

The volume flow rate is not a measurement of actual gas volume in a compressed state, but rather of air that has been re-expanded back to inlet conditions. A 47-L/s (100-cfm) compressor takes in 47 L/s (100 cfm) of atmospheric (ambient) air through its intake and may compress it to a gauge pressure of 7.8 bar (100 psig). The original 47 L (100 ft^3) of air has been reduced in volume 7.8 times, and it now only occupies 6 L (12.8 ft^3) in its compressed state.

The compressor used with a top hammer rig will typically be operated for just 45% of the cycle, being operated only when the hole is actually being drilled. For perhaps 35% of the cycle, the compressor will be unloaded but still running and retaining its pressure while actions are carried out such as changing the rods. For the remainder of a cycle, the rig will be in transit, and the pressure vessel can be depressurized.

Appreciation of the times for loading/unloading during the cycle is an important factor in calculating operating costs for the equipment. A typical example is shown in Figure 9.2-3, which indicates times such as 2 to 6 minutes for drilling each rod, up to a minute for adding the next, a few minutes for collecting the rods before moving to the next position, and time for providing a collar to seal the hole.

The deeper the hole, the greater the inlet pressure and flow that will be required to clean it. Maintaining a constant air speed will require increased pressure.

Compressor flow is a function of the pressure at the compressor inlet. It also depends on various factors, including flushing speed, distance, and volumetric efficiency.

Compressors are rated for operation in a particular range of ambient temperatures, which can be an important factor in mining. However, a machine that can work in higher temperatures will cost more, and there may be no need for the extra expense.

The latest advanced machines have been built to perform in a wider range of ambient temperatures—including options to work at up to 50°C (122°F)—and to save energy though the use of features such as automated switching off of the dryer in light load conditions.

Energy Savings and Heat Recovery

Rising fuel costs and environmental issues have increased demand for energy-saving equipment. Manufacturers continue to develop new ways of improving efficiency. For instance, Atlas Copco's compressors feature a fuel-saving system that operates when the compressor is under partial loads. Savings are typically 10% to 20% compared to a similar machine without the system. The investment cost of a system such as this can soon pay for itself in countries where fuel costs are high or where fuel supply is difficult, as in remote locations.

Energy usage is becoming increasingly important, and manufacturers aim to combine the best possible FAD with a reduced specific-energy requirement. The use of advanced computational-fluid-dynamics techniques in designing the equipment helps minimize internal pressure drops and drive down the energy costs. There are sound economic reasons for operating a compressor at the lowest possible discharge pressure.

Economical Compression Through Variable-Speed Drives

The cost of compressed air can represent more than 40% of the total electrical costs. Therefore, energy-efficient solutions can bring substantial savings. One of the key ways of doing this is to use a VSD, which tunes the total compressor

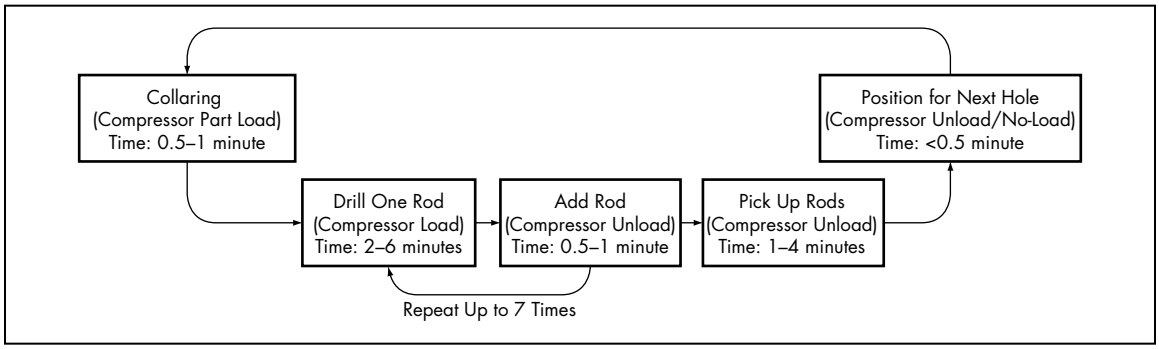

Figure 9.2-3 Loading/unloading times during cycle

capacity from a series of stationary compressors to match the demand for air. Besides providing immediate energy savings, a VSD can reduce overall life-cycle costs of the compressor by an average of 22%. Fixed-speed machines are ideal when they can run at full load for most of their operating time, but where air demand fluctuates, VSDs can achieve savings of up to 35%. The VSD enables provision of constant net pressure, which provides stability for all processes that use compressed air. Peaks in electrical current during start-up are eliminated, and VSD compressors can be started and stopped without limitation.

Another way of saving is to recover energy, through an integrated heat-exchanging module that makes direct use of the heat coming out of the compression element and transforms it into hot water as a form of energy. Uses include space heating and showers.

Preventive Maintenance

Proper maintenance is vital to prevent breakdowns, especially in hostile environments such as underground mines. The ideal is to carry out the maintenance before the machine breaks down, and a growing body of evidence about component life makes it ever easier to schedule maintenance and replace parts at the optimum time.

Manufacturers complain that compressors at mines tend to be undermaintained. The equipment may be underground, exposed to dusty environments, and at risk of a much shorter life than in less-hostile conditions. Many mining companies use their own maintenance crews to service the machines instead of bringing in the manufacturer's expertise. This can be another contributory factor to reduced life if in-house personnel have not received adequate training.

It takes effort to bring the machine up to the surface; consequently, maintenance of bigger underground machines tends to be performed in place.

Atlas Copco points out that in most industries about 50% of its compressors are regularly serviced by its maintenance crews, whereas in mining the proportion is closer to 5%. When machine maintenance is neglected, major problems are likely to occur and operating costs increase. In combination with what can be a hostile environment, lack of maintenance can contribute to an unnecessarily short equipment life in a mine—perhaps 3, 4, or 5 years compared to twice that in other situations.

Special options, such as heavy-duty filtration, are available for dusty environments, and trained technicians would immediately identify where these would be beneficial. The lack of contact with suppliers often means that compressors are ordered without discussing the operating environment by centralized purchasing based on initial costs alone. Specifying extra features such as heavy-duty filtration is particularly important in situations where maintenance is likely to be difficult and sporadic.

New technology brings advanced options for monitoring wear to help plan preventive maintenance, which can help overcome the traditional shortcomings in mine maintenance.

Some types of mining, such as salt mining, are particularly corrosive with a consequent impact on the life of wear parts. In situations such as this, there is a temptation to shun maintenance given that the machine's life will inevitably be short. Nevertheless, proper service would help extend the life of the equipment.

Compressor Rental

Rental, even of major machines, can be useful in cases of short-term additional demand and can be useful from a financing and tax perspective by spreading the costs and dispensing with the need to buy a major plant. Furthermore, with a rental, the supplier is responsible for all maintenance and for supplying a replacement in case of breakdown.

For instance, Atlas Copco has a division dedicated to specialty rental with a focus on industrial applications and the mining sector. The fleet specializes in oil-free and oil-injected high-pressure compressors for mining applications, as well as generating sets. The units deliver air at the rate of up to 755 L/s (1,600 cfm) with pressures up to 45 bar (650 psig). High-pressure compressors can be mounted in a crash frame and are used for deep-drilling application; deeper holes means that higher pressures are required to extract cuttings. Compressors are also available housed in 6 m (20 ft) International Organization for Standardization (ISO) containers that offer ease of transportation (see Figures 9.2-4 and 9.2-5).

Demand for a specialty rental fleet is particularly high in the United States, and rentals are typically from a week to a year, which is ideal for situations where the compressor needs to be constantly relocated. Being diesel driven, there is no need for a generator, making it ideal for use in remote locations. This type of equipment is also brought in where there is a short-term demand for extra air above that available from the permanent installation or in the case of a breakdown. Low-pressure rental units can be used for driving pneumatic tools, breakers, pneumatic pumps, diaphragm pumps, and general cleaning duties. Medium-pressure units, for example, 9.5 bar (125 psig), are used to inflate mine truck tires, to power high-flow pumps, and to supply air to blast furnaces.

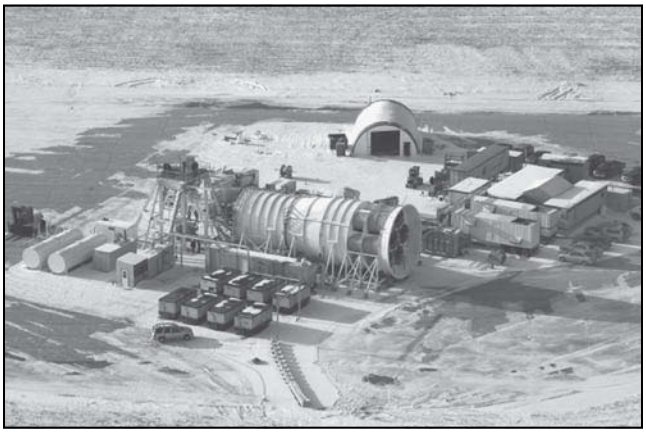

Figure 9.2-4 Compressors in ISO containers at a remote site

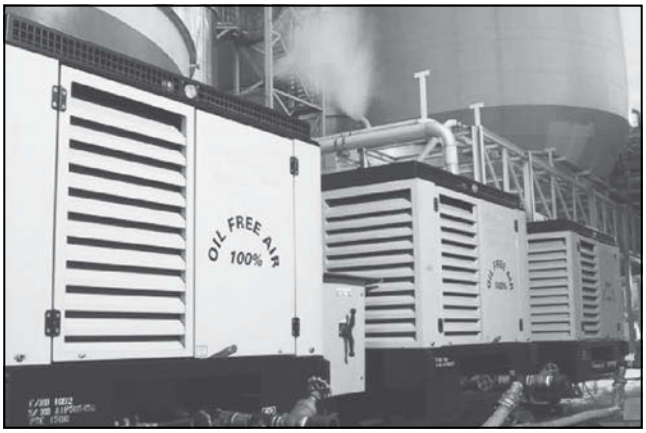

Figure 9.2-5 Compressors in ISO containers

AIR QUALITY

Necessity for Treating Air

Attention has to be paid to minimizing three contaminants that occur in compressed air: solids, moisture, and oil residues. These can otherwise contaminate the compressed air to a considerable degree, leading to corrosion in pipes and resulting in costly repairs. Air treatment solutions can be thought of as insurance for the plant, rather than simply an extra cost. Specification of equipment to remove moisture in particular can be thought of as insurance against corrosion, malfunctions, and production shutdowns. Without it, the costs can be high.

Untreated air may cause extensive damage and lead to serious performance degradation. All plants need basic air treatment to protect equipment, production processes, and end products; more critical applications require enhanced solutions to meet air quality requirements.

Equipment can be specified to improve the quality of the air downstream from the compressor by removing contaminants, including moisture, particles, and oil. The presence of these can be harmful in particular situations. Some form of air treatment is normally required to provide compressed air of the quality required at the point of use. Otherwise, there could be severe effects from the contamination, including damage to tools and valves; corrosion and damage to equipment, piping, and machinery; and contamination of products. Contaminants can cause rust and scale to form within pipelines, leading to the increased wear and maintenance of pneumatic devices, sluggish and inconsistent operation of air valves and cylinders, malfunction and high maintenance of control instruments, and effects such as spotting in paint and other types of spraying.

Many plants need only part of the air treated to a very high quality. (However, if the majority of the air is needed at a high quality, it would make sense to treat all compressed air to the level required by the highest-quality user.) Where compressed air is supplied from a central point, there may be purification equipment in the compressor room to protect the distribution system, with further purification at the point of application. An extensive range of purification equipment is available for both centralized and decentralized compressed air systems. This allows the user to tailor the quality of air for each specific application, from general-purpose ring-main protection through critical clean dry air point-of-use systems.

Purification may also be required for decentralized applications such as operation of pneumatic equipment, machinery and tools, and air instruments. Air treatment that removes moisture and particles increases efficiency—the production of dry, clean air prevents corrosion. Clean, dry air extends the life of equipment in the mine, enhances system reliability, and avoids costly downtime and production delays.

Design Criteria for Air Purity

Whether designing new compressed air systems or reviewing existing systems, the first step is to define the compressed air purity requirements. Air purity requirements vary widely but can all be met with the right equipment. However, unnecessary levels of air purification can significantly increase the associated energy cost.

The quality of air required depends on the application, particularly for oil-free air requirements. To assist in the selection of the necessary air purity, a series of classifications has been developed. Many applications need only part of the air treated to a high quality. In such cases, it is generally more effective to treat all the generated air to a minimum acceptable level and to improve the quality to the desired level close to the usage point. Points to consider for a given application include

- Required air quality,
- Estimated air demand,
- Required working pressure,
- Atmospheric contamination,
- Position and type of compressor intake,
- Temperature of the compressed and cooling air, and
- Condition and configuration of existing piping.

Choice of Treatment Approaches

Air quality requirements vary considerably from application to application. To achieve the levels of cleanliness specified by ISO 8573-1 (2001), careful thought must be given to systems design, commissioning, and operation. Point-of-use purification equipment should be installed as close to the application as possible to remove the maximum amount of rust and pipe scale prior to the application.

Filtration systems can be used with oil-injected compressors to yield air of a satisfactory quality. Different applications have different air quality demands. The ISO 8573-1 standard specifies the quality of the air, in terms of particle content—the quantity of dust particles that the compressed air can contain—as well as the acceptable oil and moisture contents.

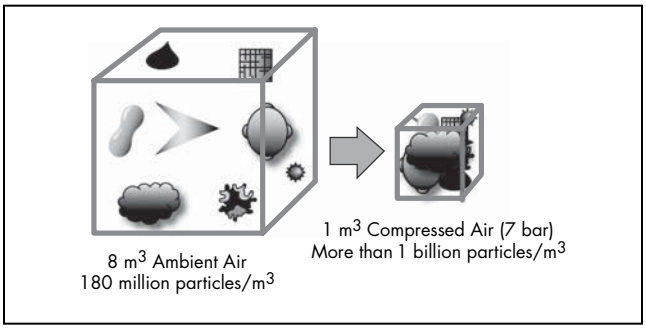

Figure 9.2-6 Increase in dust concentration due to compression of air

A primary compressor can be fitted with different purification systems according to specific categories within ISO 8573-1 and hence be suitable for different applications.

Oil filters are extremely important for ensuring the reliability and availability of compressors. Heavy-duty filters are available that can retain 99% of particles as small as 10 μm, in contrast to conventional filters that retain 50-μm particles. Another advance in reducing component wear is the use of special oil for lubrication of rotating parts, which brings about a significant extension in the life of components. Such changes have resulted in a doubling of the filter life, which is particularly beneficial in remote locations.

Concentrated Contamination

The compressor uses ambient air for compression. Without treatment, any contaminant in the air, such as dust, will also be in the compressed air. Even with filtration, some contaminants will remain, resulting in the introduction of dust into equipment downstream of the compressor, which could cause malfunctions.

Compression reduces the air volume and thus increases the concentrations of airborne contaminants in the intake air. Consequently, compressed air generally requires some form of treatment. These contaminants may also be joined by other substances originating within the compressor or in the piping and hoses. Research indicates that dust concentrations of 173,000 particles/cm^3 are common. Up to 80% of these particles are small enough to pass through a compressor intake filter.

In a typical example, the air volume is reduced by compression to one-seventh of its original. The resulting concentrations of particles such as oil and dust are not compressed, and their presence will be increased by a factor of 7. Thus, as shown in Figure 9.2-6, if there were 180 million particles of contaminant in the original volume, there would be more than a billion after compression.

Preventing Blockages

The presence of solid contaminants is the result of corrosion and rust plus mineral deposits, all of which build up within the aftercooler, storage tank, and piping system. Contributing to this load of solid particulates are solids that bypass the intake filter of the compressor as well as particles resulting from compressor wear. These abrasives range in size from microscopic to large bits and flakes.

Particles can be removed through filters, which are a cost-effective means of eliminating all types of contamination with minimal pressure loss. To protect the compressor from incoming dirt, a prefilter is always provided. In the case of piston, vane, and screw compressors, these filters have a dirt retention capacity of around 5 μm. Centrifugal compressors are more sensitive to incoming dirt, and inlet filtration is normally in two stages, retaining down to 0.2 μm.

Although droplets are visible to the naked eye, particles such as coal dust may only be visible under a microscope, whereas a scanning electron microscope is necessary to identify particles such as paint pigment and oil vapor. Particulate matter includes small solid and liquid particles such as dust, smoke, sand, pollen, mist, fly ash, viruses, and bacteria.

The presence of particles such as dust can block a pipe, increasing resistance to the airflow and, therefore, increasing energy use, decreasing performance, and increasing operating costs. Moisture can add to a blockage by forming a sludge. Moisture also promotes fungal and bacterial growth. Pneumatically controlled valves that control items such as conveying or filtration equipment may also become blocked over time, with a resulting impact on the equipment they control as well as downtime for repairs. With a blockage, a compressor will need to be run at a higher pressure to achieve the desired output pressure, which requires more energy.

Reducing Moisture

Water is probably the most familiar example of a liquid contaminant in compressed air. When the air is compressed, the density of the moisture increases. Water in pressurized air does not present a problem as long as it remains in a vapor state. But condensed water can lead to corrosion in pipes, interference with the lubrication of air tools, and the risk of freezing in pipes and tools.

Moisture is an important pollutant to consider in mining system design. It causes two problems—condensation, which can be troublesome downstream, and corrosion that can develop. Dry air is important for avoiding corrosion of air lines and the subsequent leaks and pressure losses. Replacing a long underground pipe is expensive. Corrosion begins to occur even before condensation is observed. It destroys the interiors of both piping and equipment. Ultimately, it leads to pipe ruptures and equipment malfunctions. Corrosion also introduces rust particles that can damage the equipment using the air. Further costs come from the shutdowns needed to reinstall the pipes and equipment.

Condensation occurs at a relative humidity of 100%, but corrosion starts even at a relative humidity of 50%. When it reaches 60%, there is an exponential growth in the rate of corrosion (Figure 9.2-7).

Moisture can also lead to damage in the bearings of any equipment that uses oil films for lubrication. There can also be resulting losses if air is used to control the filling of containers with final products—valves may stick, resulting in under- or overfilling. The corrosion caused by moisture in the air piping can drastically increase operational costs. Leakage translates into a loss of air capacity. This means increased usage of the compressor as it works to compensate.

A 5-mm (0.2-in.) hole leaks 27 L/s (57 cfm) at 7 bar (90 psig). To compensate for this loss of airflow capacity, 8.3 kW (11 hp) of additional compressor power is required, which can equate to costs of thousands of dollars per year, even from such a relatively small hole.

Even a 3-mm (0.12-in.) hole can cause leakages of up to 10 L/s (22 cfm), which in terms of energy consumption equals an annual cost running into thousands of euros/dollars/

pounds, as shown in Table 9.2-1. This 3-mm hole would leak 100 L/s (212 cfm) at 6 bar (85 psig), giving a power loss at the compressor of 3.1 kW (4.2 hp). For a 10-mm (0.39-in.) hole, the energy loss would be increased tenfold.

Humidity

The maximum water content that the air can hold without condensation depends on the air temperature—more can be held at higher temperatures. At high air temperatures, a relatively large quantity of vapor can be carried in the air, but condensation occurs as the air cools. Moisture condenses out of the air as it encounters lower temperatures. At night, as the air temperature cools and the air's capacity to hold moisture is reduced, dew forms. The air contacts the colder surface and sheds moisture.

Every kilogram of air contains a certain quantity of water in grams, which is the absolute air humidity. Relative humidity is a comparison of how much water vapor is in the air compared to the vapor pressure at the ambient temperature and pressure, which is the vapor capacity. Relative humidity is therefore expressed as a percentage. If the temperature of a volume of air is raised without adding more water vapor, then its relative humidity decreases.

The dew point of air is the temperature at which the water vapor held in the compressed air is equal to the compressed air's capacity to hold water vapor. It is the temperature at which condensation starts to occur when the air is being cooled. If the temperature of the air drops any lower than the dew point, the additional water vapor will condense and drop out in liquid aerosol form.

For instance, inlet air with a temperature of 30°C (86°F) and a relative humidity of 50% will have a dew point of 18°C (64.4°F) (see Figure 9.2-8). After passing through the aftercooler, the air temperature may be (ambient +10) 40°C (104°F), with 100% relative humidity.

Treatment in a refrigeration dryer can reduce the temperature to 20°C (68°F) and the pressure dew point to –15°C (5.4°F), greatly reducing the likelihood of moisture droplets forming.

For most industrial applications, compressed air can be considered dry when there is no liquid water present. Liquid water causes corrosion, contributes to the mineral deposits found in air pipes, and washes away the necessary lubricants required in air valves, cylinders, and motors.

For every 20°C (36°F) increase, the capacity of air to hold water vapor doubles. Conversely, for every 20°C (36°F) decrease, the capacity to hold water vapor is cut in half. Removing the water from compressed air can be accomplished in various ways. An air receiver stores the air after the compressor. Hot compressed air cools in the air receiver, where the condensation water is collected and separated out. This is the least expensive way and though an old method, it also gives the lowest degree of water separation.

Mining applications normally feature an aftercooler. Aftercoolers are used in virtually all stationary compressor installations as a standard feature. If the air goes in at 25°C (77°F), it will typically emerge (before going into the aftercooler) at 90°C (194°F). The aftercooler cools it to perhaps 35° to 40°C (95° to 104°F), removing most of the moisture. The ambient air will generally be cooler than this, resulting in heat exchange between the pipe and the surroundings so that the temperature in the pipeline drops, which leads to condensation. Optional dryers can be used to further reduce the moisture content of the compressed air to very small quantities.

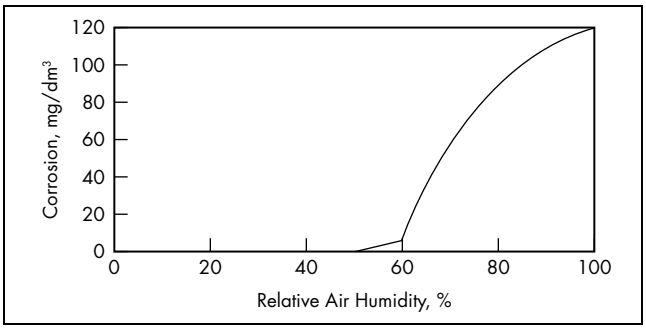

Figure 9.2-7 Corrosion as a function of relative humidity

Table 9.2-1 Compressor leakage losses

	Hole diameter, mm			
Measurement	**1**	**3**	**5**	**10**
Leakage, L/s at 6 bar	1	10	27	105
Power loss at compressor, kW	0.3	3.1	8.3	33
Energy loss at 24/7 kW·h	2,628	27,156	72,708	289,080
Annual costs,* euros, €	131	1,358	3,635	14,454

*Assuming 1 kW·h costs € 0.05.

Air exits a compressor with 100% humidity, and droplets of water form as soon as the temperature falls around the piping. Refrigerant drying is used to condense and separate a large amount of the water. Refrigerant dryers remove moisture from compressed air in even the harshest conditions. Other types of dryers include adsorption dryers, heat-of-compression dryers, and membrane dryers, with the choice depending on the desired dew point.

COMPRESSED AIR NETWORK DISTRIBUTION

Portable compressors can be set up alongside drilling equipment and can supply air via a short length of hose. However, some mines use permanent networks fed by fixed pipelines from banks of stationary compressors. The most important issue in designing a piping network is not the quantity of air but rather achieving the correct pressure to operate the equipment. Air pressure is reduced because of the friction in passing through obstacles such as restrictions, bends, and narrow passages. The pressure drop increases if the air supply chain is long or if the air supply piping is small in diameter.

For the user of compressed air, the airflow rate is of less interest than confidence that the compressor will meet the pressure needs of the work in hand. Machines with a low operating pressure of about 6.5 bar (80 psig) are used in industries such as cement production or coal mining in pneumatic conveying and unloading, or in blowing dust away. This type of application demands huge amounts of air at a relatively low pressure. A higher-pressure of about 8.5 bar (108 psig) is used for materials handling of larger items, and it is a common practice to provide a single air circuit for both uses, even though the result is delays to the higher-pressure use while the air supply is diverted to service a high-volume, low-pressure application. Today, independent lines can readily be set up to supply different pressures for divfferent types of operations, which can result in considerable reductions in operating costs.

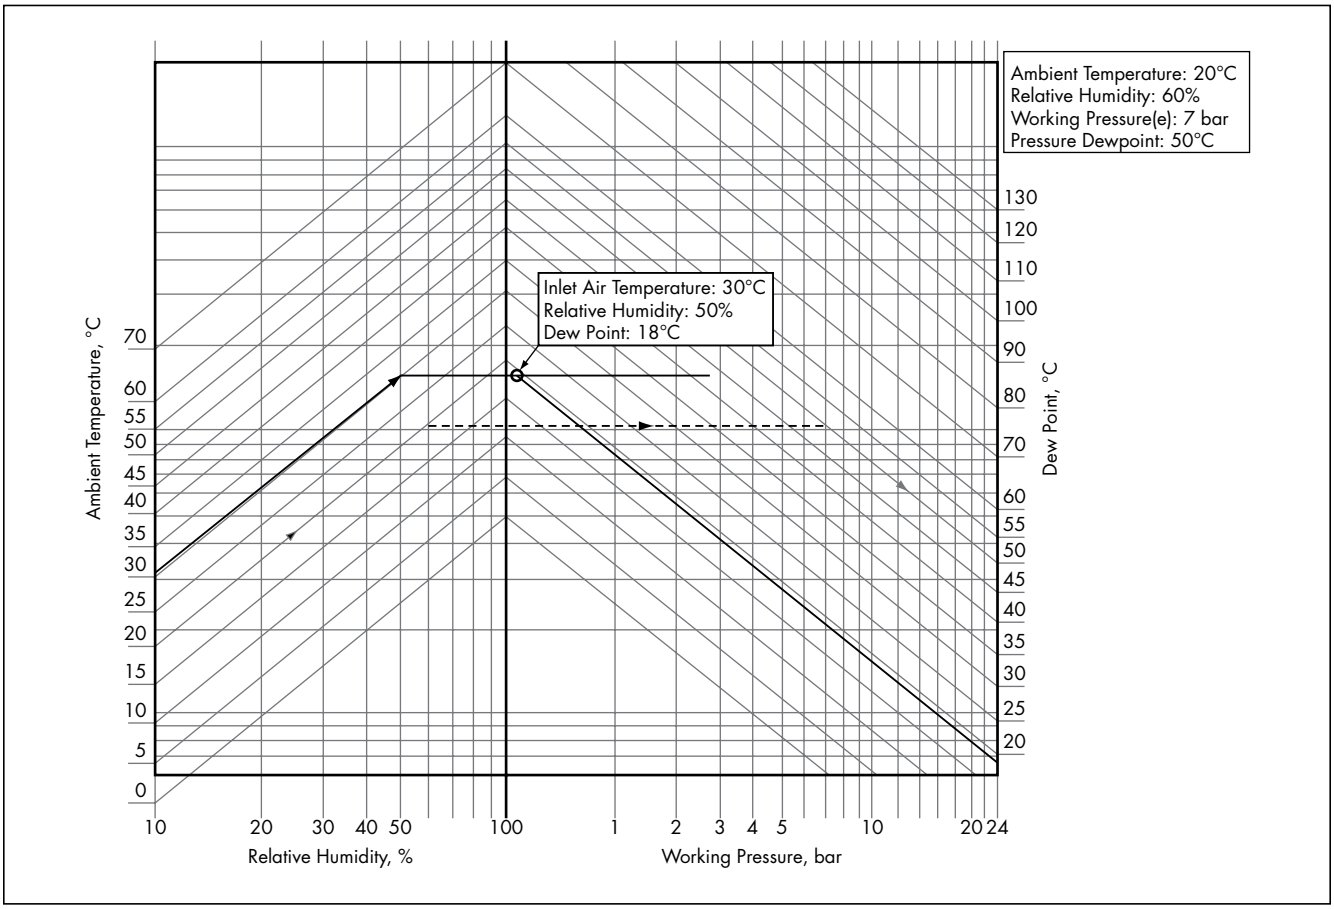

Figure 9.2-8 Dew point as a function of ambient temperature, relative humidity, and working pressure

Air distribution is the critical link between the compressor installation and the machine or tool that is using the air. Distribution requires an effective system of air lines and accessories, particularly in harsh environments such as mines. A well-designed and properly maintained air distribution system should have leakage of no more than 5% of the capacity of the installation. Unfortunately, 15% to 20% leakage is quite common.

The design of the air line and the choice of the fittings are important for minimizing losses. Pressure losses are created by restrictions such as small-size couplings or hoses that are too long or too small in diameter.

Every coupling in an installation creates a pressure loss, but the losses can be exacerbated through the use of incorrect fittings. Specialist fittings are required in particular situations, such as swivels that prevent the hose from getting in the way when working with hand tools and torque arms to reduce fatigue in operators. Ideally, the distance between the tool and the off-take should be no more than 3 to 5 m (10 to 16 ft), though this is often impractical to achieve in major installations such as mines.

The main line distributes the air from the compressor location to the point at which the air will be used. In a large compressed-air system serving several zones, the main line should be arranged so that each branch can be shut off without affecting the rest of the system. This ensures that when working on the piping system, only the branch involved has to be shut off. Leakage may be decreased if nonoperating units are shut off. This approach also makes it possible to ensure that the most important unit is supplied with air if the compressor capacity proves insufficient for the whole system to operate simultaneously.

A ring main distributes the air within the working zone. Excessively long off-takes should be avoided. Use of a ring main means that if an unexpectedly large air usage occurs in any service line, air can be fed from two directions. This reduces the pressure drop and provides level and more-stable air pressure in the entire system.

The off-take or branch line is the final part of the permanent installation and should be carried as close to the workplace as possible. The users in an air distribution system are the air tools together with their air preparation units or any other equipment consuming compressed air. Air-line accessories such as pressure regulators should be of high quality.

Diameters and lengths of a branch line depend on the amount free air to be supplied. The materials used for the pipe and couplings are also important for avoiding leakage and corrosion while minimizing pressure drop along the length to ensure that air at correct volume and pressure is delivered to the work face.

The performance of air power tools is largely dependent on the ability of the system to supply an adequate quantity of air of the correct quality and pressure. Too low an air pressure reduces the performance of most air tools. If the pressure

is lower than the design value, efficiency drops radically and productivity decreases. For a system supplying hand tools that operate at 7.8 bar (100 psig), the pressure should not be less than 7.1 bar (90 psig) at the tool end to ensure acceptable productivity.

Tests on a typical grinder showed that a pressure loss of 1 bar (15 psi) leads to almost 30% less material removed—so the worker has to work longer to do the job. Similarly, tests with a hand drill have shown that every hole that takes 2 seconds at 7.1 bar (90 psig) would take 3.2 seconds at 6.8 bar (85 psig), which would lead to substantial additional operating costs over the course of a year.

EMISSIONS AND NOISE DIRECTIVES

Two widely adopted requirements regarding machine emissions are the Tier 3 standards in the United States and the Euro 3 and 4 standards in Europe. Similarly, noise regulations continue to be enhanced to comply with national and international standards. Equipment from major manufacturers complies with the key international standards, though customers may need to confirm equipment suitability for use in specific countries. Some countries have no specific requirements on either emissions or noise.

Dust can create a considerable nuisance in drilling if not collected, and it is particularly important to control particles smaller than 5 mm (0.2 in.) as effectively as possible. The basic requirement is for the dust collector to operate with a partial vacuum, which means that a suction ejector should be the final piece of equipment in the sequence. Larger drills are fitted with a brake ejector, which dispenses with the need for a seal against the rock and facilitates collaring and allows drilling to be performed with no appreciable drop in production.

REMOTE MONITORING AND CONTROL

Many mines today run a series of independent portable compressors. Those mines that retain a stationary surface compressor room are increasingly adopting centralized remote control to optimize the usage of a bank of multiple compressors. Automatic control ensures that the correct combination of machine size is automatically adopted for maximum efficiency. To achieve this, one or more variable-flow compressors are required in the network. The control ensures that each runs in its optimum range for enhanced efficiency.

Compressor controls can consist of hard-wired digital contacts or a choice of three major field bus industrial interface protocols (Modbus, Profibus, and Ethernet/IP [Industrial Protocol]). This allows the machines to be integrated easily into the control panels so that the operator can start a machine remotely without needing to be in the compressor room.

Today's remote monitoring capabilities are ideal for use in mines, as diagnostics and checks can be performed by experts away from the site. Use is made of the global system for mobile communications (GSM) network to relay information from the compressor to the monitoring system—the system can be used by both portable and stationary compressors. Satellite solutions are also available and are ideal for portable compressors in locations that are outside mobile phone networks.

Different tiers of service are available, starting with a simple notification process when there is a problem. The text message carries details of the problem—for example, a warning status due to the oil temperature. Such notifications can be very useful even where there are technicians on-site, as they receive an instant warning.

Another option offered by manufacturers is local monitoring, where the equipment is connected to a special communications box that displays the status. This requires a physical connection to the box, which may not be ideal in some mining situations.

Portable compressors can be equipped with a special controller that supports both GSM and satellite networks. This box broadcasts the compressor's status and its most important parameters, including its GPS (Global Positioning System) coordinates. This means that it can be used for theft protection—it can be located on maps or satellite photographs. The system will send a text message if it is moved away from a set location. This feature is particularly used by rental companies in checking up on their fleet locations and usage.

Use of such a system ensures that the service operations are well planned—service engineers can check on efficiency, analyze any faults before visiting the site, and plan predictive maintenance. The machines can be monitored and analyzed, with any drop in efficiency highlighted and remedied. Use of this kind of system also helps keep down the costs of servicing, as schedules can be planned for maximum efficiency including making best use of the technician's time.

Internet monitoring is also available for industrial-scale machines. A central password-protected Web site provides access to data about the compressors that are connected to it. This approach supports both Ethernet connections and all types of modems. The data are refreshed every minute, alarms are sent out as required, and service engineers can analyze any problems from thousands of miles away if necessary.

CHAPTER 9.3

Mine Communications, Monitoring, and Control

Rajive Ganguli, Scott Beer, and Mark Watson

INTRODUCTION

A mine communications system, which includes communication, monitoring, and control, is an integral part of modern mine operations and management. Basically, a communication system is a network of devices that collect, receive, or transmit information. With the passage of the Mine Improvement and New Emergency Response (MINER) Act of 2006 following recent mine disasters, especially those at the Sago mine in West Virginia and the Crandall Canyon mine in Utah (both in the United States), two-way wireless communication systems between surface and underground and electronic miner tracking systems are now required in U.S. mines. However, mine communications systems are not limited to tracking miners in case of emergency. The subject also includes sensing systems used for process control.

BASICS

As shown in Figure 9.3-1, a mine communication system (MCS) has three basic components: the information source or transmitter (such as sensors), the communication pathway or network, and the information receiver. The technological success of an MCS depends on the successful functioning of all three components. However, the receiver may be passive; therefore, the critical components are the source and the network.

The fundamental nature and technology of sensors vary drastically from one to another. A sensor's required accuracy, precision, and sensitivity depend on the need the measurement fills. Thus, a motor stator voltage measurement would be significantly more accurate and precise than, for example, a semiautogenous grinding (SAG) mill ball-loading measurement. However, the precision of measurements is increasingly important, because sensor information is increasingly being used for automatic control, which will be discussed further in a later section.

The part of an MCS currently undergoing rapid change is the communications network. Although Tesla and Marconi first demonstrated wireless radio communication a century ago, mine communication systems, like most industrial communications systems, have been mostly wired. Mines have traditionally used multiple communication networks, each serving a unique purpose. Therefore, there was a telephone network, a sensor network for belt conveyors, and so forth. However, technological breakthroughs in the nonmining world, such as digital radio communications, pressure for mine productivity improvements, and newly legislated mine safety requirements, are driving the industry toward single unified communications systems for entire mines. Communications systems now have options for wireless connectivity or a hybrid of wired and wireless connectivity, although most successful underground networks currently employ cables. Transmission is mostly by means of electricity (such as through phone lines or Ethernet cables), radio signals (such as wireless networks and leaky feeder systems), or light (fiber optics). The mode of transmission is a major determinant of a communication system's ability to meet the needs of a given purpose.

MAJOR TRANSMISSION TECHNOLOGIES

The most popular transmission medium is radio signals because they allow wireless implementation. The various radio transmission technologies are discussed later (Beerbower 2006; MSHA, n.d.; NIOSH, n.d. (a); Schiffbauer and Mowrey 2006).

Low Frequency Technologies

Low frequency (LF) radio systems use the very low frequency (VLF) and ultra low frequency (ULF) bands. The LF band includes frequencies from 30 to 300 kHz, VLF from 3 to 30 kHz, and ULF from 300 Hz to 3 kHz. LF signals are least attenuated when they travel through the earth. In that sense, they are best suited for underground mines. However, their application is limited underground because they have very narrow bandwidth; that is, only minor amounts of information can be transmitted as LF signals and over limited communication distances. A majority of the underground emergency communication technologies that are designed to survive

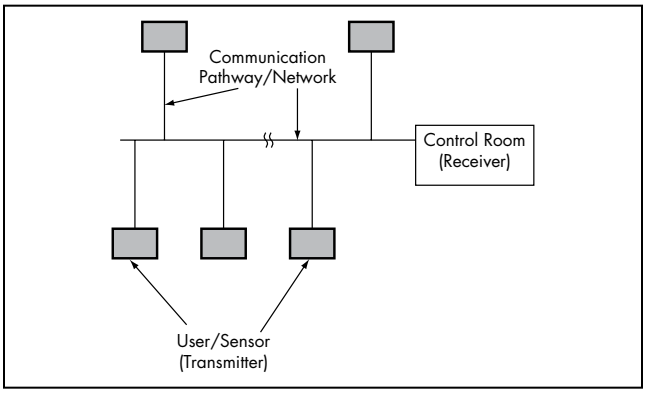

Figure 9.3-1 Simple representation of a communication system

postaccident are LF technologies. Such technologies are commonly implemented as transmission from surface to underground (one-way), though two-way systems exist. Surface antennas are typically large loop antennas laid out over the mine area. Some systems (one-way or two-way) use underground loop antennas.

LF radio systems have a variety of advantages and disadvantages.

Advantages

- Signals travel through the earth. Communication can be in the form of voice or data.
- Communication can be broadcast to all or sent to a single miner.
- When attached to an integral accessory (such as a cap lamp), receivers are always close to the miner.

Disadvantages

- The transmission depth can vary. Most natural and human-made electromagnetic noise is in the lower frequencies. Therefore, LF radio systems are susceptible to interference from noise. Transmission from surface antennas can additionally be affected by foliage and the presence of workings above the current working level. Local noise sources can create shadow zones in a mine that is otherwise covered.
- When surface antennas are required, surface land ownership and terrain can become major issues because of the large area taken up by the antenna. When an underground antenna is needed, the system may not survive a catastrophe. Additionally, underground antennas are not intrinsically safe, so they would have to be turned off during events such as blasting, fires, or fan shutdowns.
- With currently available technologies, if a message is transmitted when the receiver is off, the message is lost. In a one-way system, there is no way to confirm whether a message has been received.
- Message length can severely impact transmission time. Transmission of a 32-character message can take up to 3 minutes.
- Two-way systems may not have portable antennas.

Medium Frequency Technologies

Medium frequency (MF) technologies (300 to 3,000 kHz) combine the benefits of low and high frequencies. External environmental noise is not the major problem that it is with low frequencies. MF signals can also penetrate the earth to some extent. However, because they can couple (parasitic coupling) to existing electrical cables and pipes, their effective range can be very high. Existing mine conductors not only act as conduits but also as antenna (Dobroski and Stolarczyk 1982). Entries in bedded deposits can act as wave guides and extend the range (A.R.F. Products 1986).

MF systems have a number of advantages and disadvantages.

Advantages

- Signals travel through the earth to some extent. Communication can be in the form of voice or data. Parasitic coupling can extend the range of these signals significantly.
- These signals are not severely affected by electromagnetic noise.

Disadvantages

- The bandwidth of these signals is limited.
- Very few commercial products use this technology.
- Antennas can be large, making portability a problem.

High Frequency Technologies

High frequency (HF) systems use the very high frequency (VHF) and ultra high frequency (UHF) bands. The HF band includes frequencies from 3 to 30 MHz, VHF from 30 to 300 MHz, and UHF from 300 MHz to 3 GHz (gigahertz). HF signals are the least suitable for underground applications because they suffer the greatest attenuation when penetrating the earth. Akyildiz and Stuntebeck (2006) report higher attenuation for higher frequencies, with moisture content also deleteriously impacting signal propagation. These limitations are also observed in VHF and UHF devices, such as radios, which are commonly used in mines. For wireless transmissions, higher frequency technologies work best in line-of-sight applications, with VHF working best in wider mine openings and UHF performing well even in smaller openings such as 1.8-m coal seams (Nutter 2007).

HF systems have a variety of advantages and disadvantages.

Advantages

- Many commercial products use this technology. Significant advances have been made in UHF technologies in recent years, many of which are finding application in surface mines (and, to some extent, underground mines). UHF voice radios are a common (industrial) communication tool.
- UHF ranges are extended by mine entries that act as wave guides.
- HF systems are not severely affected by electromagnetic noise.
- Safety-related issues are well understood.
- The high bandwidth of these systems allow for voice and video communications.

Disadvantages

- Signals suffer severe attenuation when going through earth/physical barriers.

Table 9.3-1 Comparison of various communication technologies

Technology	Typical Application	Advantages	Disadvantages
VHF/UHF	Voice, data, tracking	High bandwidth, can allow many users, accommodate high traffic; multiple voice channels; small and wearable antennas; factors impacting safety are known	Best for line-of-sight applications (not good around bends)
MF	Voice, data	Can turn corners; metal infrastructure (pipes, track, wires, etc.) in the mine can help increase range (parasitic propagation)	Limited bandwidth; existing electrical and communications system may cause interference, though not as much as for ULF/VLF/LF
ULF, VLF, and LF	Personal emergency devices	Can go through the earth	Natural phenomena, existing electrical and communications system can cause severe interference; very limited bandwidth; require surface or underground loop antennas
UWB	Tracking, data	Ideal for tracking; no interference from existing electrical and communication systems and multipath effects; very high bandwidth; simple architecture (potential to be inexpensive)	Very short range

Source: Nutter 2007; Chehri et al. 2008; Friedlos 2008; Swedberg 2008; NIOSH, n.d. (a).

- In wireless implementations, multipath effects can make the signals extremely noisy. When an HF signal is transmitted, it reflects, refracts (*multipath*), and interferes with itself on its way to the receiver, thereby reducing the quality of the signal.
- These systems require a lot of infrastructure (such as repeaters, routers, and cables), which makes them susceptible to mine disasters.

Ultra Wideband Technologies

Ultra wideband (UWB) technologies are low-power (short range), high-bandwidth communications spread over a wide spectrum of frequencies. UWB technologies make use of all frequencies, low to high; that is, their short pulses have a bandwidth of 500 GHz or 20% of the center frequency, whichever is less. As a result, they differ from the technologies discussed previously, which were restricted to a single category and therefore had a narrow spectrum. However, because of their higher bandwidth, they have low power on any one frequency.

UWB systems have a variety of advantages and one disadvantage (Chehri et al. 2008; NIOSH, n.d. (b); Intel, n.d.).

Advantages

- UWB systems are not affected by noise from narrowband systems.
- They do not suffer from multipath effects like higher frequencies do because their short pulses are easily identified. The technology can determine the time of travel of the signal. Thus, it is ideal for location/tracking applications.
- They support high data rates, so they can support all communication needs.
- The simple architecture of UWB systems means they can be less expensive than other technologies.

The disadvantage is that UWB systems have low power, so they have an extremely short range (around 10 m).

A comparison of the strengths and weaknesses of the various technologies is provided in Table 9.3-1.

TRANSMISSION MEDIA

Signals to and from sensors and users can be transmitted through wired or wireless media (or a combination of the two). Both media have their own sets of challenges. Wired networks can become logistically and financially challenging. They may not accommodate sensor/user mobility and cables can get damaged. Cable protection through armoring, conduits, or burial is difficult on a massive scale. Creating redundancies in wired networks can also be difficult.

The major challenge for wireless transmission is that the technologies with the greatest bandwidth (VHF/UHF) do not travel through the ground very well and/or have very low range (UWB).

Wired Networks

Wired networks can transmit radio, electrical, or optical signals. The various transmission technologies employ differing types of wiring or cable: twisted, multiple-wire cables for electric signals, coaxial cables for radio transmission signals, and fiber-optic cables for optical transmission signals.

The most common wired system is probably the leaky feeder. Leaky feeders are cables designed to "leak" radio signals (i.e., the cable shield has holes). Signal frequencies can be in the VHF or UHF range. Considerable signal loss means leaky feeder cables require repeaters to continue propagating their signals. Leaky feeder cables can also serve as antennas or conductors for MF communication. Leaky feeder cables maintain a low voltage; therefore, certain low-voltage communication devices need only one cable to power them and to keep them connected to the network. This makes these devices intrinsically safe.

Leaky feeders are usually used in conjunction with two-way voice radios (MF/VHF/UHF), with VHF/UHF being more common because MF antennas can be large and cumbersome. Radio coverage depends on the frequency. Typically, UHF voice radios provide better coverage than VHF radios. To maximize the benefits of all types of radio communication technologies, researchers are attempting to improve the interface between MF radios and UHF/VHF leaky feeders. The intent is to examine whether the parasitic coupling abilities of MF transmission will improve coverage and help create redundancies during emergencies.

Advantages

- Leaky feeders extend the range of the frequencies that have the most bandwidth.
- They can carry voice and data.
- Leaky feeders can power low-voltage devices.
- They can serve as a conductor/antenna for MF communication.

Disadvantages

- The signals that leaky feeders carry do not penetrate the earth.
- They can be expensive; they require skilled labor for maintenance and installation.
- Like all cables, they can be impaired following a mine disaster. Also, they require battery backups for emergencies.
- Repeaters are required to extend signals.
- Redundancy can be complicated to achieve.

The other types of wired communications systems are telephones, pager systems, trolley wire systems, computer networks, or network backbones (such as fiber-optic cables).

Telephones and pagers have so far been the most important communication link in underground mines. They are easy to install and are battery powered. However, they have significant limitations that make them unfit for emergencies or as productivity tools. First, communication is limited to fixed locations. Second, although they are easy to install, they can be difficult to maintain because cables can get easily damaged. Pagers have the added limitation that the communication may not be private. Although telephone lines can be used to transmit data, the bandwidth is limited. Trolley wires are becoming obsolete as rail haulage systems become less common, but they can transmit communication signals on the direct current cable that powers the trolley system. Therefore, this method of communication is noisy. However, because they allow communication on the haulage way, they enhance safety.

Computer networks are a critical component of a modern mine. Networks are usually minewide, though corporation-wide networks are becoming common as well. Corporation-wide networks would probably require a multitude of transmission media. Modern data transfer protocols (such as TCP/IP [Transmission Control Protocol/Internet Protocol]) and networking technology (such as Ethernet) allow most mining equipment, especially in processing plants, to be part of the mine network, making monitoring and data transfer seamless; however, for security and optimal network management, there should be a barrier between office management networks and operation/safety networks (Pamel and Pederson 2007).

Standard Category 5 (Cat 5) twisted pair copper wire Ethernet cables are used to connect devices in a wired Ethernet network. However, they are noisy and subject to energy losses beyond short distances. Fiber-optic Ethernet cables are another (new) option for local networks, though they are commonly used when transmissions occur over long distances (such as for mine communication backbones).

Fiber-optic systems work by sending light signals through a clear core using the phenomenon of total internal reflection by a reflective coating (*cladding*) covering the core.

When the core is very thin, the light travels in a straight line through the core (*single-mode*) so that signal loss is minimized. When the core is thick, the light is reflected and refracted (*multi-mode*), resulting in higher losses. Though multi-mode cables have a smaller range, they can carry many more light frequencies than single-mode cables. In addition to the core and cladding, fiber-optic cables also contain multiple protective layers to add strength.

Advantages

- Fiber-optic systems have very low losses, so the repeater requirement is minimal.
- They have a significantly high bandwidth.
- They are not susceptible to electromagnetic/radio interference.
- Fiber-optic cables are intrinsically safe, though optical transmitters (devices that convert electrical signals to optical signals) may not be. Electrical pulses must be converted to light pulses prior to their transmission through fiber-optic cables.
- Because they do not conduct electricity, fiber-optic cables eliminate ground loop problems (Dubaniewicz and Chilton 1995) and are not impacted by high voltage cables, lightning, and other electrical disturbances.

Disadvantages

- Fiber-optic transmission can be expensive over short distances.
- The inability to carry electricity along with communication signals (as leaky feeders do) can be a major disadvantage because many devices in sensitive areas depend on the communication cable also to provide intrinsically safe power.

Wireless Networks

Wireless networks employ devices (*clients*) that communicate wirelessly using the 802.11X IEEE standard of UHF (2.4 GHz and 5 GHz band) communication. They traditionally required mobile clients to be near a fixed access point that connects directly or routes data back (back haul) to the wired network. Because a mine is constantly changing, fixed access points must be continually added or relocated to maintain network integrity. Access points attached to mobile trailers with battery and solar power are often used for this purpose in a surface mine. This reconfiguration of the network is a continuous process and can be a significant burden. One mine noted that they had more mobile trailers than haul trucks and operated a large crew of technicians to support the daily reconfiguring of the network. Blind spots can also occur regularly, resulting in missed assignments and reduced efficiencies.

Recent advances in wireless technology support greater mobility. These solutions (*wireless mesh networks*) extend message routing capabilities to each mobile node, allowing messages to be routed between mobile nodes back to the closest access point. Each node automatically locates and configures a connection with every other mobile node or access point within its range, resulting in a *mesh* of network connections (*client mesh network*). A small mesh network may be connected through routers to a broader network (see Figure 9.3-2). Message routes are dynamically analyzed and selected to provide optimal throughput. This mesh technology not only extends the flexibility and range of the mobile network but increases the effective throughput by allowing the message load to be distributed across the mesh (load balancing).

High bandwidth wireless mesh networks connecting the underground mining locations to the surface are possible, though they may require that routers be very close to each other. In a test in the Canada Centre for Mineral and Energy

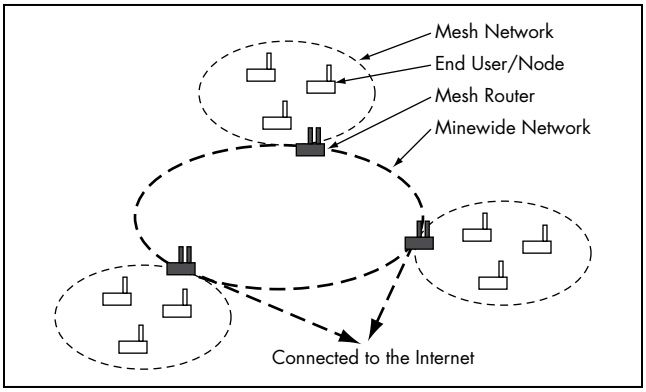

Figure 9.3-2 Wireless mesh network

Technology's (CANMET's) experimental mine, bandwidth dropped by 50% for each hop using TCP (Hakem et al. 2007). TCP is the protocol computers use to talk to each other. The term *hop* is used to describe transmission of signal from one router to the next. Maintaining bandwidth is not the only challenge. Because they are based on UHF radio signals, mesh network systems have the strengths and weaknesses listed previously for VHF/UHF radio systems. Interference from existing electrical and communication systems, the existence of shadow regions, and the magnification of noise when amplifiers are connected in series (Ortega 2007) can still impair such networks. Other issues with wireless networks include reflection/refraction of signals from ground–air interfaces, multipath fading from features such as plants and rocks, and lower propagation velocities in dielectric material.

Advantages

- Given the ease of integrating modern wireless devices with computer networks, wireless devices and networks in mines can usually be easily integrated into a minewide computer network. This enhances safety and productivity.
- At least in a surface mine, wireless mesh networks are easy to establish.
- To a certain extent, bandwidth is not an issue.
- Wireless devices and networks are more prevalent in the nonmining world than in mining, so they are constantly being improved.

Disadvantages

- Wireless signals are UHF radio signals. Therefore, they have all the disadvantages of UHF signals, such as the inability to penetrate the earth and their degradation as a result of multipath effects.
- Wireless devices/networks are not truly wireless because they still must be connected to a power source. Additionally, they need battery backup for emergencies. Powering some of these devices requires explosion-proof (XP) enclosures, which in turn makes them cumbersome. Complicated battery backup systems (such as those used in the northern latitudes where solar systems do not work) can also come with a significant maintenance burden.
- Wireless mesh networks can require a significant amount of infrastructure, especially in an underground mine.
- Very high bandwidth requirements (such as for videos) can be difficult to maintain across multiple hops.

CHARACTERISTICS OF A MINE COMMUNICATIONS NETWORK

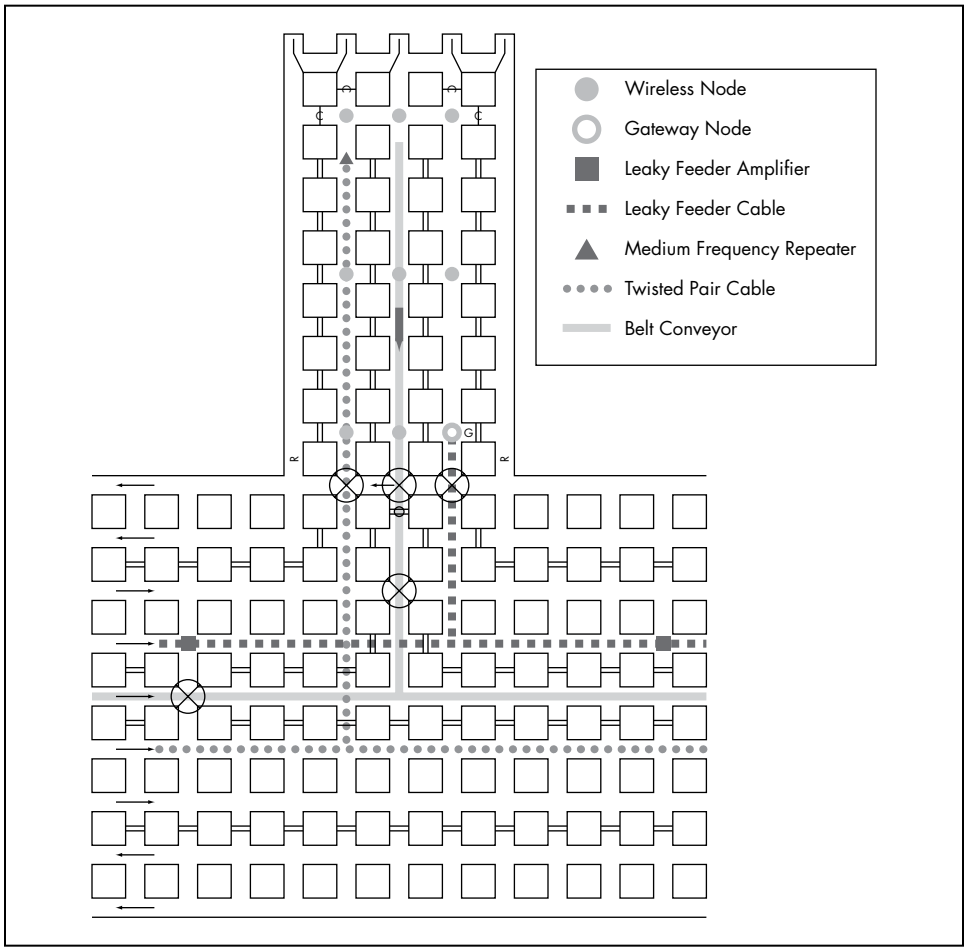
An effective mine monitoring, communications, and control system requires a communications network that can support all its demands.

Desired Attributes

A mine communications network should have the following major attributes:

- Ability to accommodate different types of information sources and existing infrastructure
- Ability to accommodate information source mobility
- Safe, robust, and redundant (survivable) operation
- Ability to expand easily
- Ease of maintenance

Ability to Accommodate Information Sources and Infrastructure



A modern mine has a multitude of information sources. Not only can individual sources differ from each other (e.g., a drill is very different from a methane monitor or a radio), but even within a source, there could be different information sources. For example, a mine truck may be transmitting machine health information (such as engine temperature) and haulage–jolt information (derived from accelerometers and pressure transducers).

Although a mine communications network would ideally have the ability to accommodate different information sources, this ability is often absent because vendors have developed systems optimized for different information sources (atmospheric monitoring, voice communications, tracking, etc.) and different mine types (aboveground vs. underground, coal vs. noncoal). For example, in underground mining, leaky feeders are generally acknowledged to account for more than 90% of all handheld voice communications systems.

A new communications system also may not be compatible with existing infrastructure or systems. The Cayuga mine in New York (United States) had to replace existing fiber-optic backbone and switching hardware before a new system would work (Pamel and Pederson 2007). Mine management at the Bingham Canyon mine in Utah required not only that a new wireless network be compliant with the industry standard but also that the communications vendor ensure compatibility with existing equipment and applications (Beer 2008). Network and data standardization also allows proper data warehousing, which is critical for mine-to-mill type optimization. Indeed, Chen et al. (2007) report on an MCS at a coal mine in China that standardized data generation and transmission with a goal of creating a standardized data warehouse. The industry is certainly headed in the direction of data standardization. For example, International Rock Excavation Data Exchange Standard (IREDES 2008) is creating a standard format for mining machinery.

Ability to Accommodate Information Source Mobility

Humans and other information sources are not stationary but move from one location to another in the course of their work activities. Thus, the MCS should not only be able to accommodate their mobility but should not put any constraints on their movement. In surface mines, wireless mesh networks are making it easy to handle mobility, though the ability to maintain high bandwidth at all times can be a problem. As

Source: Chirdon 2008.

Figure 9.3-3 Two-way hybrid voice communication network in a longwall development section

discussed previously, in an underground mine, mobility is even more of a challenge. Mobility-related problems can be overcome by mixing technologies and making compromises. For example, as shown in Figure 9.3-3, an underground mine could use wireless mesh networks in conjunction with leaky feeder or fiber-optic cables to allow some mobility at the end of wired communication. To ensure postdisaster mobility, it could also have a layer of LF technologies for basic voice/text communications. Communications can also be prioritized to ensure that important communication streams always get transmitted, no matter the bottleneck.

Safe, Robust, and Redundant Operation

Both the sources of information, such as sensors, and the communications network should be able to function safely under typical and atypical mining conditions, including moisture, dust, vibrations, and postdisaster conditions. Sensors and communications equipment that are deployed in areas susceptible to explosion must be intrinsically safe or enclosed in XP boxes. There are other legal requirements as well. The MINER Act (in the United States) requires that underground mines provide means for two-way wireless communication between underground miners and the surface at all times, including after massive disasters. It also requires that miners be tracked electronically at all times and that the communication system be redundant. Redundancy is not legally mandated for productivity purposes (though desirable); it is mandated only for safety purposes. Thus, redundancy requirements have to be met only at the level (bandwidth) necessary for safety-related communication.

One way of achieving redundancy is by means of a self-healing, ring-type communications architecture. *Self-healing* implies that the network will automatically resume transmitting communications after a fault condition occurs. Under normal conditions, communication is one way. When there is a fault in the system, the architecture allows communication to loop back into itself at the location of the fault (Figure 9.3-4), thus enabling two-way communication.

The self-healing, redundant-ring architecture can be achieved in different ways. In a fiber-optic network, the redundant-ring architecture may use two fiber-optic cables for the ring; that is, there are two rings, with each node/user connected to both rings, which carry communication in opposite directions. In the event of a fault, the system connects the two rings on either side of the fault, maintaining communications. In an underground mine using a leaky feeder (or other)

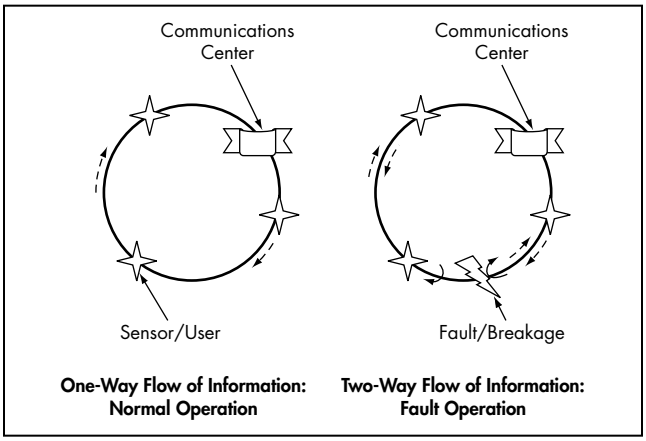


Figure 9.3-4 Redundant communications system

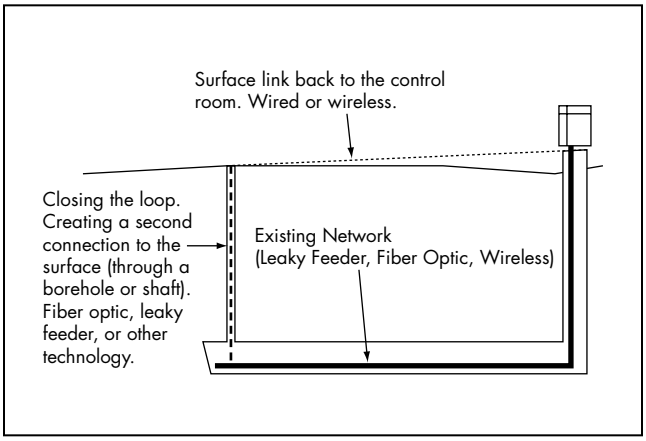

Figure 9.3-5 Creating redundancy in an underground communications system

backbone, redundancy can be achieved by closing the loop, as shown in Figure 9.3-5. The connection to the surface can be through an existing shaft or a borehole. If none exists, a small-diameter borehole could be drilled to extend the leaky feeder back to the surface. The final link to the communications center can be wired or wireless.

An alternative would be to use another communications network, such as an MF radio. The National Institute for Occupational Safety and Health (NIOSH) has recently funded research into an MF radio that may prove useful as a backup or emergency network communications system. Similarly, nonfiber Ethernet TCP/IP communications can be made redundant with a ring topology. Many Ethernet switches are available that provide ring management functionality. This would allow a break in the communication infrastructure to occur; switches would automatically adjust to allow the flow of data traffic around the location of the break. Redundancy can also be achieved by means of wireless mesh networks (especially in surface mines) or hybrid (wired and wireless) networks. An all-purpose (one that meets production and safety requirements at all times), redundant, purely wireless system can be difficult to achieve in an underground mine because of transmission problems through the earth.

Wireless or not, redundancy requires that the components of an MCS remain powered even after a disruption in power supply. Kohler (2008) reports battery backup durations of 8 to 96 hours for redundant systems.

Ability to Expand Easily

Mines are perpetually evolving as the mining face moves constantly. Mines may also increase or decrease their production rate to reflect product demand or change their mining method in response to technological changes. Although it is unrealistic to expect that the communications system will not need significant changes if the mine changes drastically, one can expect a communications system to accommodate minor changes and expansions easily. It is good practice when installing a system to include excess capacity to handle future expansions.

Technology upgrades or changes can be frustrating because new versions of technology do not always work properly with older versions. Proprietary systems can also pose challenges in that they may not integrate properly with other systems. Thus, any additions or changes to communications systems must conform to the existing/broader system. The mechanics of the changes are also important; for example, will the changes require a significant amount of infrastructure to be moved or reinstalled?

Ease of Maintenance

While considering any new technology, the maintenance requirements for that technology should be fully understood. In evaluating maintenance requirements, one must consider the type of mine (aboveground or underground, coal or noncoal, large or small) into which the system will be installed and the level of technical expertise on its staff. One should also contact mines with similar systems and ask them about maintenance issues associated with that type of network.

New Communication System: Before Installation

Prior to installing a new communications network/system, the following checks should be conducted (Schiffbauer and Mowrey 2006):

1. Is the mine's electrical noise environment (surface and underground) understood? That is, have noise sources been identified, quantified, and studied?
2. Have signal propagation tests been conducted?
3. Is the candidate system safe, robust, redundant, easily expandable, easy to maintain, and able to accommodate different, often mobile, information sources? Does the new communication system have any safety issues? Will it set off explosions or affect other monitoring systems?
4. Have other mines that have installed the candidate system been contacted? Any issues? Note that what works in one mine may not work in another. For example, many coal mines in Australia are two-entry mines. Thus, line-of-sight problems can be easily addressed as miners are restricted to only two entries (Beerbower 2006). However, the same line-of-sight-limited solution will not work in a coal mine that employs multiple entries. Therefore, before investing in a new communications system, one must consider all factors as they apply to a specific mine.

However, technical issues are not the only challenges a new system will face. Mine personnel, comfortable and familiar with existing systems, will often resist the introduction of new technology for a variety of reasons. Thus, the new system may not be fully used until the on-site personnel are comfortable with it.

INSTALLATION OF A MINE MONITORING SYSTEM

A wide variety of mine monitoring equipment is available. Although some suppliers may provide solutions for a range of disciplines, no single supplier can deliver an integrated system that spans all disciplines and can address the vast array of mining equipment.

Mine Monitoring Solutions

The design of monitoring systems can vary widely depending on the mining application. For example, monitoring systems for underground mining differ significantly from those for open-pit mining. Generally speaking, mine monitoring systems can be divided into three main categories:

1. Production monitoring
2. Equipment status monitoring
3. Safety and environmental monitoring

Production Monitoring

A number of monitoring systems have been developed to monitor mine production. These systems often concern processes that use expensive equipment. As a result, these systems are almost always aimed at improving asset utilization. For example, instrumentation systems have been specifically developed for drilling, excavating, loading, and hauling. These systems provide monitoring and record parameters such as ore produced, waste removed, commodities consumed, and changes in equipment status. Production output is recorded and reported. Commodity consumption is reported and purchase orders for replenishment made. Equipment status characteristics are analyzed to identify reasons for delays or stops in production so that changes can be implemented to improve efficiency. Some systems provide added control functions such as dispatching that assist in optimizing the routing of equipment through the mine. Mining operations deploying production monitoring solutions may expect increased equipment utilization; however, that may not necessarily occur.

Equipment Status Monitoring

A focus on production efficiency often results in equipment operated in ways that are unsafe and/or result in high maintenance costs. Monitoring systems have recently been developed that focus on improving equipment reliability and availability, as well as on production output. These applications monitor various critical equipment status indicators and alert maintenance personnel to the need for repairs before equipment failure occurs. This facilitates a move toward routine preventive maintenance. These systems provide information that can be used to resolve equipment warranty claims and lead to design changes that improve reliability. The financial benefits of such systems can be significant. A specific case study conducted across a fleet of 65 haul trucks reported maintenance savings of more than $2 million per month and a 57% reduction in the average number of trucks awaiting repair.

Safety and Environmental Monitoring

Personnel safety and protection of the environment are vital to maintaining mining operations. Multiple systems have been developed to track the location of personnel and provide voice communication. Solutions have been developed to track the proximity of equipment and personnel. These systems alert operators when equipment distances violate predetermined safety ranges and can cause equipment to be temporarily disabled or shut down to avoid accidents.

Sensing systems are also available to monitor weather conditions, air quality, ventilation systems, seismic activity, and slope or wall movement. Water handling is often a critical function in mining operations, and functioning effectively requires sensors that continually monitor pump stations and water flow and are interlocked with pumping equipment switchgear. Monitoring systems are used to help maintain process water recycling systems and ensure that water released back into the environment meets regulatory requirements.

Reporting and Interfaces

Effective monitoring systems are always underpinned by effective reporting systems. All monitoring system providers can generally supply a reporting system for their specific application. However, because no single supplier provides the entire range of monitoring systems, multiple reporting systems are the usual result. Consequently, there is a need for communication between monitoring systems.

Reporting solutions often report against their production databases. This can be dangerous if those performing data analysis create such an excessive load on the production system that it disrupts the performance of the monitoring solution. Additionally, in order to keep the real-time systems performing optimally, it will be necessary to have an archiving strategy that keeps the production databases trimmed.

Monitoring systems often use information from other production systems as inputs. In turn, monitoring results need to be reported and communicated to upstream systems. Because of the proprietary nature of monitoring systems, one cannot assume that support systems such as databases will be accessible to outside systems or that interfaces are necessarily readily available. Interfaces are often sold separately and can be costly to have developed. Care must be taken in selecting monitoring solutions to ensure that databases can be accessed directly or through interfaces that will allow the various mining, management, and accounting systems to be integrated. It is critical that the supplier provide clear and accurate documentation. In selecting monitoring systems, preference should be given to vendors who use standard database and interface components.

To address these interface and reporting issues, companies may wish to implement a data warehousing or data historian system that collects and aggregates data from the various mining systems into a single data store that is used for maintaining history, reporting, and analytics, and for providing interfaces to other systems (see Figure 9.3-6). Although there are multiple providers of data warehousing/historian systems, very few have been developed specifically for mining. An understanding of mining operations and processes is necessary to develop an effective reporting system.

Implementation

Multiple approaches to implementing mine monitoring systems can be taken. Prior to selecting an approach, companies should develop a mine monitoring strategy that provides an overall vision and specifies the guiding principles that will be used to select and implement monitoring solutions. Clearly defined business requirements that articulate the scope, goals, objectives, priorities, and timelines will need to be developed for each specialty area. It is vital for this process to involve representatives from each of the various mining departments

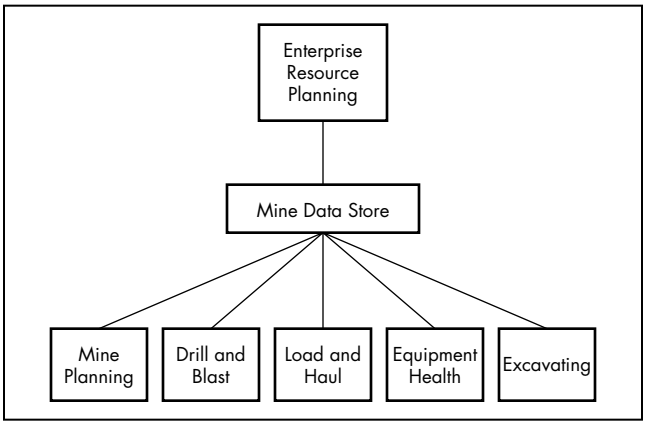

Figure 9.3-6 Potential data warehouse

or disciplines and have senior leadership endorsement and sponsorship.

Strategic Vendor Approach

One commonly used approach to implementing mine monitoring systems is to select a strategic vendor around which to build the mine's monitoring solution landscape. This vendor is selected based on its ability to supply an integrated solution that covers the greatest number of business and technical requirements. This vendor is also used as the system integrator to provide interfaces with other mining solutions that fall outside its specialty area. This approach focuses on delivering a broad, highly integrated solution. It is important that there be wide acceptance within the overall organization for this approach because the needs of specific departments may not be completely met in order to maintain overall simplicity and greater integration between systems. Specific departments may be disappointed with the performance of their specific disciplines or applications because of their awareness that there may be systems available that better suit their purposes.

This approach places a high degree of responsibility on the vendor to deliver the overall solution. It simplifies initial implementation by reducing the number of personnel required for implementation and can also simplify education and training needs for mine personnel. It can reduce the mine's direct labor requirements by allowing support functions to be outsourced to the vendor. This approach depends strongly on the strategic suppliers and requires that a strong business relationship be developed between the mine and the vendor to ensure that the mine's short- and long-term needs are considered and given priority in support and future development.

Best-of-Breed Approach

This approach involves selecting a combination of monitoring solutions, each chosen based on its ability to address the needs of a specific function or discipline. This approach focuses on delivering solutions that can provide both breadth and depth; less emphasis is given to the integration of the entire solution.

MINER TRACKING SYSTEMS

The MINER Act has made manual tracking of underground miners obsolete. Although real-time miner tracking has obvious safety benefits, the benefits extend to production as well. The ability to locate and speak with any miner underground quickly, to call for a part immediately when needed, and to control and track travel efficiently are all important functions of the production cycle in a modern underground mine.

System Components

A typical electronic system for tracking miners is composed of five major components: an identification tag, readers, underground infrastructure, a data storage unit, and a data display. The functions of these components are as follows:

1. The identification tag is a piece of equipment worn by the miner. In the majority of the systems, this is an active (battery-powered) radio-frequency identification (RFID) tag that sends a unique identification signal at a predetermined time interval. There has been considerable debate on the proper location of the tag on the miner's person. This tag can be mounted in a variety of ways—on a lanyard, on the belt, in a radio, on the miner's hat, or in the cap-lamp assembly. Testing has shown that an elevated location works best, away from the clutter of a miner's belt, and high enough to let the signal from the tag radiate outward toward the reader.
2. Readers are the units that receive signals from the tags and transmit them over a network to a storage database. Readers may communicate either by a wired network or wirelessly via radio transmission. All readers must have a wired power source.
3. Underground infrastructure is the equipment required to provide and maintain electrical power to the readers and facilitate data transfer to the data storage unit located aboveground. Underground infrastructure is composed of a wired component to provide power to the reader, a battery if needed, and a cable or radio transmission between readers. Some systems provide power and data over the same cable infrastructure.
4. The data storage unit receives data from the readers, stores that data in a database, and may perform tag location calculations.
5. The data display presents information on tag locations, provides reports on which miners are underground, and may contain other information useful to mine rescue operations, such as emergency contacts. Typically, the display will contain a graphical representation of the mine and the location of the readers. Some systems support multiple data displays for larger mine operations.

System Selection

Mine type, size, seam height, regulatory requirements, numbers of personnel and equipment underground, and support are important factors to consider when selecting a tracking system.

Mine type—metal, nonmetal, coal, and so forth—is an important factor in tracking system selection. Coal mines in particular have intrinsic safety, layout, and regulatory requirements that metal mines do not. A U.S. coal mine must have a system that is either intrinsically safe or XP, can be configured for redundancy in separated entries, and is approved by the Mine Safety and Health Administration (MSHA).

Mine size is also a crucial factor in selecting a system. Large mines must take into account the number of readers that will be installed in a mine and consider the maintenance issues (electrical connections, battery testing and replacement, antenna alignment, etc.) associated with supporting those readers.

Seam height is an important factor if a wireless system is being considered. Because of line-of-sight limitations, reader placement with redundancy in low-seam-height mines could be as frequent as every 20 to 25 m.

Regulatory requirements such as the MINER Act and recent West Virginia (United States) legislation require that tracking systems in coal mines have redundancy, or *survivability*, and may also specify a maximum distance between readers (also referred to as tracking *granularity*).

The numbers of personnel and equipment underground are also important is making a system selection. Systems using low-speed serial communications may have difficulty transmitting tracking data reliably during shift changes in mines with more than two working sections.

System support is crucial for selection. Local distributors with knowledgeable technical staff should be a requirement. A proven track record for the support staff as well as the company is also important.

System Types

The types of tracking systems currently available can be segmented by the type of underground infrastructure used: wired mesh, wireless mesh, leaky feeder, fiber, or serial. The advantages and disadvantages of each type are noted.

Wired Mesh Systems

In a wired mesh system, reader nodes are organized into a mesh topology, providing redundant data and power paths via another single cable. Communications and power are self-healing in the event of a cable problem.

Advantages

- Wired mesh systems are able to achieve redundancy/survivability via interconnections between readers in different entries.
- They can provide power and data over a single cable with no underground power connection or underground batteries in some mine configurations.
- Line of sight between readers is not required, so high density of readers is not required.
- Wired mesh systems scale to any mine size and offer a lower per-node cost than wireless mesh systems.
- These systems are proven in coal mining applications.

One disadvantage is that these systems do not provide a voice communications option at this time.

Wireless Mesh Systems

In a wireless mesh system, radio nodes (generally with integrated reader electronics) are organized into a mesh topology to provide redundant data paths. Although termed *wireless*, power must still be supplied to each node via some type of cable. Each node generally contains a battery to provide backup power in the event of a loss of power.

Advantages

- A wireless mesh system may provide communications and tracking over a single infrastructure.
- This system type may provide 802.11 wireless data transfer.

Disadvantages

- A wireless mesh system requires line of sight between nodes; redundancy requires line of sight between at least three nodes.
- This type of system requires underground power connections and, for survivability, underground batteries.
- This system type involves a much higher level of complexity than competing systems.
- These systems require a higher level of technical competence to maintain.
- These systems have a higher per-node cost than competing systems.
- These systems are unproven in mining applications; there are scalability concerns due to per-node cost and hop-to-hop transmission delays.

RFID Leaky Feeder Infrastructure Systems

These systems use leaky feeder cable as a method to convey transmissions between system components, generally using one of two different methods: a reader can either be directly connected to the leaky feeder cable for power and communications or transmissions may be relayed over the leaky feeder using analog data radio modems with power delivered independently with a separate cable. In both cases, the data from the readers are routed through a device in the leaky feeder "head-end" to the tracking system data server (normally using Ethernet or serial communications).

An advantage is that an RFID leaky feeder infrastructure system may provide communications and tracking over a single infrastructure.

Disadvantages

- An RFID leaky feeder infrastructure system requires underground power connections and, for survivability, underground batteries.
- A system of this type has a higher per-node cost than competing systems.
- These systems are still unproven in mining applications and have associated scalability concerns due to their per-node cost.

Fiber Infrastructure Systems

These systems use standard Ethernet communications to connect fiber-optic cables between tracking system components. Depending on the cable used, distances of 50 km (or more) can be achieved at extremely high data rates (1 gigabyte/s). Although copper Ethernet connections are possible at the terminus of the fiber, no intrinsically safe (as defined by MSHA) components have been developed. Additionally, power must be supplied from intrinsically safe (MSHA-approved) power supplies with battery backup capability. Copper Ethernet can be used if the devices being interconnected are housed in MSHA-approved XP enclosures.

Advantages

- Fiber infrastructure systems provide the potential for communications and tracking over a single infrastructure.
- These systems are high-bandwidth media.
- These systems are able to connect to current underground infrastructure.

- These systems work well in mines without intrinsic safety considerations.

Disadvantages

- Fiber infrastructure systems require underground power connections and, for survivability, underground batteries.
- These systems make it difficult to attain intrinsically safe status for postaccident use in coal mines.
- These systems require XP boxes for postaccident use in coal mines.

Serial Infrastructure Systems

These systems use standard serial communications methods such as RS-232 or RS-485. Generally, standard copper wiring provides a communication path between system components; another pair of wires provides power. Using RS-485 communication can allow multiple devices to be placed on the communications cable and addressed independently. Depending on cable lengths, communication rates up to 115,000 bps (baud/second) can be achieved. For longer cable lengths, rates of 4,800 bps are more common. In order to maintain intrinsic safety, RS-485 requires the use of barriers to isolate areas. Power must be supplied from intrinsically safe (MSHA-approved) power supplies with battery backup capability.

An advantage is that serial infrastructure systems are able to use current underground infrastructure.

Disadvantages

- These systems have low bandwidth.
- Their common infrastructure cannot be used in postaccident implementations.
- XP boxes are required for postaccident use in coal mines.
- No voice communications option is provided at this time.
- The scalability of these systems may be of concern because of bandwidth limitations.

System Layout

Most mines will install tracking readers in the travelway to cover equipment and personnel movement. Coal mines in the United States, following clarification of the MINER Act, will likely also be required to install tracking readers in the primary escapeway, usually the intake entry.

Typically, mines will install readers at intervals of 300 to 1,500 m, with the distance between readers determined by the accuracy of tracking desired, regulations, and cost considerations. The sections delimited by the readers are typically known as tracking zones.

Generally, mines will also install readers or antennas from readers that support multiple antennas at the intersection of travelways to determine the direction of travel. This is typically referred to as gating.

For determining the suitability of a system for a given mine, it is helpful to ask the system vendor to provide a layout showing the placement of readers in the mine and aboveground areas with coverage areas, electrical connections, battery connections, and antenna placement noted.

Redundancy/Survivability Concerns

To achieve redundancy, readers communicating via a wired or wireless infrastructure must be connected to at least two other readers or have a direct connection back to the data storage unit.

Readers communicating via radio transmission are limited to line-of-sight communication and so must be within the line of sight of at least two other readers. In coal mines where ventilation concerns require separate entries for the intake, return, and (possibly) belt, each reader communicating via radio transmission must be connected to at least two other readers in the same entry to achieve redundancy.

For wired mesh systems, readers must be connected to at least two other readers in any entry, as line-of-sight concerns are not present.

Integration Options

Ideally, a tracking system would use a common, redundant, intrinsically safe communications network with the ability to incorporate atmospheric monitoring, belt monitoring and control, maintenance, and voice communications systems, as well as general data transfer. Unfortunately, no current communications network supports all of these capabilities in a cost-effective, redundant, intrinsically safe configuration.

However, ideally, one should select a system that provides the level of redundancy needed, with options for supporting data for some of the other underground systems needed. Some tracking systems support atmospheric monitoring sensors; others support general data transfer.

Summary

Implementation of an electronic tracking system not only improves a mine's safety infrastructure but can also have a tremendously positive impact on production. Many systems are being introduced to the marketplace; the selection for each mine should be carefully researched to find a system that will work best under its particular conditions.

GLOBAL POSITIONING SYSTEM APPLICATIONS

Global Positioning System (GPS) devices rely on spatial and temporal information from a group of satellites for proper functioning. Many major mining activities, such as digging (shovel or dozer), rock transportation, subsidence, and blasthole layout, are typically defined by their movements in space and time. Therefore, there are many benefits to quantifying them accurately and automatically (Flinn and Fileccia 2006): accurate selection of mineralized zones and coal seams by an excavator; reduced need for survey work for laying out drilling patterns or marking dig areas; precise delineation of static hazards; better dozer control, leading to more even benches and ramps; and the automatic creation of as-built digital terrain maps (DTMs).

GPS-based arrangements usually imply a GPS device mounted on a mining machine that provides input to a mine operations system (such as machine guidance or mine management systems). The role of the GPS device is simply to obtain and broadcast its spatial and temporal information in real time. However, this information becomes more valuable when it is used to obtain computed information (such as volumes or updated mine plans) or to guide machine operation. Therefore, it is important for the GPS device to be able to interact with the broader mine operations systems.

Challenges with GPSs

Several common problems are associated with GPSs:

- **Vendor/equipment-specific system.** GPSs are currently vendor or machine specific and because mines use a wide variety of equipment provided by a wide variety of vendors, it is very difficult to integrate the disparate systems. Open-source GPS solutions designed to be vendor and machine independent are, however, under development (Flinn and Fileccia 2006). Such systems will be essential for an integrated mine operations system.
- **Satellite availability.** GPS devices need access to multiple satellites (typically five) for accuracy. This can be a challenge in remote geographical locations or deep mines, under certain atmospheric events, or with certain satellite positions. Also, large equipment can hide satellites from their own GPS devices. Zywiel et al. (2005), however, list the following potential solutions to the satellite availability/shading problem:
  - Use of satellites from other systems, such as the Russian GLONASS (Global Navigation Satellite System). The advantage of this solution is that it can probably be implemented with no additional infrastructure.
  - Use of pseudolites or ground-based transmitters that transmit positional information. An issue with these is that the transmitters would need to be moved as the mine profile changes.
  - Use of advanced tracking sensors. These sensors combine a GPS with a laser and increase availability to up to 90%. These may, however, suffer from line-of-sight limitations.
  - Use of GPSs combined with inertial (or movement) data from odometers. Inertial systems use GPS devices for original spatial information. Subsequent locations are computed or determined from sensors that provide information on direction, speed, and so forth. A disadvantage of this system is that, without guidance data, its accuracy declines with time.
- **Latency.** Latency is the time lag between an object being in a given position and the time when it shows up as such on the operator's screen. Although this may not be an issue for drills, it can be an issue for shovels that use GPS information during digging or for GPS-based proximity warning systems. Latency effects can be minimized by opting for high-speed GPS, data networks, and computers, and/or using inertial systems.
- **Bandwidth.** Lack of bandwidth can also be a problem as high bandwidths are needed to transmit complex information (such as DTMs) between the mine management system and the GPS-based guidance system. However, with wireless-mesh networks, bandwidth is less of a problem.

Improving GPS Accuracies

Seymour (2007) provides suggestions for improving GPS accuracies on excavators. Speed and accuracy can be improved by using two antennas and two receivers (instead of one), and placing them in the back corners of the machinery house. Bucket location can be more accurately determined using tilt sensors and rope drum rotation encoders (in rope shovels). It is essential that these components be robust. Proper maintenance, such as prevention of slack bearings, can also improve accuracies.

PROXIMITY WARNING SYSTEMS

Proximity warning systems (PWSs) alert miners of the presence of static or moving hazards in their immediate vicinities. There are typically two types of PWSs: a system that detects proximity based on spatial locations as determined by GPS devices and a sensor-based system.

GPS-Based Proximity Warning Systems

These are used in surface mines primarily to alert large truck operators to the presence of smaller vehicles in their blind zones. Although a properly placed mirror or video camera can do the job, it may not be satisfactory because of difficulties in judging distances, operator inattention (to the mirror or video screen), or poor-visibility conditions.

GPS-based PWS implementations need very accurate GPSs and a good wireless network. The wireless network is essential because the success of the PWS depends on the ability of each vehicle to transmit its location continually to other nearby vehicles. The system uses this vehicle location information to determine whether another vehicle or object (*hazard*) is within its proximity zone or bubble. The presence of a hazard in the proximity zone sets off an alarm and/or disables movement in a static truck (Miller 2005). Errors in satellite or wireless network transmission or reception caused by antenna placement location, latency, multipath effects, or other effects can seriously reduce the performance of the PWS. Static hazards, such as buildings, are easily detected because their locations can be programmed into the PWS. The systems typically also allow defining the proximity zone or bubble.

One advantage of the GPS-based PWS is that there are very few false alarms. Also, the system can use the existing wireless network. A disadvantage of this system is that unless all moving objects (including humans) are equipped with GPS devices, the system is not completely effective.

Sensor-Based Proximity Warning Systems

These systems consist of source or emitter units and (portable) detection units. The source unit is usually on a large machine, while detection units are on humans or smaller mobile equipment. Source units consist of a loop antenna surrounding the machine or signal sources that are strategically placed on the machine. Examples of sensor technologies that have been used for PWSs include pulsed radar (Ruff 2006), low-power LF magnetic fields (Schiffbauer and Mowrey 2001), and RFID (Ruff and Hession-Kunz 2001).

Radar systems can detect humans and smaller pieces of mobile equipment. However, they are prone to false alarms, especially if they are sufficiently sensitive to ensure absolute detection of humans. Direct sunlight, reflections, and hot equipment can generate false alarms in infrared-based systems. Physical orientation of pedestrians can impact detection in RFID-based systems, though these systems usually have few false alarms.

As with GPS-based PWSs, as the number of persons or objects to be detected increases, more tags/sensors are needed, increasing maintenance requirements.

AUTOMATIC CONTROL

Automated controls play an important role in mining, be it robotic control (such as a telecontrolled or remote-controlled device) or algorithmic control. This section only discusses algorithmic control, where the goal is to control a process parameter within tight limits by manipulating relevant process variables. For example, a SAG mill may be operated to optimize power consumption, by varying parameters such as feed rate and recirculating load. Similarly, the quality (and

quantity) of a pile of coal is controlled by acting on real-time quality of coal on a moving conveyor belt. As communication networks have expanded, so has automatic control and, therefore, they are more important than ever. This section discusses aspects of automatic control that are relevant to mining engineers; some other aspects such as artificial intelligence are covered in Chapter 9.10.

Factors Affecting Control

Simply speaking, *controlling* implies manipulating/controlling a set of process parameters, based on process information, to achieve certain goals. For example, in a particular process for physically segregating coal, a flop gate directs a block of coal either to the wash pile or no-wash pile. The process parameters used for determining whether to open or close the flop gate (the action being controlled) are (1) the quality of the unit block of coal being considered, (2) the average quality and tonnage of the no-wash pile, and (3) the target quality for the no-wash pile. Such a process cannot be controlled using mathematics alone. Accurate real-time data from the on-line ash analyzer is essential if the segregation algorithm is to work as designed.

Sensor Accuracy

Although the need for sensor accuracy is obvious, defining the required accuracy of a sensor is not straightforward, especially for sensors that control processes. It is important to know how often control decisions are made in the process. The decision interval could be defined in units such as time (time between actions being controlled) or throughput (every 1 t [metric ton], 10 t, etc.). Therefore, for the previous example, an on-line ash analysis that is within ±0.25% of the true ash content for every 100 t of coal could result in the gate flopping the wrong way up to ten times for every 100 t if the gate flops every 10 t. It is possible to compensate for such errors by lowering or raising targets, but at that point, optimization, the much-touted benefit of using sensors and automated control, is lost.

Therefore, for a sensor to be useful for automatic control, accuracy standards have to be relevant to the function being controlled. Also, control algorithms should be examined as to the effect of measurement errors (of the process variables that go into the algorithms). Mine management should also ensure that sensors are properly calibrated at all times. Sensors are often neglected after initial installation; unless they are maintained properly, they can hurt rather than help optimization.

Relevancy of Process Inputs

In modeling SAG mill power consumption, Ganguli et al. (2006) examined the usefulness of many seemingly relevant process variables, such as feed rate, density, bearing pressure, revolutions per minute, noise, and recirculating load, as inputs. However, modeling revealed that only revolutions per minute, feed rate, and recirculating load had any noticeable impact on electric current draw. The study demonstrated that the assumption that a process parameter is relevant to the process may be erroneous.

There are two major reasons a seemingly relevant process parameter is found to be irrelevant. The first is simply that the parameter is truly not (sufficiently) relevant. The second and more subtle reason is that the sensor is not appropriate for the process. For example, its accuracy may be at such a broad or coarse level that the short-term information/measurement it provides is simply noise, in which case, any attempt to control the process using the short-term measurement data will be unsuccessful. Note that the inability to control based on a process parameter does not make that parameter irrelevant; it simply means that the *data* being provided by a sensor concerning that parameter are irrelevant. If engineers are confident that a particular process parameter should indeed be relevant, they should invest in a different sensor. Conversely, if the sensor is accurate and is providing appropriate data, then that parameter is truly irrelevant to the process.

Validity of Assumptions

Most algorithms, whether a truck dispatch optimization algorithm or a coal segregation algorithm, make mathematical and informational assumptions. Common mathematical assumptions include data characterization (such as assuming a statistical distribution) and model type (assuming that a particular model still holds). Informational assumptions include cost figures (such as the cost of processing is X-dollars) and values of various constants. Optimization algorithms that run with the wrong assumptions will not be successful. However, assumptions are rarely examined. Many figures, especially cost numbers, are constantly changing. Introduction of new mine monitoring and control systems should, therefore, be preceded by a thorough analysis of the benefits.

CONCLUSIONS

This chapter presented an overview of mine monitoring, communication, and control. Mine communications systems are no longer dictated only by productivity requirements; safety-related communication demands are now an important consideration when setting up a communications network. The desired attributes of a communications system include the ability to accommodate a wide range of applications, users, and bandwidth; it must also be safe, redundant, and robust, as well as able to handle information source/destination mobility. Wireless communications, especially mesh networks, have strengthened surface communication networks. Although high-bandwidth, fully redundant networks are still not possible underground, advances in technology may make such technology possible one day. Real-time tracking of miners underground is sure to push technological limits. Technologies such as GPSs and RFID will continue to make mine-to-mill optimization a reality. Modern communication networks, along with sophisticated control algorithms, certainly allow for that possibility. To optimize sensor systems, sensor accuracies should be properly understood and taken into account.

CHAPTER 9.4

Mine Surveying

Andrew Jarosz

A mine surveyor provides services from early design and project implementation throughout a mine's life to closure. Surveyors deal in spatially referenced information—that is, information associated with known positions in space. They measure angles and distances to document the positions of mining features and boundaries, and present the information in the form of mine maps. That information is the foundation upon which mineral resources and reserves are defined, mineral and land rights secured, and environmental and mining plans defined, directed, and monitored.

Mine surveying has always been recognized as crucial for the efficient management and safety of mining operations. Because of its impact on safety, the position of the mine surveyor may require authorization, which is issued by regulatory bodies on the basis of education and experience.

Recent technological advances have greatly improved the precision and speed with which spatial information can be gathered, processed, and stored. Mine surveyors must constantly supplement traditional measuring skills with new skills focusing on management, processing, and storage of large amounts of gathered spatial data.

The changing role of the mine surveyor and changes in mine surveying as a discipline are recognized by mine-surveying professional organizations. The International Society for Mine Surveying (ISM) offers the following definitions in the preamble of its statute:

> Mine surveying is a branch of mining science and technology. It includes all measurements, calculations and mapping which serve the purpose of ascertaining and documenting information at all stages from prospecting to exploitation and utilizing mineral deposits both by surface and underground working.
>
> The following are the principal activities of mine surveying:
>
> - The interpretation of the geology of mineral deposits in relation to the economic exploitation thereof.
> - The investigation and negotiation of mineral mining rights. Making and recording, and calculations of mine surveying measurements.
> - Mining cartography.
> - Investigation and prediction of the effects of mine working on the surface and underground strata.
> - Mine planning in the context of the local environment and subsequent rehabilitation.
>
> These activities involve the following:
>
> - The determination of location, structure, configuration, dimensions and characteristics of the mineral deposits and of the adjoining rocks and overlying strata.
> - The assessment of mineral reserves and the economics of their exploitation.
> - The acquisition, sale, lease and management of mineral properties.
> - Providing the basis of the planning, direction and control of mine workings to ensure economical and safe mining operations.
> - The study of rock and ground movements caused by mining operations, their prediction, and the precautions and remedial treatment of subsidence damage.
> - Assisting with planning of rehabilitation of land affected by mineral operations and collaborating with local government planning authorities. (ISM 2009)

Clearly the mine surveyor plays an important role in almost all engineering activities carried out at a mine site throughout the life of a mining project, from exploration to closure.

Mine safety is always a key concern in mine surveying, and deficiencies in survey information can result in direct risks to safety (with the possibility of multiple fatalities), finances, legal status, and reputation. Mine surveyors are responsible for accurately measuring, recording, and informing mine

Andrew Jarosz, Associate Professor, Curtin University, Western Australian School of Mines, Kalgoorlie, Western Australia

management of the position of the mine workings relative to mine design and to geological features, boundaries, hazards, areas of restricted mining, and surfaces and/or adjacent workings that require protection. Most mine-surveying legislation is directed at regulating this function and ensuring that accurate mining records are kept. In the absence of regulations, the United Nations International Labour Organization (ILO) describes mandatory minimum requirements for mine surveying in its codes of practice for mine safety (ILO 1995).

SURVEYING EQUIPMENT AND TECHNIQUES

Generally, a mine surveyor measures geometrical elements—angles and distances—to determine the relative positions of survey control points (benchmarks) as well as terrain and underground features, and presents this information graphically on a map.

The Cartesian coordinate system is commonly used to define the positions of measured objects by means of x- and y-axes on the horizontal plane pointing east and north, respectively, and the z-axis pointing in the zenith direction. This system imposes specific requirements on angular and distance measurements that can be used for the calculation of position:

- Angles must be measured in horizontal or vertical planes.
- Distances must be measured along horizontal or vertical lines. If a distance is measured along a slope, the angle between the slope line and the horizontal plane must also be determined.

For many years, accurate measurement of angles and distances posed a significant technical challenge. Over the last century, however, developments especially in precision mechanics, optics, and electronics have led to the fabrication of surveying instruments that are capable of reliable and highly accurate angular and distance measurements. Today's standard instruments can measure angles with an accuracy of better than 1 arc-second and distances with an accuracy of ±(1 mm + 2 ppm).

Instruments for measuring angles are called theodolites. Instruments for measuring distance include tapes, subtense bars, and electronic distance measurement (EDM) devices. The previous strict division between these types of instrument is now blurring, and these instruments are merging into one universal instrument, the so-called "total station."

The past 20 years have also seen the development of new surveying instruments capable of determining position without reliance on traditional geometrical structures linked to benchmarks on the earth's surface. This new technique uses the Global Navigation Satellite System (GNSS) as a framework of reference points, and space triangulation as a means to determine the location of surveying benchmarks and ground features. However, because this technique uses electromagnetic signals as a carrier, distances between a Global Positioning System (GPS) receiver and satellites can be determined only in open areas on and above the earth's surface. Surveys of tunnels and underground mines must still be performed by means of classical surveying techniques.

Detail surveying has also undergone significant technological change. Recent developments in laser scanners have led to instruments capable of providing reliable and almost instant three-dimensional (3-D) models of terrain and objects. Scanners also have application in underground mine surveying where they can be used remotely to determine the extent and volume of mined cavities without compromising surveyor safety.

SURVEYING AND MAPPING PROCEDURES

In open-pit and underground mines, a mine surveyor is usually responsible for the following tasks:

- Conducting all mine-site surveys
- Producing and maintaining all mine-site and underground level plans
- Managing all survey-related data
- Managing landownership issues and lease tenements
- Monitoring slope stability and subsidence effects of underground mining
- Providing maps and spatial information to other engineering departments

In most western countries, national or regional (state) regulations establish minimal standards for mine surveys and map requirements. Of the extensive list of regulations, the following deserve special mention:

- U.S. Federal Mine Safety and Health Act of 1997, Section 312, amended by the Mine Improvement and New Emergency Response Act of 2006, or MINER Act (MSHA 2006)
- West Virginia (United States) Chapter 22A, Article 2, Miners' Health, Safety and Training—Underground Mines Mining Laws, Rules and Regulations (West Virginia Legislature 2008)
- Government of Western Australia Mines Safety and Inspection Act 1994, Section 87 (Government of Western Australia 1994)
- New South Wales Mine Health and Safety Act 2004, Section 75 (AusLII 2009)
- South African Mine Health and Safety Regulations, 1996, Chapter 17: Surveying, Mapping and Mine Plans (SAGI 1996)

Regional laws and regulations for all types of mines vary and in many cases are more rigorous than are national (or federal) laws and regulations. An example of this phenomenon is the West Virginia code pertaining to requirements for underground maps for deep coal mines (West Virginia Legislature 2008).

Laws and regulations in most states and countries require that mine maps be referred to the national mapping coordinate system and at least two or three permanent survey monuments be established on the mine property. The monuments should be described and shown clearly on the maps so that they can be found quickly and easily in case of emergency.

Mine maps are useful not only for determining relative location but also for determining volumes of ore and rock extracted, so that quantity control can be exercised and royalty payments calculated. Almost all mine engineering work depends on mine maps.

SURVEYING AND MAPPING OF OPEN-PIT MINES

Surveys of open-pit mines combine characteristics of engineering and topographic surveys. The surveyor provides guidance for miners to develop mining operations according to the earlier-established mine plan, then surveys the progress of mining and develops maps and models representing its current state. The maps and models are used for calculating the volumes and tonnages mined and for reconciling mining progress with the mine plan. Surveying of open pits usually involves the following activities: (1) establishment of a mine-survey control network, (2) detailed topographic surveying

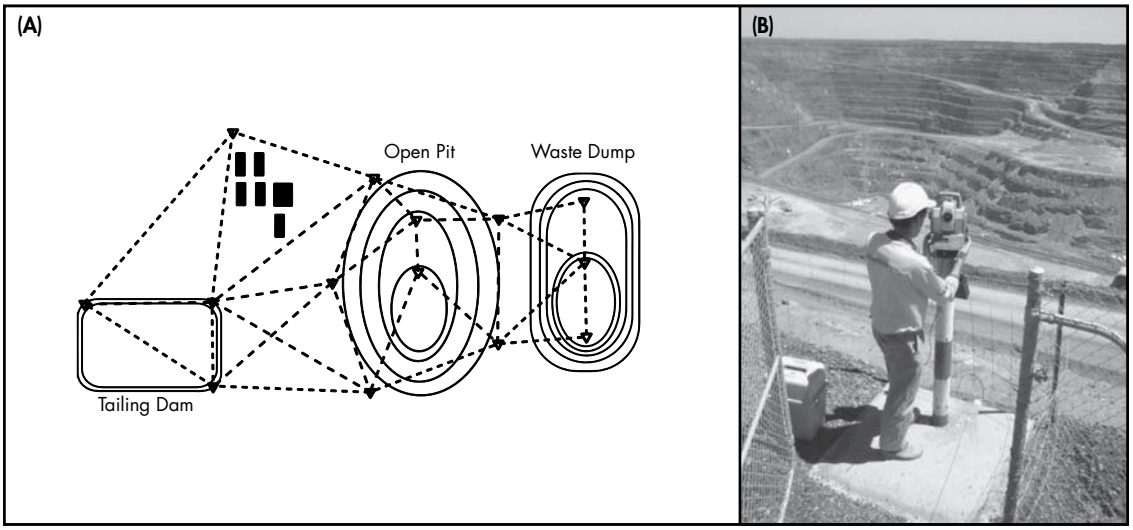

Figure 9.4-1 (A) Mine-survey control network and (B) surveyor using a theodolite on a control pillar

of open-pit and waste dumps, (3) data processing to calculate mined volumes and tonnages, (4) stability control surveys of open-pit and waste dump slopes, and (5) support surveys for earthmoving-machine control systems.

Mine-Survey Control Network

A mine-survey control network for an open-pit mine site is a basic, highly accurate, spatial infrastructure for relative referencing of natural and constructed topographical features, mining roads, benches, buildings, and other structures. It enables surveyors to

- Conduct cyclic surveys for the control and reporting of mining progress,
- Determine and control the elevation and slope of working benches and haul roads,
- Determine the volumes of mined ore and waste, and
- Control and manage the mine dewatering system.

A control network should be linked with the national survey network to enable transfer and use of the national coordinate system.

In most cases the primary control network for a mine is based on triangulation and/or trilateration (Figure 9.4-1A). It is important that control-point positions be (1) clearly visible from the main working areas of the mine site, (2) visible from multiple other control points, and (3) clear of mining activities and other disturbances that could lead to their destruction. Control-point positions are usually determined from angle and distance measurements that can be supported by GPS observation.

As a general guideline, the horizontal accuracy of a primary control network should be 1:20,000 or better. Control benchmarks are usually stabilized permanently by means of concrete-filled steel pillars set on concrete foundations (Figure 9.4-1B).

A primary control network can be densified with secondary and tertiary control networks by means of any combination of micro-triangulation, intersection and resection, traversing, and profile lines. Lower-class control points can be used as stations for detailed topographical and setting-out surveys. The positional accuracy of such points should be no worse than about ±0.2 m. For such accuracy, closed traverses should be ≤2.5 km and open traverses should be ≤1 km.

Topographic Surveys

A detailed topographical survey at an open-pit mine focuses on the locations of bench-slope crests and toes, berms, road edges and gradients, ditches and water dams, waste dumps, power lines, buildings, and other permanent and temporary structures. It includes the collar positions of exploratory and blasting drill holes and information on existing cavities created by previous mining activities. The following survey methods are available: total station survey, aerial and terrestrial photogrammetry survey, GNSS (GPS) survey, and laser-scan survey.

Total Station Survey

A total station survey involves determining the directions and distances to measured points and then simultaneously calculating the horizontal and vertical positions of those points by means of the so-called radiating method. Such a survey is especially useful in open-pit mines where benches, slopes, and roads can differ significantly in elevation. Survey data are collected, stored in instrument memory, downloaded to a computer in the survey office, and converted by application software into a map of the surveyed area.

In the past, to obtain such data, surveyors sighted instruments on reflectors positioned by assistants at various points of interest, and the risk of falling down a slope or being struck by falling rocks was significant. Today's total stations do not require reflectors and can measure distances to almost any object up to several hundred meters away. Some total stations can be combined with GNSS receivers (such as the Leica SmartStation) for rapid station positioning, which is useful when a station cannot be set directly over a control point but should be done only in exceptional circumstances when a rapid survey is required. Obtained results must be checked later or linked back to the mine-survey control network.

Figure 9.4-2 shows a typical total station survey of a mining road and benches.

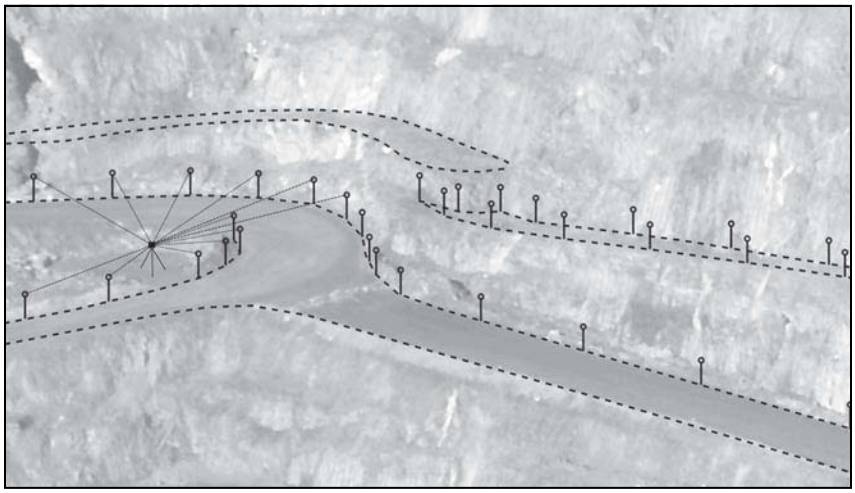

Figure 9.4-2 Typical total station survey of a mining road and benches

Aerial and Terrestrial Photogrammetry Survey

Mapping by aerial photogrammetry is useful for large surface operations, especially those with large differences in elevation, areas that are difficult to access, or areas with large amounts of traffic. The method provides numerous advantages, including (1) real-time registration of details that can be revised at a future date, (2) remote and safe collection of data, and (3) relatively rapid surveying of large areas. Major disadvantages are that final results are not immediately available, but rather require weeks of data processing and that significant advance preparation is required to mark and survey control points, so the method is not economically feasible for smaller mining operations. The positional accuracy of details obtained by this method is in the range ±0.1–0.2 m.

Mapping by terrestrial photogrammetry is useful for high scarps and slopes with rock structures and slope deformations. The method involves taking images from control points of known position with special dedicated metric cameras. From images of an object taken from different locations, a 3-D model can be developed for use in map creation. Some systems use images produced by high-quality commercial digital cameras equipped with nonmetric lenses.

GNSS (GPS) Survey

Current GNSS receivers using GPS real-time kinematic (RTK) technology deliver relatively high positional accuracy (better than ±0.1 m) comparable to that delivered by total stations. GNSS is now the survey method of choice for open-pit mines and is used not only for inventory surveys but also for conducting setting-out surveys, positioning blasthole collars, and locating mining equipment (particularly dozers, draglines, drill rigs, shovels, and tracks). Survey data are collected, stored in instrument memory, downloaded to a computer in the survey office, and converted by application software into 3-D models and maps of the surveyed area. With wireless data-communication systems, maps can be produced in real time.

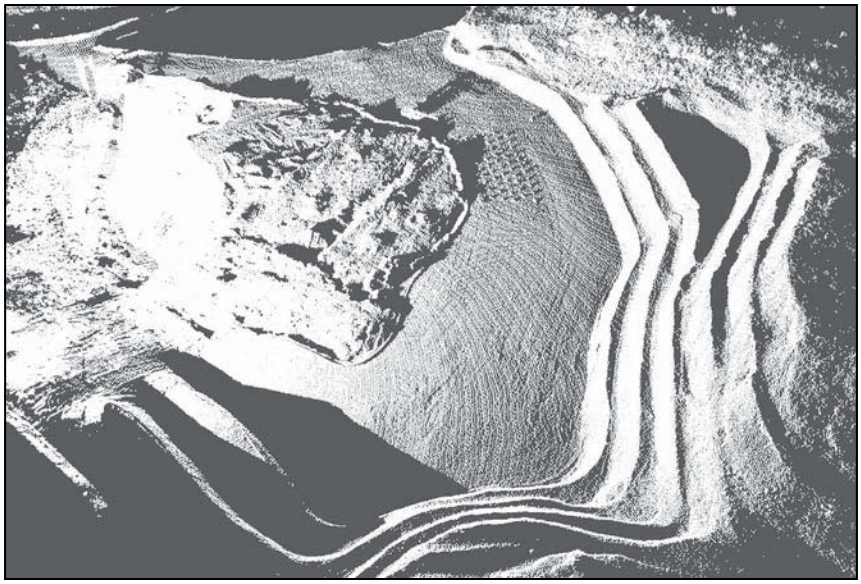
Laser-Scan Survey

Since 2000, laser scanners and associated processing software have developed into fast, reliable, and accurate long-range surveying devices. Because they do not require the use of reflectors or staff at a mining face, they have made the entire range of surveying operations significantly safer.

Scans are performed from a stationary position, and collected data are transmitted directly to the surveying office. Alternatively, some scanners can be mounted with GNSS receivers on the roofs of four-wheel-drive vehicles.

Figure 9.4-3 shows a laser scan of an open-pit mine.

Data Processing



As mentioned previously, survey data are collected, stored in instrument memory, and downloaded to a computer in the survey office where specialized surveying software manipulates the data, performs calculations, and creates 3-D digital models and maps. Mining regulations often require that maps be created to specific standards with respect to, typically, a scale or map coordinate system. In recent years, constantly updated 3-D digital models have replaced classical mine maps.

Among the many surveying software packages available today, most popular are the so-called general mine design packages for creating geological models, mine designs, and plans. The following are particularly popular: Gemcom Surpac (Gemcom Software International), Datamine Studio 3 (Datamine Corporate Limited), Vulcan (Maptek), and Carlson Survey (Carlson Software).

Three-dimensional digital models of mining operations enable relatively easy calculation on a personal computer of the volumes of waste and ore that have been mined. Most of such models use triangulated irregular networks (TINs) to represent the original topography and working levels of a mine. Rock volume between mine levels is calculated by taking the difference between solids, with the base at an arbitrary level (e.g., 0 m) and the top at the mine level represented by the TIN (Figure 9.4-4). Volume can also be calculated from a block model by summing the volumes of individual cells representing these deposits.

Slope-Stability Surveys

Modern open-pit mining operations increase in efficiency as the ore-to-waste ratio increases, usually leading to maximization of pit-wall slopes. However, steeper slopes pose greater risk to personnel and mining equipment due to increased potential of slope failure. To uphold the required safety standards and reduce risk to an acceptable level, many open-pit mines must develop a holistic slope-monitoring program (Cawood and Stacey 2006). Such programs should distinguish

Courtesy of RioTinto Iron Ore Technical Services Group.
Figure 9.4-3 Laser scan of an open-pit mine

the following three slope-monitoring stages: (1) overall monitoring of all pit walls and adjoining areas, (2) focused monitoring of potential instability areas, and (3) detailed monitoring of areas with earlier-detected instability or failure.

Monitoring techniques should also take into account the expected mode of slope failure. There are four major modes of failure in open pits:

1. Circular failure with large rock movements along vertical planes at the top of failure and horizontal movement in the toe zone
2. Planar failure with rock-mass movement along an existing geologic discontinuity, such as a bedding plane, parallel to the slope face
3. Wedge failure when two sets of flat failure surface planes intersect and dip out of the wall; moderate vertical and horizontal movements are expected
4. Toppling failure when vertical or near-vertical structures dip toward the pit wall; large horizontal rock-mass movement is expected at the top of failure

The relative locations of control stations and targets used in a slope-monitoring network should be selected so as to be maximally sensitive to expected rock movement.

Traditionally, specialized geotechnical and surveying methods were used for slope-stability monitoring. However, recent developments in satellite and terrestrial remote-sensing technologies have significantly impacted the methods currently used. Monitoring on a large scale can be done using interferometric radar technologies. If the primary concern is vertical movement (subsidence) of areas adjacent to slope crests or bench areas of large open-pit slopes, satellite-based interferometric synthetic-aperture radar (InSAR) can be used to detect these movements (Jarosz and Wanke 2004). InSAR images can easily cover large areas of the whole open-pit mining operation. Ground-based radar systems, also using interferometric technologies, recently became the tools of choice for continuous monitoring of wall faces. The most successful and popular systems are Slope Stability Radar by GroundProbe (Australia) and Movement and Surveying Radar by Reutech

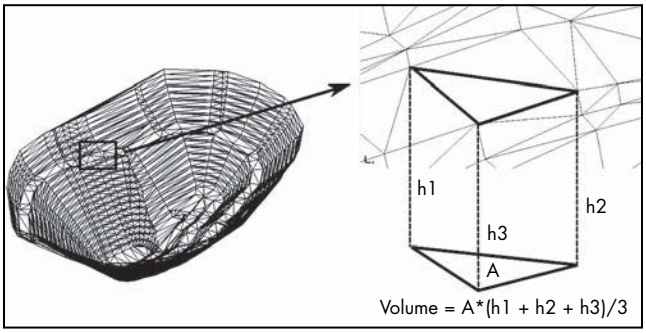


Figure 9.4-4 Triangulated irregular networks used for volume calculations

Mining (South Africa) (Reeves et al. 2001; McHugh et al. 2006). These systems can provide continuous measurements of rock movement across the entire face of a slope wall with submillimeter accuracy. Real-time processing of collected data enables confident tracking of slope movement and management of risk while optimizing safety and productivity.

Monitoring on a smaller scale or of distinct targets can be done using classical surveying techniques. Control stations must be established at stable locations from which targets placed on pit walls are observed. Station stability must be ensured and controlled. Stations should be erected as concrete pillars set into bedrock or into a stable foundation. Stations should be linked by means of a control network with other stations located far from the mining area and considered to be stable. Repetitive surveys, once or twice a year, must be performed to check the stability of the control network. For continuous monitoring of wall targets, automatic high-precision total stations can be used. Such robotic total stations are programmed to automatically measure directions and angles to targets and transmit data to a control computer in the survey office. Data are processed in real time and information regarding target movement is reported out. If movement is greater then the earlier-defined critical value,

an alarm is triggered, enabling timely withdrawal of mining personnel and equipment. Automated slope-monitoring systems are offered by major producers of surveying equipment as well as by independent developers. The most advanced and popular are the Leica Automatic Deformation Monitoring System (GeoMoS) by Leica Geosystems and slope-monitoring software from SoftRock Solutions (Western Australia).

Support Surveys for Equipment and Machine Control

Timely and accurate positioning, as well as monitoring, of mining equipment is increasingly important to efficient mine operation. The following activities are highly influenced by equipment positioning:

- Drilling, where accuracy is critical to efficient blasting operations
- Dragline positioning, where accurate and efficient movement of overburden material is critical for strip mining
- Elevation (gradient) control, where continuous assessment of ground movement must be performed and adjusted in real time
- Grade control, where 3-D mapping of mineral deposits and control of ore digging and loading are required
- Track assignment, where mining haul trucks must be directed to the right place at the right time and each load of ore or waste, depending on its quality and characteristics, must be dispatched to its proper destination

Accurate equipment positioning can be achieved by means of GNSS receivers using RTK technology. However, the vertical accuracy of a standard RTK GPS system is two to three times less than its horizontal accuracy, with vertical standard errors of ±0.01–0.02 m. Such accuracy is sufficient for most mine sites other than finish-graded roads that require tolerances of just a few millimeters. Such greater tolerances can be achieved by combining a rotating laser with a GNSS system. Accurate positioning of a dozer blade can be obtained in the horizontal position by using an RTK system and in the vertical direction by using a laser collimation plane. Lasers with a 10-m vertical swath increase this range even farther, allowing multiple machines, working at distances up to 300 m (linear) and 10 m (vertical) from the base station, to receive grade corrections. Such systems provide the tightest machine controls technically available.

The leading machine-control systems have been developed as collaborations between manufacturers of mining equipment and providers of GPS receivers.

A computer-aided earthmoving system (CAES) combines GPS (the United States's Global Positioning System) and GLONASS (Russia's Global Navigation Satellite System) positioning with an onboard display for the machine operator and wireless IP (Internet Protocol) communications between the machine and the office. Graphical and textual cut/fill information provided to the operator eliminates the need for most survey staking. CAES can be used for haul road and bench construction and maintenance, production dozing, leach-pad construction and maintenance, reclamation, ore-grade control, material identification, and coal load-out terminals. It is designed to be used on scrapers, loaders, dozers, shovels, motor graders, hydraulic excavators, and track-type tractors. Data on the status of each machine are sent wirelessly to the control office for monitoring by mining supervisors (Figure 9.4-5).

SURVEYING AND MAPPING OF UNDERGROUND MINES

In an underground mine, surveys are typically performed in dark, confined, and often wet spaces, and special equipment and methods have had to be developed to comply with underground safety regulations. Mining drifts (drives) and tunnels tend to be long and narrow, requiring the use of traverses as the main survey control. Control points are generally located in the back (roof) rather than in the floor, where they are less subject to heavy traffic and less vulnerable to damage. For use in the dark, instruments must have illuminated cross hairs, targets, and reading systems. Other adverse conditions to which instruments are exposed include dripping water, high-velocity ventilation air, high temperature, dust, strong electromagnetic fields, and mine gases, and therefore only safety-certified equipment can be used (Hart and Parrish 1995). Areas that are unsafe to access may require the use of specialized equipment that can be remotely controlled.

Horizontal and Vertical Control

Deep-mine surveys must be performed in 3-D, and underground and surface surveys must be correlated. If a rescue borehole is required between the surface and a specific underground location, or between two underground locations, survey data and survey marks must provide sufficient reference to enable accurate directional drilling. The location of mine workings must be accurately controlled, especially in relation to mining lease boundaries and other important surface features such as highways, railroads, power lines, gas lines, wells, and historical buildings. Adjacent mine workings must be surveyed and presented in the same coordinate system to eliminate unintended breakthrough that could lead to disastrous gas or water inrushes. Maps of all surrounding mines and other relevant areas must be reviewed and fitted to the master map of the mining operation before the start of any mining project—a job made difficult because, all too often, adjacent mines, highways departments, railroad companies, gas companies, surface landowners, or mineral owners use different coordinate systems.

Chrzanowski and Robinson (1981) recommended that surveys be performed at three levels of accuracy: (1) creation and survey of a primary control network for the mining area and permanent workings, (2) survey of mine headings and development areas, and (3) survey of short traverses necessary to map active mining areas.

In the United States and many other countries, the first level of survey, a primary control network, is generally tied to the second or third order of the U.S. National Geodetic Survey (NGS) network and must adhere to the same accuracy specifications. In many cases the configuration and geometrical characteristics of the mine entrances require use of traverses as an underground control network. Traverses usually have many short (40–50 m) traverse legs and direction is difficult to maintain. It is advisable to perform surveys using quality theodolites or total stations that are maintained and checked regularly. When an underground control network extends over a large area and traverses are long with many legs, the use of gyro-theodolites may significantly improve their directional accuracy. The surveying and mapping of a control network is often performed by a specialized external contractor.

An example of a control network with ties to the NGS network is shown in Figure 9.4-6.

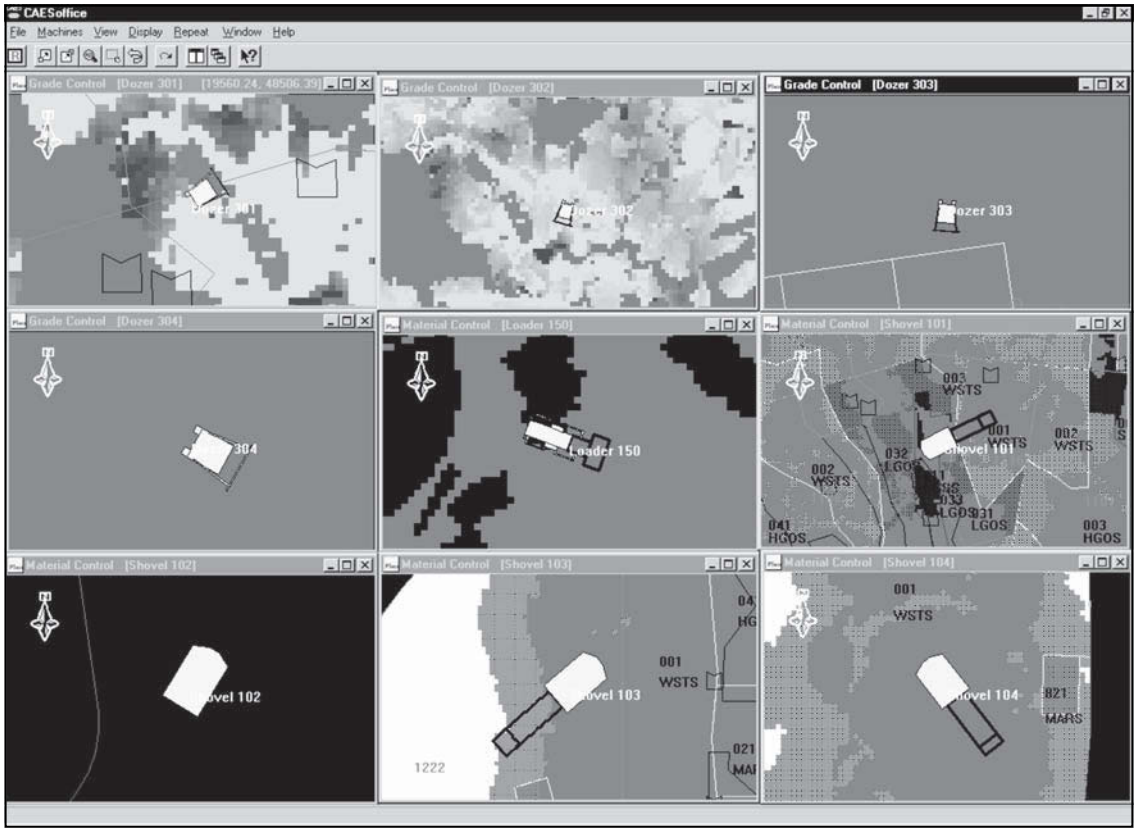

Figure 9.4-5 Computer-aided earthmoving system data on equipment position

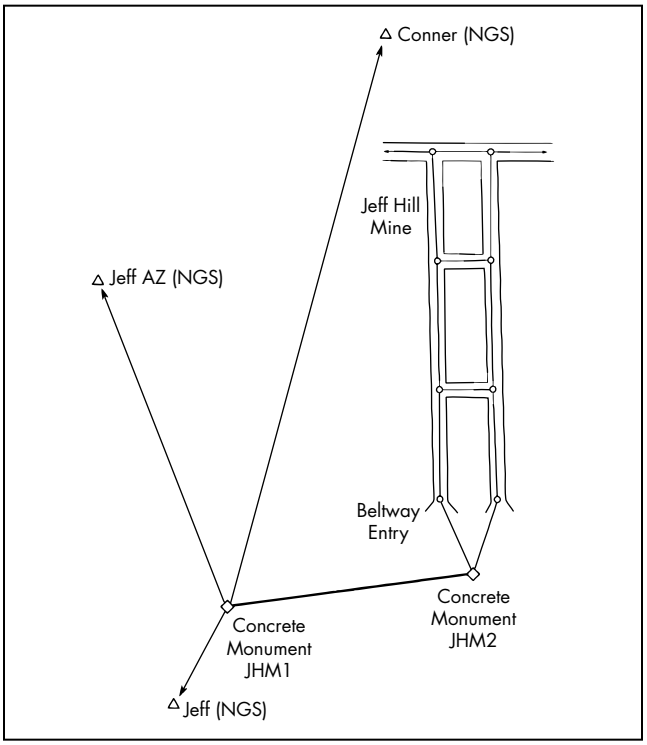
The second and third levels of survey are generally performed by resident mine surveyors using typical surveying equipment such as total stations, standard theodolites, EDMs, tapes, and levels.

Traversing with Total Stations in the Backs (Classical Traversing)

Equipment used for surveying in underground traverses is not too different from that used on the surface. Electronic total stations, the primary angle- and distance-measuring instruments, enable automatic reading and storage of directions and distances. Distances are measured electronically with the help of EDM devices that are coaxially mounted in a telescope. For use underground, instruments should be protected from dust and moisture. For use in gassy mines, instruments must be certified for use in such environments; that is, they must be explosion-proof. Most theodolites and total stations today have been properly sealed at the factory and can be used in such environments. If, for safety reasons, EDM devices cannot be used, a steel tape can be used for distance measurements.

Underground survey stations are usually stabilized in the backs of underground drives by the following means to protect them from damage:

- Standard spads driven into wooden plugs set in holes drilled in native rock (spads are hooks for attaching plumb bobs and have defined spots for sighting)
- Power-driven studs driven directly into rock by a stud gun using an explosive charge
- Adhesive spads attached to the rock by adhesive plastic cement or epoxy
- Spads with clamps attached to steel arches or roof bolts



Survey stations should be identified with brass, aluminum, or plastic tags. It is important that tags are permanent and that metal tags not be attached directly to survey stations to prevent corrosion. Identification numbers on the tags can be either (1) sequential, assigned to stations as they are created, regardless of location; or (2) position-coded to identify station location (level, drive, or station number).

Modern theodolites and total stations are equipped with optical or laser plummets for fast, easy centering over or under the control point. If laser plummets are not permitted, standard plumb bobs can be used. When hung from a spad in the roof, the bob can be illuminated by a cap lamp held behind a translucent screen or sheet of paper. Small reflectors and targets can be attached directly to spads and conventional reflectors can be used on forced-centered traverses.

Most underground leveling is performed while traversing, due in part to time constraints, generally by means of the trigonometric leveling technique. Vertical angles can be measured with high accuracy, and thus trigonometric leveling provides similarly accurate results. During traversing and leveling, it is important that instrument height and target or signal height also be measured accurately. Measurements collected at an underground traverse station are shown in Figure 9.4-7.

Traversing with Total Stations in the Walls (Wall-Station Traversing)

Although the back provides a secure location for control points, it presents a number of disadvantages for mine surveying, the most obvious of which is the difficulty of installation

Source: Adapted from Hart and Parrish 1995.
Figure 9.4-6 Control network for an underground mine

and access. Locating control points in backs in a modern high-volume underground mine usually requires lifting apparatus to heights of >5 m. In contrast, locating control points in walls makes installation and access easier, faster, and safer.

Because a theodolite cannot be set under a control point, wall-station traversing requires use of a surveying technique other than that used for classical traversing. Rather, the resection technique (free stationing), with all available distances and horizontal angles measured, is used to determine instrument position. Wall-mounted points are observed from a temporary instrument station located in the drive.

Wall-station traversing has become popular in underground mining operations, particularly in Western Australia, and it is important that surveying professionals have an in-depth understanding of the methodology, accuracy, and limitations of the technique.

The instrument and target are shown in Figure 9.4-8. The surveyor secures a target to the wall by inserting a target stem into a wall sleeve mounted in a drilled hole. The method requires specially designed target prisms that retain a central position regardless of their rotation. Total station instruments must be coaxial; that is, distances and angles must be measured along the same line of sight and software must be able to determine instrument position from resection observations by means of the least-squares best-fit calculation method.

Analyses of wall-station traverse accuracy suggest that, for optimal directional accuracy, a configuration must have acute-triangle geometry (Jarosz and Shepherd 2004). Temporary instrument stations located normal or near normal to wall stations decrease the accuracy of bearing transfer. If acute-triangle geometry is not always possible, the surveyor should take additional observations to the previous and next instrument station to add rigidity to the survey structure and use forced centering when observing consecutive instrument stations, ensuring that the initial triangle geometry is acute (Figure 9.4-9).

Recent experiences suggest that wall-station traversing significantly increases the safety of surveying operations in modern underground mines with large drives. However, it requires the use of modern coaxial theodolite and zero-constant reflectors. Distance measurements must be accurate to ±(1 mm + 2 ppm) and angular measurements must be accurate to ±5″.

Position and Direction Transfer (Surface to Underground)

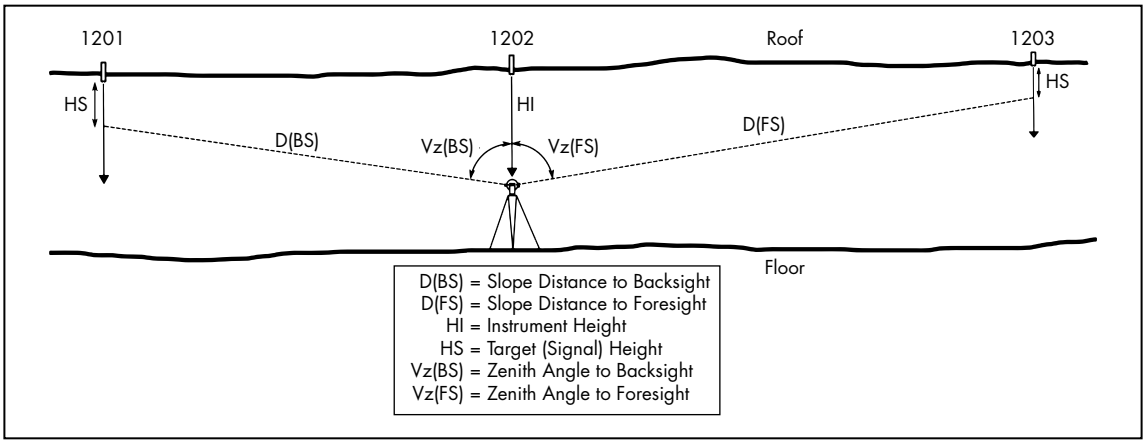
Determination of an underground baseline with coordinates and orientation (azimuth) to a surface coordinate system involves position and direction transfer. Special care must be taken with direction transfer, because errors significantly impact the correct positioning of underground control points. The standard position error σ_P is linked to the initial orientation error σ_{Az} by the following relationship:

$$\sigma_P = \frac{\sigma_{Az}}{\rho''} \cdot L$$

where

$\rho'' = 206265''$

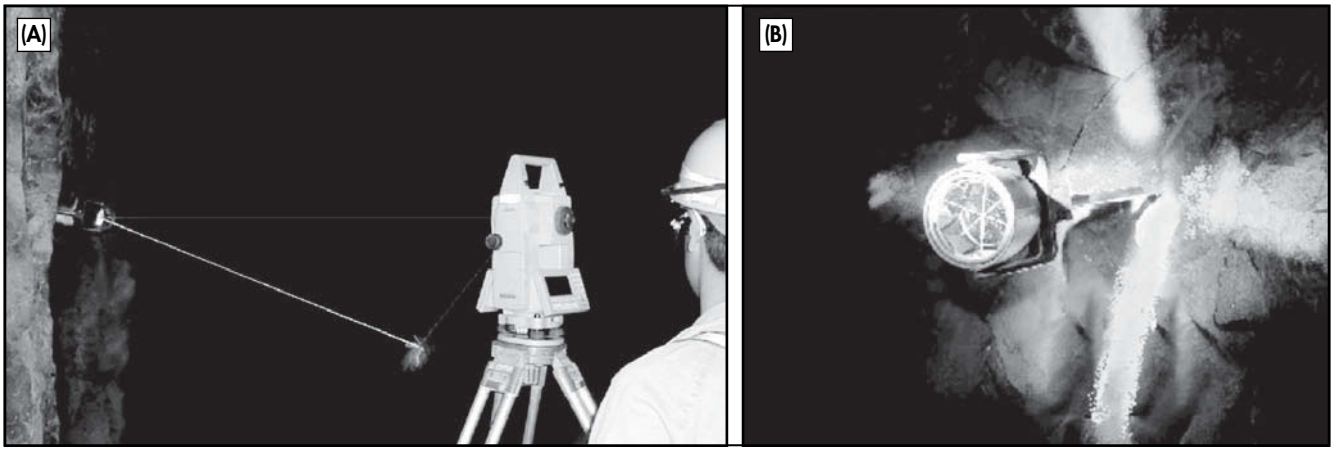
L = direct distance between baseline and a traverse point



How position error grows as a function of initial orientation error and distance from the baseline is shown in Table 9.4-1. The total position error for a traverse point includes components linked not just to orientation but also to measured angles and measured distances.

The means of underground access determines the method for positional and directional transfer. The following methods are available:

- Traversing directly from surface to underground through a mine adit and decline
- Shaft plumbing using two or more plumb lines in one vertical shaft
- Shaft plumbing using a single plumb line with gyro orientation of the initial azimuth underground
- Shaft plumbing using a single plumb line in two or more separate shafts or rises, followed by so-called fitted-traverse linking of these wires



The traversing method involves creating a traverse that starts at permanent monuments on the surface and passes through an access tunnel or adit to the underground workings. After initial traditional traversing, the procedure is as follows: Establish a position on a spad in the roof of the underground drive and measure subsequent traverse legs with the instrument set under the surveying stations. When extending a control network, use double-angle traverses. Measure both left and right (clockwise and counterclockwise) angles at each station and check for closure. Double-center the instrument—that is, re-center it before each measurement. For improved traverse accuracy, force-center the instrument and targets to eliminate centering errors between instrument and targets. Level the theodolite accurately, especially in the steep sections of a decline, for accurate direction transfer.

The shaft-plumbing methods assume that the plumb lines are truly vertical. This assumption is particularly critical when the distance between plumb lines is relatively short (<5 m), as

Source: Adapted from Hart and Parrish 1995.

Figure 9.4-7 Classical traversing

Source: McCormack 2001.

Figure 9.4-8 Wall-station traversing: (A) configuration of instrument and target and (B) reflector inserted into a wall sleeve

when both lines are located in one shaft. Two plumb lines with random deflections e_1 and e_2, separated by distance b, result in a direction error σ_{Az} of

$$\sigma_{Az} = \frac{\rho''}{b}\sqrt{\frac{e_1^2 + e_2^2}{2}}$$

For example, plumb lines with random deflections $e_1 = e_2 = \pm 1$ mm, separated by distance $b = 4$ m, result in a direction error of $\pm 52''$.

A typical single-shaft plumbing setup is shown in Figure 9.4-10. When plumb lines are located in different shafts, the baseline is at least several hundred meters and the resulting errors have significantly less impact on direction transfer.

For the plumb line, piano wire can be used that is small in diameter but strong enough to support applied weight with a safety factor of between 2 and 3. It should be in good condition and stored on winch reels to prevent kinks.

The procedure is as follows: Lower the wire initially with a small weight attached, fix it in position at the upper end, ensure that it hangs freely without touching any shaft fixtures, and attach a heavy bob to the wire. As a general guideline, the weight of the bob in kilograms should be one-third to one-half the shaft depth in meters. To dampen oscillation, immerse the bob in water or oil and eliminate disturbances such as strong air currents from the ventilation system or falling water. Note, however, that oscillation of freely hanging bobs cannot be completely eliminated. Determine the vertical position of the plumb line by taking readings at the extreme left and right of oscillation on a scale placed behind the wire. Take readings from two stations located on two perpendicular lines. Determine the mean position of the line from these readings by fixing (clamping) each plumb line to its mean position using a special apparatus called a Smith plate.

Because a theodolite cannot be set under a plumb line, for direct measurement of orientation angles, the theodolite should be positioned next to the shaft and one of the following special geometrical solutions should be used to determine the orientation of the plane passing through the plumb lines (Figure 9.4-11):

- **Coplaning or aligning.** The instrument is set exactly on the line passing through both plumb lines.
- **Weisbach triangle.** A triangle is used to link both plumb lines and the instrument station. The instrument is

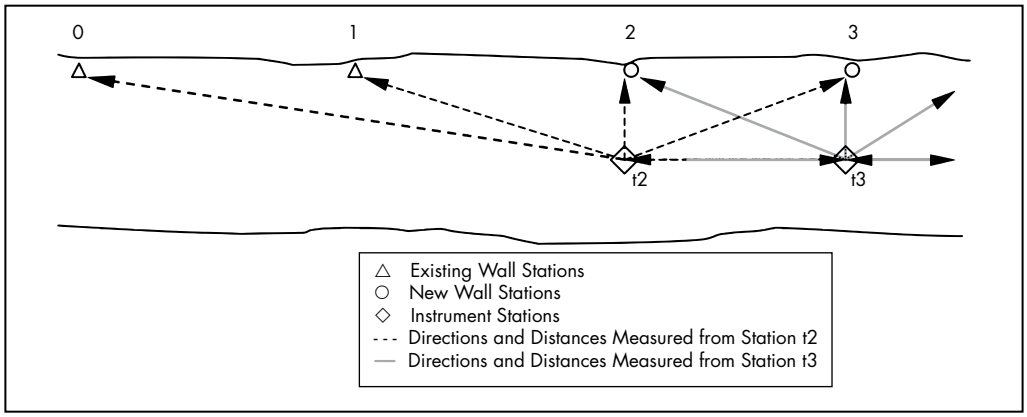


Figure 9.4-9 Wall-station traversing: additional observations between instrument stations

Table 9.4-1 Position error σ_P induced by orientation error

Distance from Baseline L, km	Initial Orientation Error σ_{Az}, m		
	±15″	±20″	±30″
0.5	0.036	0.048	0.073
1.0	0.073	0.097	0.145
2.0	0.145	0.194	0.291
3.0	0.218	0.291	0.436
4.0	0.291	0.388	0.582

positioned close to one of the plumb lines in such a way that the angle at the instrument station is acute (<10') and measured with utmost accuracy.

- **Hause quadrilateral.** When the instrument cannot be set at or close to the line passing through both plumb lines, a quadrilateral can be used to link both plumb lines and two instrument stations.

For optimal orientation accuracy, standard shaft plumbing should be performed in two shafts that are far apart from one another. The procedure is as follows: Conduct a simple surface traverse survey to give the location of each wire in the official map grid system. Then conduct an underground traverse survey to connect the two plumb lines. Initially calculate coordinates of this traverse in a local, arbitrary coordinate system. Then, because the map grid coordinates of the traverse endpoints (plumb lines) are known from surface surveys, recalculate the coordinates of all other points to the surface coordinate system by means of coordinate transformation. Transfer elevations underground by means of long shaft tapes. Calculate corrections to the tape length due to temperature, stretch, and pull, and adjust the measured length accordingly. Measure vertical distances with the help of an EDM device.

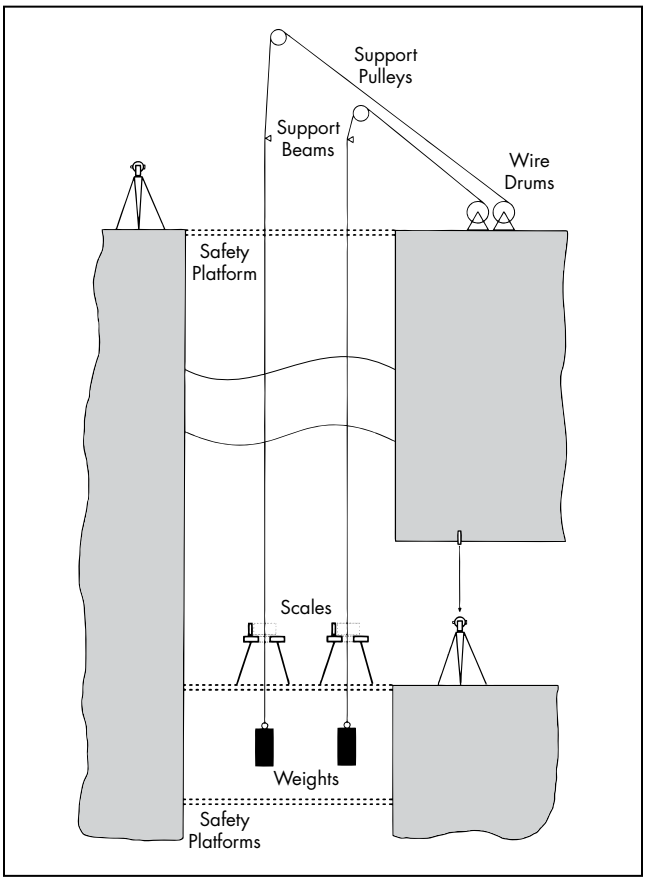

Figure 9.4-10 Single-shaft plumbing setup

Detail Surveys

The details of underground drives, drifts, and tunnels are derived from control stations established in mining structures. In most cases, detail surveys are conducted concurrently with control surveys.

Traditionally, the method of chains and offsets was used to perform detail surveys. The procedure is as follows: Stretch a reference tape between traverse stations. Measure offsets to the right and left walls at regular intervals (2–3 m) with a short tape. Measure vertical distances to the roof and floor with surveying staffs/poles. Note the details, distances, and offsets of existing features. It is sufficient to approximate the perpendicularity of offsets, due to their shortness and the measurement accuracy (±0.05 m). Higher accuracy (±0.01–0.02 m) is required in drives or tunnels with permanent roof and wall supports. Prepare a sketch of the survey in approximate scale. In cases such as when rebuilding a tunnel or drive, prepare a detailed cross-sectional survey. For a reference line, it is traditional to use a plumb line attached to a spad installed in the roof. Measure offsets at different elevations between the plumb line and the walls.

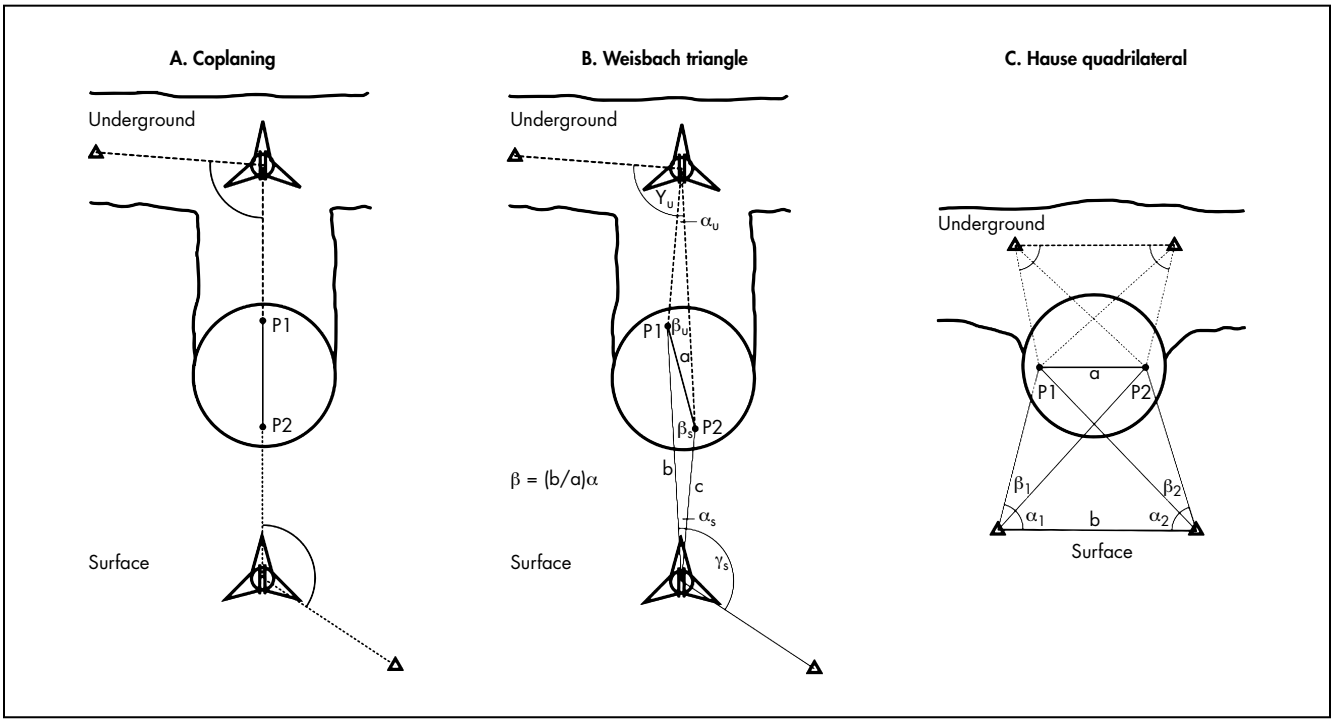

Figure 9.4-11 Geometrical solutions for direct measurement of orientation angles

Today, total stations with reflectorless EDM devices are used almost exclusively to perform detail surveys. The procedure is as follows: Survey a few lines (strings of points) running at different elevations and representing the outline of the structure of interest. Download the collected data from instrument memory to a computer in the survey office for processing, plotting, and, in most cases, creation of a 3-D model of the structure. The newest surveying technologies use laser-scanning devices for fast, continuous collection of detailed and accurate transverse profiles when the device is moved.

Massive Deposits

Mines extracting massive deposits are surveyed almost exclusively in 3-D. Total stations are used to survey access and development drives; laser-based monitoring systems are used to survey cavities and stopes—in the latter case, with the instrument inserted into the stope by means of a boom. The motorized surveying head scans the opening with the help of a laser rangefinder. A total station can determine the position of a device by tying it with positions of existing control stations.

Special inspection and surveying devices are also available to survey inaccessible vertical shafts and orepasses (Jarosz 2008). Collected data are converted to 3-D models with the help of specialized computer software. These models are linked with other models of development and access drives to provide a 3-D model of the whole mine. Such models enable creation of (on-demand) plans and cross sections in any scale or projection.

Tabular Deposits

Relatively thin tabular deposits are traditionally surveyed in two dimensions, with the projection plane parallel to the deposit. Such surveys should be performed in coal mines or mines from which metalliferous reef-type deposits are extracted (as in the gold mines of South Africa), using chain readings and orthogonal offsets to provide detail. The procedure is as follows: For a reference line, use a steel dip tape stretched between strike gullies or drifts. Use orthogonal offsets and triangulation to relate the position of the dip tape to spads installed in the gullies. Use a short tape and a surveying stick to measure offsets between the tape and the stope face. Also measure the width (height) of the face. If the deposit is on an inclined plane (reef), reduce the distances measured along the dip to true horizontal distances. In the survey office, create a horizontal map and use a planimeter to determine the areas between face positions and the volumes extracted.

Recent developments enable 3-D surveying of thin tabular deposits by means of electronic total stations combined with data-collection and display hardware and software. The results of an underground survey can be viewed in real time on a ruggedized laptop computer.

Thick tabular deposits extracted by room-and-pillar mining are surveyed almost exclusively with total stations. The surveying procedure is similar to that used for access and development drifts, as described previously.

Setting-out Surveys

Setting-out surveys provide direction and grade for mine drives, extensions, and tunnels, and are crucial to mine development. The following are common methods for performing this type of survey:

- **Grade sticks.** Two spads are placed at a set distance in the backs, and wooden poles are suspended from the spads. Marks are placed on the poles in such a way that, when lined up, the marks indicate the direction and gradient. The gradient is transferred to the development face.

- **Grade chains.** The method is as above, but chains are used instead of poles and small rings attached to the ends of the suspended chains are used instead of marks.
- **Strings and grade pegs.** Two sets of pegs, spaced 5–10 m apart, are placed in the sidewalls of a drive at calculated levels. Strings are run between the pegs to create an inclined plane with the design gradient. The gradient is transferred to the development face.
- **Direction and grade lasers.** For a short extension of direction and grade, a small laser is positioned in the wall opposite the development heading. The laser is inserted into a sleeve cemented into a hole drilled into the rock in such a way that the laser beam projects the direction and gradient for new development. A drilling pattern is marked at the heading. For a long extension, a larger laser is mounted in a special enclosure attached to the back of a drive. In both cases, a total station is used for laser setup. The direction and grade of the laser beam should be checked regularly. Today, lasers are used almost exclusively to determine direction and grade.

CHAPTER 9.5

Dewatering Surface Operations

Paul R. Peppers

INTRODUCTION

Hydrology is an imprecise science developed by empirical observations by many people over the course of 3,000 years. Complex nonlinear systems are involved; many of the factors that go into the computations are probability based, time variable, imprecise, or uncertain.

Identifying and quantifying the risks associated with system failure usually sets the level of effort that is justified. More precise calculation methods are evolving, but, considering the uncertainty of the data, approximations are commonly used. The locations, quantities, and detrimental effects associated with water in the operating areas are continually changing as the mine development progresses. This effect renders the precise calculation of the performance characteristics of the pumping system at any particular point of limited operational value.

Computer-based systems hide the complexity of the calculations and allow more rapid solutions of the empirical equations. Complex computational fluid dynamic calculations are usually justified only if the costs and development times are substantial. For example, a manufacturer of a new class of pumps could justify the effort because upfront computer modeling may well reduce the cost and time needed to build prototypes. However, a mine engineer trying to decide if that pump would have sufficient capacity to pump from his pit probably could not justify that level of computation.

Some factors from the mine planning process are predictable with reasonable precision. For example, the hydrostatic lift necessary to pump water from a planned shovel face is predictable because engineers design the elevations of the pit face and pit rim in advance. Changes in these factors are predictable as long as mine operations follow the plans. The size and shape of the drainage basins that contribute to the runoff into the mine area are measurable in advance, but other critical factors affecting the quantity estimation of runoff are difficult to measure accurately. Meteorological factors, climatology, and actual rainfall can vary significantly from the predictions. Changes in land use and development over time reduce the predictive ability of long-term rainfall monitoring and flow-gauging station data. These can show up as drift in the mean runoff levels and intensity over time because removal of ground cover and construction of paving tend to limit infiltration and reduce the concentration time. Some examples of these factors follow:

- Natural basins and channels are nonhomogeneous in their ground cover, slopes, soil type, and moisture content.
- The variability of rainfall intensity over a basin increases with the size of the basin. Larger basins are subject to locally heavier precipitation intensities.
- Most precipitation records are point measurements. Rainfall gauges are small samples of the larger precipitation event. Spatial variability of storm patterns makes even nearby locations difficult to predict without on-site data.
- Streamflow gauges are better indicators than rainfall gauges, where these records are available, because of the integration of the runoff from the upstream basins, as long as the characteristics have not changed over time.

Historic observations used to determine the probabilistic frequency of rainfall events are uneven. In some places, reliable precipitation records may have recorded the variability over several centuries, while in others, only for decades. In the case of some greenfield developments, no historic data may exist at all. In semiarid regions, empirical methods are commonly used to predict rainfall runoff events, which make it difficult to quantify the magnitude of potentially damaging high-return period storms such as 100-year or 500-year events. Coverage is definitely better in the developed world than in remote areas.

MINE DEWATERING TEAM

Few people think of mine dewatering at a surface operation as a major issue when compared to other production tasks such as fragmentation, loading, hauling, crushing, or milling. If neglected, however, no other operations are possible in the mine. Mine dewatering requires applying knowledge from many fields to create practical, cost-effective, and efficient

Paul R. Peppers, Supt. Central Maintenance & Projects, Sierrita Operations, Freeport-McMoRan Copper & Gold Co., Green Valley, Arizona, USA

systems to manage the water. This chapter discusses practical field methods that provide sufficient levels of accuracy and precision to limit risk. The objective is to put tools in the hands of the engineers and technicians to manage mine water inflow and accomplish production effectively and economically. All of the following specialists have a role to play in managing water, but it is the role of the generalist to understand the big picture and know when to call the experts.

- **Mining engineers** overlap and coordinate with other specialty engineering disciplines to develop a cross-disciplinary engineering approach to the issues involved with prediction, collection, and handling of water in mine workings.
- **Meteorologists** track the data related to historic precipitation patterns, utilizing rainfall-measuring stations, streamflow gauges, radar, satellites, and modern database systems that supply the data to predict probable precipitation values and the associated statistical risks.
- **Civil engineers/hydrologists** predict the runoff recurrence and design the surface drainage controls, storage basins, and conveyance structures.
- **Mechanical/structural engineers** provide the expertise to design pumps, pipelines, and mechanical aspects of pumping stations, including concrete, supports, and pump engineering.
- **Electrical/instrumentation engineers** design the electrical power, distribution, instrumentation, and controls required to run, interlock, and control pump stations and dewatering systems.
- **Environmental engineers** provide the knowledge of federal, state, and local regulations for obtaining permits prior to commencing operations. They assist mines to predict, evaluate, and mitigate pollution from operations.
- **Land, legal, and water rights professionals** manage the legal aspects of obtaining permission to extract and use specific water quantities for industrial purposes. They also help miners manage disputes over historic ownership and water rights law.
- **Government agencies** fund and manage the basic research and development that provide much of the background hydrology data available. In the United States, the National Weather Service and the National Oceanic and Atmospheric Administration (NOAA) collect and distribute much of the precipitation data that are critical for predicting runoff. The U.S. Geological Survey provides a database of streamflow records for drainage basins and groundwater levels in monitoring wells located throughout the country.

REVIEW OF SURFACE HYDRAULIC CALCULATIONS

This sections gives a brief outline of the process of designing a runoff control system for a mine. The process can be broken down into a series of estimates required to scope the problem. Detailed explanations for these estimates are in Chapter 16.4.

Precipitation/Storm Events

To determine the amount of protection necessary for the various mine operations structures, the risk level of the proposed structure can be estimated based on failure consequences. The appropriate design storm point precipitation frequency (PPF) event can be selected from NOAA or other sources to determine precipitation amount and intensity (NOAA 1980).

An example of a design storm selection based on risk follows:

Risk	Design Storm
Low risk	10 years: 6-hour storm
Medium risk	100 years: 24-hour storm
Catastrophic risk	1,000 years: 24-hour storm or probable maximum precipitation

Basin Runoff Calculation

Using the rational method or one of a number of computational runoff-calculating models (U.S. Army 1971):

- Basin characteristics for each basin in the watershed are measured: shape, area, channel length, ground cover, and relief.
- PPF from the design storm for the area is applied: A measure of precipitation (millimeters or inches) that falls within the storm period (e.g., 25 mm or 1 in. of rainfall in 6 hours expected once every 10 years).
- Peak flow rate Q, time of concentration, and total runoff volume are calculated.
- Routing network is designed.

Using the flow information from the individual basins, the runoff protection network can be designed. This may consist of a number of structures to route the water from the source to the discharge point: open channels, culverts, detention and sediment control basins, spillways, weirs, and flumes. The U.S. Army Corps of Engineers Hydraulic Engineering Center (HEC 2009) tools are helpful, as is the American Iron and Steel Institute handbook (Spindler 1971).

SAFETY ASPECTS OF DEWATERING

Water in mine workings presents a number of hazards to the safe operation of the mine. Sudden precipitation events result in rapid, high-volume runoff into surface mines along the road network and over the pit rim. Water allowed to run over highwalls can cause erosion, bringing down debris, talus, and raveling, thereby creating hazardous conditions to mining operations below. Ponding, erosion, and degradation of the haulage surfaces and working benches mean that all operations slow down to maintain control of the equipment. Slides and rockfall risks increase when water percolates into cracks in the highwall.

In cold climates, ice and freeze–thaw cycles increase the risk of raveling and rockfalls as the freezing water swells inside the fractures, wedging the blocks apart. Ice builds up where water seeps out of the highwall. When these overhangs fail and fall, they can cause extensive damage, especially if the ice mass is large. Seasonal thawing causes these ice buildups to break loose and rain rocks and ice into the pit.

Drainage control maintenance should be conducted prior to the arrival of seasonal precipitation in areas where this is predictable. Such control measures include filling surface cracks around the pit perimeter and diverting runoff from the pit rim to limit water infiltration. Regular inspection of ditches, culverts, and drainage channels for damage and cleaning away debris to allow maximum water flow should become standard operating procedure. Scheduling of major construction or modifications should allow for completion during the dry seasons, avoiding critical system downtime on dewatering systems.

High-volume precipitation events cause flash flooding, particularly in mountainous areas and arid climates, such as in the American Southwest. Proper planning of the pit location and associated mine facilities must take into account drainage protection. Significant storm runoff can be controlled by properly designed drainage controls that direct runoff away from the pit to prevent problems before they occur. In-pit haulage roads and benches should be sloped to prevent ponding and direct water through perimeter ditches to sumps for collection. Culverts must be adequately sized to convey water where roads intersect drainage crossings.

Emergency Planning

Contingency plans must exist to protect personnel from entrapment if flooding from sudden inflow of runoff results in loss of the main access route. This can happen if the haul road washes out or slides off the wall because of slope failure. Ensuring that the pit designs include emergency evacuation routes must be part of the mine planning process. Surface mines usually have more than one escape path from the pit. Ramping down to start a new bench in the pit bottom, commonly called drop cutting, can be particularly hazardous during monsoon season. It may be necessary during intense precipitation events to abandon mining equipment in the drop cut and evacuate personnel to a safe location until the runoff subsides. Escape route planning is even more important in underground mines that may be subject to rapid inundation if old, flooded workings exist in the area.

Mine pumping systems cannot keep up with storm runoff in real time due to extremely high inflow rates that are usually at least one to two orders of magnitude higher than economically feasible pumping rates. In severe events, power may be disrupted, and sumps designed to capture the entire runoff volume of a particular design storm can be overwhelmed. Most dewatering systems cannot function during heavy rains and must be shut down to prevent damage from excessive sediment and debris. Floating barge pumps handle these events much better than fixed pump stations as long as their sumps can handle the runoff. After significant precipitation, operators may have to excavate mine sumps in order to recover the original volume lost due to sediments washed in from erosion of the roads and walls above. Pumps may be inundated or buried under sediment and may need to be replaced before pumping from the pit can resume.

Impoundments

An embankment that impounds water at a level above its previous channel elevation creates a potentially hazardous condition. Failure of the impoundment can release a tremendous amount of stored energy, which is then directed at anything below. Embankments, dams, and diversion dikes require higher than normal safety factors if that structure's failure could lead to loss of life or significant property damage. This higher safety factor is based on risk assessments of downstream structures and populations.

Periodic inspections, monitoring, and maintenance of operating impoundments must be carried out to ensure that the structure remains safe and its operation is within its designed limits. The size of the impoundment often determines the frequency and level of inspections required by the permitting agencies. Knowing the applicable regulations can reduce the costs of monitoring and inspections. For example, under the U.S. Mine Safety and Health Administration regulations for coal mining, embankments larger than 6 m (20 ft) high and ones with a capacity exceeding 24,670 m^3 (20 acre-ft) require inspections every 7 days. Impoundments only slightly smaller have less onerous inspection requirements (MSHA 1977).

Dam breaks are now rare because of regulatory vigilance imposed in the wake of significant disasters in the past. The potential damage from a failure can be very high due to the high volumes of water that can be released in a short time and the proximity of population and structures downstream. When impoundments fail, investigations into the causes usually find that the fault lies with improper design, construction, operation, inspection, and/or poor maintenance practices.

Slope Failures into Impoundments

Evaluation of the potential for slope failure should be part of the design criteria for all deep sumps adjacent to highwalls. Backfilling operations into flooded pits create the potential for dump failures to produce large damaging waves. The volume of sumps built under slopes with a history of stability problems should be as small as possible. Shallow sumps with large surface areas are preferred to smaller deep-water sumps.

Miners working near large in-pit ponds and sumps must be extra vigilant if any risk exists of slope failure into the water. Procedures for real-time monitoring of wall stability can mitigate the hazards to provide advance warning if raveling develops. If personnel are required to work near the shoreline of sumps, shallow areas such as old ramps are most hazardous because a wave approaching from deeper water can rise significantly.

An example of slide-induced waves occurred at the Valdez Creek mine in the Alaska Range (United States) during backfilling into a previously mined pit, when a dump failed and created a very large wave. The area, a long, sinuous valley 67 m (220 ft) deep by 457 m (1,500 ft) wide and 1.6 km (1 mi) long, was concurrently collecting tailings and dump material from the stripping operations. The pit had a standing water pond 53 m (175 ft) deep against the toe of the dump. Mine dumping was from the original pit rim elevation in a single lift about 24 m (75 ft) above the water surface.

Tension cracks developed behind the dump crest, and a large section 18 m (60 ft) thick slid into the water. The dump material displaced the water at the toe, resulting in a wave 11 to 12 m (35 to 40 ft) high that hit the wall across the pit. At the far end of the valley 1.6 km (1 mi) away, the wave was still more than 2 m (6 ft) high where it damaged a pump station. Fortunately, no one was hurt, but the potential for severe injury existed for anyone working on the ground near the surface of the pond. As a historic note, in 1958, the largest wave ever recorded, at 533 m (1,750 ft) high, was caused by a slope failure into deep standing water in a fjord in Lituya Bay, Alaska (BBC 2000).

Access Safety and Maintenance Planning

Heavy machinery, deep water, limited access, and people in close proximity create significant safety challenges that must be mitigated when considering floating barge applications. Long-term sumps must have access structures designed into the system. These can include floating gangways complete with handrails, cableways, and pipeline flotation systems. Anyone working around the barge must wear appropriate flotation protective devices. Whenever the barge and pump draft are too deep to allow the barge to be pulled close to shore, docks may need to be built. In sumps with shorter design lives,

the barge may be accessed by boat, providing that its weight limits and stability are not exceeded as a work platform. The following are important factors to be considered:

- Servicing plan for pump/control maintenance
- Weight and center of gravity for the barge, crane reach limitations, and control access requirements
- Occasional operator access for pump maintenance
- Support for pipelines and electric cables to account for water level changes

Moving equipment and machinery on barges creates the possibility of capsizing the barge. To avoid tipping, major shifts in the center of gravity during maintenance or operations need to be carefully planned. Special marine engineering expertise may be required to identify hydrodynamic, stability, and buoyancy issues before construction or major component replacements. Buoyancy control adjustments can be accomplished with air chambers that allow the deck level adjustments. Pipeline supports must include additional buoyancy where the discharge pipe connects to the barge to compensate for the weight where the pipe rises above the water.

Lifting Plans, Weight, and Crane Capacity

Site access must be designed to allow pumps, motors, and other equipment to be successfully lifted from the barge to transport equipment onshore. Pump and barge draft requirements may limit the ability to drag the barge close enough to the bank for service. The slope of the sump bank frequently causes the barge to run aground well before it is close enough to shore to enable convenient access. For small, steep-sided sumps, this is less of a problem due to the higher wall angles.

Large sumps or pit lakes require the development of standard operating procedures that include the weights of the barge, pumps, switchgear, and pipe fittings that will need to be placed both during construction and changed later during maintenance cycles. Some sumps have access limitations that preclude using shore-based lifting equipment. In these specialized cases it may be necessary to employ sky-crane heavy-lift helicopter services to fly the equipment to the operating location.

Generous factors of safety are needed to account for the barge weights that will increase when mud, water-logged floats, and scale accumulate over time. The suction force that has to be added to the weight to break free of the mud if the barge settles to the bottom should not be underestimated. The critical factors in these plans are the crane locations, reach limits, and estimates of the weight that must be lifted. Bank stability is also a concern in sumps with fluctuating water levels.

IN-PIT WATER CONTROL

The primary objective of the in-pit water control network is to expeditiously convey water through the workings to the temporary collection sumps for removal without adversely affecting the mining activity. Runoff sources include the point sources from groundwater infiltration, streams entering the pit, and rainfall collection on the surfaces inside the pit's perimeter.

Factors that water control system designers must consider as engineering trade-offs are the cost/performance designs involving the pump capacity, pipeline diameter, power requirements, system duty cycle, and number of lift stages. Large-capacity pump/pipeline systems with few stages are designed to run intermittently compared with smaller systems with larger sumps that run almost continuously. The large system has a higher factor of safety to handle unusually large inflows but comes at a higher capital cost than the smaller system, which accepts higher risks of being overwhelmed in infrequent precipitation events but handles normal dewatering needs better. Smaller, redundant parallel pumping systems can provide the surge capacity of a larger system while increasing system availability. Increasing sump capacity is one of the least expensive ways of reducing risk without sacrificing the efficiency of the pumping system.

Indirect Costs of Water in the Pit

Water in the rock fractures adversely affects the geotechnical stability of the pit walls. Mining pits at the steepest stable pit highwall angles is the most profitable because it lowers the stripping ratio. Proper water control increases the pit wall stability, thus maximizing the wall angles. Preventing water from infiltrating the fractures in the rock is critical to maintaining maximum stability. Horizontal drain holes drilled to intercept the fractures can successfully reduce the pore pressure.

Water in the mine working areas causes inefficiency in all materials handling operations. Water buildup at the ore-loading face degrades the crushing and conveying efficiencies. Dewatering efforts should move the water to local sumps that follow the loading equipment close enough to prevent digging in wet ore. Fines and water combine to form a highly abrasive grinding medium that destroys moving parts. Excessive moisture can cause backsliding on inclined belts where the feeders drop ore onto a moving belt. The steeper the belt, the worse the problem becomes. When conveying saturated material, water seeps out of the muck, running down the belt until it spills and builds up in the drives and under the rollers. Particularly in cohesive ores with many fines, wet material causes a buildup in chutes, resulting in plugging and costly downtime. Slabs from material buildup on the walls of the chutes can break off, fall onto the belt, and cause adverse wear or torn belts.

Haulage Road Runoff Control

Haulage roads act as arcs in the flow network in the pit because they are continuous and interconnected, and lead from the pit's upper reaches to the bottom working levels, making them ideal channels for water. Haul truck tires are becoming one of the major costs of mining; wet roads, tire slippage, and sharp rocks are primary causes of premature failure. Drivers must reduce their speeds to maintain control under wet road conditions. Maintaining good drainage control prevents visibility degradation and reduces spray from haulage roads. Muddy conditions create poor traction, resulting in increased stopping distances for mobile equipment.

Properly designed haul roads should be crowned or slanted to prevent ponding on the road surface. Crowned roads with at least 2% cross grades have fewer problems (than surfaced roads without drainage grades) with washboard ruts because the road surface retains most of its strength by having the cross grade eliminate standing water. Perimeter ditches concentrate the water and direct it down toward the sumps. On long ramps, the water volume can build up significantly before it reaches the bottom, as smaller tributary streams and rivulets join the main flow. It is desirable to divide the flow before the water accumulation gets deep enough to overflow the ditch

into the haulage lane. Where the ditch is located on the pit side of the road, creating holes in the berm allows part of the runoff to escape the ditch and sheet flow down the wall, reducing the size of the ditch necessary for the remaining portion of the flow. The water flows over the highwall, travels to the next lower area in the pit, and from there to an intermediate sump or another berm relief on its journey toward the bottom.

Switchbacks in the haul road present challenges to handling the water collected in the ditches along the highwall. Haul roads usually have superelevated curves raising the outer edge of the road perimeter. If the straight road section is crowned or sloped back toward the highwall, water runs in a V-ditch between the road and the wall. When approaching the switchback, the ditch elevation increases as the road nears the superelevated curve, and the water escapes the ditch, running across the active traffic lanes to continue downhill. The result is erosion of the travel surface, creation of washboard ruts, and tendency of the water to meander over the entire road surface. Several ways are suggested to mitigate these problems:

- A trench between the highwall and the superelevated curves should be created to allow water to continue past the curve and cascade over the wall. This has the effect of moving the water off the road but does so by directing it to the pit bottom. Most pit designs do not allow enough width to accomplish this because the trench takes up too much room.
- Diagonal swales, grooves, or water bars should be cut into the road surface prior to the curve to force the water to cross the road at a designated location. Aggregate can be selectively placed and compacted to prevent erosion in these designated water crossings. Approach transitions must be gradual enough to ensure no adverse effects on the speed of trucks traversing the swales.
- The most expensive way to move the water is to divert the ditch into a culvert running under the superelevated fill. The culvert can run along the same route that the trench would have taken but without the width "penalty." Alternatively, the culvert can cut the corner under the lanes, thereby diverting the water to the inside edge below the switchback, continuing the V-ditch down the road. The culvert entrance design usually involves a small sump but must prevent water from backing up and flooding over the road. There is a width penalty to construct this, and sufficient fill depth must be available under the road to prevent the weight of a loaded haul truck from crushing the culvert pipe.

Sumps

Sumps capture and temporarily hold runoff to allow for sediment control and for pumping the clarified water. Properly designed water collection networks concentrate the accumulated runoff as high in the pit as possible. Sumps can be located in a pit bottom, a wide spot in the bench along the wall, or at a switchback along a haul road. Obviously, pumping costs increase with the elevation difference between the sump location and the discharge elevation.

Sumps should be large enough to ensure that the active volume will keep the pump running for a reasonable period. Efficient sump design matches the pump capacity to the inflow rate for normal groundwater infiltration, reducing the need for periodically cycling the pump. If a sump has low or infrequent flows, it may not be in the right place. In such instances, it may be necessary to combine the inflow from other ditches to increase the utilization or consider eliminating the sump by rerouting flows elsewhere.

Removal of expected sediment and debris must be part of any sump design. The extent of the cleanout structure depends on the planned life of a sump, the velocity of the water in the approaches, and the presence of sediment traps in channels. Sediment traps have weirs and larger-flow cross sections in the channel, which slow the water flow, allowing the entrained solids to drop out of suspension. Sumps collecting runoff from high-intensity storms can rapidly fill with sediment if the velocities are erosive because of steep channel grades or easily eroded soils. It is easy and advisable to inspect the sumps periodically to ensure that necessary capacity exists.

Slope-stability effects must be part of the design and location of the sump. Geologic structures known to have stability issues should be avoided. Long-term sumps on the highwalls are a source of water infiltration that percolates into the rock, resulting in an increase in the pore pressure along the fractures. This increases the probability of slope-stability problems as mentioned in the safety section.

GROUNDWATER

The "Review of Surface Hydraulic Calculations" section discussed handling runoff water from meteorological sources that originated outside the mine. This section will give a brief outline of the process of identifying, quantifying, and controlling groundwater infiltration into the mine. Groundwater infiltration from aquifers, water-filled cavities, or other sources exists in nearly all mining operations. A more detailed treatment for these issues is found in Loofbourow 1973 and in Chapter 16.4. The process can be broken down into a series of estimates required to scope the problem depending on the status of the project.

Premining feasibility studies:

- The subsurface geologic structure and hydrology of the deposit are mapped and understood.
- Exploration wells are drilled to locate and quantify potential water resources for processing and potential mining hazards.
- The wells are tested to model flow rates, porosity, temperature, and chemistry, looking for possible adverse issues.
- The quality and chemical makeup of the water are assessed in order to design the treatment methodology.
- The interception strategy is chosen for handling the predicted water inflow rates:
  - Interception wells in the aquifer are pumped to dewater outside the mining area.
  - Inflow outside the mine perimeter is blocked by reducing porosity.
  - Inflow into the mine is accepted and handled along with other water sources.

Mine development phase:

- Predictions from the pre-mine feasibility studies are verified.
- The flow outside the mine perimeter is blocked through grouting, freezing, or other methods to reduce porosity of aquifers or fractures identified as high risks.
- Water is intercepted and drawn down using well fields, preventing quality degradation and avoiding treatment issues.

Mine operation:

- Groundwater infiltration is routed into sumps and handled through the in-pit pumping systems.
- Water quality issues are treated along with affected run-on water prior to discharge or reuse.
- Pump system redundancy and capacity are maintained to handle unexpected changes in flow rates. (See the Valdez Creek case study later in this chapter.)
- Interception well fields and blocking structures are maintained and expanded as mining progresses through the reserve.

The presence of groundwater in a mining claim has both beneficial and detrimental effects on the economic viability of the operation. All mining operations and processing plants need water to function, and it must be imported if insufficient supplies exist on the property. However, groundwater intercepted in the pit is usually in the wrong place with inconsistent flow rates and may have quality problems that must be handled before it can be used in the process. The main objective in mine dewatering is to economically capture the water, route it around the operations with minimal disruption, and store it for beneficial use; or, failing that, treat the water prior to discharge.

Wet Drilling and Blasting

Drilling under wet conditions is more expensive and less productive than if the operation is dry. One method of limiting the effects of water on the drill bench is by digging perimeter trenches into the bench. This is particularly useful in deposits that have considerable water present in the rock but relatively low permeability. Perimeter trenching would not be effective if the ore is highly porous because this allows water intercepted by the trench to recharge back into the drill pattern. Even if it is not possible to pump or drain the perimeter trench, it may lower the local water table, sufficiently drawing the water from the bench's upper couple of feet to improve the conditions for starting the hole (collaring). Fracturing from blasting the previous bench is usually sufficient to provide the additional permeability to draw down the local water table from the drill area to the perimeter trench. The permeability in the unfractured, surrounding rock is lower, preventing excessive flow from the walls back into the drilling area.

If the bench conditions are wet, redrilling is often required and may or may not be successful because the same water conditions that caused the initial problems still exist. It is not uncommon to drill a pattern while drop cutting only to find that 90% of the holes are collapsed or plugged by the time the blast is scheduled. After the good holes are loaded and shot to create additional porosity to pull down the water table, redrilling starts again. Under wet conditions like this, it can take a month to develop a 152-m- (500-ft-) long drop cut that might take only a week if the bench were dry.

Although factors such as energy density, detonation velocity, or energy distribution usually dominate the decision about the explosive type, the presence of water in the blastholes prevents using the least expensive blasting agents. Commonly used ammonium nitrate and fuel oil (ANFO) blasting agents will not detonate or will misfire if the powder gets wet. Water-resistant emulsions must be used if the water cannot be removed, but they are nearly twice as expensive to use as dry-hole, ANFO-based products of equivalent energy.

Blasthole dewatering with hydraulic-driven pumps can offset some of the emulsions costs if the water infiltration rates are slow enough. Pumping the holes and using impermeable polyethylene sleeves allows the placement of inexpensive water-sensitive ANFO in areas that otherwise would require emulsions. The cost of the sleeves adds to the blasting costs but significantly offsets the cost of using expensive emulsions.

Case Study: Valdez Creek Groundwater Control

Between 1993 and 1995, Cambior Alaska's Valdez Creek mine in the Alaska Range was reaching the end of the mine's reserves. This large placer gold mine operated year-round above timberline in a remote subarctic stream valley.

This mine operation's primary defining challenge was groundwater infiltration. Flow in Valdez Creek ran year-round across the entire length of the mining claim and continually recharged the subsurface aquifer. Groundwater flowed through the gravel deep in the deposit year-round, although the pit walls froze solid to a depth of 3 to 4.6 m (10 to 15 ft), blocking the flow during the winter. Blasting occasionally breached this frozen wall, resulting in sudden inflows of water and sediment into the pit. The inflow increased during the annual spring breakup with a significant spike in water volume as the walls thawed, draining the water held back during the winter.

Management scheduled closing of the mine by freeze-up in the fall of 1995 due to reserve exhaustion and marginal economics. The company was under pressure to limit spending, particularly on fixed infrastructure that it would have to abandon or scrap at closure. The remote location required more time and logistical effort than most mines to make major improvements. Adding incremental diesel-powered pumps was feasible with some notice (weeks), but adding high-density polyethylene (HDPE) pipeline capacity was difficult, expensive, and required a long lead time (months).

The mine experienced increasing water inflow rates. In 1993, the pit had an approximately 69-L/s (1,100-gpm) inflow with a pumping capacity of 82 L/s (1,300 gpm). By mid-1995, the inflows had increased to 454 L/s (7,200 gpm). Pipeline and pumping capacities were barely adequate for initial conditions. Surges overwhelmed the system, flooded the pit floors for weeks, and interrupted ore production until the inflow subsided. The initial 20-cm- (8-in.-) diameter pipeline was not adequate beyond about 63 L/s (1,000 gpm), requiring two pumps in series to keep up and maxing out pipeline capacity. Because the surge capacity of the system was limited, the mine added a second 20-cm (8-in.) pipeline.

Flows increased in 1993 to nearly 126 L/s (2,000 gpm) by freeze-up, interrupting production more frequently. Management agreed to fund an upgraded 30.5-cm- (12-in.-) diameter pipeline because it was essential to regain control over the water in the pit. This pipeline was in place before breakup in 1994.

The new pipeline worked well for about a year before it was deemed insufficient to keep up with increasing demands. The inflow tripled over this period to 391 L/s (6,200 gpm). The pumps that were on-site or readily available had to be pressed into service even though they were not well matched. The system started with one large diesel-powered pump and then added a large electric slurry pump and finally an additional large diesel pump in series. Two of the pumps operated at poor efficiencies, well beyond their curves due to flows above their designed flow rate. Only one pump was still operating on its curve. Adding the second and third pumps in series to the pipeline resulted in smaller incremental flow increases. Extremely high flow velocity in the pipe, approaching 6 m/s

(21 ft/s), resulted in high friction head losses (3 m [10 ft] of loss per 30.5 m [100 ft] of pipe), causing the hydraulic grade line (HGL) to exceed 10% slope.

Pumping in series adds the pressure of the last pump to the discharge pressure of the previous stages, so the sequential order of the pumps is important. Pumps, like pipelines, have maximum design internal case pressure ratings to avoid overpressuring and cracking the cases. Additionally, the discharge pressure exceeded the recommended working pressure for the HDPE pipeline, which was operating at a reduced safety factor. The operating point for this system was only possible because it pumped cold, near-freezing water, doubling allowable working pressure.

The last incremental 63 L/s (1,000 gpm) required additional pipeline capacity 6 months before closure. Because no additional funds were available, the pump crew salvaged the original 20-cm- (8-in.-) diameter pipeline from the 1993 pit and relocated it to the final pit. Two pumps in the series pushed the incremental flow up the wall, extending production nearly to the end of the mine's life.

Ultimately, the lack of a pump caused abandonment of a portion of the final ore face in the last 3 months. The pit filled with water because of the lack of a 189-L/s (3,000-gpm) capacity cross-pit pump and the availability of a short pipeline to move water from the shovel-loading area. This inundation resulted in the loss of approximately 3,000 to 4,000 oz of gold contained in ore that was uncovered and awaiting haulage to the wash plant.

The mine lost the water battle in late summer when an additional 442-L/s (7,000-gpm) inflow occurred through the pit wall, immediately forcing the operation to abandon production efforts and to commence reclamation. When considering the increasing magnitude of the water inflows over a short period, the mine did an outstanding job managing the pumping problems with limited resources available. It managed to mine more than 95% of the planned tonnage from the final pit even with seriously deteriorating pit water conditions.

SPECIALIZED PIT PUMPING PROBLEMS

Because mines are located where economically recoverable minerals are found, they are frequently in inhospitable locations with extreme climates. Mountainous areas have high relief, topographically controlled rainfall, and steep channels that cause erosive flow velocities. Jungles frequently add extremely high rainfall and seasonal monsoonal patterns. Arctic areas have extremely cold climates, ice, glaciation, and permafrost. Deserts defined by low annual precipitation can be very hot (Sahara), high altitude and cold (Antarctica, Atacama in Chile), or dry with most of the annual precipitation in a few intense storms (Arizona's Sonoran Desert in the United States). Each of these climates has unique challenges that affect the dewatering system designs.

Arctic Conditions and Permafrost

Permafrost is the condition in the soil below the seasonal active layer where the temperature never rises above the freezing point of water. This is not a problem by itself, but if the soil contains moisture and fine-grained soils, it tends to create thick lenses of clear ice. Permafrost that exists in foundation areas must either be kept frozen or removed. If the conditions that formed the permafrost such as ground cover and shading are changed, thawing is possible. Fine-grained soils must be removed from the foundations of the pump stations and replaced with coarser, nonwicking material.

Any source of heat, such as flowing water in pipelines, must be insulated to prevent thawing around the pipe. If the ground thaws, the bearing capacity may be lost, causing collapse of the overlying structures. Buried pipes in frozen ground can melt an annulus around the pipe that changes the permeability of the soil. In the case of an impoundment, sump, or artesian well, this can result in uncontrolled flow outside (and around) the pipeline.

Above about 60° latitude, permafrost may exist in all subsurface areas unless the area has been tested and been found to be clear. Even in areas generally free of widespread permafrost, there may be sporadic permafrost containing clear ice lenses in local areas. Cold climate areas without permafrost have seasonal freeze–thaw cycles that occur in the active layer. Depending on the severity of the climate, these can affect ground support stability as much as 3 m (10 ft) below the surface. Haulage traffic can push the frost line considerably deeper than usual, up to 5 m (18 ft) under the roadway, because of increased compaction, reduced moisture content, and the complete elimination of snow or ground cover.

In permafrost areas, most pipelines are installed aboveground in insulated utilidors for small-diameter installations. Pumps, valves, and other control stations should be enclosed, heated, and insulated to prevent freezing. Steel has a much higher heat-transfer rate and is usually much thinner than HDPE, so the pipes will begin to form ice at the fittings and flanges quicker. The pump crew should be equipped with a propane-fired burner to thaw valves that have frozen in place. Water standing in dead zones will freeze rapidly, preventing the actuation of the valves.

The time that it takes pipes to freeze depends on initial water temperature, pipe-insulating value, heat transfer rate, outside temperature, heat capacity (C_p) of the water, and the latent heat of fusion. Once the water reaches the freezing point, the time required for freezing the pipeline is shown by the first term in Equation 9.5-1. The second term in Equation 9.5-1 is the time required to lower the temperature of the water from an initial temperature T_i to the freezing point. If at some point the pump becomes available before the pipe freezes solid, water could flow and begin thawing the ice by applying the wasted energy from the system inefficiency. Large-diameter (40.6-cm [16-in.]) pipe can be laid on the surface in very cold areas if outages are kept within the heat capacity of the water. Even a small flow will prevent freezing in the pipeline; however, exposed valves and metal fittings may initiate freezing faster. Snow piled on a pipeline acts as additional insulation, further adding to the time available to get the pumping system back in service.

$$\text{time} = \left(\frac{R(\text{mass})H_f}{\text{area}\Delta T}\right) + \left(\frac{R(\text{mass})C_p(T_i - T_f)}{\text{area}(\text{average}\Delta T)}\right) \quad (9.5\text{-}1)$$

where

R = insulation value per inch, 0.17611 ((m^{2}K)/W), ((1 h-ft^2°F)/Btu)
mass = fluid mass per unit length of pipe
H_f = latent heat of fusion
area = outside area of pipe
ΔT = temperature differential between outside air and fluid

C_p = heat capacity of water 4.187 kJ/(kg-K), (1 Btu/°F-lbm [pounds-mass])
$(T_i - T_f)$ = difference between initial temperature and freezing point

Example 1. The following example of Equation 9.5-1 calculates the time to freeze the entire mass of 0°C (32°F) water setting in a pipeline at an ambient temperature of –40°C (–40°F).

Pipe characteristics (derivation not shown) for this example:

- SDR 15.5, 40.6-cm (16-in.) outside diameter pipe, wall thickness 26 mm (1.03 in.)
- Internal diameter, 353 mm (13.9 in.)
- Mass, 29.7 kg (65.7 lbm) water per foot length
- Latent, H_f for water, 334 kJ/kg (144 Btu/lbm)
- Outside area of pipe, 0.39 m^2 (4.18 ft^2/ft length)
- Insulation, R = 0.053 (m^2K)/W (0.3 (h-ft^2°F)/Btu)

Solution. Time to freeze solid

$$= \left(0.3 \frac{\text{h-ft}^2\,^\circ\text{F}}{\text{Btu}}\right)\left(\frac{1 \text{ linear ft}}{4.18 \text{ ft}^2}\right)\left(\frac{65.7 \text{ lbm water}}{1 \text{ linear ft}}\right)\left(\frac{144 \text{ Btu}}{\text{lbm water}}\right)\left(\frac{1}{72^\circ\text{F}}\right)$$
$$= 9.4 \text{ hours}$$

Pipes begin freezing where the sections are most exposed and where internal structures allow ice to anchor, such as elbows, fittings, and valves. As freezing progresses, these areas fill with ice and push water pockets ahead of them. This usually means that the last place liquid water pockets exist is inside walls where the insulation slows down the freezing process and the pipe usually ruptures in the area where it is most difficult to repair.

Desert Pumping

Deserts uniquely challenge pit-dewatering operations in several ways. Extreme swings in seasonal rainfall require system designers to consider both too much and too little water. Water is usually (but not always) in short supply, except when flooding occurs. The sources are frequently deep wells drilled into alluvial valley deposits and may require long overland pipelines to bring the water to the mine site. Because the supply is usually short, the systems design must avoid waste or contamination wherever possible. The temperature range of deserts has extremely wide variations, both seasonal and diurnal. Electrically operated pumps need additional care to ensure that insufficient cooling does not shorten component life. Evaporation and reusing water can cause undesirable concentration of contaminants.

It is necessary to derate the HDPE pipe working pressure for conditions above 22.8°C (73°F). The working pressure ratings must be reduced 50% at 60°C (140°F). Pipe lying in the sun while empty or with the water not flowing can quickly reach this temperature. Pressure surges on start-up can cause the hot pipeline to rupture.

Anchoring pipe along narrow rights-of-way prevents thermal expansion cycles from expanding and deforming into sinusoidal loops (snaking), causing pipe encroachment onto the road. Deserts frequently experience large temperature swings exceeding Δ22.2°C (Δ40°F) daily. Allowing the pipe to lie in the sun with no flow to stabilize the temperature simply exacerbates thermal expansion issues.

Alkalinity or other mineral content of the water in the sumps increases with evaporation. Recycling increases this effect because limited freshwater sources are available for dilution because of arid conditions. To prevent processing issues, the buildup of dissolved minerals must be managed. Bleeding a small split off the main process stream and replacing it with fresh makeup water may prevent undesirable concentration of minerals. If the quality reaches unacceptable levels, it may be necessary to segregate water for less critical uses—for example, haul road dust suppression.

Seasonal monsoon rains can create an excess water volume that overwhelms the sump capacity. Storage reservoirs should be as large as practicable to capture and hold the excess runoff for use during the dry season. If too much water becomes a problem, an alternative to pumping from the pit can be spraying water into the air to enhance evaporation. This sometimes becomes a dilution issue with large collection areas on top of the leach dumps in solvent extraction/electrowinning circuits.

OPEN CHANNEL DESIGN

Open channel designs must include adequate safety factors to carry the required peak flow without eroding the channel and while maintaining sufficient freeboard to prevent overtopping. Manning's equation is the primary tool available to design open channels flowing under gravity at atmospheric pressure. This method covers the design of ditches, rivers, and culverts flowing partly full. Equation 9.5-2 is the basic velocity form. When combined with the flow discharge Equation 9.5-3, it creates the flow quantity Q, Equation 9.5-4, that the channel will carry.

Manning's equation:

$$V = \left(\frac{k}{n}\right) R^{2/3} S^{1/2} \tag{9.5-2}$$

$$Q = AV \tag{9.5-3}$$

$$Q = A\left(\frac{k}{n}\right) R^{2/3} S^{1/2} \tag{9.5-4}$$

where

V = velocity, m/s (ft/s)
k = dimension conversion factor—1 in metric (1.486 English)
n = Manning's friction factor, a unitless characteristic of surface roughness of the channel material normally ranging from 0.010 to 0.050
R = hydraulic radius, defined as the (area/wetted perimeter), m (ft)
S = channel slope, m/m (ft/ft)
Q = flow rate, m^3/s (ft^3/s)
A = flow area, m^2 (ft^2)

From the basin runoff outline given, the normal calculation sequence is to determine the maximum flow rate Q, then design the channel to carry the flow. However, Equation 9.5-4 assumes that the flow depth and channel geometry are known.

Hydraulic radius, depth, and area are interrelated variables and are dependent on the shape of the channel. Depth is the usual unknown value and is a non-isolatable factor in both the hydraulic radius and the area calculations. Because the flow depth cannot be solved directly, the usual methods

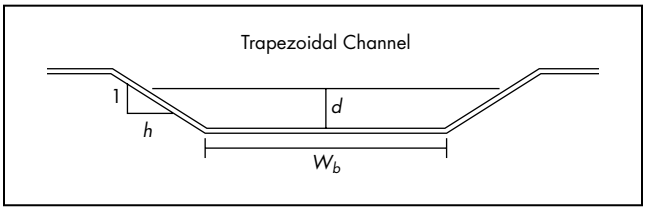

Figure 9.5-1 Trapezoidal cross section

of solution are to assume a channel width and depth, and then iteratively solve the equation.

$$A = W_b d + hd^2 \tag{9.5-5}$$

$$R = \frac{W_d + hd^2}{W_b + 2d(h+1)^{1/2}} \tag{9.5-6}$$

$$Q = (W_b d + hd^2)\frac{k}{n}\left[\frac{W_b d + hd^2}{W_b + 2d(h+1)^{1/2}}\right]^{2/3}(S)^{1/2} \tag{9.5-7}$$

where

W_b = bottom channel width
d = flow depth
h = side slope ratio in the design channel in the form h:1, horizontal to vertical
S = Manning's channel slope

Most channels built for mine drainage use trapezoidal channel cross sections. Figure 9.5-1 shows the general trapezoidal section parameters used to develop Equation 9.5-7. The hydraulic radius (Equation 9.5-6) and area (Equation 9.5-5) calculations are expressed in terms of the channel parameters: bottom width, depth, and side slopes.

If field solutions are necessary, spreadsheet programs with a solver function running on laptop computers or programmable calculators can be set to do these computations. The normal solution starts with Q as a known value from the basin design, and field constraints on W_b, d, S, n, and h.

Example 2. Parameters for a typical trapezoidal channel construction design might be the following:

- Required flow rate Q, 14.15 m^3/s (500 ft^3/s)
- Minimum bottom channel width (equipment width limited), 4.53 m (15 ft)
- Three to one (3:1) side slopes ($h = 3$)
- Channel slope, 0.005 (ft/ft) (0.5%)
- Minimum freeboard above the water surface, 0.61 m (2 ft)
- Maximum flow velocity to minimize erosion of 1.52 m/s (5 ft/s)
- Coarse gravel bottom Manning's roughness coefficient n, 0.045

Solution. From the preceding example, an iterated solution is

W_b = 5.3 m (18.8 ft)
d = 1.05 m (3.46 ft)
V = 1.51 m/s (4.96 ft/s)
Channel depth with freeboard = 1.66 m (5.46 ft)

The use of Manning's equation in the field by technicians or less experienced designers may lead to errors. Nomographs, graphical representations of the underlying relationships, which were widely used prior to the availability of modern computers, are safer. Nomographs for Manning's equation solutions are complex, making assumptions of the specific channels shapes, and are sometimes only valid for particular flow conditions. When using them, it is important to understand the underlying assumptions.

PUMP SELECTION

Most surface mine–dewatering systems use centrifugal pumps because of their wide range of operating characteristics. The required head (H) and flow rate (Q) will determine the pump design scheme. Operating pumps in parallel allows additional flow capacity beyond what is practicable for a single pump and provides system redundancy. Higher head requirements than single-stage pumps develop can be handled by utilizing multistage pumps driven from a single shaft or by using several single-stage pumps in series. Extremely high head applications such as grout pumping or underground dewatering may require positive displacement pumps: piston, diaphragm, variable cavity, or gear pumps. The flow pulsates because of the periodic nature of the pump mechanisms and requires dampening to prevent shock damage to system components (see "Issue: Water Hammer" section later in this chapter). Systems employing positive displacement pumps require more care matching the system's power, flow, and pressure capacity to the required operating point and are less flexible in changing conditions than centrifugal pumps.

Centrifugal Pumps

Commonly available centrifugal pumps have head ranges up to about 107 m (350 ft) in single-stage configurations with flow rates up to 681 m^3/h (3,000 gpm). Pumps are available that have capabilities exceeding these but are less common. Centrifugal pumps can be grouped into the following categories based on their configurations:

- End suction pumps use a single open suction eye from the side of the impellor with the drive motor on the other side. These are the most commonly used single-stage pumps but have high net positive suction head required (NPSHR).
- Double-suction pumps use a manifold to route suction from both sides of the impeller. The drive motor axis passes through both sides of the pump case and can be driven from either side. These are moderate NPSHR pumps.
- Vertical turbines use multiple stages driven from a common shaft and generate very high discharge heads. These usually mount through a horizontal deck with the motor above and require that the suction bell be submerged under the barge or in a deep well. These pumps require the least NPSHR because the suction and the first pump stages are submerged.

Pump Curves

The primary source of pump data is the manufacturer's data sheets. Manufacturers will usually supply a line card showing ranges of each family of pumps they offer, covering a wide range of head/flow requirements. This is the tool most designers use for preliminary screening of the specifications to find a pump with the appropriate capacity for the application. After a general pump family is selected, it is time to get the detailed data specifications from the manufacturer.

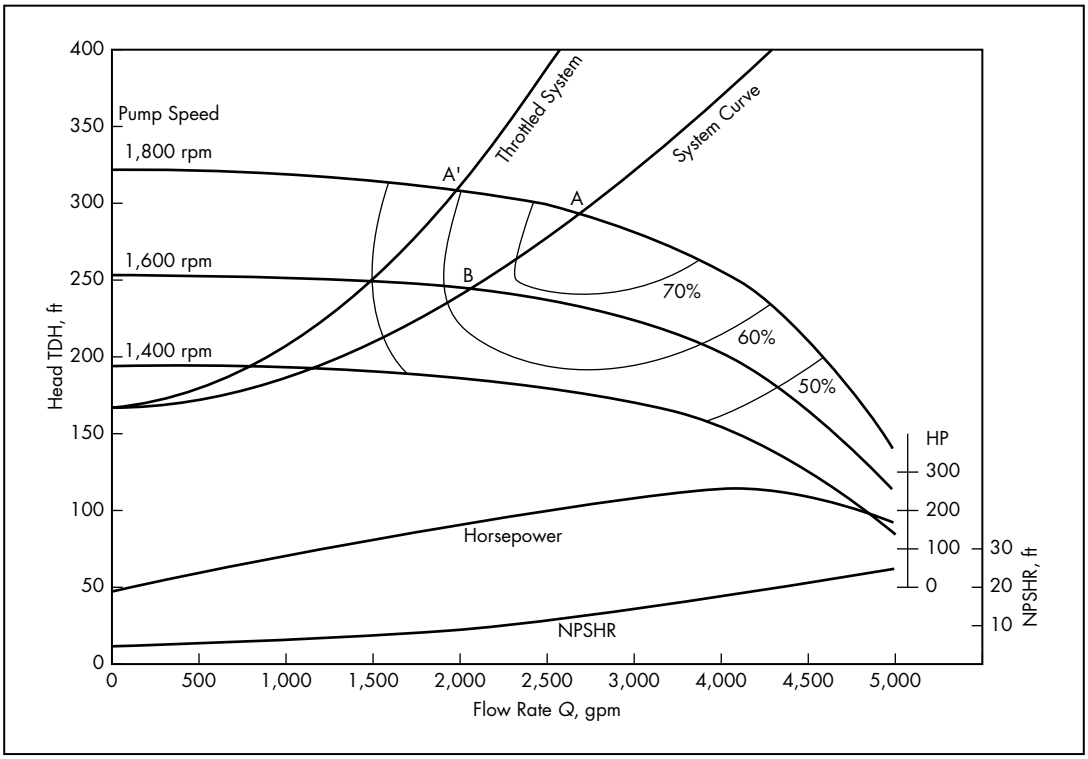

Figure 9.5-2 Pump system head curve

The following are some of the most important specifications that the system designer must determine from the manufacturer's pump operating characteristics curves:

- Total dynamic head (TDH)/flow (Q) range requirements
- Revolutions per minute (rpm)—motor rotational speed
- Driver type, coupling, and efficiency
- Power
- NPSHR

System Operating Point Example

Figure 9.5-2 is a typical system head curve (system curve) showing the pressure–flow characteristic curve for a pumping system. This system consists of a single-stage pump with field-variable rpm. The pipeline system has both a hydrostatic head (elevation lift) of 52 m (170 ft) and friction losses that increase as the flow rate increases. A family of curves that are rpm dependent represents the pump's TDH versus flow rate Q output.

The system curve lines represent the head and flow relationship of the pipeline, valves, and fittings. The system curve intersects the left side of the chart where Q is 0 at 52 m (170 ft) total static head. The pump must develop at least this amount of TDH to overcome the hydrostatic head and begin pumping water. As the system curve moves right with increasing Q, the curve starts to rise as friction losses increase. The difference between the total static head and the system curve is the energy either lost to friction in the system or used accelerating the water column in the pipe (velocity head).

The pump system operating point is the intersection of the system curve and the pump TDH curve: Point A, where the 1,800-rpm pump curve and the system curve intersect at 88 m (290 ft) TDH pumping 170 L/s (2,700 gpm).

This pump works at its best efficiency point (BEP) at a Q of around 177 L/s (2,800 gpm). Ideally, the designer would select a pump for the system that matches the operating point as close to the BEP as possible. Because of internal pump dynamics, the efficiency is not only a function of Q, but there is usually a shift in efficiencies when changing the rpm. Pump efficiency is overlaid on the pump curve and resembles a bull's-eye with the BEP in the center.

Each pump is designed to work within a particular flow range. Centrifugal pumps have a limited ability to continue to pump water past designed upper limits for the pump family. Flow in a pump has a maximum point beyond which TDH drops off rapidly. Above 659 m^3/h (2,900 gpm), the efficiency drops, and, by 1,022 m^3/h (4,500 gpm), the pump's TDH begins to fall rapidly. At zero flow, the TDH rises to the maximum head that the pump can develop (deadhead pressure)—98 m (320 ft). However, the pump is doing no work so the efficiency is zero; all of the input energy is wasted as heat.

Throttling

There are several ways to change the system flow to accommodate variable demand. In a fixed-speed system, such as one driven directly by an electric motor, the most common way to reduce the flow is by installing a control valve in the discharge pipe. The system head curve is modified by partially closing a valve, shifting the operating point from A to A' as the valve creates additional frictional losses, and reducing the flow from 613 to 454 m^3/h (2,700 to 2,000 gpm). The pump is still working hard, but the energy lost across the valve causes the hydraulic efficiency to drop.

In a variable-speed system, similar changes in the operating point require reducing the pump's speed from 1,800 to 1,600 rpm, which would shift the pump curve. This would move the operating point from point A to point B at TDH of 75 m (245 ft)

Table 9.5-1 Pump affinity laws

Characteristics	Speed Ratio	Impeller Diameter Ratio
Flow	$Q_1/Q_2 = (N_1/N_2)$	$Q_1/Q_2 = (D_1/D_2)$
Head	$H_1/H_2 = (N_1/N_2)^2$	$H_1/H_2 = (D_1/D_2)^2$
Power	$P_1/P_2 = (N_1/N_2)^3$	$P_1/P_2 = (D_1/D_2)^3$

and Q slightly less than 613 m^3/h (2,000 gpm). The efficiency would be better than if the system was throttled using the control valve method because less energy is wasted.

When considering a pump curve, the designer must be aware of several limitations that may preclude the system from achieving the desired operating point. Most pump curves show two additional curves that increase with higher Q: the hydraulic power required and the NPSHR (a characteristic of the pump from the manufacturer). Care must be taken when locating the pump to ensure that suction head requirements are met: The net positive suction head available (NPSHA) is above the NPSHR under all operating conditions. The pump driver must be able to supply sufficient power to overcome the pump inefficiency and the electrical losses of the motor and to supply the hydraulic power requirements.

Affinity Laws

Manufacturers design pumps for particular operating ranges, but within these ranges the curves can be shifted. Speed changes are practical methods for modifying the operating characteristics of pumps when the applications change in the field. The effects of changing the speed ratio between the original operating point and the new pump speed (N_1/N_2) are shown in Table 9.5-1. As can be seen, the flow ratio changes are linear with the speed ratio; head is a squared function, and power requirement increases as the cube. Speed ratio changes are most useful when coupled to a variable-speed motor. Keep in mind the old rule of thumb for rotating machinery that if you double the speed, the maintenance costs go up eightfold.

Impeller sizes/trimming ratios (D_1/D_2) have the same effects as changing speed ratios but are more difficult to change after manufacturing. This capability allows adjusting fixed-speed pumps to match the required operating point of a long-term installation without sacrificing the efficiency that a throttling valve would cause. Limited adjustments by reducing the impeller diameters can be done at the mine site machine shops, but this requires that the pumps be disassembled. Increasing impellor diameters is not possible without obtaining a new impeller from the manufacturer. Efficiencies suffer if the impeller diameter is significantly reduced from the original diameter (Casada 2006).

PIPELINES

Pipelines are the hydraulic analog of wires in an electrical system. Like the electrical system, the pipelines have carrying capacity (flow rate Q), voltage capacity (pressure ratings), and resistance to flow (H_f frictional losses).

Bernoulli's equation (Equation 9.5-8) shows the total mechanical energy in a fluid flowing in a pipeline as the HGL. The difference between the HGL and the Z elevation in the profile represents the gauge pressure inside the pipeline. If energy were conserved along the flow in a pipe, the HGL would be constant, and energy could be exchanged among the four components. The first three terms can be reversibly transformed one to another; however, the H_f is usually lost as heat from the system. All of the energy terms in Bernoulli's equation have units of length, allowing modeling the system HGL as a cross-sectional elevation grade line.

$$\text{HGL} = \frac{V^2}{2g} + \frac{P}{\rho g} + Z + H_f \tag{9.5-8}$$

where

V = fluid velocity
g = gravitational acceleration
P = internal gauge pressure
ρ = fluid density
Z = elevation or hydrostatic head
H_f = frictional head losses

The contributions of the individual energy terms (all in length units) are the following:

- HGL
- Velocity head ($V^2/2g$)
- Pressure head ($P/\rho g$)
- Elevation head (Z)
- Friction head (H_f) losses

Practical Graphical Solution for Rapidly Designing Pump Locations

One of the most straightforward ways to lay out a pipeline and locate booster pumps along the route is a graphical cross section. This process works because all factors in the dimensional analysis of the Bernoulli equation reduce to length. The sum of these factors represents the total energy in the system or the HGL.

The topography is drawn in cross section along the actual proposed route (Figure 9.5-3), scaled to compare the pit surface elevations against the HGL in the pipe system. When the HGL intersects the topography, the system has used all of the available energy, and as a result water will no longer flow. By using cross sections in this manner, it is readily apparent where to install booster stations along the pipeline route.

System designs use the high-pressure pipe in the bottom and lower-pressure-rated pipe (less expensive) as the elevation increases. The required pressure ratings drop as the pipe elevation increases (internal pressure decreases) and the H_f slope in the HGL flattens. The first pipe connected to the discharge of Pump A has the highest HGL, is at the lowest elevation, has the highest internal gauge pressure, and thus has the thickest walls required to resist bursting. The highest-pressure-rated pipes have the smallest inside diameters and the greatest frictional head losses (H_f).

Beginning at the sump, the HGL is at the water surface elevation. Entrance and suction side losses reduce the HGL further in the pump inlet piping (NPSHA). The pump adds energy to the system, raising the HGL by the TDH of Pump A. Continued plotting of the HGL in each pipe segment shows H_f as percentage slope related to the pipe friction losses until the HGL reaches the discharge location. Sumps, pumps, and discharge locations are included along the pipeline route.

The point where the topography intersects the HGL is the maximum elevation that the available TDH energy from Pump A can push the water. The booster Pump B is placed at an accessible location along the pipeline below the elevation of the HGL/topography intersection. The additional TDH from Pump B raises the HGL sufficiently to arrive at the tank with no further booster pumps required. The residual pressure

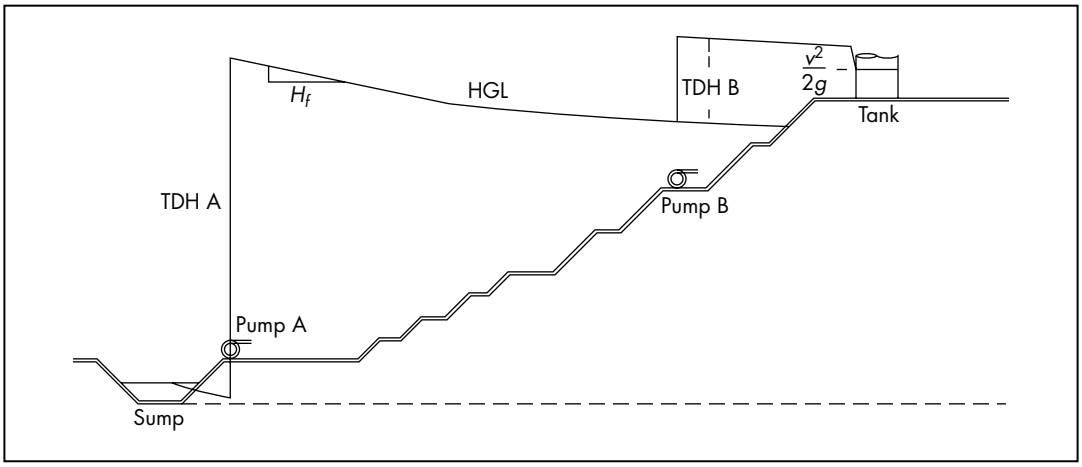

Figure 9.5-3 Pump station design cross section

in the line above the minimum necessary to reach the tank will accelerate the flow from the pipe end. At the discharge, the HGL consists entirely of velocity head as the pressure head drops to atmospheric and delta elevation term falls to zero.

After the pump locations have been determined, it is possible to increase the safety factor by systematically placing the booster pumps at lower elevations than the profile indicates. Note that Pump B is placed on a bench well below the HGL/topographic intersection from Pump A. This accounts for future wear in the pumps and scaling or system degradation, as well as for approximations in estimates of the minor head losses. This method assumes that the entrance, shock, and fitting losses are minor compared with the elevation change in the system. If this is not the case, more precision should be applied to the NPSHA analysis of the pump inlet structures.

Pipeline Material Selection

Selecting the appropriate pipeline materials for pumping projects involves balancing many competing characteristics. The factors that determine which material is best for any given project include the following.

Pipe material characteristics:

- Corrosion resistance
- Electrical conductivity
- Chemical compatibility
- Thermal expansion
- Cost
- Availability, lead time, logistics

Pipe materials:

- Metal
  - Carbon steel
  - Stainless steels
  - Copper
  - Ductile iron bell and spigot
  - Corrugated steel pipe (CSP)
- Plastic pipes
  - Polyvinyl chloride
  - HDPE
- Masonry
  - Vitrified clay
  - Concrete precast
- Composite
  - HDPE-lined carbon steel
  - Grouted steel

HDPE pipe:

- Ease of construction, joining
- Labor skills available
- Weight
- Ductility
- Strength
- Pressure ratings
- Temperature

High-Density Polyethylene

The invention of HDPE pipe is among the most influential products to appear in mining since 1960. Its unmatched combination of low weight, strength, flexibility, ease of installation, and corrosion resistance revolutionized pumping processes in mining. HDPE pipe has many advantages over steel pipe for use in the harsh mine environment. It is much more flexible than steel, allowing installation in areas where it would not be practicable to install steel pipe.

HDPE pipe is resilient and often more suitable in the mine pit environment than are metal or concrete alternatives. Occasionally, heavy equipment can be driven directly over HDPE pipes, although it is necessary to protect the pipe from damage with a thin layer of fine material or conveyor belting. Before driving the equipment across the pipe, the pipeline should be depressurized to limit the transfer of hydraulic pressure to other locations in the system. An HDPE pipe will crush flat and then begin to rebound immediately after the load is removed. Attempting this with any rigid pipe results in permanent deformation or crushing.

HDPE is resistant to most chemicals and is not subject to corrosion—crucial characteristics when dealing with acidic or caustic leach solutions. The main alternative material to HDPE for these applications is expensive stainless steels. Cathodic protection systems are not required for buried installations because the HDPE pipelines are nonconductive and not subject to galvanic corrosion. These characteristics give HDPE pipelines a design life of 50 years' service when buried.

The low density of HDPE makes it an ideal material to connect floating barges to the shore, and its flexibility allows

it to follow the barge as the water level changes. HDPE is slightly less dense than water; trapped air gives it enough buoyancy to float the pipe out to barge pumps.

HDPE pipe is the easiest material to work with in the field because of its low melting point. Joining HDPE requires specialized fusing machines that combine the three operations of the fusing cycle: (1) milling the pipe ends, (2) melting the surfaces, and (3) fusing the ends together. Typically, pipe larger than 6-in. diameter arrives at the job site as a truckload of 12.2- to 15.2-m- (40- to 50-ft-) long segments. The assembly process is considerably faster than welding steel pipes. Semiskilled workers with field-fusing machines can make three to four joints per hour. Because HDPE pipe is flexible and light, the pipe bed preparation requires little work, and small forklifts or backhoes are the largest pieces of equipment necessary to handle the pipe segments.

When it becomes necessary to make repairs, a chain saw is usually sufficient to cut out the damaged section and replace it with a new one, using the fusing machine. When repairs are necessary in areas that are too tight to excavate fully, it is possible to slip an electrofusion coupler over the ends of the broken pipe. This sleeve system allows repairs in inaccessible locations and contains its own internal heating elements. A generator is connected to an electrofusion controller, which melts the collar onto the pipes, sealing the ends.

Several characteristics limit the applicability of HDPE pipe in some situations. HDPE is limited to moderate pressures, with the upper end of its range limited to design pressures less than 2,068 kPa (300 psi) for SDR 6 pipe. The larger the SDR, the lower the pressure rating due to thinner pipe walls. Common working pressure ratings range from 207 kPa (30 psi) for SDR 40 pipe to 1,758 kPa (255 psi) for SDR 7.3 pipe. Steel pipe, on the other hand, has thinner walls and is useful for extremely high pressures. Additionally, the maximum depth of burial for HDPE is shallower than for that of steel.

The pressure ratings of HDPE pipe are temperature dependent, because HDPE is a thermoplastic with a low melting point. The designed pressure rating temperature is for a pipe at 23°C (73°F) and has a service factor of 2. The working pressure needs to be derated 50% for pipes installed at 60°C (140°F) and increased to 200% working pressure rating for installation at 4°C (40°F). As the temperature of the installation diverges from 23°C (73°F), the allowable pressure ratings continue to move toward both extremes. Ultimately, the pipe becomes brittle at very cold temperatures, crystallizing at about –101°C (–150°F), and softens and loses its strength as it approaches its melting point.

Other Pipe Materials

Other materials have characteristics that make them the choice for some circumstances. Composite grouted steel pipelines combine concrete, grout, or other masonry material as a liner inside steel pipe. These are useful in slurry pipelines, tailings, or culverts carrying large amount of debris where the main issue is erosion resistance. Galvanized CSP is one of the major culvert, manhole, and sewer construction materials. Zinc galvanizing offers corrosion protection, allowing long-term installations at competitive costs.

Combining welded steel pipelines with a liner of thin HDPE has the advantages of corrosion resistance of the HDPE and the pressure ratings from the strength of the steel pipe. Pipe joints usually use bolted, raised-face steel flanges, and inner smooth HDPE flanges to prevent the corrosive fluids from contacting the steel. These double-layer pipelines allow for integral leak detection by installing sample ports in the outside steel line.

Anchors, Point Loading, and Thrust Blocks

Anchors need to support the weight of the pipe, water, and live loads developed by the flow in the pipelines. These axial loads can be quite large where pipes hang from supports high on the side of pit walls. The pipe walls must also be strong enough to hold these loads between anchor points; the wall's strength determines the maximum distance between anchors. Pipes need support at pump stations and wherever they are attached to pumps, valves, or other fittings. It is poor engineering practice to allow loads from the pipe's weight to transfer through the flange bolts. Case deformation due to external loads may reduce internal clearances, causing unacceptable wear or binding in valves and pump impellers.

Thrust blocks are designed to help pipes resist the forces developed when water flow changes direction or velocity; for example, the thrust from an uncontrolled fire hose nozzle. Calculations for the thrust block must counter the changes in the momentum of the water stream. The impulse/momentum changes result from the forces applied to the water and resisted by the thrust block.

Confined Stress Due to Temperature Changes

Pipelines subject to changes in temperature will expand or contract proportional to the length of the pipe and the temperature change. HDPE pipe is particularly problematic in this regard, because it has a coefficient of expansion six times higher than steel, and its flexibility makes it less able to resist bending stresses. Warming pipelines can deflect into sinusoidal loops (snaking), and this may result in them moving off the designed right-of-way. Placing piles of earth on the pipe at regular intervals, called point loading, serves to control the lateral movement. If the temperature is high during installation, shrinkage occurs as the pipe cools. This can result in pulling the pipe completely out of fixed pump stations, tanks, or concrete anchors.

As an example of these issues using PlexCalc II, a 41-cm (16-in.) diameter SDR 15.5 pipe can be installed without taking into account thermal expansion. HDPE has a thermal expansion coefficient of 9×10^{-5} in./in./°F (Performance Pipe 2003). (Note: For a 22°C [40°F] temperature swing, a 914-m [3,000-ft] pipe changes length by 3.3 m [10.8 ft]).

Hot installation at 27°C (80°F) cooling to 4°C (40°F) is the short-term temperature change induced by pumping cold water into an empty pipe and will result in a tensile force of 107 kN (24,000 lb-force) trying to pull out the fittings. The change associated with cold installation at 4°C (40°F) warming to 27°C (80°F) will result in a compressive force of 160 kN (36,000 lb-force) if the pipe is constrained and must be guided at 49-m (160-ft) intervals to prevent buckling.

FIELD FLOW MEASUREMENTS

The two necessary measurements that indicate the current operating conditions of a pump are the pressure (head) and the flow rate (Q). The intersection of these two parameters defines the operating point on the pump curve. Many types of pressure gauges are available to obtain the head, but measuring the flow is more difficult. For permanent installations, flow measurements use preinstalled devices in the pipeline at strategic points to monitor flow. These include mechanical rotating

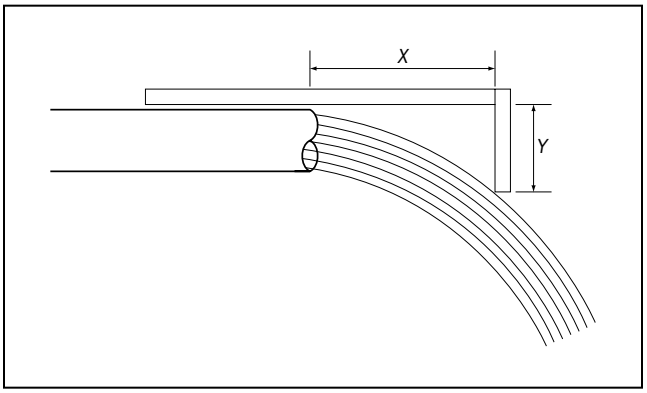

Figure 9.5-4 Pipe discharge drop method

vanes, hot wire transducers, differential pressure manometers with orifice plates, ultrasonic flowmeters, and numerous others. The common factor is that these devices (except the ultrasonic flowmeter) must be inside the flow to function. The ultrasonic flowmeters are portable and use transducers strapped to the outside of the pipe. All of these instruments measure the flow velocity (V): calibrating them for measuring Q requires knowledge of the inside diameter of the pipe to calculate the flow area (A). $Q = VA$ is used to calculate the flow rate.

Pipe Discharge Drop Method

The simplest flow measurement method is the pipe discharge drop, which can be used any place where the pipe protrudes from the bank and the flow discharge drops freely by gravity (Figure 9.5-4). This measurement method uses projectile kinematics to calculate the velocity of the discharge stream. The only instrument necessary is a calibrated stick for measuring the horizontal distance (X) from the mouth of the pipe to the point where the stream drops a fixed distance (Y). A folding carpenter's ruler is a perfect tool for this measurement. The ruler is moved until the distance from the top of pipe to water flow at the pipe end is Y: X, Y, and the flow depth are recorded as a fraction of the pipe diameter. Y is corrected for the wall thickness and compensated for the discharge running at less than full pipe flow to obtain the actual stream drop.

If the operators take measurements at the same locations frequently, it is a simple procedure to precalculate the tables matching the distance dropped because the pipe diameter, wall thickness, and table of partial area flow corrections are constant. Even better is setting up a spreadsheet with the parameters and calculations prebuilt to calculate flows from any pipe discharge, using Equation 9.5-9 to calculate the discharge velocity of the flow. If the flow is not a full pipe discharge, it is necessary to estimate the area of pipe flow. Precalculating a table with this conversion only requires measuring the fraction of the pipe diameter that contains running water.

$$V_o = \frac{X}{\sqrt{\frac{2Y}{g}}} \qquad (9.5\text{-}9)$$

where

V_o = discharge velocity
X = horizontal distance to measurement point
Y = vertical drop of flow stream adjusted for wall thickness and partial flow
g = gravitational acceleration

Open channel flows use similar schemes to determine the velocity of the water flow in natural channels. Various methods include measuring the time that wood chips take to traverse a known distance, allowing the observer to calculate the velocity of the surface flows. Measuring the channel cross section is necessary to estimate the flow area, allowing the flow rate to be calculated. This method neglects the vertical gradient in the velocity profile. Bubble streaming lines can give a visual representation of the velocity variations across the channel.

Weirs and flumes are calibrated structures installed into open channels that are useful for creating fixed gauging stations to measure flow. These use characteristics such as specifically constructed long-throated flumes or broad-crested weirs that correlate the depth of flow to the quantity traveling through the section. Long-throated flumes are replacing the previously used Parshall flumes because their streamlines are more linear and do not have to be calibrated in the laboratory (Swanson and Baldwin 1965). Many computer programs are available for designing flumes for specific flow.

MODELING, INSTRUMENTATION, CONTROLS, AND POWER

Bearing in mind the limitations of the accuracy of the hydraulic predictions previously discussed, an understanding of these highly complex systems requires simulation and modeling. It can be difficult to calculate the complete state of even the simplified system used in the "Simplified Control System Example" section. Given the construction costs tied up in systems that perform poorly, simulation is essential to design an effective pit-dewatering system.

Consider the piping network flow diagram as an interconnected series of arcs and nodes analogous to electrical networks. Many of the computer-based, pipe network modeling systems force designers to break the system down into basic components and assign characteristics to each before running iterative passes until the system operating point is found. Dewatering systems do not operate as disconnected discrete components (Wood and Lingireddy 2010).

Hydraulic networks simulations are based on the same mathematical relationships that govern electrical networks, the hydraulic equivalent of Kirchhoff's laws:

- The sum of flows into and leaving any node equals zero.
- The sum of pressure drops around any closed loop equals zero.
- Hydraulic simulations use specialized boundary nodes that have fixed pressures or act as flow sources or sinks.

Control System Components

Like the electrical network, hydraulic networks contain other components besides pipes (wires) and nodes (connections) that transform the pressures and flows. Components are specialized arcs that connect one or more nodes and transform the pressure, accumulate flow, or perform other specific functions. Table 9.5-2 shows some of the common modeling components in the hydraulic system, their electrical analogs, the functions they perform, and the number of nodes they connect to other components.

Because water is noncompressible under ordinary conditions, communication and feedback are necessary between different parts of the network. The problem is that unless

water accumulation components, such as tanks or reservoirs, exist somewhere in the system, the volume flowing into the system must be the same as that which leaves. To ensure this happens without incident, the components at the end must be able to communicate and control the components at the beginning of the pipeline. In order for this to happen, the system must contain the following components:

- Hydraulic sensors detect fluid levels, pressures, and the presence or absence of flow.
- Sensors detect the mode/state of pumps, valves, control positions, and system demands.
- Actuators, motor controls, and relays control the active components in the system.
- Communication links collect the inputs, transmit them to the command and control component, and send command signals to the actuators.
- The controller (the brains of the system) executes command and control logic, evaluates inputs, and sends appropriate commands to the actuators over established communications links.

Simplified Control System Example

Complex control relationships can be derived from the simplified network shown in Figure 9.5-3, which contains a pump drawing water from a sump and pumping it uphill through a second pump to a tank. For the following description, it can be assumed that pipeline from Pump A discharges directly into a tank feeding Pump Station B.

Hydraulic sensors are necessary to measure the state of the hydraulic network and should be able to detect if the sump contains enough water to prime the pump, fill the pipe, and deliver sufficient water to the tank. The system should have a sensor to detect if the tank needs water or if it is too full and, therefore, about to overflow. When pumping, flow sensors would tell the controller if flow exists downstream from the pumps in order to avoid damage.

In the simplified system, only one actuator is necessary to turn on each pump. The mode sensor to supply the feedback that this has occurred could come from an additional set of contacts to supply the binary state of the starter to the controller as an input, "on" or "off."

Communication links carry the inputs from the sensors and outputs from the controller. The controller is physically connected to these links and to the distant sensors and actuators through wires running to the controller. Other options require that radio links, wireless computer networks, or other telemetry hardware carry the signals. These have the advantage of not requiring physical cables, although they increase the complexity and potentially the cost of the communications network.

The command and control system (controller) is the intelligence behind the pumping system. The controller takes the inputs from the hydraulic and state sensors and the feedback from the actuators and applies the preprogrammed control scheme to create the appropriate action commands to the actuators. A controller can be as simple as a manual switch operated by an employee; when activated, it sends power to the motor and an indicator light, showing the pump status. Remote operations controllers (ROCs) allow the system controller to be located almost anywhere as long as the radio communication link is reliable. ROCs sometimes supply both the programmable controller and the radio hardware in the same box, simplifying system design.

Table 9.5-2 Hydraulic modeling components and electrical analogs

Hydraulic Component	Electrical Analog	Hydraulic Function	Number of Nodes
Pump	Battery	Adds pressure (head) between nodes	2
Valve	Switch	Opens or closes arc to flow	2
Flow control valve—partly opened	Rheostat or potentiometer	Modulates or changes flow by changing arc resistance	2
Tank or reservoir	Capacitor	Accumulates and releases water volume based on conditions (may also have fixed HGL elevation if used as boundary node)	1 or 2
Check valve	Diode	Allows flow in only one direction	2

Most of the modern controllers use some type of a programmable computer-based system. Programmable logic controller (PLC) systems are the most commonly used type of industrial controller. Programmers program a PLC using a simplified language called "ladder logic" that uses simple constructs to simulate signals that enable contacts, timers, and sequences to create the appropriate output for each system operation. Systems that are more complex run on larger computers incorporating powerful programming languages that can create internal simulation models capable of controlling entire water-handling networks with many components and interrelationships.

When the pump network has more than one stage in a series, it becomes necessary to interlock the pump stations and holding tanks. Intermediate tanks receiving water from below and supplying water to a local pump pushing up to the next stage must balance the flows to avoid overflowing the system. Normally, tanks in this sort of configuration use three level sensors to feed information to the controller about the tank level state:

1. High tank level sensor shuts down the lower stage pump—the tank is full.
2. Low tank level sensor shuts down the next stage pump—the tank is empty.
3. Mid-tank level sensor starts the next stage pump in the series when the tank has enough water to pump without quick cycling. This allows both stages to pump simultaneously for part of the cycle, improving the system's efficiency.

PUMP STATION DESIGNS

Design of pump stations must balance a number of competing constraints in the pumping system, especially the availability of electric power. The design life of the pump station at a particular location will determine the effort that goes into its layout and construction. The access quality and space availability for the station may also limit the selection.

Deciding on the type of motor to drive the pump is among the primary design constraints. Selecting the appropriate drive system depends on several competing characteristics. Under normal circumstances, diesel is generally the more expensive power source than electricity. However, at remote sites where

utility company electric power is not available, it may be less expensive to run the pumps from diesel engines than to use the same fuel to generate electricity for electric-driven pumps.

Diesel-Driven Pumps

Diesel-driven pumps are convenient to use for self-contained trailer-mounted pumps that operators can deploy quickly. This makes diesel pumps the choice for pumping water out of the shovel-loading faces or other in-pit situations where the sump must move every time the pit advances. The most effective pit-dewatering crews have a number of these pumps covering a wide performance range. The variable-speed operation inherent in the design of the diesel power plants allows considerable flexibility in the varying performance of the head and flow rates at the operating point of the attached pump.

The main disadvantage of diesel engines is that they require operator access for daily fueling and engine servicing. This requires maintaining an access road capable of carrying fuel trucks to the pump station as well as a turnaround area. The energy conversion efficiency of the best diesel engines falls far short of comparable electric drives. High-efficiency, low-speed diesel engines have thermal conversion efficiencies of more than 50% compared with electric motor efficiencies in the mid- to upper-90% range.

When using diesel engines, automation is not as viable as when using electric motors. Some diesel engines can operate remotely with sensors controlling the starting and stopping, but these features do not account for the fine-tuning that diesel starting and shutdown procedures usually require. The engine speed must usually be set manually, although pneumatic dashpot controls may allow automatic operation requiring a complex feedback system if the operating point is not constant.

Electrical Motor-Driven Pumps

One of the most critical parameters that determines pump performance is the rotational speed at which the pump operates. As discussed in the "Affinity Laws" section, changes in the pump's discharge head are proportional to the speed ratio squared. Maintenance costs for rotating machinery are proportional to the speed ratio cubed; doubling the speed raises the maintenance costs eightfold. The lowest rpm that meets the required operating point is the most reliable. Low-speed pumps usually cost more and are proportionally heavier than the higher-speed pumps to achieve the same performance, so the initial costs versus operating costs need to account for these factors.

Motors for common pumping applications are usually three-phase induction motors with power ratings ranging from 4 to 224 kW (5 to 300 hp). The rotational direction of the motors must match the designed rotation because centrifugal pumps can only run in one direction. When using a three-phase powered system, reversing any two phases to the motor changes the motor's rotation direction.

The number of poles, p, in the stator windings and power line frequency, f, determine the motor's synchronous speed:

$$\text{synchronous speed} = 120\, f/p \qquad (9.5\text{-}10)$$

Induction motors produce torque at any speed less than synchronous, so the motor's armature runs slower. Synchronous motor rpm ratings appear odd because of the armature lag; for example, a four-pole motor whose synchronous speed is 1,800 rpm may run at 1,750 rpm.

In synchronous motors, the more the motor speed lags behind the synchronous rate, the more current it consumes and the more torque it produces. This effect is highest during start-up when the motor's current can be up to 10 times larger than the normal running current. Starting requires special attention in order to prevent excessive current causing undesirable voltage fluctuations in the incoming power grid. Soft-start motor controllers are necessary on the larger motors, particularly if the installation is at the end of a long power line. Soft starters can also control the system's ramp-up speed, thereby effectively acting to control the dynamic shock effects to the system (see the "Issue: Water Hammer" section).

Electric-driven pumps are more suited for fixed installations that move infrequently, such as booster stations or floating barges. The selection of the electric pump operating point requires more engineering than does the variable-speed diesel-driven pump. The highest-efficiency installations couple the pump directly to its drive motor so the electric motor's speed must match the pump at the desired operating point. Field speed adjustments are limited to changing drive pulley ratios if the pump is belt driven. Otherwise, adjustments to the pump operating point involve throttling valves in the discharge pipe network with a commensurate loss of efficiency.

Ratios not obtainable by changing the number of poles are possible by using belt- or geared-drive systems. If variable speeds are necessary, variable-frequency drives (VFDs) can be economic for smaller pumps up to about 56 kW (75 hp). VFDs change motor drive speeds by electronically converting the line power frequency supplied to the motor, thus making a wide range of output speeds possible. However, this comes at a significant cost, both in acquisition and efficiency.

Automatic operation is easy to design into these pumps because numerous types of level switches or instruments for switching electric signals are available. Start-up against an empty pipeline may present problems keeping the pump "on the curve" because there is little backpressure until the water rises enough to prevent cavitation (a damaging condition caused when internal pressure falls below the vaporization point of the fluid (see the "Issue: Cavitation" section). VFD motor controllers are available that can control the start-up speed profile, gradually increasing the pump output pressure as the pipeline fills.

Pump stations with electric drives do not have to maintain regular access for daily operations, which makes electric pumps suitable for installation in difficult terrain and confined areas. The major constraint is that power lines or flexible trailing cables have to be run to the pump's location from the motor control panel. The starter panels and other controls must be located where operators have access, but these can be some distance from the pump.

Booster Stations

Pumps capable of handling large variations in the suction lifts are well suited for pumping from sumps but often do not have high head discharge pressures. This is where the pump system frequently combines booster pumps in a series with sump pumps, fully utilizing the best characteristics of both. Fixed booster pumps maintain constant discharge heads because the hydrostatic lift to the discharge location does not change. Fixed boosters stations may be in-line or tank fed with level controls that cycle the pumps to match inflows. Tank-fed booster pumps are normally designed to maintain the water

level above the suction eye of the pump, ensuring a positive suction head.

Floating Barges

The decision to use a floating barge system is usually a good fit when pumping the water from a long-term sump with fluctuating levels due to irregular or seasonal inflows. Water elevation changes result in changing pump static lift conditions that can affect the pump capacity. This can happen in very deep ponds where the surface elevation drops significantly during the life of the system to the point where the static head exceeds the dynamic head capacity of the pump. Booster stations may be required but can be added later if the barge pump's initial capacity is adequate.

When properly designed, barge pump installations do not suffer from suction head issues (NPSHA) because the pumps maintain a fixed distance between the pump inlet and the water surface. This is a dramatic improvement over trailer-mounted pumps that have to be moved down the ramp each time the water surface drops by between 3 and 4.6 m (10 and 15 ft). Increasing sump levels float the barge, whereas the trailer pump would risk inundation. Barge pumps are much less labor intensive to operate, but their installation and maintenance costs are likely to be higher.

Minimum water depth must be maintained in the sump to account for the pump and barge draft requirements. To avoid grounding the pump or sucking debris and rocks into the system, minimum clearance must be maintained between the suction inlet and the sump bottom. The suction line must be located deep enough to avoid the formation of vortices that suck air into the inlet screen or pipe. This is detrimental to performance and can cause the pump to lose prime. In horizontal centrifugal pumps, the flexible suction lines must be weighted to prevent the screen from floating too close to the surface, but they must also be supported to keep it out of the bottom sediments.

Bottom clearance issues can be a problem with vertical turbine-style pumps, because the intake depth is fixed by the design distance between the pump intake and the barge deck. This style of pump is more likely to ingest debris if the sump's water depth drops to the minimum necessary to float the barge. With proper barge design, the pump intake can be kept at a safe distance from the bottom by keeping the pump intake pipe shorter than the bottom supports of the barge, thereby leaving sufficient clearance.

The use of a vortex prevention collar around the suction intake can allow the suction to be closer to the surface than the flow would otherwise allow. This collar is essentially a fin that prevents the streamlines that are approaching the suction line from rotating. The depth required above the suction hose to prevent the formations of vortices is dependent on the pumping rate (McNally n.d.).

TROUBLESHOOTING PUMPING SYSTEMS

Because pumps are simple machines that are good at pushing water, a system that suddenly fails is most likely because of operator error. Upon pump failure, mechanics need to (1) check for improperly set control valves or broken valve shafts, (2) ensure that the source has water and the motor has power before blaming the pump, and (3) determine whether the discharge pressures are as expected and that the discharge pipelines have had time to fill with water. Depending on the diameter and length of the pipe, it takes a surprisingly long time for an empty pipe to fill enough to begin discharging (Equation 9.5-11). A 1.6-km (1-mi) pipe with a cross-sectional area of 0.1 m^2 (1 ft^2) will take almost 40 minutes to fill from a pump pushing 227 m^3/h (1,000 gpm).

$$\text{time to fill pipe, min} = \left(\frac{\text{area}(\text{length})k}{Q}\right) \qquad (9.5\text{-}11)$$

where

area = pipeline cross-sectional area, m^2 (ft^2)
length = pipeline length, m (ft)
k = unit conversion factor, 60 min/h (7.48 gal/ft^3)
Q = flow rate, m^3/h (gpm)

If the causes are not immediately apparent after checking the obvious, the second thing to do is look for changes in the system that may or may not have been intended. Changes in piping during normal maintenance are a common reason that pumping networks that have been running successfully for some time suddenly appear to fail. These include changes in length, pipe diameter, new valves, or other physical changes that could result in the pump capacity being no longer sufficient. Maintenance on the pipe may have created an air-locked condition in the pipeline or the pipe may be empty.

Issue: Air Locking Pipelines

Air in the pipeline can consume all available pump energy trying to push the air against the hydrostatic lift. An example is the force needed to push a balloon down to the bottom of a swimming pool. The air's buoyancy resists the flow in the pipe when flowing water tries to push the entrained air bubbles down from a local topographic high to a lower elevation. Under less extreme air conditions, the fluid in the pipe can flow under a relatively stable air pocket. Even in the flat-lying areas of the pipe, air bubbles restrict the cross-sectional area, increasing the flow velocity and friction losses in the pipe. Eliminating air from all overland pipelines prevents loss of pumping efficiency. Turbulence increases the friction losses, and gas compressibility robs the system of energy, converting it to heat.

Air release/vacuum breaker combination valves should be used at all significant topographic high points on the pipeline profile. These valves are usually large ball-check valves with a floating ball and must be installed vertically. Air release function allows the air bubbles out of the pipe where they naturally accumulate. The ball falls from the seat while air is present, allowing the trapped air to escape from the pipeline. When the water rises into the valve body, the ball moves up into the seat to seal the valve. If the flow conditions drop the internal gauge pressure into vacuum, the ball check falls back, allowing air into the pipe and preventing suction collapse. This is necessary to prevent vacuum conditions where the flow is intermittent or where the pipeline profile significantly declines in elevation, particularly when using HDPE or other flexible pipelines.

Pumping over a ridge frequently results in the hydraulic flow regime changing from pressurized flow (Hazen–Williams equation) to open channel flow in a partly filled pipe (Manning's equation). The pipeline flows with the pipe full until reaching the maximum elevation of the section. Depending on the flow rate, either the pipeline will develop a steady open channel flow or will begin cycling the trapped air bubble, as previously described. An air release/vacuum breaker valve will allow air into the pipe, thus smoothing the

flow, and should create a stable open channel flow. The pipeline may convert back to full pipe pressure flow near the bottom of the hill. Computations of the parameters in this sort of mixed-flow regime are complex. It is usually sufficient to be aware of the potential issues when evaluating a pipeline in rolling topography.

Issue: Cavitation

Cavitation occurs wherever the local flow conditions reduce the absolute pressure below the fluid's vapor pressure. Rapidly moving water creates low-pressure areas, particularly when passing through structures that result in flow area reduction, resulting in formation of bubbles. Velocity increases at flow-control valves, restrictions in the cross-sectional area, or around the ends of rapidly moving components as they reduce the pressure, causing the fluid to begin vaporizing. The bubbles themselves are not damaging, but, after the restriction, the fluid slows and the pressure rises above the vapor pressure. This causes the bubbles to collapse suddenly, resulting in localized shock waves and pitting.

Cavitation occurs most frequently at the suction eye of the pump impeller, behind the impeller tip, and on the downstream side of valves where this collapse zone exists. It occurs on pumps when NPSHA is less than NPSHR due to the design of the inlet piping failing to maintain a proper positive suction head. Fittings and elbows too close to the pump inlet can cause the restrictions and turbulence, leading to excessive friction losses. Cavitating pumps frequently sound as if they are pumping gravel even though no sediment is present in the fluid.

Issue: Priming

Priming the pump is the operation that removes the air from the pump body and fills it with fluid. Centrifugal pumps cannot handle much air in the pump chamber; below 0.5% is usually acceptable, but above 6% by volume, the pump's capacity is seriously degraded. Removing air from the pump chamber is necessary to allow positive suction lift to develop. Self-priming pumps usually have a vacuum pump to remove air from the pump case, allowing external atmospheric pressure to push the fluid into the intake. Foot valves (check valves at the end of the suction pipe) hold the prime by keeping water from draining back into the sump when the pump is turned off.

Issue: Insufficient Suction Head

Many pumping problems occur when the pump is located too far above the water surface of the feed source. The elevation difference between the suction eye of the pump and the water surface varies as the sump level changes. The pressure of the fluid must be higher than the vapor pressure at the suction eye of the pump at the operating temperature, or cavitation can result.

Pumps are efficient at pushing water along pipes, which is the main reason why they are useful in mining. There is a common misconception that pumps suck water out of sumps with equal efficiency, but this is not the case. Pumps must maintain a positive pressure at the inlet of the pump in order for water to flow (Equation 9.5-13). A pump's NPSHA is limited by available pressure P_o, the vapor pressure of the fluid P_v, the static head assisting (resisting), and minor losses h_L (Figure 9.5-5). The gauge pressure inside a pressurized tank, P_o would be equal to atmospheric pressure, P_a on an open sump. When calculating minor losses with Equation 9.5-12,

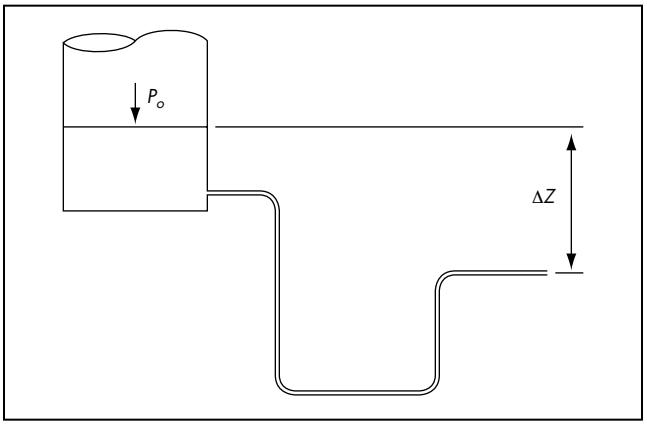

Figure 9.5-5 Simplified net positive suction head

the loss coefficient (k) must be used; this is a characteristic of the particular transition geometry.

$$h_L = k\left(\frac{V^2}{2g}\right) \tag{9.5-12}$$

The pump's inlet is frequently located above the water surface, requiring additional lift. The maximum NPSHA from an open sump is limited to the elevation-adjusted atmospheric pressure (P_a) less the vapor pressure of the fluid less the elevation head below the suction eye. The pump manufacturer determines the NPSHR while testing the pump during design and manufacturing. The operating point of the pump affects the NPSHR because minor losses in the entrance piping increase with higher velocity heads. The NPSHA must be higher than the NPSHR throughout the entire operating point range.

$$\text{NPSH} = \frac{P_o + P_v}{pg} + \Delta Z - h_L \tag{9.5-13}$$

where

NPSH = net positive suction head
P_o = pressure on the water surface (P_a if tank is not pressurized)
P_v = vapor pressure of fluid
pg = specific weight and gravitational acceleration
ΔZ = elevation head (lift if negative)
h_L = head losses due to transitions and fittings

Methods to solve problems on the suction side of the pump include the following:

- Lowering the pump closer to the water surface of the sump, reducing the static lift.
- Ensuring that the pipe is clear and the suction screen is not blocked.
- Reducing the length of the suction hose and increasing the diameter of the suction piping—both of which reduce friction losses in the intake piping.
- Ensuring that the suction side fittings are not leaking; air ingestion can break the priming.
- Ensuring that the pump is not cavitating; cavitation can have the same effects as air ingestion, limiting the pump efficiency.
- Ensuring that the foot valve is holding to maintain prime.

- Reducing the number of fittings and keeping them as far from the pump as practicable to limit the friction losses in the suction line.
- Ensuring that the pump is operating near the BEP.
- Splitting the load by using several smaller pumps in parallel instead of a single large pump.

Issue: Minimum Flow

Centrifugal pumps must have sufficient fluid flow to avoid overheating. Pumps convert the mechanical energy from the drive shaft into various forms, including

- Hydrostatic pressure (head),
- Fluid kinetic energy (velocity head), and
- Heat (friction losses).

Fluid flowing through the pump carries the heat from the mechanical and hydraulic losses in the system. If the system is prevented from flowing by closed valves, insufficient suction head, or insufficient discharge head pressure to overcome the system's static head, most of these losses are converted into heat, eventually causing the water inside the pump casing to boil. Explosions are possible if the pressure due to vapor expansion exceeds the maximum casing pressure rating.

Significant damage will occur to the pump impeller from cavitation at temperatures well below the normal boiling point. As the temperature increases, the vapor pressure of the fluid increases, resulting in more cavitation. This has the same effect of operating the pump with insufficient NPSH by increasing the necessary static pressure required to prevent vaporization.

Issue: Sediment, Debris, and Screens

The primary source of debris entering the pumping system is through inadequately maintained intake piping. The first line of defense is to install an appropriate screen over the suction pipe to prevent large solids from entering the pump suction. The suction hose should be kept above the sump bottom to prevent the flow from sucking debris onto the screen.

During construction, pipe segments must be inspected and cleaned before they are joined. When dragging pipes into place, the ends act as a scoop and can pick up a surprising amount of rocks and debris, which require flushing before closing the section. Large rocks will migrate along the flow and jam against valves, preventing them from properly actuating. Pipe that has been stored outside should be inspected prior to construction for animals that have moved in. In-line screens, traps, or cleanout fittings should be installed periodically in the pipe and located to protect valves, pumps, regulators, or other sensitive fittings. Drains and cleanout fittings should be placed where the discharge during cleaning does not cause damage.

When the pipeline runs through hilly country, it is important to ensure that the pipeline has sufficient drain valves installed at logical topographic low points to allow flushing of the system. This allows removal of sediment buildup in pipe systems before blockages occur and is particularly necessary if the pump system handles turbid runoff or slurry, because the solids will pass through the normal intake screen but may settle in the pipe.

Issue: Pressure Bleed Through Check Valves

In a high-lift multistage system, pressure can bleed through check valves, causing excessive hydrostatic pressure in the lower stages and resulting in pipeline ruptures when the pump system starts. Systems can experience problems with pipe segments splitting in the bottom stage of a series of pumps because of starting pumps against excessive hydrostatic head. This can be a problem when using pumps in a series without an atmospheric pressure break between stages.

Check valves are designed to allow flow in only one direction. When holding pressure against the upstream face, the valve closes, preventing backflow and holding the differential pressure across the valve. Pitted faces or improperly sealed valves allow small water seeps that can equalize pressure on both sides. Because water is incompressible, this can happen with little seepage volume over time in systems that have almost no trapped air.

The lower stages of the pipeline are the most likely to experience pipe rupture because the pressure cascades through multiple stages above. The dynamic head from starting the lower pump is added to an already overpressurized pipe segment. Indications of this problem show up in HDPE pipe sections that have been repaired numerous times. The solution is to design multistage pumping systems with transfer tanks between the stages at atmospheric pressure. More area is necessary for the pump stations, and the system will be less efficient, but the starting sequence and dynamic interactions are easier to control. An alternative would be to install accumulator tanks to allow expansion against a compressible air bladder.

Issue: Water Hammer

Water hammer is a dynamic shock/pressure wave that travels through the fluid in a pipeline. The primary cause is a shock wave created when the flow's velocity or direction changes rapidly. Water hammer shock waves can travel at the speed of sound in the fluid, not at the fluid flow velocity. The speed of sound in water can exceed 1,219 m/s (4,000 ft/s).

Equation 9.5-14 is a simplified peak pressure formula empirically relating pipeline pressure spikes and the transitions caused by rapidly closing the valves (Plast-O-Matic Valves 2002).

$$\Delta P = \left[\frac{(0.07)VL}{t}\right] + P \tag{9.5-14}$$

where

ΔP = pressure spike from water hammer
V = flow velocity in ft/s
L = pipeline length in feet
t = time in seconds
P = pipeline pressure in psi

For example, consider the magnitude of the pressure spike from an ordinary action: An operator closes a butterfly valve in a 4.8-km- (3-mi-) long pipeline flowing at 1.5 m/s (5 ft/s), thereby stopping the flow. The operator takes 5 seconds to close the valve on a pipe that is carrying 690 kPa (100 psi). What is the pressure spike from this action?

$$\Delta P = \frac{\left[(0.07)5\frac{\text{ft}}{\text{s}}\left(5{,}280\frac{\text{ft}}{\text{mi}}\right)3\text{ mi}\right]}{5\text{ seconds}} + 100\text{ psi}$$
$$= 8{,}270\text{ kPa}\,(1{,}200\text{ psi}))$$

Added to the hydrostatic pressure, spikes of this magnitude can overstress pipes, valves, and pumps, causing significant structural failures. Water hammer can cause oscillations in

both positive and negative (limited by vapor pressure and kinetics) excursions in a system, resulting in damage.

Valves should operate by controlling opening and closing times using automated valve actuators at programmable rates. Pump stations should have flywheels on the pumps to slow the velocity change rate, *dV/dt* during start-up, and unplanned power interruptions. Electrical motor soft starters should be used to ramp pump motor speeds when starting and stopping pumps. In some installations, the time constants for flow changes may be as long as an hour to limit system pressure damage. Water has inertia and carries considerable momentum when moving. The longer the pipeline and the higher the flow rate, the larger the mass that is moving. Check valves that slap closed rapidly when flow direction reverses are a common cause of water hammer.

Long pipelines with high flow rates need to have shock-absorbing structures designed into the system. Hydropneumatic dampeners, accumulator tanks, air traps, or air bladder tanks absorb and dampen shocks by using compressible gas and must be sufficiently large to absorb the shock energy expected from sudden transients in the pipe. Air release/vacuum breaker valves can be useful for allowing air into the pipe to cushion the shock of a water slug moving away from a closing valve. The air acts as a shock absorber, thereby limiting damage.

COSTS

Due to the cost of designing and building pit-dewatering systems, efforts to keep water outside the pit are usually a good investment. Intercepting and diverting water at the pit rim is less expensive than pumping from the bottom of the pit. The direct pumping costs include power, infrastructure, and required space designated for the pump stations and pipeline rights-of-way. Pit water may also require treatment before discharging off-site. Indirect costs can be significantly higher because of the effects that water has on productivity, reducing highwall stability, and safety hazards that the operation must mitigate.

Direct Cost Example for Pit Pumping

If a mine allows water to flow into the pit because of the lack of an effective diversion, at an average inflow rate of 6.3 L/s (100 gpm), this accumulates 200,000 m^3 (52.6 million gal) annually. Water has to be pumped vertically 305 m (1,000 ft) from the pit floor. If the pumping rate is 63 L/s (1,000 gpm), the pumps would need to run 10% of the time at 60% hydraulic efficiency of the pump and a power cost of \$0.05/kW·h. The annual costs in terms of power and the infrastructure to set up the dewatering system can be estimated using the applicable power equations in Equations 9.5-15 through 9.5-17:

$$\text{hydraulic hp} = [(H)(Q)(SG)]/3{,}960 \quad (9.5\text{-}15)$$

$$\text{hydraulic kW} = [9.81(H)Q(SG)]/1{,}000 \quad (9.5\text{-}16)$$

$$\text{brake hp} = \frac{\text{hydraulic hp}}{\text{pump efficiency}} \quad (9.5\text{-}17)$$

where

H = total dynamic head, m (ft)
Q = flow rate, L/s (gpm)
SG = fluid specific gravity

Results:

- Motor power required = 314 kW (421 hp) (without pipe friction losses)
- Annual power cost = 8,760 h/yr (10% duty cycle and 314 kW at 0.05 \$/kW·h)
- Annual power cost = \$13,770/yr in electricity

Infrastructure cost estimate:

- \$250,000 for 3,048 m (10,000 ft) of 8-in. pipe at \$25/ft installed (along 10% road)
- \$75,000 for three pumps with head capacities of 107 m (350 ft) TDH per stage, including motors at \$25,000 each

$$\frac{\$200{,}000 \text{ power to pit floor}}{\$525{,}000 \text{ total infrastructure}}$$

The annual cost for power in this example just to pump the water was \$13,770, or \$2,180 per L/s (\$138/gpm) allowed into the pit. These costs are avoidable (or at least reduced) by intercepting the water higher up the wall or diverting it completely.

Direct Cost Example of Hauling Wet Ore

Increasing moisture content increases the density of the material, adding to the costs of haulage and conveying. If the dewatering crew can lower the moisture content of the ore from 4% to 2% by improving water control at the shovel-loading face, a mine processing 89,290 t (100,000 st) per day saves 1,786 t (2,000 st) of excess water previously hauled to the crusher daily. This is the equivalent of pumping 21 L/s (333 gpm) of water out of the pit using the most inefficient of pumping systems—the haul truck. If haulage costs \$0.75/t, on an annualized basis, this reduces annual operating costs by \$548,000.

CHAPTER 9.6

Dewatering Underground Operations

Peter L. McCarthy and Malcolm G. Dorricott

The inflow of water can affect the cost and progress of underground mining, limiting the mining methods used and presenting hazards. Mine dewatering has effects both on the groundwater table, which is usually a shared resource, and on the environment receiving any discharge. Although many mines have been worked successfully beneath perched underground reservoirs, streams, lakes, rivers, and seas, there are also many examples of catastrophic inrushes. Experts such as hydrogeologists, hydrologists, and pumping engineers can contribute to the success of mining projects and should be consulted when appropriate.

The general objective in the control of water in underground mining is to permit safe, efficient work with acceptable consequences. The most common method of control is pumping. Where an impervious cover above a mineral deposit can be maintained, it may not be necessary to draw down the groundwater aquifer, provided accesses, including shafts, can be developed by grouting, ground freezing, or casing. Many salt, potash, and coal mines are of this type. Pregrouting with cement slurries can reduce the hazards of serious water inrushes and minimize delays during shaft boring or sinking, whereas cover grouting using chemical grouts can reduce inflows to underground development.

As part of any mine plan, an overall water balance is essential to ensure that enough water is available and that surplus water is managed and disposed of in an acceptable manner.

SOURCES OF WATER

The main sources of water encountered in underground mining are

- Inflows of surface water through natural (geological) conduits, mine openings, and boreholes;
- Inflows of groundwater through the natural permeability of the rock and from secondary (fracture) permeability;
- Mine service water, such as water used for drilling and dust control sprays; and
- Drainage from hydraulic backfill.

Although prediction of the volume of mine service water is straightforward, the magnitude of natural inflows sometimes can be difficult or impossible to predict until mining takes place. Nevertheless, experienced engineers, geologists, and hydrologists are able to make satisfactory predictions in many cases, so that appropriate control measures can be put in place. Sudden inrushes of water or mud can arise from

- Heavy rainfall events via mine openings or surface subsidence and caving zones;
- Unplanned connections to the sea, lakes, rivers, swamps, clay deposits, wet cover, tailings dams, and water dams;
- Connections to water pockets such as caverns in carbonate rocks and fault conduits;
- Magmatic water, if mining near a volcanic caldera; and
- Connections to adjacent flooded mines.

IMPACT OF WATER ON OPERATIONS

The presence of water in underground mines impacts virtually all operations and activities. Its main beneficial effect is in the control of dust in drilling and during rock transportation. It also serves as a transport medium for hydraulically placed backfills and sometimes, as at the McArthur River uranium mine in Saskatchewan, Canada, as a medium for transporting ore.

The negative effects of water include the following:

- Increased heat transfer from the rock in hot mines
- Freezing in very cold mines
- Increased humidity, causing less comfortable working conditions and reduced labor productivity
- Reduced ground stability due to water pressure
- Corrosion of plant, equipment, and ground support elements
- Requirement for more expensive explosives
- Spillage from trucks and conveyors
- Water and mud rushes from orepasses and other sources
- Erosion of roadways, particularly ramps
- The need for special precautions for mining in the presence of water under pressure
- Increased power consumption for pumping and ventilation

All of these impacts add to the cost of mining, and in extreme cases may be the difference between profit and loss.

Peter L. McCarthy, Chairman and Principal Mining Consultant, AMC Consultants Pty Ltd., Melbourne, Victoria, Australia
Malcolm G. Dorricott, Principal Consultant, AMC Consultants Pty Ltd., Melbourne, Victoria, Australia

PREDICTING WATER INFLOWS

Prediction of water inflows requires an understanding of the climatic and hydrogeological factors plus any existing human-caused conditions, such as abandoned boreholes and nearby flooded mines, and the effects of planned mining work. Many sites present no significant water problem, but this should never be assumed. It is difficult to predict groundwater flows into underground mines, as they are dominated by structural controls that usually cannot be identified from exploration drilling. Hydrogeologists have access to sophisticated numerical modeling tools, but experience shows that these models often fail to accurately predict inflows to an underground mine because of the lack of data, particularly in the early stages of a project.

To maximize the reliability of predictions, data should be collected at all stages of a project or mine development. Each mine should have an efficient data management system, which covers the collection, storage, and distribution of the data to the relevant people. The data to be collected at each stage of a project or mine should be determined by a group of competent persons prior to work commencing. For example, the following is a checklist for the collection of information required for the prefeasibility stage of a mine project:

- Topographical information
- Rainfall quantity and intensity data
- River flow and flood level history
- Tidal levels and flows
- Earthquake frequency and strengths
- Climatic conditions including temperature, humidity, and evaporation rates
- Surface water runoff characteristics
- Groundwater characteristics including levels, salinity, temperature, recharge, discharge, and general flow directions
- Hydrogeological conditions, including geological units and their permeabilities and storage, and general geological features (faults)
- Information on soil and rock types, their characteristics, depth of weathering, and so forth

Precipitation and Runoff

To predict the likely inflow from a single precipitation event is quite straightforward and can be calculated from the following equation (rational method):

$$V = C \times i \times t \times K$$

where

V = volume of potential inflow
C = catchment area
i = intensity of precipitation
t = duration of event
K = runoff coefficient

It may be useful to consider the rate ($Q = C \times i \times A$) as i is a time-dependent variable (and A = area). The catchment area can be estimated from topographic data and an understanding of the regional hydrogeological conditions. It may be feasible to reduce the catchment area by diversion of water courses or containment.

Intensity is derived from historical records. However, a choice must be made as to which event should be the basis for design. Typically, a 1-in-100-year event is considered reasonable, assuming such records exist for the location, but the expected life of the operation needs to be taken into consideration. A short-duration mine is less likely to receive such an event than one that has operated for decades, but many mines have much longer lives than initially expected. The decision should be based on a risk assessment and a realistic consideration of the consequences of the scenario selected.

The runoff coefficient must be selected carefully, because high-intensity events are more likely to occur when the ground is already wet from normal precipitation, thus initial abstraction is small.

There is also a trade-off between storage capacity and pumping rate. Once the inflow volume of the worst-case scenario has been estimated, the option exists to divert the inflow to available storage and pump it out slowly after the event or to cope by matching the pumping rate to the expected inflow rate. The best option is usually somewhere between these two extremes. Of course, storage capacity must be empty if it is to be relied on in an emergency.

An example of such a calculation is provided for the Mount Lyell mine in Tasmania, Australia (Atkinson 1982). At the time, the open-pit mine, located in an area of high rainfall, was transitioning to an underground mine, with breakthroughs from the underground mine to the base of the pit. The emergency storage capacity required for a 1-in-50-year storm event was calculated from the following equation:

$$\text{required storage capacity } V = C \times i \times t \times K - (\text{pumped volume} - \text{other inflows})$$

$$V = 45 \times 10^4 \times (1–0.25) \times 1.1 \times e^{(3.2 - 0.58 \text{ Ln } t)} \times K - (600 \times 0.75 - 60) \times 3{,}600 \times t \times 10^{-6}$$

where

- The catchment area C is 45 ha or 45×10^4 m^2, and the proportion of runoff intercepted and diverted away from the mine is 25%
- 10% of the rainwater flow returns to the mine from the mud displacement pump system
- The 1-in-50-year rainfall intensity-duration relationship is approximated by Ln i = 3.2 – 0.58 Ln t (Ln = log normal)
- The runoff coefficient (K) increases from 0.5 to 0.9 during the event
- Pumping capacity is 600 L/s with an availability of 75%
- The water inflow from mining operations and groundwater is 60 L/s
- The event duration (t) ranges from 1 to 22 hours

The results of this analysis (Table 9.6-1) show that the maximum storage required is 7.5 ML (megaliters) after 10 hours. A lower pumping rate would require more storage and vice versa. A cost–benefit analysis is required to determine the optimal balance, taking into account the level of risk.

Hydrological Studies and Modeling

Hydrogeologists, petroleum engineers, and civil engineers all start with Darcy's 1856 observation that velocity of laminar fluid flow through sand is directly proportional to the permeability of the medium and the hydraulic gradient. Hydrogeologists find pumping tests useful in predicting the performance of water wells. Petroleum (reservoir) engineers

Table 9.6-1 Emergency storage required for a 50-year storm

Duration, h	Runoff Coefficient	Intensity, mm/h	Storage, ML

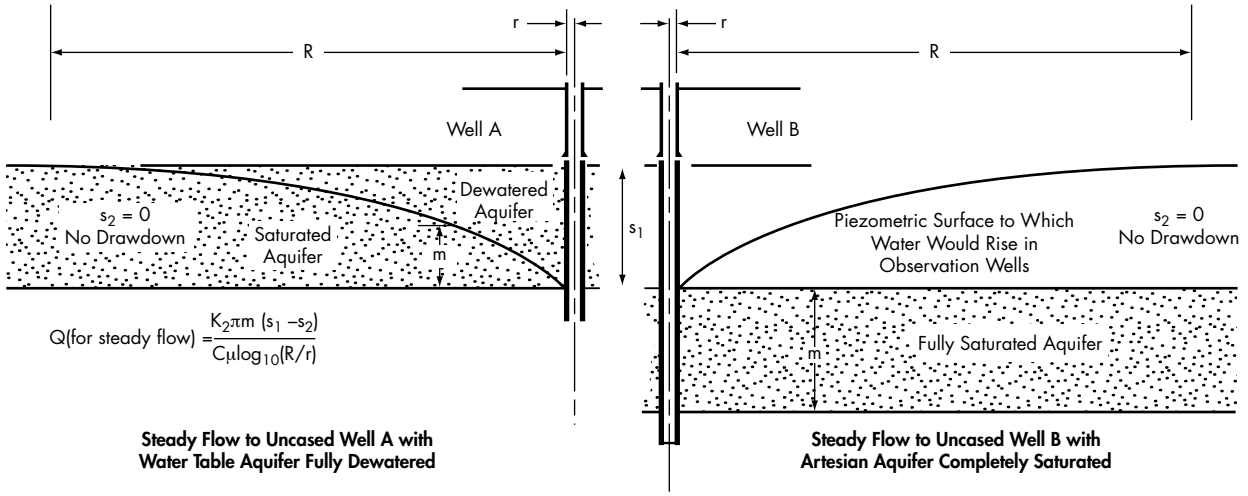
test within much deeper wells and on cores taken from them to forecast production of oil and gas. Civil engineers concentrate on soil moisture and the effects of pore pressure on stability. Efforts to calculate flow to tunnels, shafts, and underground mines are made difficult by complex geology and lack of data.

In simplest form, the water table, below which the ground is saturated, is nearly a horizontal plane. In a succession of layers of diverse permeability, there may be multiple water levels. Artesian water is trapped under a layer of comparatively low permeability so that water rises above the ground surface. Where permeability is irregular or discontinuous, the water level is similarly erratic. Where water feeds into the ground, the water table is higher, and groundwater flows from such points to lower points of discharge. The slope of most natural water tables is gentle, which usually mimics land surface, and the motion of flow is slow.

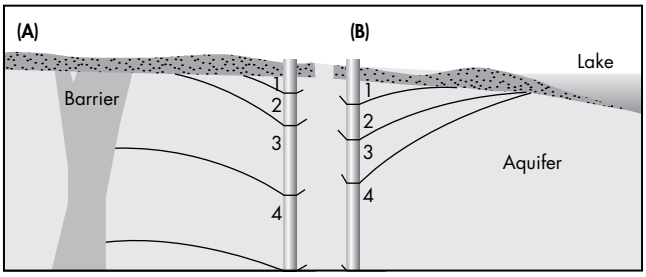


The water table, or piezometric surface, is depressed by pumping a well. The resulting gradient causes flow toward the well. The simplest analysis, such as the Theis solution (Theis 1935), is based on an ideal aquifer—homogeneous, isotropic, and horizontally infinite—and a perfect well, which is open to the full thickness of the aquifer or is very long compared to its diameter and thus receives water by horizontal flow. The depression is an inverted cone, symmetrical around the well. Its slope decreases logarithmically to the radius of effect where the depression is not measurable. If permeability is not uniform, the cone is distorted. Where water is only in fractures, it is discontinuous.

As a well is pumped, the drawdown increases until the well is dewatered or until, because of the steepening gradient, the rate of inflow balances the pumping, and flow becomes steady (Figure 9.6-1).

As the cone expands, its shape may be changed by masses of higher or lower permeability or by recharge or barrier. Schematic profiles in Figure 9.6-2A show the extreme effect of a barrier surrounding a shaft being deepened. Those in Figure 9.6-2B show the effect of an irreducible recharge (e.g., on a shaft being sunk in the center of an island). The cone around such a shaft expands normally in Stages 1 and 2, but its shape is changed by a barrier or continuing recharge.

The void space within a soil or rock is referred to as its porosity. The amount of water that can be stored within the porosity and subsequently released is referred to as *effective porosity* or sometimes *coefficient of storage*. The total porosity of shales and clays is very high, generally greater than 25% and in some cases 50%, but the water is absorbed in the crystal structure and cannot be removed easily, whereas the intergranular spaces are typically so small that movement of water under usual conditions is negligible unless huge areas are considered. Most of the porosity of coarse sandstones is effective as storage. Close-spaced open fracturing can give dense rock important storage capacity, but it is rare. Solution cavities can provide storage in otherwise dense limestone and dolomite. Some lava contains ash, erosion surfaces, and tubes with high permeability and more or less storage. Weathered surfaces of most strong rocks are likely to carry water. Induration (hardening) closes pores and fractures.



The amount of water that can actually flow through and from the rock mass and into the mine depends on the

Note: In Well A, 100% dewatering is, in fact, impossible; if water is to continue flowing to the well, there must be some saturated wall through which it passes.

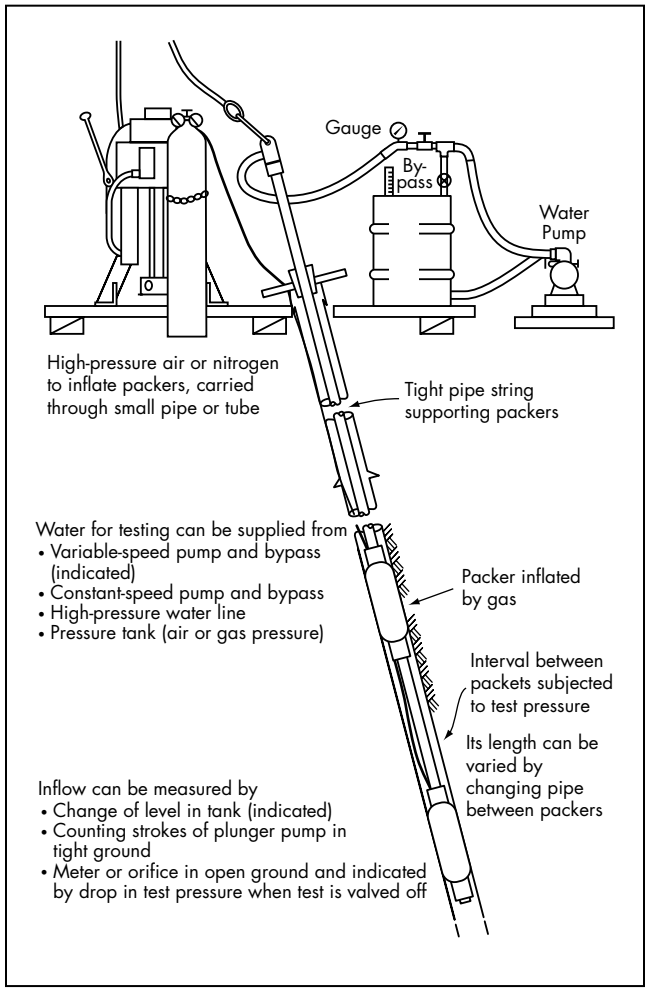
Figure 9.6-2 Extreme effects of a barrier and continuing recharge



permeability of the rock mass and, more importantly, the presence and permeability of flow paths such as faults, shears, and bedding plane breaks. These are generally not measureable before mining, hence the limited value of modeling. Pumping tests can sometimes yield limited guidance.

Pumping tests are made by pumping water from a well at a sufficient rate long enough to lower the water level measurably in several observation wells, which should be at prescribed locations with respect to the pumped well. The pumped well should penetrate the entire aquifer and, in usual tests, receive water freely from all of it. In thick aquifers this may not be possible, but useful conductivity data could still be obtained. The time and cost of pumping tests generally limit the number that can be made on a project. Hence, it is difficult or impossible to determine properties of more than one part of a complex rock mass, indicate uniformity of any part of the mass, or establish averages that can be used with confidence. Where these points can be determined in other ways and where the test can be set up to provide the information needed, there is no better source of data.

Pressure tests with packers are water injection tests, in some ways the reverse of pumping tests, but they can be made in holes of usual diamond-drilling size, and the packers can be set to test any interval of open hole and can be reset repeatedly (Figure 9.6-3). Generally the water pressure at the section under test can be between 1.1 and 2.5× the hydrostatic head without danger of opening fractures. Where permeability is high, there is an advantage in testing at a low pressure difference to limit pipe friction and the likelihood of turbulence. Where it is low, a higher pressure difference provides a measurable inflow more quickly.

Packers may fail to seat where erosion of weak rock has enlarged the hole and water can leak around them through fractures or connected pores. Such leakage can be reduced by using long packers, by making successive tests below a single packer near the bottom of the hole as it is deepened, and by testing below double packers. A series of tests can be checked by a single test of the same section of the hole. Leakage around packers or through pipe joints leads to overestimating inflow. However, any mud or grease caked on the walls of the hole would have the opposite effect.

Borehole flowmeter surveys may be used to measure water flow patterns within a well. The flow log reveals zones of water entry and exit and allows flow contributions from individual zones to be measured. Spinner flowmeter logs are used during well pump tests to measure hydraulic conductivity. With very low flow rates, the spinner flowmeter may be insufficiently sensitive. The heat-pulse flowmeter may be used

Figure 9.6-3 Pressure tests with pneumatic packers in straddle configuration

in a stationary mode at selected depths to detect linear flows down to 1 mm/s.

Holes can be cleaned by swabbing (i.e., pumping by repeatedly lifting a column of water above plastic cups on a wire line inside a string of casing or tubing which may extend 100 m or more below the water level in the hole). Measurement of the rate of water level recovery after swabbing is a negative-pressure test. The swab can be run inside tubing on which packers are set to determine inflow from the interval between them and to sample the inflow.

A series of tests between packers efficiently expanded and contracted from the surface can be made at the rate of one to three tests per hour. Packer tests take time for lowering and recovering the packers and setting up for each test. Drill-stem tests are made with a special tool lowered into the hole on a string of drill pipe. Above the tool is a packer, which can be expanded to close off the bottom of the hole. The tool can be placed between two packers to test the section enclosed. A pressure transducer and data logger can record the pressure increase as the tool is lowered, the shut-in pressure in the test section, pressure changes during the test, and pressure decrease as the tool is being removed. To start the test,

a valve is opened, permitting fluid to flow from the ground through the tool into the empty pipe, and a sample is recovered. Potential production can be calculated from the rate of flow and the recorded bottom hole pressures. Each normal drill-stem test calls for a trip into and out of the hole with a string of tight pipe.

Use of Tracers

Tracers are put into a groundwater system at some point and used to indicate the direction of water movement and, in some cases, its approximate rate, by being recognized at a point or points downstream. None of the many tracers is ideal under all conditions. A tracer should

- Be recognizable after dilution, generally with portable equipment, in some cases in test holes;
- Be unimpaired by physical, chemical, or bacteriological reaction and adsorption with the water being tested or rock in contact with it—at least until recognized;
- Move with the water;
- Be convenient to use, reasonably available at moderate or low cost, easily soluble in water, and require no elaborate equipment or procedure; and
- Present no environmental hazard or cause anxiety to anyone.

Fluorescein, an extraordinarily intense coal-tar dye, usually is purchased as a red-orange powder. When dissolved in water it is a brilliant green. One part in 40 million ordinarily is recognized by sight. One part of good quality fluorescein in 5 to 10 billion parts of clear water can be recognized in a colorless tube about 1 cm or less in diameter by 1 m long, with a black rubber stopper or other black bottom. A number of tubes can be mounted side by side in a rack. Examination should be made by good white light in front of a white reflecting surface.

Tubes containing 0 to 0.002 ppm of fluorescein can be used comparatively. Fluorescein is not affected by carbonic acid but is made colorless by contact with peat, acetic acid, and mineral acids. It is unaffected even by long contact with limestone, sand, silt, montmorillonite, and other common clays. Its vivid color gives fluorescein a special advantage where it is desired to make results evident to all observers. Other dyes—fast crimson, congo red, methylene blue, and so forth—may be used similarly.

Chloride ion or salt is recognized in test holes by decreased resistance to electric current or chemically, providing dilution is not too great. Dense solution may be trapped in low spots. Otherwise, salt solution seems to move at the same rate as the water. It is obscured by any natural brine and changes the permeability of some clays. Bromide, nitrates, and other ions are also used.

Dextrose, recognized chemically, is not adsorbed and moves at the same rate as water but is attacked by soil bacteria and is more easily lost in dilution than radioactive isotopes. Radioactive isotopes are said to be recognizable in concentrations of 10^{-18}, but are generally precluded because of public sensitivity to their use.

The normal application is to place the tracer in a possible water source and watch for it to appear in the mine. For example, a tracer may be added to mine water discharge to show whether it is returning into the mine. This may be impossible if the suspected source is a very large body of water. If the mine is flooded, the tracer could be put in the mine and water pumped behind it to cause the tracer to be observed at the surface, although the results could be inconclusive.

CONTROL AND COLLECTION OF WATER

Planning for the control and collection of water must consider all possible sources under normal conditions as well as the possibility of extreme events.

Control of Surface Water

The following measures can contribute to management of inflows to an underground mine:

- Shaft collars and ramp portals can be built on elevated ground or surrounded by earth or rock bunds. Bunds should have a uniform level with no low points that could lead to failure.
- Where a portal is built within an open pit, it should be elevated above the floor of the pit.
- Surface earthworks should not unintentionally impede or divert natural stream and sheet flows.
- Shafts should be pregrouted and imperviously lined.
- Rivers can be diverted, lakes and swamps drained, and streams cleared and straightened to reduce direct inflow and recharge.
- Intakes (including stream beds) can be covered with rolled clay or concrete.
- Water can be intercepted in shallow wells or caught in water rings in shafts.
- Slopes should be cleared and drains built.
- Trees should be planted in low, flat areas to increase evapotranspiration.

The mine should have a procedure that will be followed to manage the effects of extreme weather events. For example, with normal rain, work should be continued but awareness maintained. If cyclonic rains are in the area, the situation should be monitored continuously on weather radar and crews withdrawn from high-risk areas. If there is flooding potential, work should be stopped, all crews withdrawn, and the situation monitored until danger has passed.

Management of Drilling

In a situation that could pose a threat to future mining operations (e.g., holes from a dry lake bed or frozen lake), all drill holes should be fully or partially grouted. During exploration, hydrogeology data should be recorded for future planning needs. When working underground in areas suspected of containing high-pressure underground water, the hole should be drilled using appropriate equipment and procedures.

Exploration drill holes must be cemented in some areas to prevent migration of water from different aquifers. If the hole is left unsupported, any soil or weak rock soon caves, partly plugging the hole and hiding it, after which treatment from the surface can be difficult. If an underground working is connected to a hole to which water has access, it may enter, perhaps with gas, at such volume and pressure that sealing from below is difficult.

The practice at one salt mine is to leave a 45,000-t pillar centered on the mapped location of each hole. The capacity of high-pressure water to ravel weak rock and, if it carries grit, to erode strong rock and metal must not be overlooked. An extreme example of the problem was the inundation and loss of the Diamond Crystal salt mine at Lake Peigneur in Louisiana (United States) in 1980, when an exploration drill hole broke into the workings. Even without being connected to workings, wet holes can decrease stability by permitting water to saturate and weaken clay shales and raise pore pressure.

Some holes, if kept open, could be used for observation of water levels, treatment, geological testing, telephone or electric lines, driving raises, and so forth. Exploration holes generally should be plugged securely before abandonment, or, if needed for communication or observation, pipe or casing should be set through all weak or wet ground.

It is sometimes useful to know the maximum flow expected if a borehole is encountered, so that emergency drainage and pumping capacity can be provided. Water freely supplied to vertical boreholes falls through them with head loss of 100%, meaning that the head loss per length of hole is unity. Flow can be estimated from the empirical Hazen–Williams equation, which in metric units can be expressed (Larock et al. 1999) as

$$S = (10.67\ Q^{1.85})/(C^{1.85} d^{4.87})$$

where

S = head loss (in meters of water) per meter of pipeline or borehole
Q = volumetric flow rate, m^3/s
C = roughness coefficient
d = inside diameter, m

Flow through a clean diamond drill hole can be estimated by substituting $S = 1$ and a typical value of $C = 115$ into the previous equation, then rearranging and solving. For an AQ drill hole (1.89 in. diameter), $d = 0.048$ m, and hence $Q = 0.0108\ m^3/s$.

Flows through clean holes of standard diamond drill sizes are shown in Table 9.6-2.

Table 9.6-2 Flows through holes of standard diamond drill sizes

Size	Diameter, in.	Flow, L/s
AQ	1.89	11
BQ	2.36	19
NQ	2.98	36
HQ	3.783	67
PQ	4.828	128

Prevention of Inrushes

A risk assessment is required to identify the necessary precautions to manage potential sources of inrush. Prior to mining beneath surface water, near underground water sources or old workings, water should be drained or pumped to below the current working level. If this is not practical, a minimum safe approach distance should be determined and maintained.

The maximum flood levels should be determined for all mining areas. Access to an underground working should be constructed above the expected maximum manageable flood level in that area. In flat land, sheet flooding to a depth of only 100–200 mm can rapidly erode a channel into an underground mine and flood it.

Surface water should not be allowed to pond or accumulate near mines and should be drained or pumped away. Where this is not possible, adequately designed and constructed bunding must be in place and the freeboard monitored. The migration of water under the bund should also be monitored.

No structures, dams, tailings dams, storage facilities, mine infrastructure, roads, or rock dumps should be built over the footprint of any underground workings if any potential exists for caving to the surface. Adequate crown and shaft pillars should be provided and monitored. Notably, rock dumps can be a significant water source for deep infiltration.

Underground dams, water storage facilities, slimes dams, or any other storage facility that might be damaged and cause an inrush should be properly designed and located so they are not influenced by mining-induced ground movement.

Where mining activity is close to the base of oxidation or the surface, the area should be fenced or barricaded and bunded. Allowance should be made for the angle of repose of the possible breakthrough area.

If tailings or surface water storage facilities overlie an underground mine, a risk minimization program should emphasize water diversion, groundwater drainage, and sound slope-stability practice. Monitoring should include checking the stability of structures on a regular basis, maintaining adequate storm freeboard, and having diversion structures to deal with an overflow.

Tailings should not be used to fill surface subsidence above working mines because of the potential for liquefaction and inrush through a relatively small subsidence opening. This was the cause of the 1970 inrush at Mufulira mine in Zambia, which caused the death of 89 miners.

Backfilling

Backfill is used with many mining methods and may be used to reduce the risk of subsidence and some forms of inrushes. Planning should ensure that

- Stope voids are sufficiently filled so that caving is minimized;
- Controls are in place to prevent the fill material from liquefying during placement or remobilizing due to subsequent water inflows and ground vibration;
- Fill strength is adequate to ensure stability during adjacent mining or pillar extraction;
- Fill should be drained so that it cannot remobilize; and
- Filling schedule limits the accumulated void space in the mine.

Design of backfill may include tests for particle size, water retention characteristics, field capacity, volume, abrasiveness, transportation systems, fluidity, the possibility of liquefaction, and the need for additives such as fly ash, cement, and gypsum.

During hydraulic filling of voids, monitoring should include pressures behind the barricades/bulkheads, ponding on the fill surface, the barricade/bulkhead integrity and drainage rates, and vertical filling rate.

Draining Underground Water

In some cases, making initial openings in tight ground to drain conduits or masses of wet rock has advantages, but the procedure may be complicated by one or more of the following conditions:

- High-pressure water, hot water, or dissolved gas
- Weak ground, unstable in contact with water flowing under high pressure
- Mud and grit causing or increasing erosion
- Uncertain location of wet ground or conduits
- Uncertain rate of inflow

To indicate the water's location, pressure, and perhaps something of the rate of flow, pilot holes usually are drilled ahead of development openings. Cover drilling, which is drilling in advance and to the sides of the heading with multiple holes, may be necessary for safety.

Tapping can be accomplished by developing an opening into the water source. Where water occurs in small conduits in a rock strong enough to resist erosion, the heading can be continued until the desired inflow is obtained. If water is carried by a well-defined clean conduit, this may still be a good approach, but drilling and blasting the last round is tricky, and, unless a pressure door has been built, only friction in the conduit and in the heading restrain the inflow.

With more time and cost, tapping can be controlled by driving to a safe distance from the wet ground, cutting a drill station, and drilling many radiating holes. The safe approach distance depends on the geology, water pressure, and knowledge of location. Where high pressure is expected, and especially where it could erode the collars of the holes, work must be protected by drilling an oversize collar hole and cementing a collar pipe with a bypass tee and a full-opening valve. Drilling is completed through this valve. Water is drawn from many points throughout a sizable rock mass, which may be important to minimize erosion. Because these holes are short, head losses of 10 to 40 m per 100 m may be acceptable. In this range, each 50-mm-diameter hole may produce 4 to 8 L/s, and each 75-mm-diameter hole, 12 to 24 L/s.

It may be worthwhile to utilize the pressure of tapped water to reduce the pump head. This can be done by piping water under pressure directly or through a settling tank, or *kettle*, to the pump suctions. If the concentration of sand and solids in the water is significant, then effective settling and regular cleaning of the pressurized settling tank can be a problem.

Grouting

Grouting may be used to reduce the water flow into workings, but flow reduction is usually accompanied by a pressure buildup behind the grout, which can be dangerous. In drive and tunnel construction it is good practice to grout and then drill release holes after tunneling passes the area, arranging for the water to be drained toward sumps.

Grouting can be used to

- Control water in shaft sinking and tunneling, rarely stoping, in weak or fissured wet ground;
- Reduce or stop flow past underground plugs and bulkheads;
- Reduce leakage from reservoirs, especially under dams;
- Consolidate and strengthen ground;
- Plug a conduit through which work has been flooded; and
- Make concrete for plugs and so forth with or without preplaced stone.

Limitations are notable. The grout operator controls the nature of grout and the rate at which it is injected into the prepared hole. The operator can limit the pressure and, in some cases, influence the movement of water in the spaces to be filled. Generally, the operator's picture of these voids and what happens in them is vague. After the grout has left the pipe into which it is pumped, it goes where it wants to, unseen. Although the existence of clay in voids interferes with cement grouting, appreciable water movement interferes with all kinds. Although new grout materials have increased the range of conditions in which grouting can be used, a degree of uncertainty persists.

The usual procedure is to drill the ground through casing anchored sufficiently to withstand the pressure to be used, test permeability, and inject a grout that should be chosen and used in accordance with the conditions and objectives. Conduits below the water table should be grouted before a heading reaches them. Thereafter, water movement is much more difficult to control. Deep holes usually are grouted in stages (i.e., the hole is drilled until a degree of permeability is found, then grouted). After the grout has set, the hole is drilled out, deepened, and again grouted. A method of stage grouting from the bottom up has been developed for grouting alluvium.

Where walls are to be built, grouting should precede walling, if at all possible. If not, grout pressure must be kept as low as possible. Pressure against the ground must exceed hydrostatic; ordinarily, it is not allowed to exceed the calculated vertical stress. In special work it may be desirable to open fractures by pressure exceeding the in-situ stress. After grout pumping is begun, it usually is continued without interruption until the planned sealing-off pressure is reached.

Dyes can be mixed with grout to tag various stages of injection. Grouting effectiveness is tested by drilling new holes between or near holes that have been grouted. The degree of confidence in the result depends partly on the uniformity of the ground and partly on the nature of subsequent work.

Cement grouts do not enter the smallest fractures or pores finer than those of coarse sand. Prior treatment of the ground and admixture of sodium silicate and bentonite improve penetration, but, even with this help, pores of medium sand are a limit. Bentonite decreases strength but improves the pumpability of cement slurries and gives body. It also acts as a dispersant, reducing or preventing *bleed*, or separation of water. Neat cement slurries do not set unless the cement particles are brought together at a specific gravity of about 1.5.

Setting time is reduced by use of high early-strength cement, by the addition of calcium chloride, and somewhat more by the use of special fast-set additives. High pressures and temperatures also shorten setting time. Sawdust, shredded plastic, and similar materials can be added to help plug large openings. As far as the delivery system and the size of the openings permit, fly ash, sand, and fine gravel can be added to reduce cost without sacrificing strength. Powdered aluminum reduces or counteracts shrinkage, but where the grout sets under high pressure its effectiveness is questioned.

The water–cement ratio is important in controlling the behavior of cement slurries. In grouting deep holes that cut openings of various widths, the usual practice is to start with a thin slurry (e.g., 5:1 water to cement or even 10:1 by weight) in the expectation this will get into the smallest possible openings. Average slurry on one series of shaft pregrouts was 4:1, and water was reduced to 1:1 where possible. Cement slurries of about 0.5:1 can be pumped. Slurries can be made to stand under water at 20° to 30° from horizontal. Trial runs should be made with unusual mixtures.

Acceptance of a large quantity of grout without pressure increase generally indicates that grout is running through a sizable conduit out of the ground that was intended to be grouted. Remedies may include thickening the slurry, adding bridging materials such as sand or chopped plastic, reducing the rate of pumping, and letting the hole stand for several hours.

Where large quantities of cement grouts are to be used for an extended time, labor may be saved and slurry quality improved by mixing at a central plant with bins, weighing devices, water meters, agitators, and pumps. With pressure, slurry can be pumped through around 1.5 km of 25-to-50-mm-diameter pipe while the plant and the grout operator are connected by telephone. For short jobs, a batching plant and truck mixers are useful.

Reciprocating simplex or duplex grout-fitted slush pumps are usual. Compressed air drive is convenient because of its flexibility. For low pressure, centrifugal pumps can be used, which usually are fed by gravity from agitators.

Ground Freezing

Ground freezing has been used extensively for groundwater control and excavation support in mining and underground construction since the late 19th century. The ground is frozen using coolant pipes to convert soil water into ice. The resulting frozen material is strong enough to allow a shaft to be sunk through deep saturated soils.

The coolant, which flows through pipes installed in boreholes, can be brought to temperatures well below –150°C. Once the ground has been frozen, much less power is required to maintain it in a frozen condition.

Drainage System Design

Mud and silt from blasthole drilling, fill decant water, road traffic in wet areas, and flow through caved or weak ground are problems in many mines, even where the natural permeability of rock is low. The drainage system must cope with the suspended solids load of the water. Drains alongside rail development at gradients of 0.5%–1.0% require frequent local sumps and associated ongoing cleaning, particularly if hydraulic fill is used. Rubber-tired equipment causes more mud to enter the drainage system and requires gradients of at least 2%, favoring a free-flowing system designed to minimize settlement before the main mine sump.

Drainage should be via a dedicated system of side or center drains, boreholes, pipes, and designated storage areas. It should not be directed into old stopes, passes, or other workings unless a risk analysis has been conducted for the potential of an inrush.

The benefits of controlling mud and water may include easier maintenance of track ballast or road surfaces; substantially improved tire life; neater, cleaner, and safer traveling ways; less water percolating to any lower work; and lower cost, less congestion, and less loss of time for cleaning.

Pumping stations should be located to ensure sufficient emergency storage below the station, which gives time to carry out emergency pumping repairs at maximum expected flow rates. There should be a contingency plan for inrushes due to pump failure, including emergency evacuation procedures.

Rising mains should be placed so that they can be regularly inspected to ensure no premature failures. The mine drainage system should be recorded on a suitable plan, such as a long section or isometric plan of the mine, so that it can be understood as a system.

Contingency Planning

Each site should have a contingency plan, which is enacted when a lead indicator exceeds its threshold value. The contingency plan, which is the responsibility of the mine or project manager, is a response plan that defines

- Levels in the lead indicator that would trigger escalating responses, including possible damage reduction;
- Those responses, including evacuation procedures;
- Ongoing monitoring requirements; and
- Types and sources of emergency support available.

In addition, the plan should be reviewed annually, when there is a change of scope in the mine, or following any major incident when the plan has been enacted.

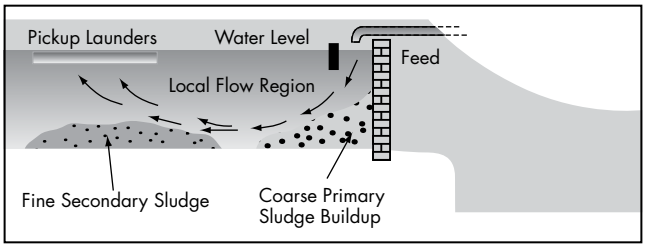
CLARIFICATION AND SETTLING SYSTEMS

Sumps are (1) accumulators to partially equalize the continuously changing rate of inflow and increase the regularity of pump operation, (2) reserve storage in which water can be held during short power interruptions and periods of suddenly increased inflow, and (3) settlers in which some suspended solids can be removed. Where pumping is substantial, the higher efficiency of separate settlers or clarifiers is advantageous.

Clarification

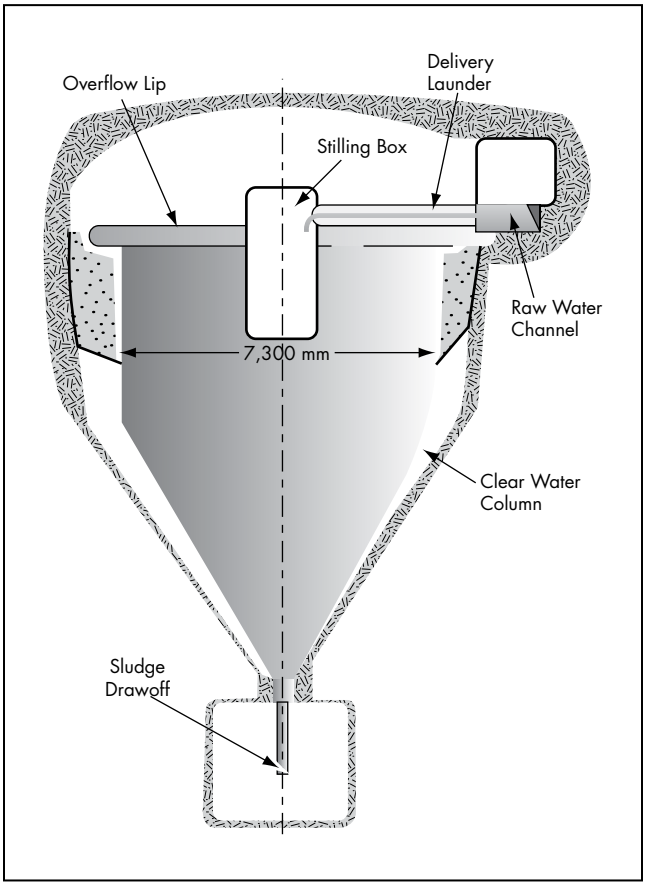
Removal of suspended solids from mine water may allow the use of more efficient clean water pumps, which is especially important in deep mines with large volumes of water to be removed. All clarification systems utilize gravity, sometimes assisted by inertial and/or mechanical means, to separate the solids from the liquid. Neutralization of acidic water can also be done at the settler. The most commonly used settling systems are described in the following paragraphs.

Horizontal Sumps



Long development openings are used with horizontal sumps, relying on laminar flow and retention time to allow the solids to settle to the bottom, with clean water discharging over a wall at the end or into a launder (Figure 9.6-4). The sumps must be periodically cleaned, so multiple sumps in parallel are the usual layout, with one sump cleaned at a time, either by pumping out as a slurry or removal by a loader. Baffles have been used to control velocities and improve settling, but their value is questionable and cleaning is more difficult.

The main advantage of these sumps is their simplicity and the absence of any mechanical devices. They are essentially labor free, except for cleaning. Their main disadvantage is low efficiency, requiring large excavation volumes, which makes them unsuitable for high water flows. To enable cleaning with mobile equipment, often the wall is destroyed and then rebuilt.



Vertical Sumps

Vertical sumps also rely on gravity and retention time to settle out the solids. They are circular in shape, sometimes with a cone at the bottom to facilitate mud removal (Figure 9.6-5). Their height is typically the distance between two sublevels. The dirty water flows in via a central pipe, which discharges at about one-third of the cylinder's depth, and clean water rises for removal via a ring launder around the top. Flocculants may be added to improve the settling characteristics of fine solids. Mud collects at the bottom and is removed at regular intervals, allowing continuous operation.

These settlers are more compact than horizontal sumps, are much easier to clean, and do not have to be removed from service for cleaning. The large-diameter (5–10 m) vertical openings require reasonable ground conditions and are typically lined with Fibercrete or concrete. Multiple units can be accommodated in close proximity to the pumping station, and the settled mud can be gravity fed to the mud removal system.

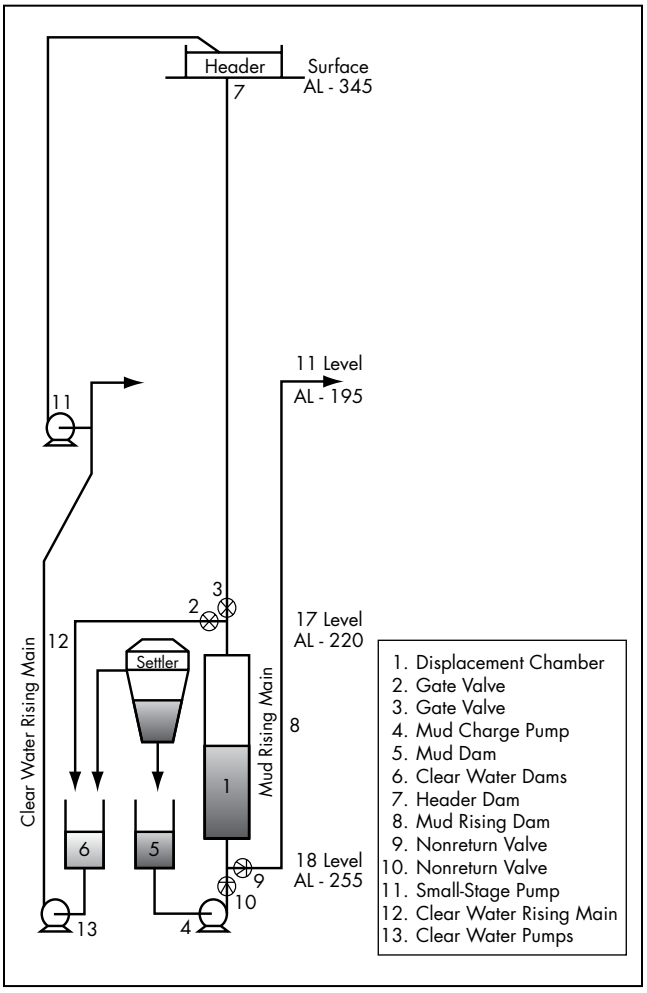
Figure 9.6-5 Cylindroconical settler

Vee Settlers

Vee settlers evolved to maximize the benefit from addition of flocculants to achieve high throughputs in relatively small excavations. The settler has three internal compartments—two for initial settling and one for mud storage and thickening (Figure 9.6-6). The dirty water is introduced under a floc bed in a V-shaped compartment. The clear water rises and is removed via a launder, while the finer solids are captured by the floc bed, which overflows into the central compartment where it thickens for eventual removal. Coarser solids settle in the vee compartments and are periodically released into the central compartment via drain cocks, which may be automatically operated. The sludge in the central compartment thickens and is drawn off for separate disposal.

Source: Adapted from Atkinson 1982.
Figure 9.6-6 Cross section of double-vee settler

Maintenance of a stable floc bed is the key to successful performance of these settlers. This is facilitated by dividing the long settlers into shorter compartments. The overall capacity can be adjusted by varying the number of compartments in operation.



Lamella Plate Settlers

In lamella plate settlers, the dirty water flows across a stack of parallel inclined plates. As the particles settle onto the plates, they slide down and out of the stream. Because the vertical distance between the plates is small, even small particles can settle out relatively quickly, provided the flow velocity is low. These devices are more commonly used in processing operations where space is at a premium.

Mud-Handling Systems

Thickened solids from settlers can be removed from the mine in a variety of ways. This material (sludge) often contains valuable minerals, particularly in a gold mine with coarse free gold, and should be delivered into the processing stream. Typical removal systems include

- **Mixing with other rock:** The sludge can simply be mixed with either ore or waste (depending on its value) and removed by the normal materials-handling system. This can be quite messy but may be satisfactory if the quantity of material is small.
- **Filtering:** The sludge may be dewatered to produce a moist cake by a filter press or vacuum filter for removal by the normal materials-handling system or separately, if desired.
- **Injection:** The sludge may be injected into the rising main, such that the clear water pumps remove the sludge

Source: Adapted from Atkinson 1982.

Figure 9.6-7 Mud displacement system at Mount Lyell, Tasmania, Australia

without being damaged by it. The velocity in the rising main must be sufficient to prevent settling of the coarsest particles.

- **Pumping:** If the solids are sufficiently fine, they may be pumped out by suitable slurry pumps.
- **Hydraulic displacement:** This method uses the head of a column of clear water, supplemented by some additional pump pressure if required, to displace the thickened slurry to the surface. The system was developed in South Africa and is used at Mount Lyell (Atkinson 1982), where the discharge tunnel is sufficiently lower than the shaft collar to eliminate the need for pumping, except for the flushing cycle (Figure 9.6-7).

PUMPING SYSTEMS

The design of pumping systems of even moderate capacity presents complications that require specialists but should be guided by those who are fully acquainted with broader plans and objectives of the work. The need to pump any inflow of water with complete reliability means at least one capable pumping unit plus one equal spare. In a three-unit system, any two should be able to pump the maximum inflow. The greater the number of units, the less the percentage of spare capacity, but beyond some point a larger number of smaller units will cost more and will have lower efficiency. Where only brief pumping interruptions can be permitted, duplicates of all essential parts must be provided, including power supply, pipes, and valves.

Positive displacement pumps are capable of handling dirty water and can greatly simplify the underground handling of water before it is pumped. In general, pumping for shaft-access rail mines is optimized with centrifugal pumps. The steeper gradients and greater volume of mud generated by mobile equipment in trackless mines favor the use of positive displacement dirty water pumps.

High-speed centrifugal pumps are capable of high efficiency provided close tolerances are maintained. They are vulnerable to wear by grit and essentially are clear water pumps. Therefore, means to remove suspended solids before pumping are an important consideration.

Unlike most positive displacement pumps, centrifugal pumps can be rotated without fluid flow. Because the power demand is least when no water is pumped, large pumps generally are started with discharge valves closed. Flow also is limited or stopped if (1) discharge pressure is not sufficient to force water into discharge pipe (as from extreme impeller wear), (2) passages anywhere in the pump system are plugged, or (3) pressure in the suction is insufficient.

Cavitation develops in the intake of impellers if pressure there drops below the vapor pressure of the fluid so that the fluid boils. The formation of bubbles reduces the capacity and efficiency of the pump, and their collapse damages it. To determine the potential for cavitation, it is necessary to calculate the difference between the total head on the suction side of the pump (close to the impeller) and the liquid vapor pressure at the operating temperature.

The net positive suction head (NPSH) can be determined from

$$\text{NPSH} = p_s/\gamma + v^2/2g - p_v/\gamma$$

where

p_s = static pressure in the fluid close to the impeller
γ = specific weight of the fluid
v = velocity of fluid
g = acceleration due to gravity
p_v = vapor pressure

The pump manufacturer will provide the required NPSH for a particular pump based on test work. The system should be designed so that the available NPSH is significantly higher than the required NPSH to allow for head losses in the suction pipe and in the pump casing, for local velocity accelerations, and for pressure variations.

Typical relations of suction head, total dynamic head, and specific speed (revolutions per minute) for single- and double-entry single-stage centrifugal pumps handling clear water at sea level are shown in Figure 9.6-8A. Figure 9.6-8B shows the various power losses typical of centrifugal pumps in relation to specific speed.

The affinity laws for centrifugal pumps can be used to relate flow rate, head (pressure), and power consumption to changes in rotational speed or impeller diameter.

The flow rate relationship is

$$q_1/q_2 = (n_1/n_2)(d_1/d_2)$$

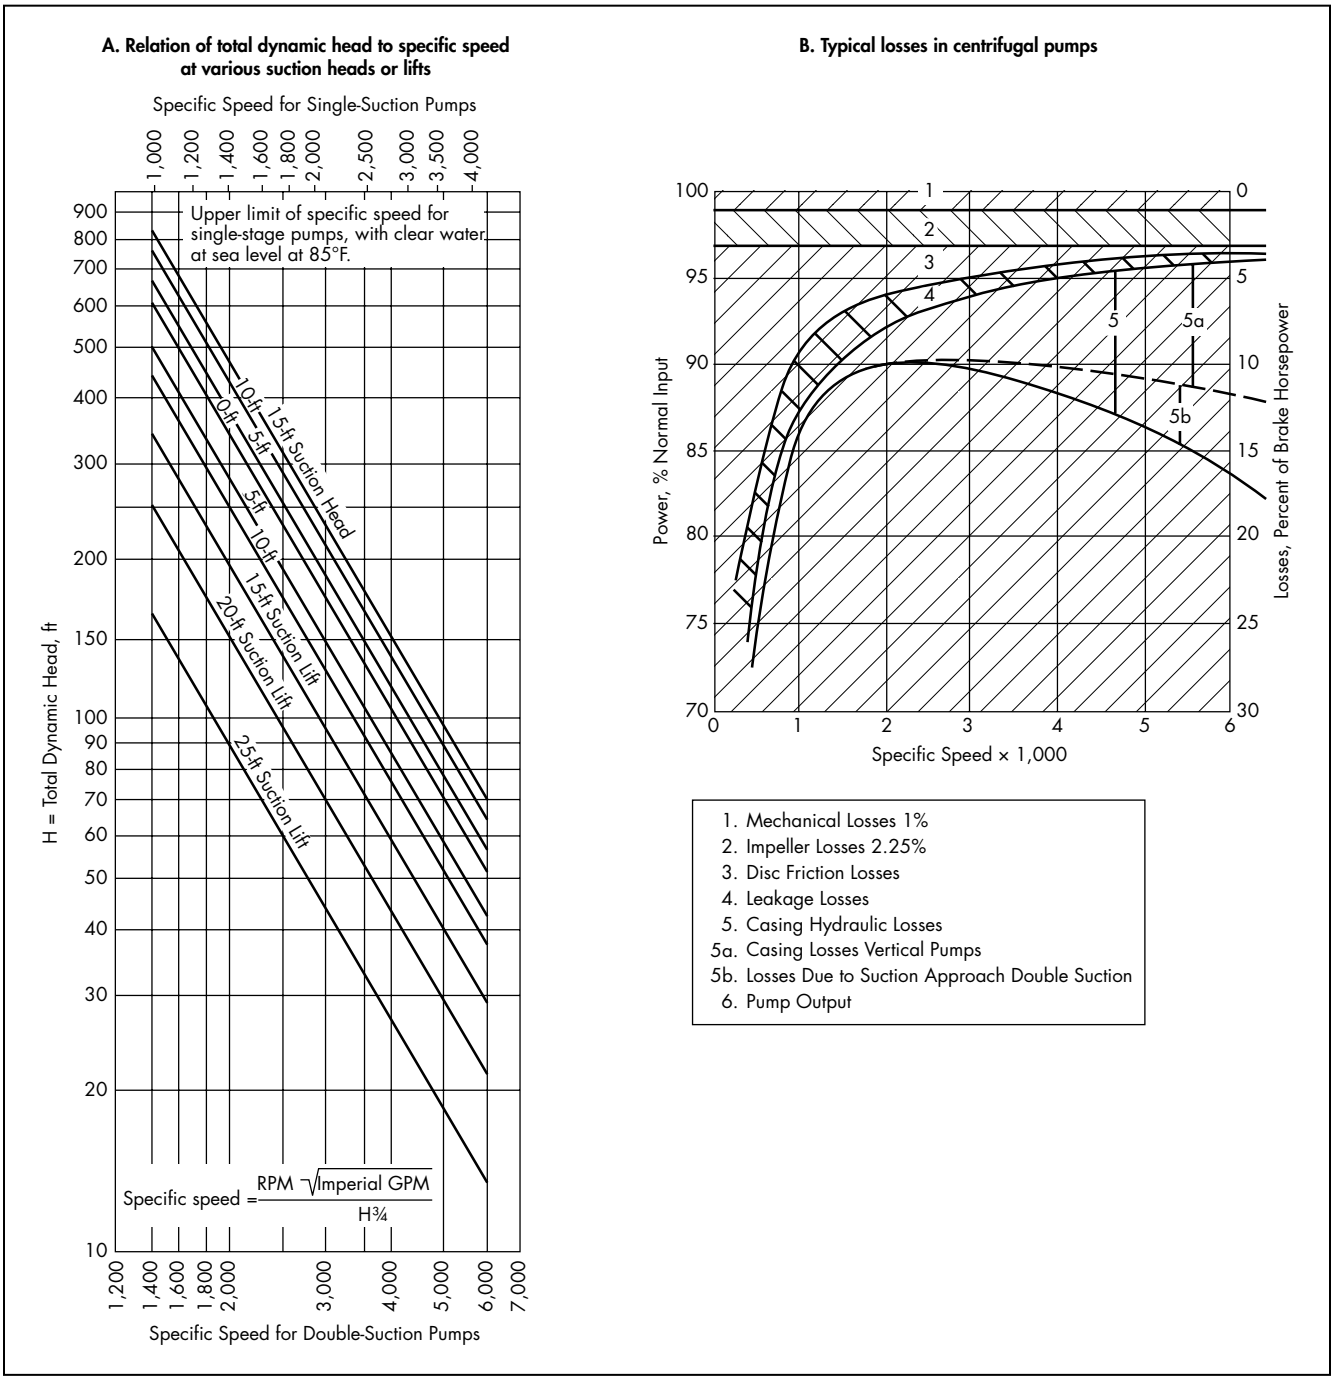


Figure 9.6-8 Suction and losses, single-stage centrifugal pumps

where

q = volume flow rate, m^3/s
n = impeller velocity, rpm
d = impeller diameter

The head or pressure relationship is

$$p_1/p_2 = (n_1/n_2)^2 (d_1/d_2)^2$$

where p is the discharge head or pressure (m). The power relationship is

$$P_1/P_2 = (n_1/n_2)^3 (d_1/d_2)^3$$

where P is power (kW). In other words, the capacity or rate of discharge varies with peripheral speed at exit of impeller, the maximum discharge pressure varies with the square of peripheral speed, and power input varies with cube of peripheral speed.

Design of Pump Stations

Objectives for designing a pump station usually include the following:

- Enough units of all essential components should be provided so that any one can be repaired while others handle greatest expected flow. Ordinarily, this requires spare units with appropriate valves and crossovers and a crane capable of moving the heaviest.
- Pumps and all electrical equipment should be protected from being flooded.
- Sufficient storage should be provided in sumps or otherwise.
- Vertical or submersible pumps should be used to take water from sumps.
- In severe conditions, the pump room should be protected with an adequate pressure door and a raise for access and ventilation.
- Capacity should be added if needed.
- Sufficient controls, usually at least automatic start-and-stop, alarms for high water, and protection for pumps and motors, should be provided.
- Positive suction head should be provided, if reasonably possible, by pumping from sump with vertical pumps or locating pump room lower than sump.
- High-tension items should be protected from accidental jets and splashes. Floor should be sloped and a drain provided.
- Ventilation should be used, as needed, for normal and emergency operation, discharging hot air to the mine or returning it to the surface or, if both are objectionable, cooling it mechanically, adding to the temperature of water discharged.

System Design

The first decision required in the design of a pumping system is whether to pump dirty water or to remove the solids to enable the use of clear water pumps. This will depend on a number of factors, including the volume of water to be pumped, the properties of the water, the depth of the workings, the expected life of the mine, and demands and constraints on disposal and/or reuse of the water.

The second decision is to consider whether to pump in stages or in a single lift from the bottom of the mine. Some of the considerations include whether the water will be clarified or not before pumping, the depth and vertical and lateral extent of the workings, the expected life of the mine, the type of access available (shaft and/or decline), whether the overall mining sequence is top down or bottom up, and whether development of the mine is progressive or largely completed prior to production.

Clearly, these two decisions are interdependent, and the overall system selection will consider all of these factors. Some general principles are listed here:

- Deep mines with large water volumes and long life will favor clarification and clear water pumping (high capital cost but lower operating cost).
- Shallow mines with low water volumes and shorter life will favor dirty water pumping.
- A top-down mining sequence with progressive mine development will favor a staged pumping system.
- A mine with large vertical and lateral extents will favor staged pumping.

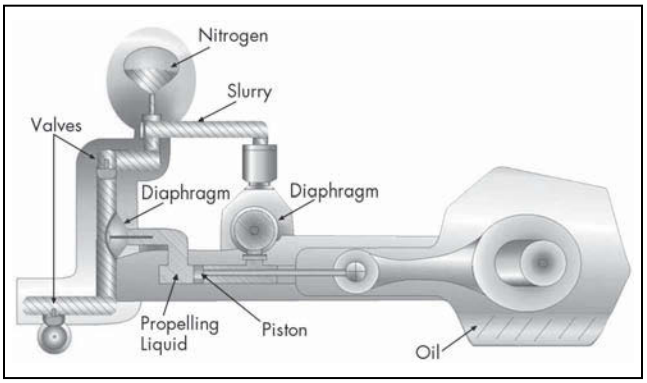

Figure 9.6-9 Crankshaft-driven piston diaphragm pump

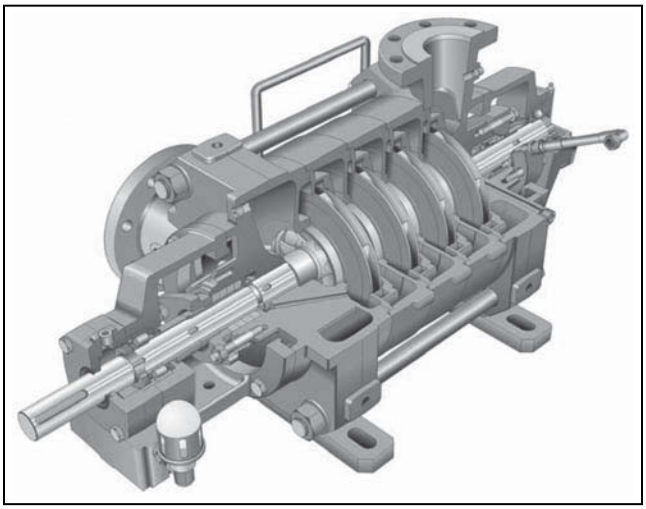
- A shallow mine with limited vertical extent will favor single-lift pumping.

Pump Selection

Some of the types of pumps used in underground mining are described in this section.

Small Portable or Semiportable Pumps

Sump pumps may be powered by compressed air or electricity. They are usually vertical centrifugal pumps with open impellers and abrasion resistance or, less commonly, diaphragm and displacement pumps. They are moved to and from sumps where they normally work submerged but can run dry without damage and must be self-priming. Compressed air pumps are limited to heads of about 100 m at flows less than 1 L/s but can deliver up to 10 L/s at low heads. Electric pumps exceed these limits and can be used to clear small inflows from shaft bottoms, clean sumps, and so forth, where high portability is desirable.



Reciprocating Positive Displacement Pumps

These include dirty water pumps, mud pumps, slurry pumps, and grout pumps powered by compressed air or electric motors through belts or gears. Plunger pumps and diaphragm pumps have high abrasion resistance and low to moderate capacity but are capable of high discharge pressure. Valves are accessible for cleaning.

Some positive displacement (PD) pumps displace the fluid directly, either via a piston working in a cylinder or a plunger working through a stuffing box. A supply of clear, high-pressure water may be required to lubricate glands and minimize wear. A diaphragm pump has a flexible diaphragm between the fluid being pumped and a chamber containing oil that is displaced by a piston, thus preventing any wear on the piston side (Figure 9.6-9). In large sizes, PD pumps are used together in main pump stations to deliver 100 L/s or more of dirty water directly to the surface from depths exceeding 1,000 m.

Single-Stage Horizontally Split Centrifugal Pumps

These are usually directly connected to electric motors for compactness, dependability, and ease of control. Discharge sizes are up to about 300 mm. Generally furnished with close clearances for clear water, these pumps can work with high efficiency to capacities of about 200 L/s and heads to about 150 m. Pumps are made for larger capacity at somewhat lower

Figure 9.6-10 Multistage centrifugal pump

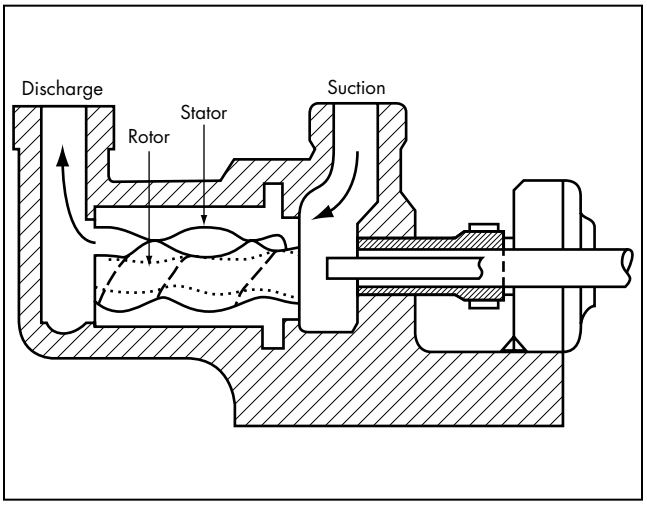

Figure 9.6-11 Progressive cavity pump

heads. Installation and maintenance are simpler than for multistage pumps.

Horizontal Multistage Centrifugal Pumps
These are usually direct-connected to electric motors for compactness, dependability, and ease of control (Figure 9.6-10). Discharge sizes are from 75 to 250 mm with 2 to 10 stages. Although total efficiency is likely to be less than that of single-stage units, efficiency per stage may be higher. Heads typically range from about 150 to 700 m.

Although the first cost of these pumps generally is higher than for single-stage pumps of similar power, their use may save the capital and operating costs of duplicate facilities. The close tolerances require clean water to prevent excessive wear, so the cost of building and maintaining settling dams is a consideration.

Vertical Turbine (Deep Well) Pumps
These are essentially vertical centrifugal pumps made in comparatively small diameters to work in water wells and similar narrow but high spaces. Water ends are essentially similar whether close coupled to a vertical electric motor, connected by a long shaft to a motor at the top of a well casing, or connected to a submerged motor in the well. Vertical turbines are made with as many as 20 or more bowls (stages) for heads of 5 to 30 m per stage. Pumps are made in diameters from about 150 to 1,000 mm or more.

Because pump intakes normally are submerged, priming is not a problem. Motors of close-coupled pumps can be well above normal water levels. Impellers can be removed if a pump is to work at less head, or more bowls and impellers can be added for greater head.

Vertical Centrifugal Pumps
These are made in one and two stages with proportions like those of horizontal centrifugals. They are direct-connected below vertical motors by short shafts. Because the pump always works submerged, priming is not a problem. They have the simplicity and high capacity of horizontal centrifugals and in many applications approach or equal the convenience of vertical turbines.

Vertical centrifugal pumps are made for capacities up to 950 L/s and heads to 250 m with motors as large as 1,000 kW. They are commonly used to raise water from a lower to an upper sump, from which it can flow with positive suction head to horizontal centrifugals. They also can pump to emergency storage.

Air Lifts
The efficiency of an air lift is low at best, yet there is no simpler pumping system. Typically two strings of concentric pipe are submerged, and compressed air is introduced through the internal pipe. Anything that can get into and through the larger pipe is pumped without doing damage. They are especially good in dewatering partially blocked shafts but require a minimum submergence of around 33% and so cannot completely dewater a shaft.

Progressive Cavity Pumps
With abrasion-resistant rotors in rubber stators, progressive cavity pumps will pump any mud that can be drawn into them. They are widely used in mine dewatering (Figure 9.6-11). Multistage units are capable of heads up to 720 m at up to 60 L/s, or flows up to 150 L/s at lower heads.

Testing Performance of Pumps
Well-equipped manufacturers have extensive facilities for testing large pumps with precision. Comparable test facilities are uncommon in deep mines, yet records of performance are essential to evaluate the results of pumping and to guide maintenance. Modern pump stations are often well instrumented, but serviceable data can be obtained by such means as the following:

- The total output by a weir on the surface can be measured, integrated, and recorded. In some cases, it is possible to measure rate by pumping into or out of a large sump or tank but usually with less accuracy. Inflow can be estimated by adding the water removed with ventilating air and subtracting any water piped into the mine for drilling and washing, and decant water from hydraulic fill.
- The pumping rate of each pump can be measured by any of several means, including magnetic flowmeters,

venturis, orifices, weirs, or pumping from or into a sump. Provision of these measuring devices in the discharge of each pump makes it possible to check each periodically with little labor and loss of pumping time.
- Individual discharge and suction heads can be measured with calibrated Bourdon-type gauges or manometers placed appropriately.
- Mechanical input can be determined from a calibrated watt-hour meter, subtracting the motor loss as taken from the manufacturer's test data. Various torque dynamometers can be used for a more fundamental determination of power input.
- Pump speed can be measured by a calibrated tachometer and stopwatch, and this is generally adequate.

The rate of discharge of a centrifugal pump and its discharge pressure can decrease with time because of scale formed in the discharge or other change increasing the dynamic head; decrease in suction head due to scale, obstruction of intakes, and so forth; decrease in effective diameter of the impeller or other severe pump wear; blocking or other obstruction of the impeller passages; and wear causing excessive leakage between stages of multistage pumps and across wear rings in single-stage.

All pumps discharging into a single line should be kept balanced to operate together efficiently. If unbalanced, the head of one pump could decrease until flow is reduced to the degree that the pump bearings seize.

Cost of Pumps

Usually other factors are likely to be more significant than the first cost of the pump. The cost of standard water ends of horizontal centrifugal mine pumps generally is 30% to 50% of the total cost of the pump-motor-starter unit. It may be only 5% to 15% of the cost of the pumping plant, including sumps, clarification, power supply, ventilation, suction, discharge, and required excavations. The construction of the pump influences the cost of the station (e.g., vertical pumps require less floor space and no suction line). Efficiency is important because power ordinarily is the largest part of operating cost. Where planning makes it practicable, a single high-head pumping installation can be more efficient, as well as simpler, than a series of pumping stations each working at a lower head.

Initial duty calculations can be made assuming efficiency of 60% (motor $\times$ pump) for small units, 75% for larger pumps, and up to 80% for units of large capacity. Large units, in which both motor and pump are excellently matched to the pumping duty, may go higher (e.g., 90% pump $\times$ 93% motor).

Pipework

Normal working pressures may be increased considerably by the pulsations of reciprocating pumps or by surging and water hammer. Special steels or extra wall thickness may compensate for pressure or corrosion but with added cost or weight.

Where significant ground movement is likely, the discharge pipe should be able to survive some misalignment. If it is likely that individual lengths or sections of a discharge line must be removed to clean scale or repair accidental damage, pipe should be coupled and supported accordingly. In some places, repair by cutting and welding is difficult.

In some cases, reasons exist for not treating water underground, and protection of the outside of the steel pipe is likely to be incomplete. The angle of the pipe, its exposure to accidental damage, working room, and service facilities also are factors in selection of pipe and couplings and how it is supported. Because many of these factors are difficult to evaluate, continuous dependable service is important, and repair can be highly inconvenient, innovation in high-pressure design pipe is uncommon.

Preference for seamless steel pipe for high-pressure lines has decreased with better quality control in welding. High-pressure lines usually are no larger than 250 mm (10 in.) to limit the weight of long, steep columns, facilitate placement and repair in limited shaft compartments, reduce the number of pumps discharging to the same line, and make it easier to provide a spare line. Wall thickness needed for any pressure is calculated from the minimum ultimate tensile stress with a good factor of safety; 5 is frequently used in shaft rising mains, whereas 2 may be acceptable in more accessible areas. There is much more latitude in choice of pipe for lower pressures, such as discharge from single-stage pumps. Where volumes are large, 500-mm (20-in.) pipe may be used.

On high-pressure lines, the practice is to join pipe with flanges. Simple flanges generally are preferred, but gasket material must resist extrusion by strength or by retention. These long strings generally are assembled from the bottom up by adding one or several lengths. With the use of a cage with extensible crawls to handle the pipe and decks where crews work, more than 100 m of pipe can be placed in a shift.

Weight usually is carried on steel bearer beams or brackets concreted into the shaft wall at intervals of 120 m or less. The provision of an expansion joint below each bearer assists in equalizing weight, adds vertical flexibility, and makes it unnecessary to raise an entire string to replace a length.

Continuous rising mains can be added in 20-m lengths, with each joint welded as it is added at the surface like well casing. Alternatively, screwed well casing may be used. Guides prevent side movement, but all weight bears either on a concrete bridge at the elevation of the pumps with the line in compression or is suspended from a bridge at the surface with the line in tension.

Gate and check valves are placed in the discharge of each centrifugal pump for use in starting and for protection during the repair of a pump connected to an active discharge line.

BULKHEADS AND PLUGS

Deep gold mines in South Africa have developed outstanding practice with plugs, demonstrated in tests and in both routine and emergency construction. Generally, these plugs were built in hard, strong quartzite, impermeable except on fractures. Culmination of this development came with the four plugs placed in emergency conditions in the West Driefontein mine in November 1968 at depths below 1,000 m. They were completed 20 days after the inrush, in 3.0 $\times$ 3.7 m crosscuts. Work was undertaken with water flowing more than 1 m deep on each level. Valves to stop bypassing water were closed on the 23rd day, and the lower plug withstood a head of 1,116 m of water on the 26th day (Cousens and Garrett 1969).

Several conclusions are reached from South African practice (Garrett and Campbell Pitt 1961). Generally, it is more difficult to stop leakage past a bulkhead than to make it strong enough to resist thrust. Passage of water through rock fractures is related to the pressure gradient, which should be moderate.

Many plugs are neither hitched, tapered, nor reinforced. Reliance is placed in the strength of the concrete bearing against the usual irregularities of the rock surface. Such

plugs have withstood pressures of more than 6.9 MPa, one at 15.5 MPa. No indication of structural failure resulting from thrust was noted in the examples reported.

Leakage is likely along the floor and roof, even at low pressure, where mud and honeycomb, laitance (a weak layer due to excess water), and air pockets commonly weaken the rock–concrete contact. These leakages sometimes are sealed acceptably by one stage of grouting.

At higher pressures, water is likely to break through rock fractures. This appears to result from rock movement induced by pressure on rock surfaces. Part of the water entering the fractures may not appear outside the bulkhead. Much of this leakage can be sealed by several stages of cement grouting at pressures to at least 2.5× the hydrostatic head, in holes drilled as far as 10 m into the rock. The effect of each stage of grouting seems to be to fill the fractures, perhaps poststressing the ground around the bulkhead, and increasing its resistance to the entrance of water.

The loss of several bulkheads subjected to more than 6.9 MPa is attributed to failure of gaskets, threaded plugs, and other fittings. The possibility that even the smallest leakage through fractures may be enlarged by high-pressure erosion should not be underestimated.

Preferred construction is by injecting cement–sand grout into clean, strong, angular rock previously packed between timber forms. This generally results in better concrete, easier logistics, and, in some circumstances, less time and cost than direct concrete placement. Ordinary portland cement usually is used but rapid-set cement can be required by urgency. Concrete should reach at least 17.2 MPa in 28 days. The four plugs at West Driefontein were made of cement–sand slurry only. Slurry can be mixed under good control at a central plant and pumped more than 1,000 m through small pipe. Horizontal cold joints should be avoided by all means.

Recommendations from this work include seeking sites in tight sound rock. In good ground, at least, keyways are unnecessary, but note the length next recommended. The plug should be long enough that the pressure gradient is moderate. In one test, a gradient of 9 MPa/m was reached after several stages of rock grouting, but for working bulkheads, designed gradients of 900 to 1,400 kPa/m have proved effective (i.e., for each 6.9 MPa, allow between 8 and 12 m of plug).

All mud and loose rock should be removed, the water flow across the floor should be stopped, and a ventilation hole provided for high spots in the roof. Pipe, gaskets, valves, and fittings should be tested at a pressure somewhat greater than that to be withstood. Several stages of grouting to reduce leaks should be planned. The first, through pipes at concrete–rock contacts, might be at around 2,000 KPa, but later stages through holes drilled successively deeper into the rock can be at successively higher pressures, up to at least 2.5× the expected hydrostatic head.

Comparable experience in other rock is unknown, but several inferences seem to deserve consideration. In any strong rock that can be grouted effectively, similar practice seems applicable. In weaker rock, however, or one with seams that do not take grout well, it appears prudent to work to lower pressures and lower pressure gradients to reduce the risk of uncontrollable leakage through erosion and enlargement of rock permeability or defects.

No large excavation should be subjected to pressure greater than the maximum hydrostatic head unless after full study and evaluation of rock stresses. Lastly, the use of expanding cement, using aluminum powder or similar, seems promising.

INRUSHES

An inrush is a low-probability but high-impact event, usually leading to major disruptions to production and multiple fatalities. For example, Vutukuri and Singh (1993) tabulate 33 mine inundations in England, Scotland, India, and the United States having an average of 31 and a maximum of 375 fatalities (at Chasnala colliery, Jharia, India, in 1975).

One definition of an *inrush* is "the uncontrolled mass movement of material," whereas *subsidence* is "a sudden collapse of a large volume of rock," often referred to as *plug* or *pipe* subsidence (McCarthy and Harvey 1998). These definitions recognize that flows of mud, tailings, wet ore, or saturated surface material may also become inrushes, and that sudden subsidence, although a hazard in itself, can create unexpected connections to these materials.

Causes of Inrushes

A review of 43 examples of inrushes, mainly in noncoal mines, shows the following causes (McCarthy and Harvey 1998); a further 18 examples gave insufficient details for classification:

- Surface flooding enters mine: 33%
- Mining broke into old workings: 28%
- Strata water enters mine: 19%
- Accidental connection made with sea, river, lake, etc.: 14%
- Failure of a dam, seal, borehole, etc.: 5%
- Earthquake: 1%

It is interesting to compare this list with the next, which was prepared by Job (1987a, 1987b) based on 208 incidents in British collieries during the period 1851 to 1970. The much greater frequency of contact with abandoned workings is to be expected in intensively exploited bedded deposits. The lack of surface flooding may reflect a greater predictability and awareness of flood levels than has been the case in arid environments. This list does not include fill bulkhead failures, which are common but rarely become public knowledge unless a fatality is involved:

- Contact with abandoned old workings: 78%
- Clearing old shafts or shaft sinking: 9%
- Failure of an underground dam or seal, or leakage of a borehole: 4%
- Contact with surface water—pond, river, canal, or stream: 4%
- Contact with surface unconsolidated deposits—glacial or organic: 4%
- Strata water entering working: 1%

Frequency and Location of Inrushes

A survey of mining periodicals for the years 1980–1996 identified 33 inrush incidents involving fatalities or loss of production. This is a rate of about two incidents per year worldwide, not including unreported incidents in China and the former USSR. These locations are for inrushes from 1980 to 1996:

- Africa: 9
- North America: 6
- Southeast Asia: 5
- Australasia: 5

- Europe: 5
- India: 2
- South America: 1

The occurrence of inrushes seems to generally correlate with the level of underground mining activity. Without new preventive measures, a country such as Australia should experience one incident every 3.4 years. As about 70 significant underground mines exist in Australia, the *return period* for an inrush incident is 238 years, which means that personal experience and awareness of the hazard are likely to be low. The nature of low-probability, high-impact events means that a severe incident could happen at any time and that special management procedures are required to maintain awareness.

More recent instances, particularly in coal mines in North America and China, suggest that this problem remains a significant one, is a serious threat to employee safety, and has a serious impact on the public perception of the mining industry.

SURFACE WATER DISPOSAL

All of the water and associated sediments removed from the mine must be disposed on the surface or recycled. Some water is disposed into the atmosphere via the exhaust ventilation and evaporation from wet rock dumps and water storages. In many mines, the water from underground is an important source for processing operations and other surface operations.

Today, even if the mine water is of better quality than the water in local streams, direct discharge into surface waterways is often not permitted or requires extensive and expensive purification. The presence of heavy metals or acidity will exacerbate this situation.

Mines with superfluous water may construct evaporation ponds for water disposal. This is not particularly effective in cold climates with low evaporation rates. In some cases, properly treated mine water can be an important water source for the surrounding community. Any water discharged into the natural environment should meet internationally accepted water quality standards.

ACKNOWLEDGMENTS

This chapter was developed from "Ground Water and Ground-Water Control" by R.L. Loofbourow, which appeared in the first edition of this handbook (Lucas and Adler 1973). The authors acknowledge the many contributors to that chapter.

CHAPTER 9.7

Physical Asset Management

John Woodhouse

INTRODUCTION

This chapter introduces and illustrates the whole picture of "joined-up" asset management. The term *joined up* encompasses acquisition, operation, maintenance, and logistics support as well as ultimate replacement, decommissioning, and/or disposal. In addition to focusing on physical mining and processing equipment, the chapter describes application of asset management principles to higher levels of asset definition, such as the ore body, mine, or whole mining enterprise (in the same way that asset management became the core business model for North Sea oil and gas operations). In particular, the chapter aims to differentiate between asset care (i.e., just equipment maintenance) and truly optimized whole life-cycle management of an ore body, the physical equipment, and mine systems. Illustrations of component methods and typical problems encountered draw on mining examples wherever possible, but some cases deliberately reference other industry practices to make the point that cross-sector learning is part of good asset management practice.

WHAT IS PHYSICAL ASSET MANAGEMENT?

A mining organization is critically dependent on mineral resources and a wide range of physical equipment, infrastructure, and operating systems. The economic performance of the enterprise is closely linked to the correct investments, extraction strategy, system design and selection, appropriate use, high performance, reliability, safety, and maintenance of such physical assets. The optimal management of these assets is therefore at the heart of good mining business management.

The term *asset management*, however, has been applied to a variety of asset types and activities over the years, so it is important to recognize and distinguish between the current usages of the term to focus on appropriate business priorities and value.

The financial services sector, for example, has long used the phrase to describe the management of a stock or investment portfolio—trying to find the best mix of capital security or growth and interest rates or yield. This vision of asset management has close parallels to the physical systems version, insofar as it involves juggling investments, risks, performance, and sustainability. However, there are big differences between financial assets and physical ones and between the options for their management.

Some engineering and industrial maintenance departments (and certain software vendors) have relabeled their functions as asset management to boost their professional standing and credibility in the organization. This, however, is a restrictive and ultimately ineffective view that misses many of the biggest opportunities. Asset care (maintenance) is just one part of asset management. Some of the biggest prizes in effective asset management, for example, involve optimizing the relationship between asset utilization ("sweating the assets") and the needs for maintenance or renewal. This is only possible if a cross-functional view is taken of (whole life) asset management.

A more holistic view of assets and their management has emerged since about 1990, and this concept of asset management is the focus of this chapter. Such a model encompasses all aspects of investing in the right assets in the first place, exploiting them appropriately, caring for them (maintenance), and ultimately replacing or disposing of them. Various levels of granularity exist in this context, depending on the definition of the asset. Some organizations limit the term to the management of physical equipment items or process units, while others take a more holistic view and define their assets at the level of the whole ore body, site, or mining enterprise. In all such cases, however, the challenges of optimizing investment, operations/utilization, maintenance, and whole life value are similar—and are addressed in a publicly available specification, PAS 55:2008. This standard defines terms and requirements for "optimal management of physical assets."

PAS 55 defines asset management as "systematic and coordinated activities and practices through which an organization optimally and sustainably manages its assets and asset systems, their associated performance, risks and expenditures over their life cycles for the purpose of achieving its organizational strategic plan."

Other wordings and definitions are in use in various industries, but the most robust ones all include the key elements

John Woodhouse, Chief Executive, The Woodhouse Partnership Ltd., Kingsclere, Berkshire, UK

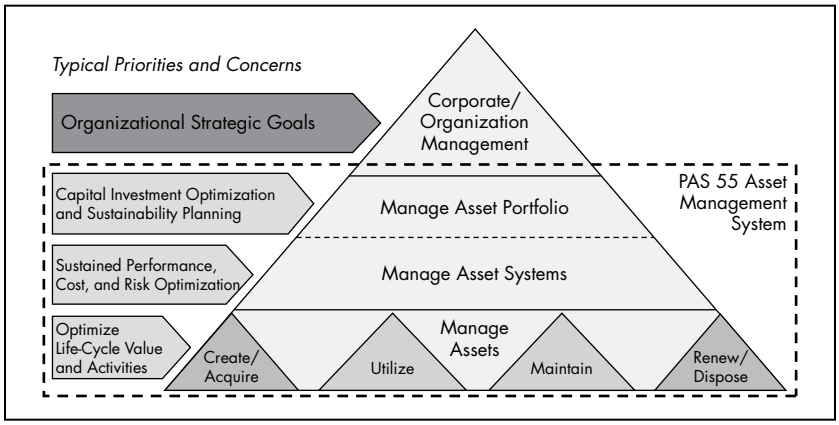

Figure 9.7-1 Integrated view of assets and their integrated management

of this PAS 55 definition: They identify the coordination and systematic approach, the need for optimization, and the combined consideration of expenditures, asset performance, and risk exposures. They recognize the need for a whole life-cycle or sustainability view (i.e., the long term) and for asset management to be directed toward a clear corporate goal. For many organizations, such aspirations represent a significant challenge, yet the prize for getting it right is substantial.

Benefits of Optimized Whole Life-Cycle Asset Management

Many organizations are tackling the integration and optimization challenges of asset management in all sorts of industries and business environments, and they are coming to remarkably consistent conclusions. A cross-disciplinary, whole life-cycle view of asset management yields significant tangible and sustainable benefits compared to the "silo" behaviors of individual functional departments that have often historically been focused on conflicting and/or short-term goals. Typical quoted benefits include

- Thirty percent reduction in total cost of ownership (Nuon electricity network, the Netherlands),
- Thirty percent reduction in mining equipment maintenance costs with 3%–10% increased system availability (copper mining, Chile),
- Seventeen percent increased output at 50% lower operating cost (Shell North Sea oil platforms),
- Twenty-eight percent reduction in planned system downtime (U.K. National Grid),
- Budget savings of A$11 million per year (New South Wales government), and
- Twenty-nine percent increased output at no extra cost (Baltimore, Maryland, United States, power generation).

Further and maybe even greater long-term benefits are found through improved credibility in the eyes of customers, enterprise investors, and other stakeholders. Good asset management also results in much greater engagement and remotivation of the work force and in more sustainable, continual improvement business processes.

It is not easy, however, to create such an integrated system in the first place, or to resolve the inevitable trade-offs that exist between short-term and long-term effects or among costs, performance, and risks. It usually involves a fundamental review of stakeholder expectations and business drivers, and a quantified or consistently scaled method for determining the criticality and value of assets and activities. Sophisticated tools and processes are also usually needed to optimize the mix of capital investment, operating costs, performance, maintenance requirements, risks, and achievable economic life spans. And education, communication, motivation, and behavioral changes have consistently proven to be absolutely critical success factors. Modern optimized asset management therefore involves an integrated business model that bridges departmental contributions to deliver net value for money on both short and long time frames, in line with explicit business goals.

What Are the Assets?

One of the key messages of PAS 55 is that joined-up asset management needs to occur at multiple levels in every organization. The characteristics and criticality of different assets and asset types vary, and the options for investment, exploitation, care (maintenance), and ultimate disposal or renewal differ, but the requirement to deliver sustainable, total value for money remains a consistent underlying objective. The PAS 55 standard for asset management illustrates this stratified view of assets and their management (see Figure 9.7-1).

In a typical mining enterprise, therefore, a hierarchy of assets would correspond to the following categories:

- Whole mining enterprise, including all business functions and locations
- Specific ore bodies and/or geographical regions of the enterprise
- Specific mine and associated extraction/processing facilities
- The different extraction and/or processing systems
- Discrete equipment items

At the corporate or enterprise level, asset management simply means good business management. However, at lower levels, asset-specific characteristics and divisions of responsibility (departments and functions) make it increasingly difficult to see the whole picture and optimize the whole life-cycle costs and value. This is the area in which a robust asset management strategy helps to ensure coherence between the organization's goals and the day-to-day realities of who does what, when, where, and why.

Emerging Standards in Asset Management

Since 1990, two very different business environments have made very similar discoveries about what is needed and what

is achievable through a more integrated approach to whole life-cycle asset management.

The North Sea oil and gas sector faced massive wake-up calls in the late 1980s: the *Piper Alpha* disaster, an oil price crash, the Cullen Report (1990) recommendations on risk/safety management, market globalization, and so on. These forced a fundamental reappraisal of underlying business models and the recognition that big companies, while holding several strategic advantages and economies of scale, were losing the joined-up thinking and operational efficiency or agility that smaller organizations naturally enjoy (and need in order to survive). BP and Shell experimented with the creation of a small-business culture within a large organization with its attendant leverage. Asset-centered production units emerged, employing multidisciplinary teams with significant budget and performance freedoms to find the best combination of investments, exploitation, and care for each reservoir or production platform. The results were spectacular, reducing total costs of ownership and raising productivity nearly tenfold, while simultaneously raising safety and environmental performance. Recent high-profile events in BP's U.S. operations (Texas City refinery and the Gulf of Mexico leak) have, of course, implied otherwise, but the underlying trend has been profound and significant; fatalities, injuries, and environmental incidents have fallen dramatically since the 1980s.

At the same time, public utilities and municipalities in Australia and New Zealand—facing a sustained period of degrading services and escalating costs combined with some highly publicized system failures—realized that a different approach to sustainability and value for money was needed. The whole asset life cycle needed to be considered, and capital investment planning began to take on a cross-functional view to find the best value-for-money options. Again, the results have been spectacular, with significant and sustained service improvements, cost reductions, and reestablished public confidence.

Now the lessons are being adapted and applied to mining, road and rail transport, water, electric and gas utilities, process and manufacturing, health, education, and other industries in both private and public sectors. There is increasing recognition, therefore, that many of the good practices in managing assets are generic, and there are many opportunities for learning and improving by exploring how other industries are addressing similar problems in different environments.

In 2002, the Institute of Asset Management (IAM) initiated a project with the British Standards Institution to document these observations in the form of a publicly available specification. PAS 55 was first published in 2004 with the backing of about 25 organizations. In the next 4 years it became a mandated requirement for the regulated U.K. electric and gas utility sectors and was picked up internationally in railways, mining, water, and manufacturing industries. The most recent update of the standard, published in 2008 (PAS 55:2008), involved more than 50 organizations from 15 different industries in 10 countries. It is currently going forward to form the basis of a full International Organization for Standardization (ISO) standard with the support of the national standards organizations of more than 20 countries. It is safe to say that asset management has thus evolved to become mainstream—an expected competency in any organization that is heavily dependent on physical assets, resources, or infrastructure. The understanding of what this involves, however, is still evolving: Best practices—or even what should be regarded as good practices—are constantly moving forward. This is why a management system is necessary: to coordinate the many functional contributions of an organization with a common understanding and clear purpose, optimally managing the inevitable (and inherently conflicting) subgoals and doing this sustainably while still retaining enough flexibility to cope with future unknowns.

Basic Terminology

Before delving into the specifics of what needs to be done, why, and how, it is necessary to be very clear on terminology. A common problem in this field is one of poor communication or misunderstanding of meanings. Some terms in asset management are used and interpreted very differently depending on role or context, while others are simply misused or confusing. PAS 55 tries to address this with a definitive glossary of 35 common terms, the most important of which are reproduced here. Other useful guidance is to be found in complementary standards such as ISO 15663:2000 for whole life costing, BS 3811:1993 for maintenance and reliability language, and ISO 31000:2009 for risk management.

- **Asset:** At the simplest level, an asset is anything of value (tangible or intangible) that is owned by the organization. In this context, however, it refers particularly to plant, machinery, property, natural resources, buildings, vehicles, and other physical items or infrastructure. However, the principles and practices of good asset management also apply to other asset types (data or information, reputation, financial resources, licenses or entitlements, natural resources, etc). Note also the relationships between individual assets within functional asset systems and portfolios of assets. See Figure 9.7-1.
- **Asset life cycle:** An asset life cycle is the time interval that commences with the identification of the need for an asset and terminates with the decommissioning of the asset or any associated liabilities. The principal stages of an asset's life cycle typically include creation/acquisition, use, maintenance, and renewal/disposal.
- **Asset management:** Asset management comprises the systematic and coordinated activities and practices through which an organization optimally and sustainably manages its assets and asset systems, their associated performance, risks, and expenditures over their life cycles for the purpose of achieving its organizational strategic plan.
- **Asset management system:** The asset management system comprises the organization's asset management policy, strategy, objectives, and plans and the activities, processes, and organizational structures necessary for their development, implementation, and continual improvement. A management system also includes the organizational structure, roles and responsibilities, planning activities, standards, information systems, practices, processes, procedures, and resources.
- **Asset management information system:** The information system, usually computerized, is for the storage, processing, and transmission of asset management information such as asset registers; drawings; contracts; licenses; legal, regulatory and statutory documents; policies; standards; guidance notes; technical instructions; procedures; operating criteria; work plans; asset performance; and condition data or audit results. *S*uch systems

are sometimes referred to as enterprise asset management systems. Their role, however, is largely that of a computerized maintenance management system, and they should not be confused with the larger scope of the life-cycle business management of physical assets (an asset management system) as described in this chapter.

- **Asset management policy:** The asset management policy is a specific mandate that states the principles, commitments, obligations, and control framework for the development and implementation of the asset management strategy and plans. It must be clearly derived from the organization's corporate values and strategic plan and must be complementary to (not conflicting with) other company policies, such as those for safety, health and environmental commitments.
- **Asset management strategy:** The asset management strategy is a vital, centralized, and cross-disciplinary view of the long-term optimized approach to the management of the assets. It needs to reflect the top-down requirements and goals of the business and the bottom-up realities of the assets, including their condition, performance, capabilities, and opportunities. It also needs to provide enough coordinated clarity and detail that specific asset management plans (who will do what, when, where, and why) can be derived and optimized.
- **Asset management objectives:** Two levels of asset management objectives should be considered. Asset management objectives need to be defined for
  - Specific and measurable outcomes or achievements required of the physical assets and asset systems (e.g., how assets themselves need to perform), and
  - Specific and measurable outcomes or achievements required of the overall asset management system (e.g., how asset management should perform). This reflects the need for a scheme of asset management performance monitoring in the context of other corporate business priorities.
- **Asset management plan:** An asset management plan is a document that specifies activities, resources, responsibilities, and time scales for implementing the asset management strategy and delivering the asset management objectives. Such a plan needs to be optimized for cost, risk, performance, and sustainability (in line with the planning horizons for the asset life cycles and the company business plan).
- **Optimization:** This is the process required to achieve the best-value compromise between conflicting factors (e.g., performance, costs, and risks) within any nonnegotiable constraints. Optimization requirements exist in many areas of asset management, such as trade-offs between short-term and long-term goals, or between capital investment and operating costs, or between costs and risks. The processes of optimization are explained and illustrated later in this chapter.

STRUCTURE OF AN ASSET MANAGEMENT SYSTEM

An integrated system for managing assets is primarily a coordination mechanism for breaking down the silos of individual departmental roles and activities in favor of delivering the mining enterprise's core objectives. Like any other management system, however, it is a set of connected processes, controls, and enablers that ensure the right things are done for the right reasons in the right way to deliver the objectives and enable ongoing flexibility and continual improvement.

Care should be taken not to confuse an asset management system with either of these systems:

- Asset system (the functions of the physical equipment and infrastructure in production systems)
- Asset information management system (asset registers, work planning, and history-collection systems)

An asset management system is not a software tool, nor is it the hardware comprising the production or processing plant and infrastructure itself. The management system for assets, rather, is in the same category as a quality management system, a safety management system, or an environmental management system. It includes statements of policy; some clear strategies, objectives, and plans; and a range of delivery mechanisms, along with performance monitoring, review, and improvement processes.

An asset management system is particularly focused on the coordination and integration of what takes place—to break down the barriers between departmental contributions and their localized self-interests or short-term goals. This requirement emphasizes the optimization of the combined effects and value for money resulting from investments, asset usage, and asset care over the whole life cycle. It also highlights the importance of clarity, communication, and alignment between asset management activities and the overall purpose of the organization—the need to understand where the organization is going and why—before determination is made of what is therefore worth doing, when, and how. For example, a mining enterprise may have the goal of maximizing the total lifetime yield and margin from an ore body, so the development, use, and maintenance of facilities developed to support extraction should be planned with this horizon and total value in mind—not just year-by-year budgeting or the selection of cheapest equipment options (or, at the other extreme, the gold-plating of technical solutions when the incremental expenditures are not worthwhile).

Figure 9.7-2 is a high-level view of the most important attributes of a joined-up management system for physical assets. The boundary of such a system can be seen as sitting just beneath the organizational strategic plan (the company's overall business plan). This is the interface at which the language of business drivers and stakeholder expectations (e.g., safety, profit, reputation, quality) must be translated into the practical and specific implications or requirements for creation, use, care, and renewal/disposal of the physical assets or systems required to deliver these objectives.

Within an asset management system that is compliant with PAS 55, it is necessary to develop and demonstrate a logical and transparent top-down chain of connectivity from the overall business objectives to a clear definition of policy (mandated obligations and principles) and from preferred or optimal strategies and objectives to the specifics of what needs to be done to which assets, why, when, and how (i.e., asset management plans). This sounds obviously desirable and logical, but it often proves very hard in practice. The language used in corporate initiatives and priorities is often very different from day-to-day operational language; priorities and expectations change and short-term objectives conflict with long-term goals. A very important bottom-up influence must also be established and exploited—the asset portfolio's diverse characteristics, needs, risks, and opportunities should

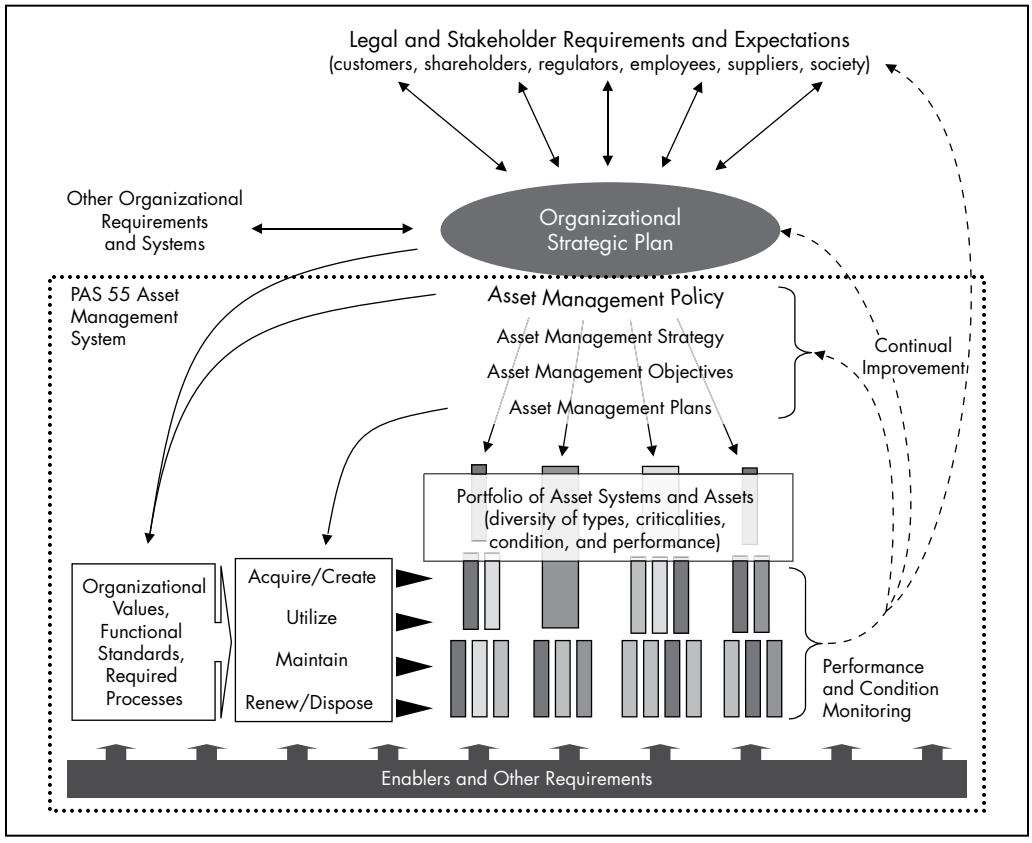

Figure 9.7-2 An integrated management system for assets

be influencing the organization's strategies and even its strategic plan. Later in this chapter the practical steps needed to establish and maintain such alignment are discussed.

Of course, asset systems and assets are diverse in type, role, importance, capability, performance, and health. So whatever the overall strategy, there is a vital optimization to be done in determining what is the best mix of investment, exploitation, maintenance, and renewals to deliver the most value for money. *Optimization* is a much overused and misused word, but it is correctly applied here—the requirement is to find the best blend of competing factors (such as cost versus performance versus risk, or capital cost versus operating costs, or short-term versus long-term results). Such optimization and decision making is at the core of good asset management, and there are many significant developments in this area—these are also summarized later in this chapter.

The right side of Figure 9.7-2 addresses the need for continual improvement, using the reality of assets and operating/maintenance experience to modify plans, strategies, the whole organization's ambitions, and even the expectations of the stakeholders.

In addition, the underlying "enablers" or lubricants of the whole management system must not be forgotten. These profoundly influence the combined performance and sustainable nature of the asset management system. Ever since the industrial revolution, businesses have increasingly specialized their activities and job functions in the search for greater efficiencies and performance. One result is the increasing difficulty for any individual or functional department to see the whole picture and understand the effects of doing something for apparently good local reasons (e.g., saving 5% in the purchasing costs for a major project) that has unanticipated performance, cost, or risk consequences on other parts of the business (e.g., performance, maintenance, or spares impact). To minimize these false economies and ensure that net value for money overrides any local, vested, or departmental interests, an asset management system must include a range of important enablers such as good communications, clear roles and responsibilities, competencies, risk management, and so on. These are discussed in detail later in this chapter.

Asset Management Processes

Business processes that are more specific can be identified in the life-cycle management of physical assets—these correspond to many of the daily functional activities in any mining enterprise. However, their integration, coordination, and optimization represent the greatest challenge and opportunity for improved efficiency and effectiveness. Figure 9.7-3 shows a simplified view of these main functions.

Seven Key Features of a Good Asset Management System

To precede an expanded discussion of the components and functions of an effective asset management system, it is necessary to recognize some underlying generic requirements. These are characteristics of the whole system and provide an important frame of thinking within which the component activities, methods, tools, responsibilities, and performance measures should be considered. As part of the development of PAS 55, the participating organizations identified seven key

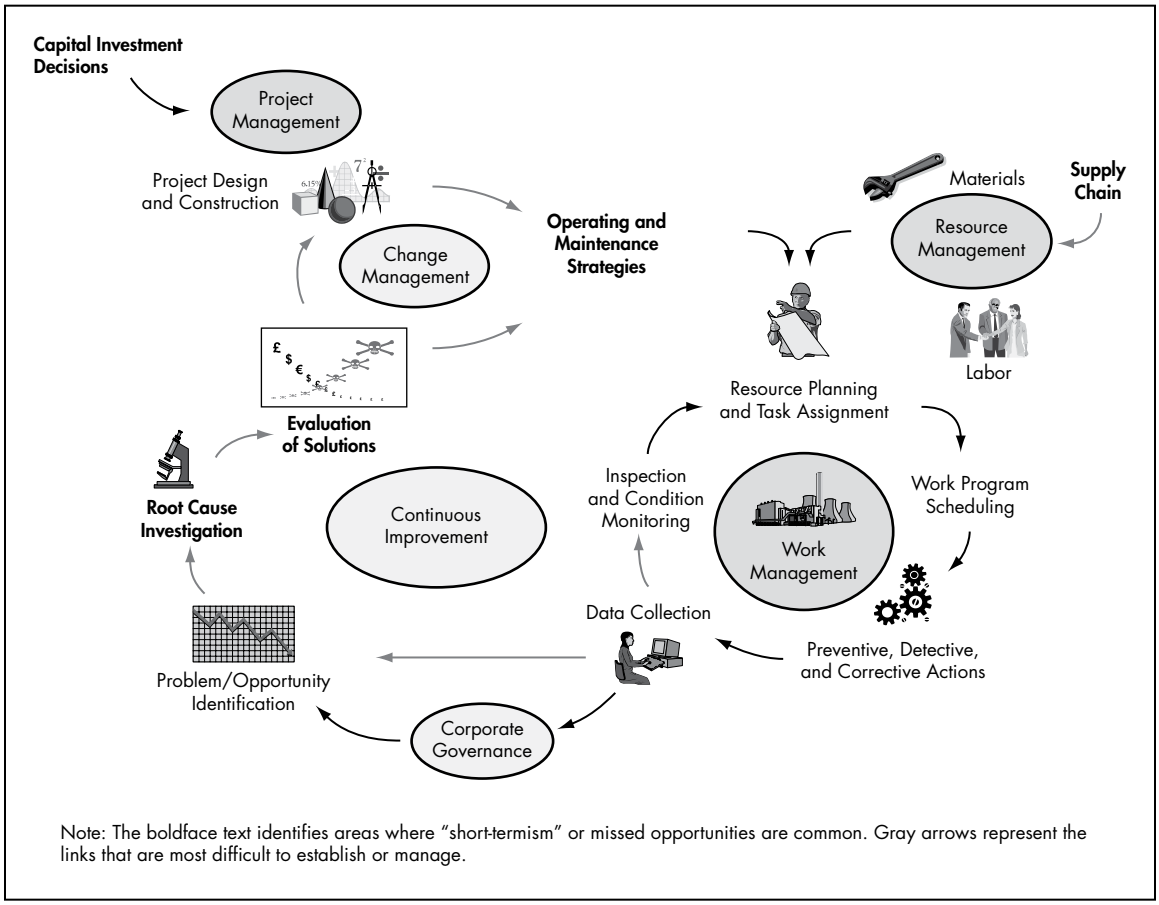

Figure 9.7-3 Typical asset management business processes

features that characterize good and effective asset management systems (see Figure 9.7-4).

1. **Holistic:** cross-disciplinary and focused on the total picture and total value.
2. **Systematic:** rigorously applied in a structured management system.
3. **Systemic:** looking at assets in their own systems context, seeking net total value for money rather than component or localized goals.
4. **Risk-based:** incorporating risk consciously and appropriately into all decision making and planning.
5. **Optimal:** seeking the best net compromise between conflicting objectives, such as costs versus performance versus risks, or short-term versus long-term benefits.
6. **Sustainable:** delivering optimal whole asset life cycles rather than artificial short-term results at the expense of long-term consequences. The management system itself also needs to be agile and sustainable in the face of future uncertainties and inevitable change.
7. **Integrated:** the importance of being joined up and collaborative. This is at the heart of good asset management; the total jigsaw puzzle needs to work, to be more than the sum of its parts.

These generic principles apply to all asset management activities—they should be evident features of investment planning, resourcing, contract management, organization structures, materials management, work scheduling, information capture and use, and a host of other business functions. They form a central feature of a maturity scale for asset management and are good indicators of the likely performance, robustness, flexibility, and sustainability of the company's core functions (if it is heavily dependent on physical assets). The IAM has, for example, developed a five-level maturity scale against all the PAS 55 requirements that is widely used for gap analysis, benchmarking, improvement planning, and so on (IAM 2002).

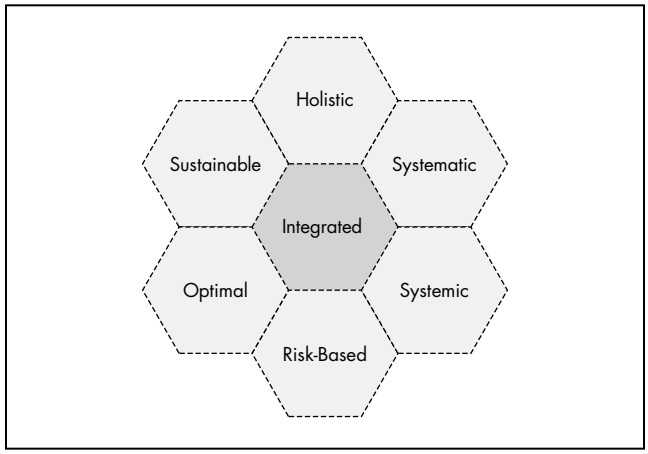

Figure 9.7-4 Seven key attributes of good practices in asset management

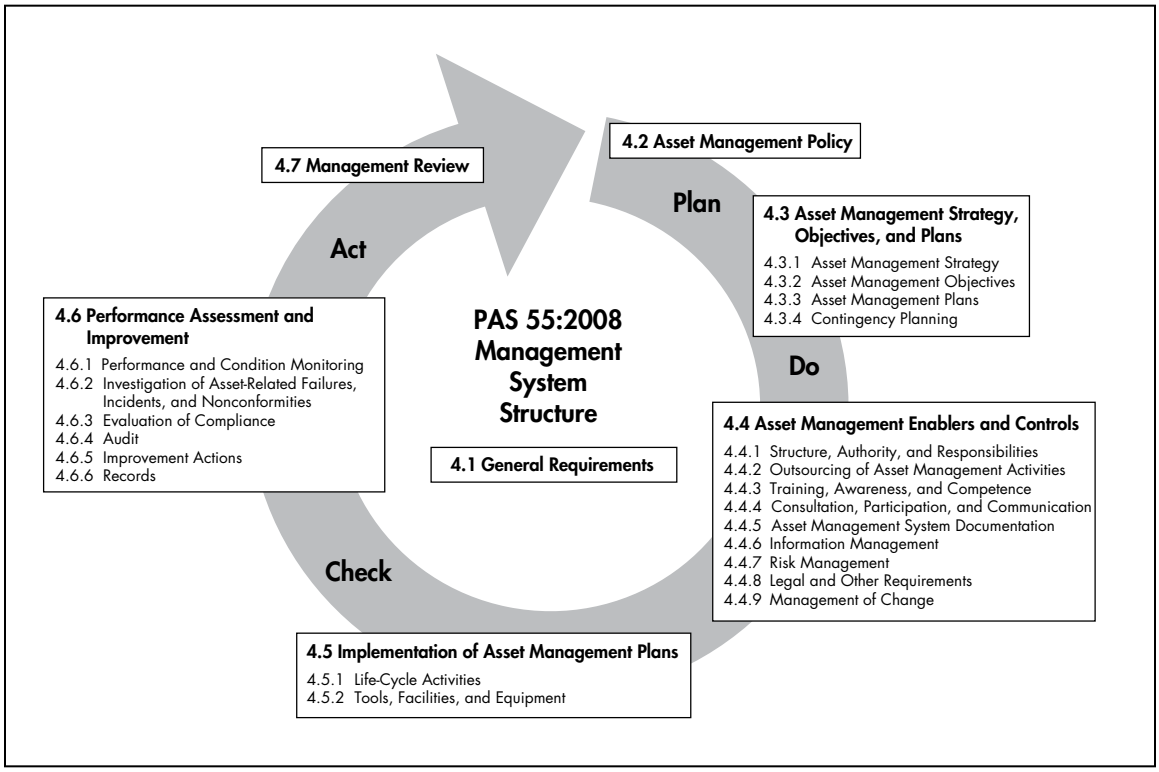

Figure 9.7-5 Closing the loop in an asset management system

SPECIFIC REQUIREMENTS FOR GOOD ASSET MANAGEMENT

PAS 55:2008 identifies a range of more specific requirements for competent asset management. These are must-do items that represent the cumulative experience of good practice, irrespective of what the assets are or what the organization is aiming to achieve. PAS 55 is not a definition of best practice, nor is it a specification for how to manage assets. What is best and what is appropriate in methods or techniques are very dependent on each organization's circumstances, such as the regulatory, cultural, technology, or business environment.

As seen in Figure 9.7-5, the requirements are grouped into the Deming cycle of plan-do-check-act. This is because good asset management is closely aligned with good quality management and the need for continual improvement. In fact, PAS 55 and ISO 9001:2008 management systems are highly complementary: A guide to this alignment (and to ISO 14000:2007 and OHSAS 18000:2007) can be found in the back of PAS 55 documents. This enables efficient, coordinated monitoring of compliance with all such requirements, with minimal duplication.

The "plan" area in Figure 9.7-5 addresses the requirement for explicit asset management policy and the derivation of corresponding strategies, objectives, and plans (including contingency plans). In the "do" area are the necessary asset management enablers and controls covering such things as human factors, risk management, and information systems, whose impact is felt in the overall effectiveness, efficiency, and sustainability of the system. Relatively little detail is needed in the area of implementing asset management plans, as this deals with the day job of developing and delivering projects, operating and maintaining assets, and so on. This reduced level of detail in PAS 55 reflects the fact that, in such areas of activity, existing capabilities and performance are often quite good already—in contrast to the bigger challenges (and opportunities) that often lie in either determining what is worth doing in the first place or in learning from experience ("check") and moving to "act" on that learning (continual improvement).

This section offers more detailed exploration of the requirements and an illustration of good practices that use the associated tools, techniques, and processes that have been applied successfully to improve the total picture.

General Requirements

An asset management system must include all the processes and documentation that define how an organization acquires or constructs, uses, maintains, replaces and/or disposes of its physical assets, including strategic planning, investments, operations, performance and risk management, and continual improvement. Top management is expected to periodically review the asset management system.

Asset management is the primary method by which an asset-dependent company delivers its main business goals—so a visible cascade of connected logic is expected to show how the strategic business plan is distilled into asset management policy, strategy, objectives, and specific plans. Figure 9.7-6 shows some of the linkage steps needed to translate corporate requirements into these specifics. Correspondingly, and shown in Figure 9.7-2 earlier, there will also be a bottom-up influence—based on the operational realities of the assets and their condition and performance—on what is desirable and achievable.

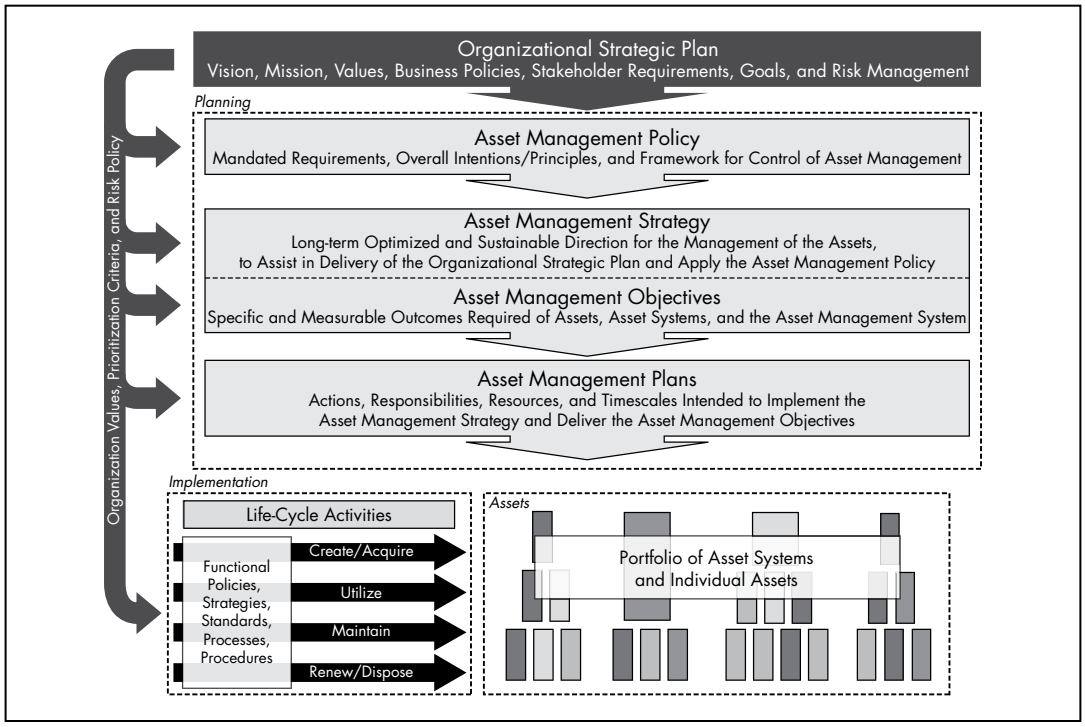

Figure 9.7-6 Transparent, logical connections between organization goals and asset management plans

Asset Management Policy

An asset management policy is a high-level document that sets out the principles, commitments, and framework of control that the company undertakes to apply in managing its assets. The policy is therefore similar in nature to a safety policy or environmental policy and is highly visible throughout the organization. An asset management policy

- Must be derived from an organizational strategic plan;
- Provides a framework for developing strategy, objectives, targets, and plans;
- Must be consistent with the risk management framework;
- Must include a commitment to continual improvement;
- Must include a commitment to legal and regulatory compliance;
- Needs to be authorized and visibly endorsed by top management; and
- Must be documented, communicated, implemented, and reviewed/maintained.

In a mining operation, for example, the asset management policy might include phrases such as these:

- A life-cycle cost basis will be used in selecting and acquiring all critical mining and primary processing equipment.
- Processing systems will be maintained using risk- and condition-based techniques in line with the organization's absolute commitments to safety and environmental standards.

Asset Management Strategy and Plans

An asset management strategy is a chosen approach for turning the asset management policy into practical reality (i.e., the preferred style, methodologies, overall long-term campaign/plan). There are differing interpretations of where and how such a strategy develops into asset plans that are more concrete and specific. However, an underlying requirement is that an adequate rationale and overall approach must be clear, from which more detailed action plans can logically be derived. A strategy should therefore have the following characteristics:

- Be long term—at least as long as the organization's business plan, and in many cases longer still (e.g., for long-life infrastructure development and whole mine life/ore-body exploitation horizon)
- Be consistent with policy, business plans, and other organization strategies
- State the required functions, performance, and condition of major assets or asset systems
- Take account of risks and asset criticality
- Contain high-level overall action plans: approximate time scales and the responsibilities/mechanisms for development of more specific asset management objectives and action plans
- Be optimized for value for money over whole asset life cycles and economic mine/ore-body life
- Be periodically reviewed and updated

Typical asset management strategies in the mining complex might include the following:

- Consolidation and updating of the asset information systems over the next 3 years
- Transition from time-based maintenance to condition-based methods for critical rotating equipment over the next 2 years using the reliability centered maintenance methodology

As these overall strategies get crystallized into more detailed asset management plans, many critical decisions have to be faced. Indeed, the backbone of good asset management

(and a source of problems in poor asset management) is usually said to be the decision making about what is worth doing, where, and when. Robust, optimized, and defensible plans will accomplish the following:

- Cover the whole asset life cycle (both in time horizon and in consideration of short-term/long-term functional requirements, costs, risks, asset performance, etc.). The term *life cycle* should normally refer to the economic production horizon of the mine/ore body or to the equipment itself if multiple equipment life cycles are likely within the mine's economic life span.
- Include capital investment, operations, inspection and maintenance, refurbishments, spares, skills, and other requirements. Some organizations only consider asset management plans to cover asset care activities (maintenance)—this misses important opportunities to optimize value by making capital investments or changing operations to reduce needs for maintenance.
- Be optimized for total value for money over the whole asset life cycle. This is a key feature in identifying the right mix of activities and in demonstrating the business justification for the costs and resources involved.
- Contain specific action plans, resource plans, timescales, and responsibilities including, in most cases, performance objectives. Longer-term plans and assumptions will inevitably be more uncertain or approximate, but visibility of these future intentions (even if they are qualified or provisional) is important to reinforce the view of the total picture. The hierarchy of plans from long-term whole life-cycle programs down to short-term tactical work programs should be transparently connected and refreshed at appropriate intervals.

One further manifestation of good asset management planning is the need to have a road map for the improvement of the asset management system itself (i.e., how to get progressively and continually better at managing the assets). Not to be confused with the asset plans described previously, this nevertheless represents an important part of the planning outputs. It requires the mining enterprise to be self-aware about current asset management capabilities and performance and to be both aspirational and flexible in recognizing the need for continual improvement. The typical development of such a road map is covered later in this chapter (see the "Asset Reference Plan" section).

Asset Management Enablers

Several factors prove particularly important in the integration, optimization, and sustainable nature of good asset management. These can be seen as generic enablers that have a facilitation effect to asset management processes. They include three principal areas of consideration:

1. Risk management
2. Information management
3. People management

All three are very big subjects in their own right, but this chapter has space only for a look at the most important features and must-do elements.

Asset Risk Management

The organization's approach to asset risk management is a strong and easily recognized differentiator between good and poor asset management competency. At the weaker end, it may be a superficial or cosmetic recognition of equipment reliability or project delivery confidence (often using purely relative terms such as high, medium, and low).

In more mature asset management models, risk management is quantitative and disciplined, and it permeates through all asset management decision making and activities. Clearly the level of detail, the appropriate tools worth using, and the business significance of asset-related risk management vary widely with the issues being considered. (Bigger risks warrant more detailed assessment, analysis, and evaluation of controls and/or mitigation.) At the very least, a competent asset management system should include an asset risk register that contains assumptions about potential failures or adverse events, their likelihood, potential consequences, appropriate controls or mitigation strategies, and accepted residual risk levels. A matrix is also commonly used to identify any cases of unacceptable risk, in which a control or mitigation action is required whatever the cost, or cases in which the cost/risk trade-off can be considered to reduce risk to as low as reasonably practicable (ALARP; see Figure 9.7-7). The scales of probability (or event frequency) and consequences vary considerably among organizations, business sensitivities, and regulatory/cultural environments, as do the chosen boundaries for unacceptable/ALARP/negligible risk.

Closely linked to the subject of asset-related risk management is the concept of asset (and activity) criticality. This, too, is a large topic, as there are usually several manifestations of importance and criticality to the business. A good asset criticality system will define the scales of importance in various dimensions, several of which may involve elements of risk (e.g., safety, environment, reputation, profit/cost), to enable a logical and auditable ranking of issues, opportunities, and activities. It will also align directly to the choice and use of key performance indicators: measures of asset management success that demonstrate achievement of the important business values and goals. The shamrock diagram in Figure 9.7-8 shows some of the complexity of considering all the interconnected and conflicting factors: The outer ring represents typical business drivers, while the inner five elements identify the available methods of scaling or quantifying the significance and contributions of those business drivers.

Asset Information Management

As mentioned in the introduction, asset information systems are sometimes confusingly called asset management systems. Even when this terminology is sorted out, there are some significant challenges and opportunities in correctly specifying, implementing, and using systems for managing asset information. Many organizations invest millions of dollars in such systems with the aim of improving efficiency, yet a large proportion of such companies do not then exploit the technologies beyond the basics of work planning and control, inventory management, and (mostly financial) reporting. Most such systems are modular and aim to support the following functions:

- Asset register and technical details storage
- Maintenance and inspection task specifications
- Work planning and scheduling
- Spare parts and inventory control, often interfaced to purchasing systems
- Maintenance and reliability history records

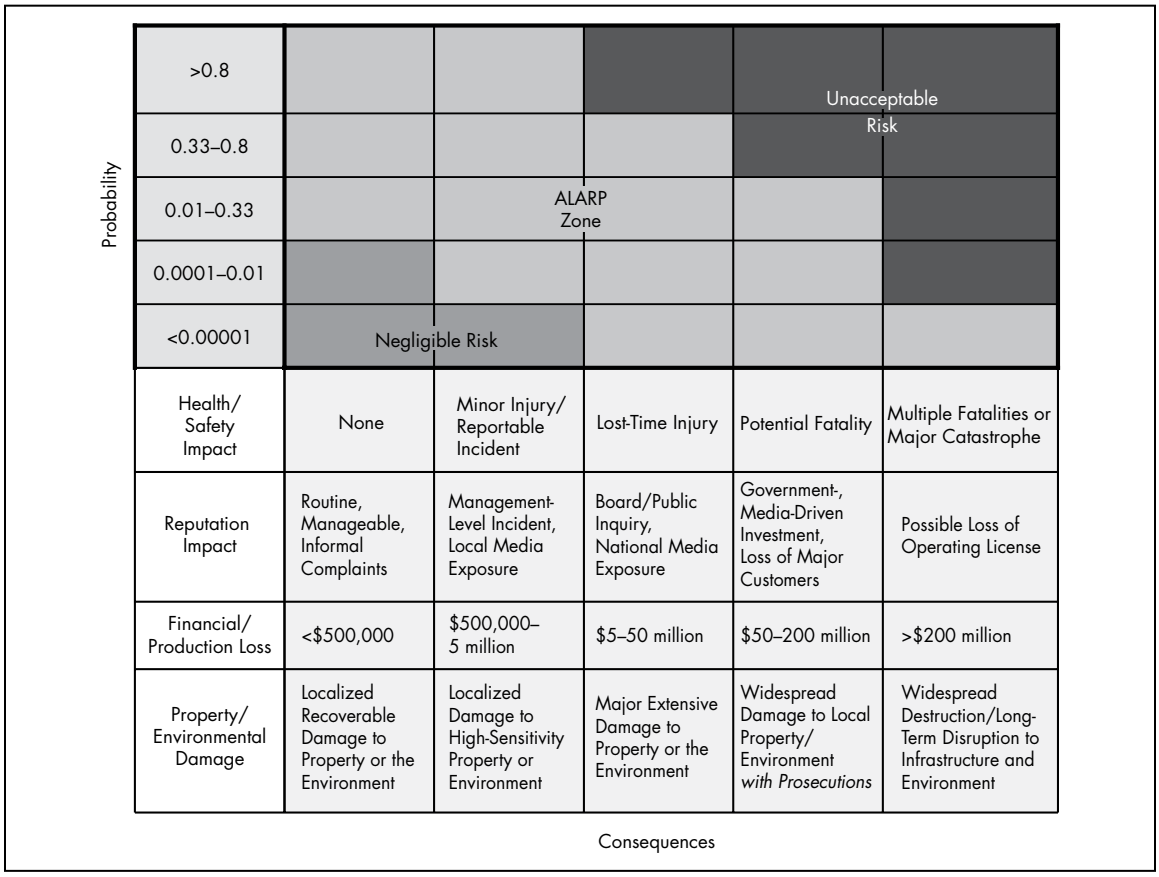

Figure 9.7-7 Risk matrix for asset-related failures and their potential consequences

- Reporting and performance analysis, often interfaced to financial systems

Asset identification and asset registers comprise the minimum starting point for such systems, and even here, great debates occur about appropriate coding and data models—for tracking individual equipment items that may perform different functions in different locations, or may be mobile, or may be embedded parts of complex systems. The key requirement is usually to identify assets by two attributes:

1. What type of asset it is (a parent/child hierarchy of equipment families, equipment types, models, components, and subcomponents)
2. What functional location it fulfills (a systems engineering view of the function provided by the asset)

The next important issue is that of granularity: Information should normally be collected and assigned at the lowest component level of an asset or asset system that requires discrete replacement or maintenance actions. For example, if the mine's maintenance strategy was always to run a particular motor to failure and then replace it, there would be little point in recording information (and procedures) for replacing the individual bearings within the motor. The normal level of detail required, therefore, is at the level of the maintainable unit. Sometimes this is referred to as a maintenance-significant item, and it is also the basis for equipment identification or tagging. However, information collected and recorded at a lower component detail may be worthwhile for the identification of failure modes and the diagnosis of failure root causes.

Information relevant to asset management normally includes the following:

- Unique asset identification numbers, often combining asset type and functional role codes
- Description of assets
- Functional and geographical locations, possibly obtained by using geographical information systems, and consideration of their static or moveable characteristics
- The criticality of assets to the organization
- Details of ownership and operations/maintenance responsibility (especially where assets interface across a system or network)
- Engineering data, design parameters, and engineering drawings
- Details of asset dependencies and interdependencies
- Vendor data (details about the organization that supplied the asset)
- Commissioning dates and data
- The condition and duty of assets, including any operating limits or constraints
- Condition and performance targets or standards, including key performance indicators
- Asset-specific standards, processes, and procedures
- Life-cycle asset management strategies, covering operations maintenance, spares, life expectancy, and obsolescence/renewal/decommissioning

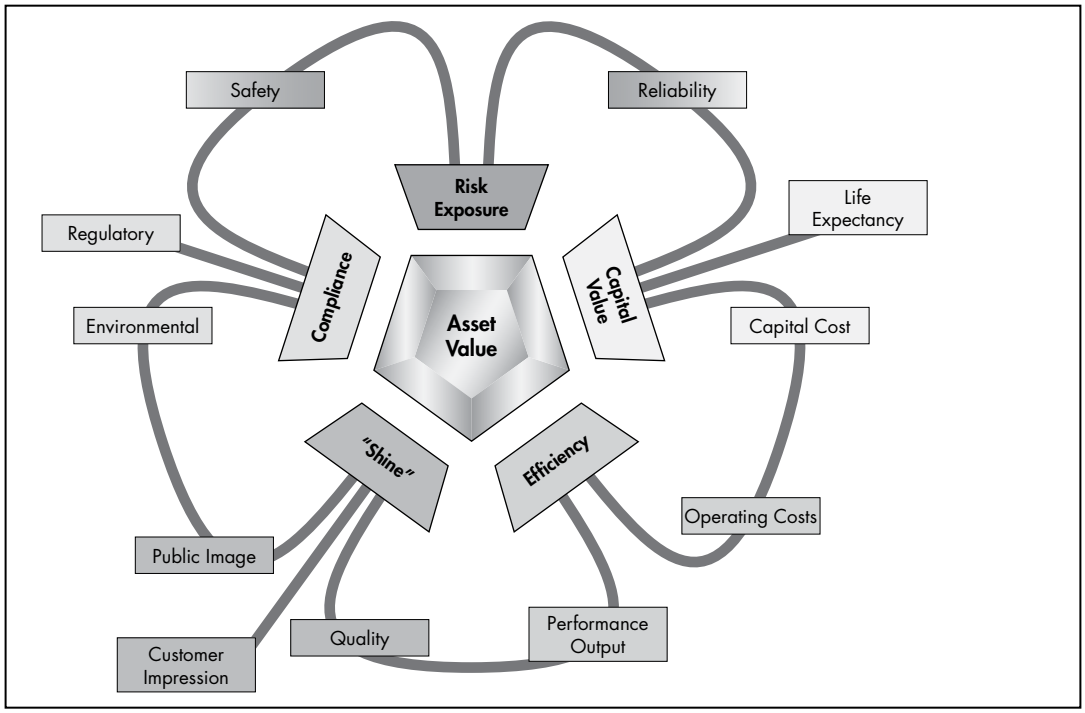

Figure 9.7-8 Shamrock diagram of conflicting business drivers and dimensions of asset value/criticality

Human Factors: Roles, Responsibilities, Competence, Communication, and Teamwork

One of the most important lessons in achieving good management of physical assets is the realization that focusing on the people who design, build, operate, and maintain such systems yields the most sustainable, biggest improvements. If people are taken care of properly, they tend to want to take care of the physical assets properly.

Work-force understanding, motivation, collaboration, communication, and good leadership are thus core and critical to optimizing physical asset management. For example, whereas a traditional competencies program ensures that a mine worker is able to perform required activities safely, productivity and engagement is increased greatly if that individual understands why the task is needed in the first place. Leading asset management organizations clearly demonstrate that ideas for improvement mostly stem from the work force (see Figure 9.7-9), so education and consultation, communication of purpose, and cross-departmental teamwork yield disproportionate benefits. This includes relationships with contractors and service providers.

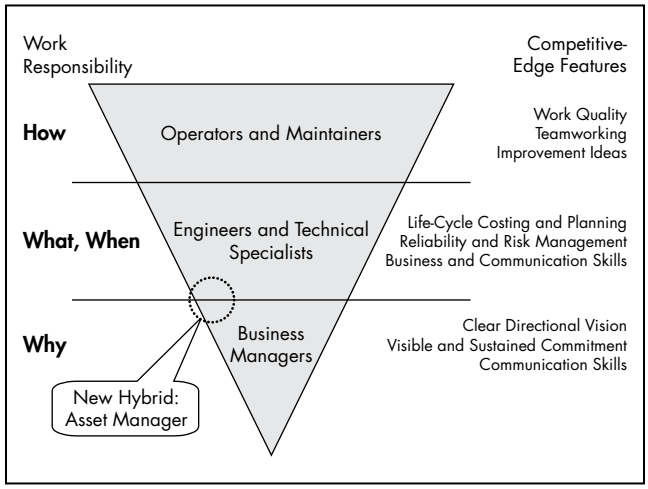

Figure 9.7-9 Support structure for ensuring the right contributions to optimal asset management

Implementation of Asset Management Plans

The requirements identified in PAS 55 for implementing asset management plans are fairly brief but they are clearly crucial—there is no point in developing sophisticated systems and optimized work plans if the delivery is poor or out of control. Yet despite the cumulative experience gained from decades of doing the day job, mining operations still suffer from operational performance and efficiency frustrations. In many cases, these occur through insufficient coordination and communication or underinvestment in competencies. Conflicting performance measures also add to the problem by reinforcing departmental silos, in turn causing inefficiencies and waste in some organizations. Each of these issues is encountered in all of the life-cycle stages of assets—from design to procurement or construction, operations, maintenance and renewal, decommissioning, or abandonment. In such cases the solutions often lie in better attention to the asset management enablers.

Monitoring and Continual Improvement

Repetitive errors and inefficiencies are also encountered through inadequate closing of the loop in capturing information and actively learning from experience. Engineering-led organizations such as mining enterprises can be very conservative or even arrogant about existing practices and ways of working. One of the challenges in asset management, therefore, is to establish and sustain the habit of looking for and evaluating improvement opportunities and acting on

them—that is, closing the loop. This represents a requirement for continual change and it exists at several levels:

- The individual assets and their life-cycle costs, reliability, efficiency, and longevity
- Mining, treatment, and other production systems—new methods, profitability, safety/environmental impact, sustainability, etc.
- The asset management system itself (processes, resources, and enablers)

The primary checklist for ensuring that such learning is taking place covers the following areas:

1. **Performance and condition monitoring** of the asset management system, the assets, and the asset systems. These should
   - Be criticality-targeted against the key business drivers (the shamrock diagram in Figure 9.7-8 provides a good check that these have been considered);
   - Be SMART (simple, measurable, available, relevant, and timely);
   - Cover leading and lagging measures (warning signs and post-event learning);
   - Look internally (e.g., asset condition and performance measures) and externally (e.g., identifying new-technology opportunities); and
   - Capture information sufficient for all legal compliances, problem identification, and root cause diagnosis.
2. **Identification of failures, concerns, trends, nonconformances, and improvement opportunities.** Formalized root cause analysis methods are usual for major incidents; however, there is also significant benefit to be had from developing a more general culture of inquisitiveness and learning at the day-to-day level: asking "Why?" to any observed problem rather than simply continuing to accept and cope with it. This style is not, however, compatible with a blame culture in which employees are driven by accountability and fear of failure. It takes time and visible behavior change by management to build trust and establish an environment of innovation and creativity.
3. **Identification of appropriate solutions or improvement actions.** There are various methods for encouraging lateral thinking in finding solutions; for example, reliability centered maintenance (see the "Reliability Centered Maintenance and Failure Modes and Effects Analysis" section) uses seven key questions to determine what type of maintenance activity is appropriate to particular equipment failure modes. One further and essential step in this process is the objective, risk-based evaluation of the potential improvement(s) in value-for-money terms. One-off changes (e.g., design modification) require different cost/benefit/risk appraisal than cyclic activities such as changed maintenance intervals or timing of asset replacement. Business skills are often a problem in technical staff, so special care is needed to ensure that processes and tools are appropriate for such evaluations and optimizations (see the "Cost/Risk/Performance Decision Making and Optimization" section; also see Chapter 2.4).
4. **Implementation of corrective or preventive action.** Even when the right changes or improvements have been identified and justified, their implementation is, of course, essential. Both the immediate actions and the confirmation of their effectiveness form part of the closing of the loop. Verification of assumptions and benefits is vital, both as ammunition to demonstrate that such innovation/change is worthwhile and as a source of further learning. For example, what proportion of anticipated improvements is actually obtained—and if not 100+%, why not?
5. **Record-keeping and documentation updates.** A sample of engineering drawings and other technical documentation often reveals that many are out of date and have not been maintained in line with the asset or management system changes. No continual improvement activity should be deemed complete until such documentation has been corrected. This is not just a matter of system integrity but is increasingly a matter for legal culpability in some jurisdictions: Out-of-date documentation can be used in a court of law as evidence of management's lack of control.

Auditing and Management Review

One advantage of an integrated asset management system is the forcing of a holistic view. Another is the requirement for regular reviews and refinement. The three-yearly certification cycle and annual surveillance requirements of PAS 55, for example, stimulate a regular practice of standing back and reflecting on the total picture. Indeed, the standard requires a formal periodic management review or audit of the whole system to ensure that it is still fit for purpose, efficient, and effective. In addition, some of the PAS 55 requirements inevitably overlap with other audit requirements, such as ISO 9001, ISO 14000, and OHSAS 18000. So it makes sense to coordinate the reviews of these systems to avoid duplication of effort.

Top management is explicitly required to participate in such periodic reviews of the overall system—this will involve senior mine management and any corporate board/parent organization. If physical assets are core to the performance of the company, then their optimal development, exploitation, and care are also critical to the success of that organization.

ASSET MANAGEMENT BUSINESS MODEL

A truly asset-centric approach to realizing business value requires an operating model that identifies the core sources of such value (the assets) and then builds activities, resources, and plans to maximize this value. The first step, therefore, is to be clear about what the real assets are.

Defining the Mining Assets

To run a successful mining business, an ore body must be found or acquired and developed, and mining and extraction facilities must be constructed, operated, maintained, and ultimately decommissioned. A wide range of ancillary services must be obtained (e.g., transport, catering, information technology [IT], telecoms, materials purchasing, recruitment, and training); these too require physical infrastructure; a wide mix of personnel, data, and knowledge; licenses; supply chain relationships; and logistics systems.

As with the North Sea oil production assets, a mining operation has to be managed as a viable business contributor or profit center. It has to include many specialist elements and yet deliver the best combination of performance and value across the whole system life cycle. To do this, the oil sector discovered that all costs and resources must be clearly measurable in relation to the resulting net outputs; the business unit (or asset) boundaries therefore needed to be as clearly defined as possible. This usually corresponded to the treatment of each

discrete hydrocarbon reservoir, with its associated production infrastructure and operating staff, as an asset business unit—albeit a very complex one, with lots of very different component subsystems and equipment types. Similarly, a typical mining operation really includes the following:

- An extraction operation
- A mineral treatment facility
- A by-product treatment facility
- A water supply and wastewater treatment plant
- A compressed air and pumping facility
- A power station or substation
- A smelter or mineral export facility
- A control and communications center
- An airport and transportation service
- A hotel or accommodation facility
- Workshops and stores
- A clinic and medical treatment facility
- An emergency control center

Such diverse component asset and system types, operational processes, people, and skill requirements comprise the dedicated asset resources, whose costs are fully attributed to the asset as a business unit. Similarly, it is the net total output of all these systems and processes working together that represents the asset's performance. This challenges and breaks down the old (strongly departmental) culture and goals, whose output measures can reinforce silo behaviors and generate internal conflicts and missed opportunities (e.g., production versus engineering/maintenance or inventory control versus maintenance/reliability).

Intermittently required resources and common services across multiple-asset business units (such as corporate finance, human resources, IT functions) should be treated as shared service providers. Some will be positive enablers, adding value to each asset at a shared cost (such as recruitment, training, and information systems support)—and these functions must be able to demonstrate competitive advantage over the alternative of using external service providers. Others may need to exert control and alignment obligations (such as common budgeting and performance reporting systems). Natural tensions do therefore exist between central command-and-control activities and individual asset needs, opportunities, and sense of local ownership. However, with clarity about the asset hierarchy and appropriate levels of delegated authority and performance measurement, the total can yield more than the sum of the parts.

Asset Manager

In mining, each asset business unit requires a specific individual with personal accountability for all costs and resulting outputs over the economic life span of the asset. Such a single point of accountability has proven to be a vital part of the business model: It involves equipping a specific person with the freedom to optimize the mix of capital investment, operating expenditures, short- and long-term production benefits, and compliance/risk management—in return for assuming accountability for the resulting net value. Clearly, such a critical role requires not only detailed asset knowledge (of all the systems and subsystems) but also commercial acumen and leadership, communication, and risk management skills. Given the strong engineering/technology and financial/management polarization of traditional recruitment, education, and career paths, however, the required cross section of skills in one person is uncommon. BP, for example, identified 20 natural asset units in the U.K. continental shelf portfolio but only 13 individuals with the requisite range of skills to become the mini-business CEOs (asset managers) to lead them. Accordingly, smaller assets were bundled together to create just 13 asset business units until such time as additional multiskilled asset managers were developed. In a mining enterprise, the corresponding role is usually fulfilled by the mine manager—with similar critical dependency on leadership, business and communication skills, and intimate asset knowledge.

Asset Management Team

As described previously, the team leader or asset manager must have clear, single-point accountability for the capital and operating expenditures and for the performance results for the asset. He or she holds the formal, signed mandate that defines the decision freedoms and constraints, asset management objectives, and responsibilities for managing the asset as a mini-business.

The asset manager is supported by the heads and/or nominated representatives of each function or department. For a typical mine, this would include the following:

- Production
- Mineral resource management
- Exploration
- Engineering and maintenance
- Human resources
- Logistics
- Finance
- Other focal-point personnel who are responsible for critical service providers

The asset management team is thus a cross-disciplinary group of managers who share responsibility for assisting the asset manager in optimization and delivery of the asset reference plan. They work with an overall asset "dashboard" or similar performance scorecard and have an obligation to seek the best overall value or asset performance irrespective of localized or departmental vested interests.

Asset Reference Plan

The asset reference plan (ARP), also called the whole life asset management plan, is a cross-functional, integrated picture that considers long-term and short-term issues and opportunities and how they affect performance, cash flow, resources, and profitability of the asset and its support activities and stakeholders. Strengths, weaknesses, opportunities, and threats (SWOT) that can affect the asset during its operational life are systematically considered, and management plans are documented. The ARP provides a shared and consistent basis for quantifying and optimizing activities for best net value to the parent organization (asset owner).

The ARP contains key information such as the asset strategy, base-case plan, and life-of-mine estimates (based on the asset strategy). Most importantly, it contains references to sources of more detailed information such as production forecasts, resource requirement assumptions, predicted dependency on critical services, SWOT analyses, and sensitivities to possible changes. The ARP also documents the main assumptions and uncertainties, and it summarizes the growth and development opportunities for an asset business unit. In short, it is the single source of truth that represents the collective understanding of what the asset is, what should be done to

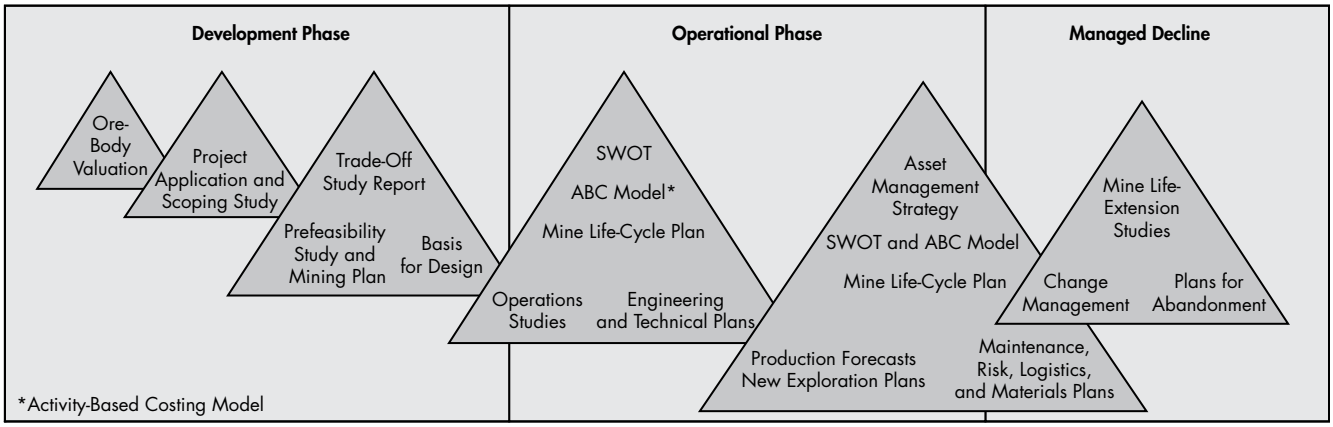

Figure 9.7-10 Evolution of an asset reference plan during asset life-cycle stages

maximize its whole life value for money, and how this maximized and sustained value will be ensured.

An ARP is the binding document that translates corporate objectives into asset-specific realities, opportunities, and plans. It has the following elements:

- Clarifying the nature, boundaries, and characteristics of the asset
- Developing and defining the whole life asset management strategy
- Planning for long-term exploitation and production (the asset utilization view)
- Integrating planned actions, responsibilities, assumptions, and uncertainties (including the asset investment and asset care/maintenance views)
- Identifying growth opportunities and risks and how they will be managed (projects, innovations, contingency planning, and alternative scenarios)
- Understanding and optimizing the life-cycle costs and production values associated with these activities and opportunities (the net value-for-money view)

The ARP is used to

- Define the boundaries of the asset at which cash flows and all aspects of performance are measured;
- Provide a clear management mandate (the responsibilities, ownership, and limits of decision making within the asset);
- Professionalize asset planning, subsurface studies, facilities design, and equipment selection by providing for better cost estimation, forecasting, and what-if scenarios;
- Integrate all process and functional strategies into a single picture, including key external dependences on service providers;
- Integrate the management team and functional contributions—all commit to a single shared purpose rather than often conflicting departmental goals; and
- Continuously assess key event dates and critical decision points in the project-development, operation, and abandonment stages of the asset life cycle (the manifestation of real continual improvement, including a record of why things are being done).

The content of an ARP evolves over time (see Figure 9.7-10) from initial design stage with its many assumptions and uncertainties to infrastructure construction and commissioning, steady-state operations, and ultimate decline (including any life extensions, reuse, and/or abandonment). Nevertheless, this living document acts as a maintained central register of the knowledge, assumptions, and plans for the asset, pooling the contributions of all relevant parties and functional disciplines. Success in any one area of activity is only measured in terms of the net impact on the total picture.

Questions That an ARP Needs to Answer

The ARP must contain a clear description of the asset and its characteristics (including SWOT); the strategic development and production plan; the key events, risks, and assumptions or uncertainties; and the component resources and functional activity plans. It is therefore the single source of truth for asset management. It should answer the following vital questions about the asset:

- What is it, and what condition is it in, today?
- Where are we going with it? (Commitments, strategies, objectives, challenges)
- Why? (Corporate business drivers and policies, asset SWOT)
- What needs to be done, by whom, when? (Life-cycle plans)
- What value will this generate? (Economic and other stakeholder views such as safety, customer satisfaction, compliance, reputation, etc.)
- What are the alternative options, risks, and contingency plans?

These elements map very closely into the requirements that have been incorporated into PAS 55, and they also align with the elements of asset management documentation that have since emerged in other industry sectors.

What Goes into an ARP?

One of the important lessons of the oil and gas asset management experience is that creation of the ARP is itself a valuable catalyst that leads an organization toward the necessary changes of focus and behavior. For example, long-term consideration of resourcing, investments, and cost-effectiveness is forced by the need to construct a whole life production (asset utilization) and a view of the asset's financial and economic life. All relevant activities, assumptions, and cost elements (e.g., engineering design, operating scope, financial

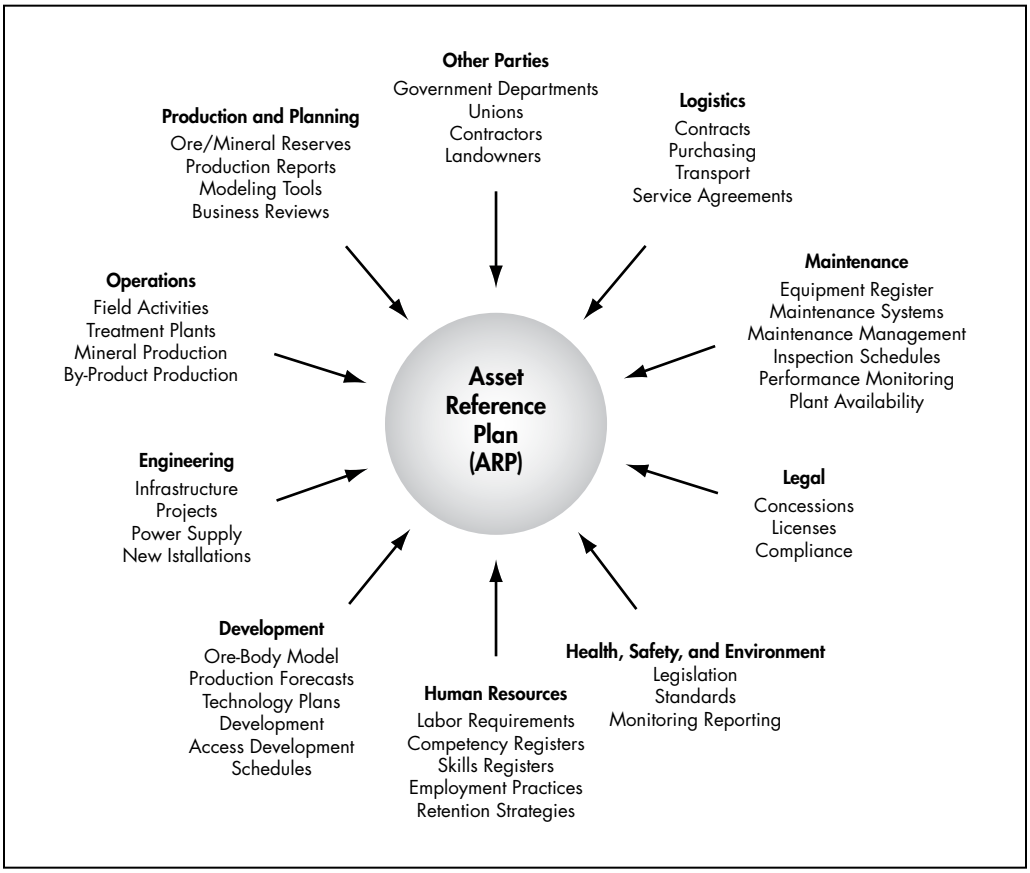

Figure 9.7-11 Inputs to the asset reference plan come from nearly all areas of the business

values, maintenance requirements, logistics, contractors, and assumptions about materials) are needed to construct such a jigsaw puzzle, and all parties can then see the whole picture (see Figure 9.7-11).

After such a full picture is assembled (one that includes recognition of uncertainties and risk elements), both the immediate priorities and the long-term plans can be made to ensure best-value delivery. So, for example:

- Capital investment requirements can be prioritized and justified with greater credibility and relevance.
- Human resource requirements can be met with adequate development (recruitment and/or training) lead times.
- Physical infrastructure, equipment, and facilities can be developed, operated, and maintained in line with the whole life business values.
- Future technology developments can be identified, explored, and exploited more flexibly, including initiation of more focused research and development.
- New legal requirements, concession/license changes, and other constraints can be identified and mitigated more readily.
- Information and data requirements can be specified more appropriately in relation to identified needs (e.g., performance criteria or key uncertainties/vulnerabilities).

The ARP provides a consolidated view of the current status of (and future plans for) the asset at a specific moment in time. It cannot hold, of course, all the detail about all the activities—if it did, it would become totally unwieldy and unreadable and would be constantly out of date. This means that a distilled summary of each contribution is needed at the total-picture level, creating a good and useful discipline for each contributor, to encourage clear explanation of what is needed in each area, why and when, with what likely or possible outcomes (and risks). Again, the collective creation of an ARP acts as a valuable catalyst to improve individual competencies and teamwork, encouraging all to think and present their proposals in more businesslike terms and to communicate in a language others can understand.

Because the information in each area is being continuously updated, the most recent ARP still needs to be frozen at a specified point so that corresponding assumptions can be made; net value/logic can be checked; and resource implications, costs, and plans can be developed or adjusted. For example, the production potential for a new mineral or mine block, including 10%/50%/90% confidence bands, must be agreed to before the facilities requirements, exploration and access development plans, and human resources can be developed. Subsequent emergence of a new drilling technology or changing environmental constraints would change these assumptions, so the ARP content will need to be reconsidered and updated—possibly in all respects. For an oil and gas company, this involves a review of the ARP at least annually plus, of course, following any significant external event or change in circumstances. Other sectors would need to update their asset management strategies and plans on different cycles or triggers, depending on the stability of the embedded assumptions and on external business influences.

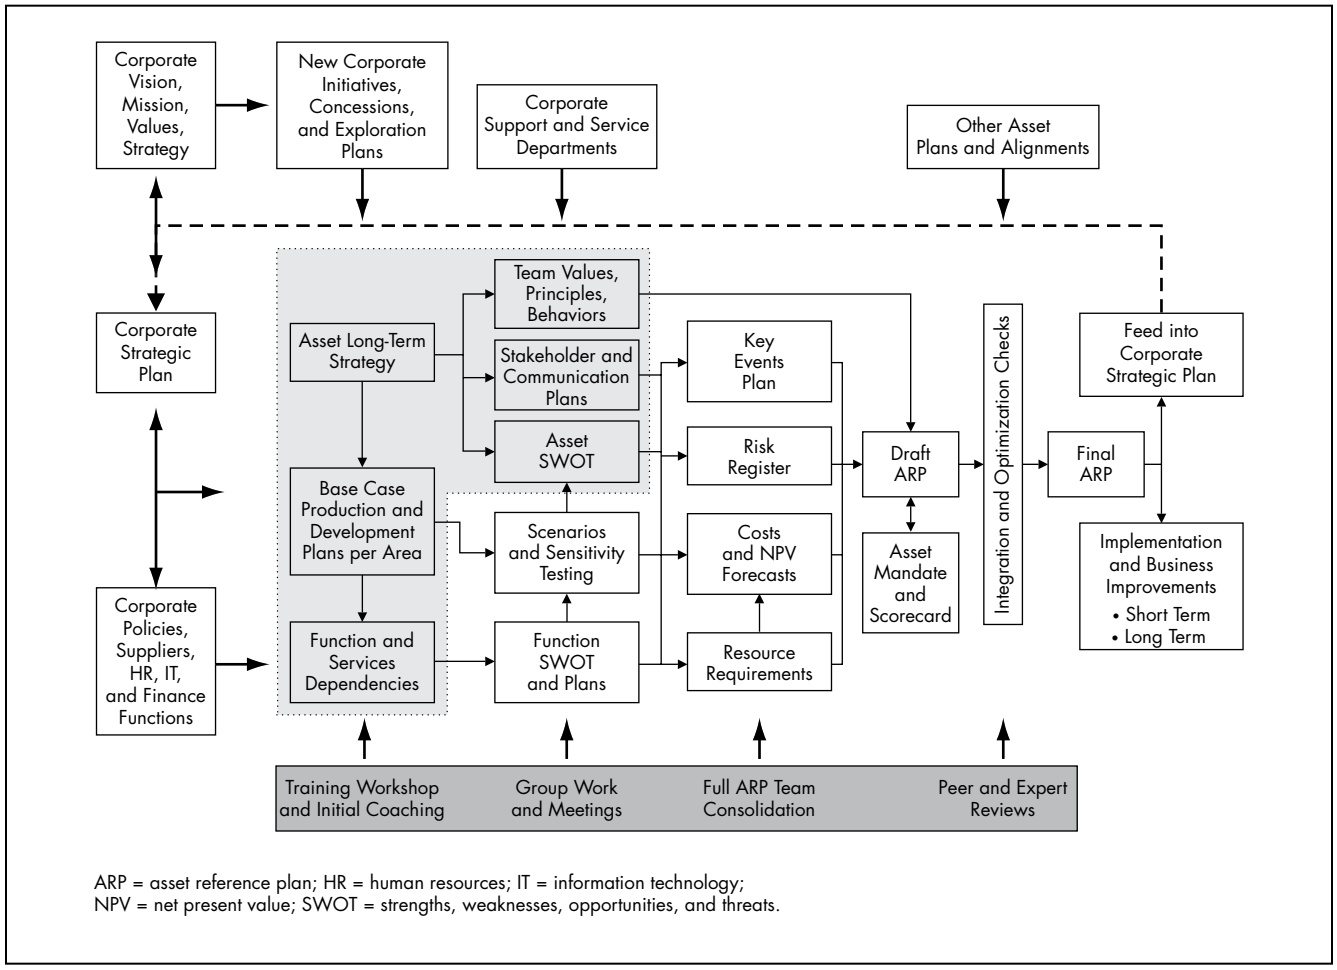

Figure 9.7-12 Development steps in building an asset reference plan

ARP Development Process

The development of a first ARP is very challenging, particularly in an organization used to working in rigid departmental silos. (These may be functional silos such as operation, maintenance, and inspection, or asset-type silos such as electrical, mechanical, or civil engineering). In such environments, staff members are often not familiar with cross-functional working, long-term thinking, or the language of business value. In the oil and gas sector and in other industries subsequently, it has been found that resistance can be reduced, and confidence built, by breaking down the development of the ARP into carefully planned simple steps characterized by good program management and leadership and allowing enough time for the development of understanding and ownership among the contributors. The first phase in particular—usually an intensive training workshop and coaching period; see Figure 9.7-12)—should involve all the key personnel who will be involved in developing the ARP and working together in the future to optimize the whole life performance and value of the asset. Thereafter, the work comprises a mix of parallel activities (each area assembling, filtering, and clarifying its contribution to the total picture) and team-based mutual explanation, integration, alignment, and iterative what-if consideration of alternatives, barriers, implications, and contingency plans.

ARP Most Likely Case and Risks/Uncertainties

The ARP most likely case, or base case, should describe the current state of the asset and future most likely development plans, including only the production and development/cost assumptions that have reasonable expectations of success or occurrence. (In oil and gas terms, this is described as P50, representing a 50% probability of achievement.) This is the baseline against which future developments, innovations, and improvement options can be tested for incremental value. The combination of such potential "stretch targets" comprises the optimistic case (e.g., P10 in Figure 9.7-13—the highest predicted performance, but with only a 10% chance of attainment). Conversely, any threats, vulnerabilities, or uncertainties about the achievement of the baseline plan are regarded as risks that need to be managed (including prevention, mitigation, and contingency plans). The least-predicted production profile is represented by the P90 scenario in which, even in the worst case, there is a 90% confidence level of extracting this performance, assuming such risks and problems are encountered. Figure 9.7-13 shows a typical production forecast example. Similar graphics might be used for the capital investment program, various operating expenditures, human resource requirements, and other dimensions of the ARP—provided that the assumptions are pooled and aligned (i.e., that the base-case expenditures, resources, and production/performance assumptions work together).

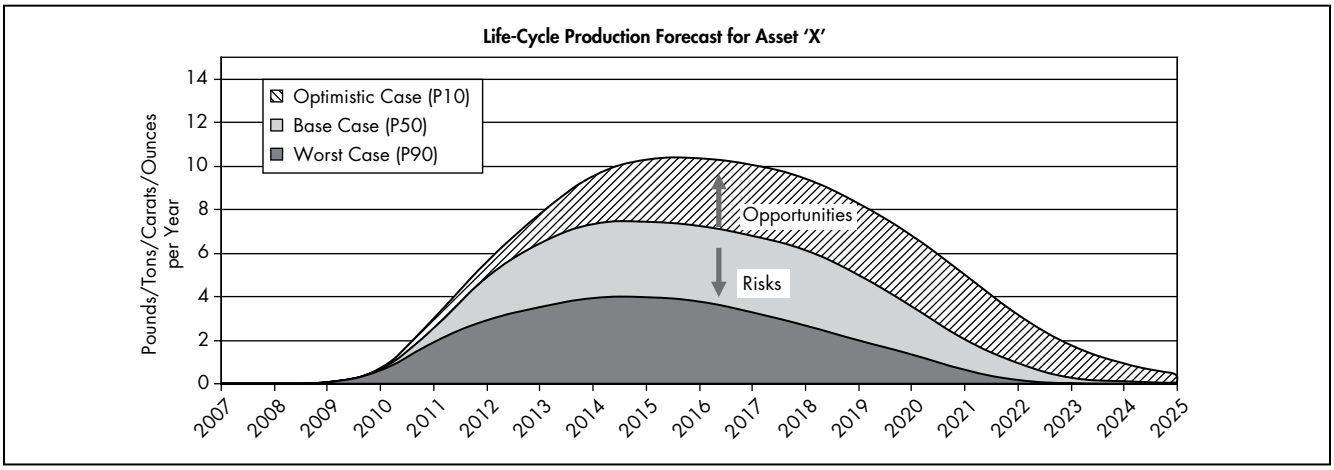

Figure 9.7-13 Performance forecasts, asset life cycle

Similar logic applies to the scope of improvement opportunities and to the identified risks.

Finally, based on many cycles of developing such a cohesive, asset-centric view of strategic plans, a key requirement of the ARP development process has proven to be the understanding and agreement of what is included in a credible base case. It is imperative that, in compiling the most likely case, only realistic and approved development assumptions are included and most likely costs estimated. ARP teams should not include immature proposals that have a low probability of success, or resource requirements/budgets that include contingencies and spare capacity. Such project proposals or budget contingencies should always be handled as possible variants from the most likely case (see Figure 9.7-13), either as improvement opportunities (with their individual cost/benefit/risk appraisals) or as identified risks (with appropriate probability and severity consideration, and prevention/mitigation/contingency justification).

METHODOLOGIES AND TECHNIQUES FOR EQUIPMENT ASSET MANAGEMENT

At the level of managing individual equipment assets and asset systems, several methodologies and good practices have evolved—many translated across from other industry sectors. The following is a short summary of the most common ones, with a brief comment about their usage and limits in the mining industry.

Life-Cycle Planning

Equipment life-cycle plans (see Figure 9.7-14) are a good way of centralizing assumptions about specific technical, management, and business issues. In many cases, these plans will start out as asset-type strategies—such as generic maintenance plans for trucks, drilling equipment, or electrical systems. The same equipment, however, can exhibit very different performance and deterioration characteristics and require very different care/maintenance if it has different business criticality or is used in different ways or in different operating environments. This is why an understanding of criticality and risk management is essential to the optimized asset management of physical assets across their life spans.

Life-cycle planning and evaluation are very different processes in the design or purchasing phase than they are in subsequent reviews and decision making. In the acquisition phase, the necessary assumptions about the downstream operating performance, costs, and achievable life spans are inevitably uncertain. Furthermore, such equipment acquisition decisions often have big, immediate cost and cash-flow implications—and the false economy of selecting the cheapest initial cost solution can result in negative consequences over the long term in the areas of performance, operating costs, or repeat investment. This is why life-cycle costing (LCC) methods are so important in this phase—to select the best value-for-money option.

Downstream refinement of life-cycle plans are, by comparison, mere fine-tuning of the equations having to do with reliability and risk, performance, cost, and life span. Only as deterioration reaches the point at which normal maintenance is insufficient, or as technology obsolescence looms, will the big price decisions need to be reconsidered. Again, LCC methods should be used to evaluate major refurbishments and life-extension options, asset replacement, upgrades, or decommissioning. Understanding of the disciplines and decision-making methods for optimal management of aging assets is still limited, but some exciting developments are on the horizon for incorporating business rigor, risks, and commercial optimization in determining what is worth spending on what and when (see the "Managing Aging Assets" section and SALVO Project [2009]).

Life-Cycle Costing

The principles of asset LCC or whole life costing are widely documented but often poorly applied, despite good intentions and the evident benefits in terms of value for money. The most important such principles are these:

- Life-cycle costs should include all capital and operating expenditures over the full economic life of the asset. They should also include all identifiable risk exposures, liabilities, and lost-opportunity costs associated with asset performance, utilization, or ownership.
- The assumed asset life should be determined based on optimal renewal timing where practicable. Calculations should be based on maximum time the asset will be required or 40 years, whichever is shorter.
- Future cash flows, risks, and performance impact should be discounted to present-day economic values using

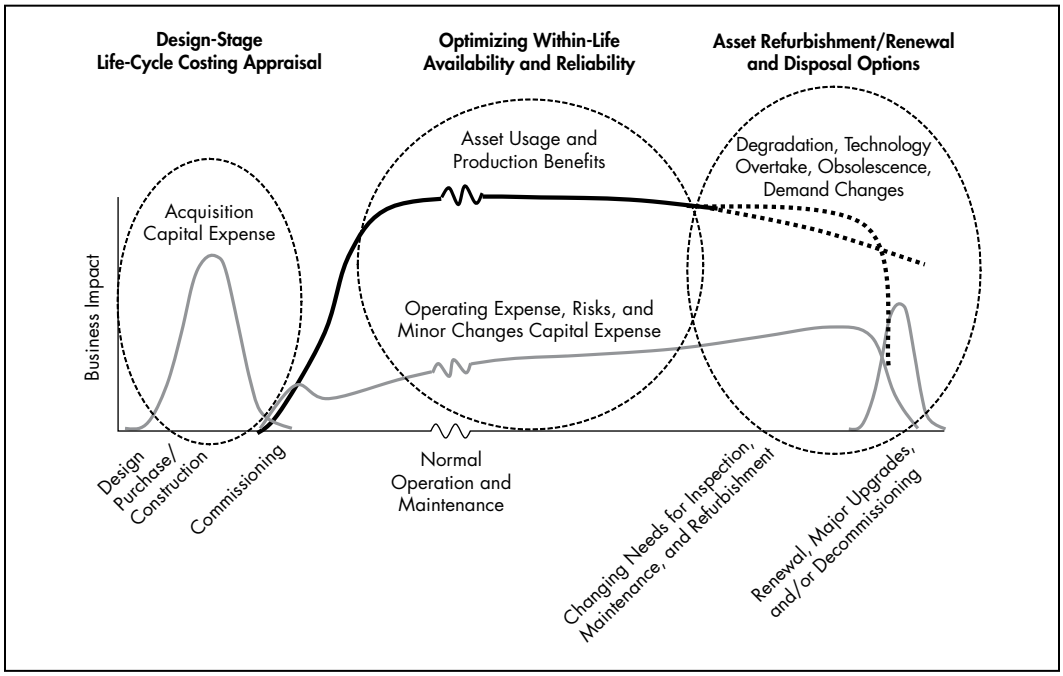

Figure 9.7-14 Life-cycle phases for equipment

standard financial accounting methods such as net present value, internal rate of return, equivalent annual cost (EAC), and process and instrumentation.
- Uncertainty in assumptions or data quality should be explored for potential impact on the asset management decision (sensitivity analysis).
- Analysis rigor, and methods or tools used for analysis, should be proportionate to the criticality and complexity of the decision being faced (see Figure 9.7-15).

Risk and Reliability Engineering

Designed-in reliability offers a valuable opportunity to eliminate maintenance and operating costs and unnecessary downtime and to achieve good economic asset life expectancy. However, the reality of many purchasing and design-stage decisions is distorted by affordability, time pressures, and "siloed" budgets. Despite this, an understanding of asset risk and reliability engineering can significantly improve the exploitable life-cycle value of physical equipment by at least guaranteeing that the right questions are asked about potential sources of unreliability, unavailability, and risk. In critical cases, it may also be worth constructing a reliability, availability, and maintainability model of a proposed system. Such a model can be used to run simulations that identify vulnerabilities in proposed designs or configuration options.

Downstream, during equipment operating life, there are opportunities to observe actual behavior and to investigate sources of unreliability based on hard evidence. The understanding of failure mechanisms and patterns is also vital at that time. The most basic of these concepts is that of the "bathtub curve"; the combination of risks associated with "infant mortality," random causes (not usage or time related), and degradation mechanisms (see Figure 9.7-16).

In practice, neat, symmetrical bathtubs are exceedingly rare (it would by very surprising to find equipment whose early-life risks exhibited the same level of threat as the old-age degradation rates). The concepts are valuable, therefore, but the quantitative treatment of such patterns needs to be considered with great care. Many academics and commercial service providers are guilty of overselling particular analytical methods for equipment reliability and maintenance data (e.g., Weibull analysis), but the lack of data volume and/or the noise in the system from other failure modes often invalidates the significance of the diagnosed patterns. In particular, looking at just one failure mode at a time in the desire for simplified analysis and understanding can result in distorted conclusions; the existence of other failure modes or planned maintenance affects the observed cases in complex ways. A few examples illustrate this problem:

- Many failure modes and effects analysis (FMEA) and reliability centered maintenance (RCM) studies—both discussed further in the "Reliability Centered Maintenance and Failure Modes and Effects Analysis" section—consider each failure mode one by one. The chosen prediction, prevention, correction, or mitigation action itself, however, may introduce other failure modes (such as maintenance or recommissioning errors). System reliability and total maintenance requirements are not just the sum of the parts.
- Analysis of the reliability and life cycles of, for instance, pump seals might involve collecting time-to-failure data for those seals. However, the existence of other pump failure modes (such as lubrication problems, overloading, damage by a foreign object, etc.) will mean that observed seal failures are only the cases that did not encounter these other problems. The degree of such censoring (or of resetting the clock through other repairs) and their implications for net reliability are complexities that render many reliability engineering studies tenuous or even invalid.

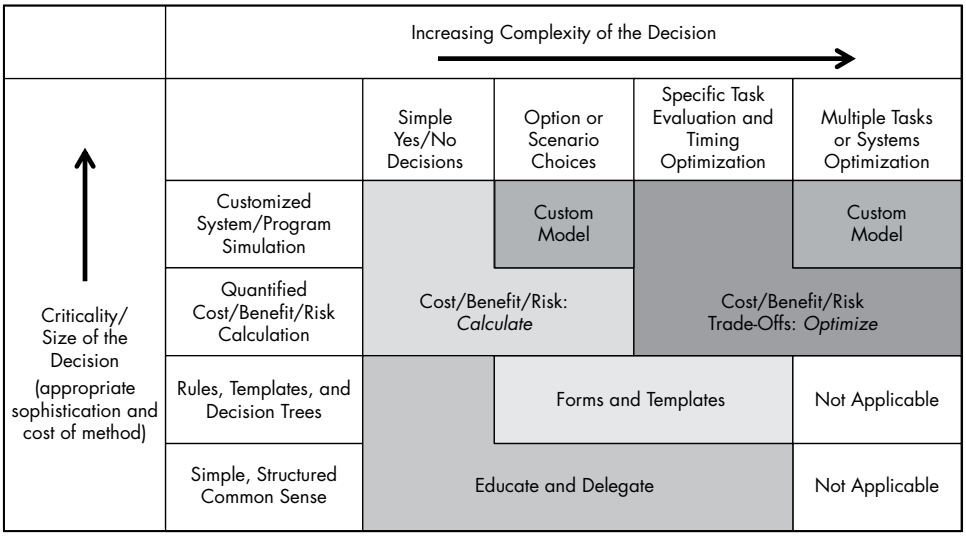

Figure 9.7-15 Level of rigor proportionate to criticality and complexity of decisions

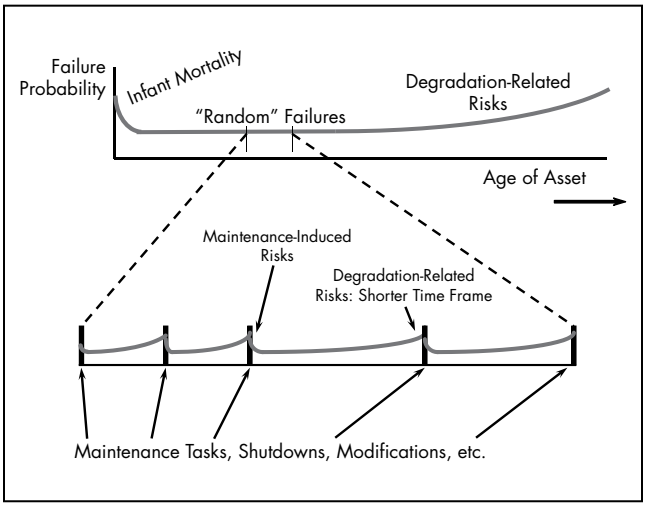

Figure 9.7-16 Bathtub curve and subsidiary hand-basin curves

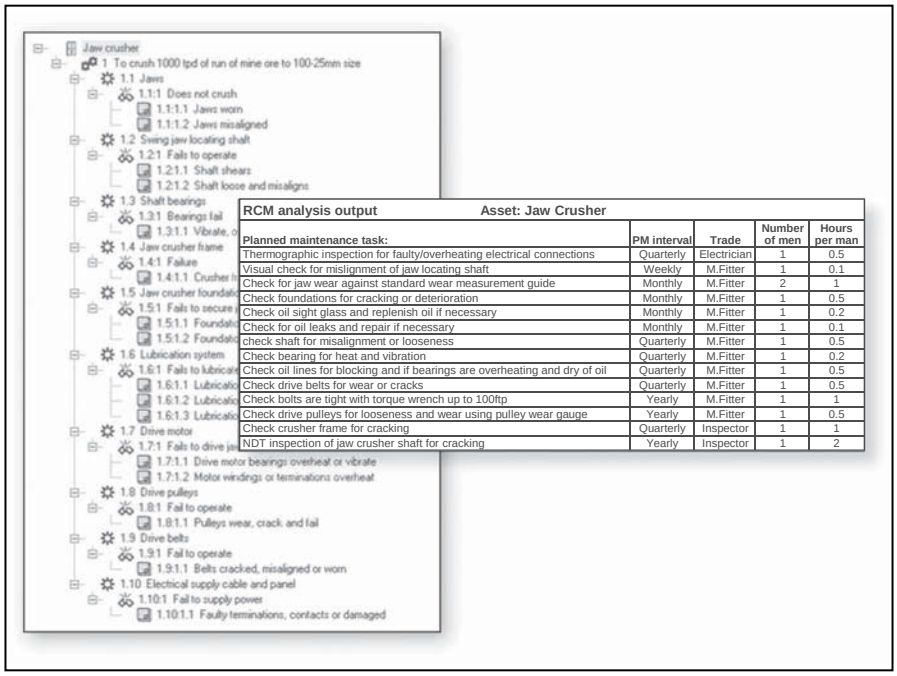

A further need for care lies in the hierarchy of components, assemblies, equipment units, and systems. What is an unrecoverable failure at one level (requiring a maintenance or renewal resetting of the clock) may be just a patch-and-continue event in the next higher level of the system hierarchy. This can lead to more confusion in the consistent recording, coding, and analysis of maintenance and reliability data. Unfortunately, few practical and robust guidelines exist for navigating this subject (an exception is www.macroproject .org [MACRO 2000]), despite the large volume of academic research and niche examples that exist. So it is important to obtain access to high-caliber reliability engineering expertise when addressing this topic.

Reliability Centered Maintenance and Failure Modes and Effects Analysis

RCM was originally developed in the civil airline industry to force early consideration of how equipment and components might fail and so the appropriate predictive, preventive, corrective, or contingency planning options could be identified. Using seven mandatory questions, it gives members of a multidisciplinary review team some auditable logic rules for determining what type of maintenance is appropriate, based on the possible failure mechanisms and consequences. This is particularly valuable when managing a complex mining or processing plant, where there are invariably many possible failure modes (see Figure 9.7-17): it provides a consistent navigation path with logical pigeonholes for predictive, preventive, detective (failure-finding), and mitigation actions.

FMEA is an older and simpler format for recording how equipment components fail, and with what effects, and for capturing the expert opinion about options to prevent, predict, or mitigate such events. In many cases, organizations use RCM for the most critical systems and complex equipment (typically about 40% of mining and processing equipment) to ensure added rigor in the process. They use a shallower, more informal version such as FMEA for less critical cases for which an RCM-level study would result in "paralysis by analysis."

However, both RCM and FMEA have their limitations—they only consider each failure mode individually and may miss some important combinational effects. They are also *reliability* centered methods, so they miss the tasks that might extend operational life (such as painting) or raise operational efficiency (e.g., catalyst changes or replacement of mill balls). Furthermore, there is plenty of debate on various flavors and derivatives of the basic techniques, such as the need for criticality prioritization, the viability of streamlining, and the need to analyze *all* equipment and *all* failure modes. The techniques also fail to determine and demonstrate that the identified solution is the most cost-effective option (sometimes an 80% solution at just 50% of the cost is better than a total solution at greater expense). Also, the majority of RCM studies during the early days of application in the mining industry were not fully implemented or sustained, usually due to lack of criticality targeting (selective usage) or inadequate appreciation of the significant training and worker hours involved. It seems that RCM programs need some aspects of total productive maintenance (TPM) to survive and deliver their full potential.

RCM analysis output **Asset: Jaw Crusher**

Planned maintenance task:	PM interval	Trade	Number of men	Hours per man
Thermographic inspection for faulty/overheating electrical connections	Quarterly	Electrician	1	0.5
Visual check for mislignment of jaw locating shaft	Weekly	M.Fitter	1	0.1
Check for jaw wear against standard wear measurement guide	Monthly	M.Fitter	2	1
Check foundations for cracking or deterioration	Monthly	M.Fitter	1	0.5
Check oil sight glass and replenish oil if necessary	Monthly	M.Fitter	1	0.2
Check for oil leaks and repair if necessary	Monthly	M.Fitter	1	0.1
check shaft for misalignment or looseness	Quarterly	M.Fitter	1	0.5
Check bearing for heat and vibration	Quarterly	M.Fitter	1	0.2
Check oil lines for blocking and if bearings are overheating and dry of oil	Quarterly	M.Fitter	1	0.5

Risk-Based Inspection

Risk-based inspection (RBI) provides a systematic criticality assessment of static equipment and provides for the choice of appropriate condition monitoring or inspection methods. Developed by a consortium of oil refineries into the American Petroleum Institute's Recommended Practice RP 580:2009, it is heavily focused on hydrocarbon processing (corrosion and other deterioration mechanisms, vessel and pipe materials characteristics, etc.), but cross-industry variants are already appearing. Its strengths lie in the systematic nature of the necessary survey of pressurized or containment assets, such as pipes and vessels, the "probability × consequence" view of the risks they represent, and the mass of technical data available on corrosion rates, materials properties, and inspection methods. It is notably weak, however, in determining how much to spend on the inspections or condition monitoring (e.g., inspection intervals requiring consideration of cost/benefit/risk optimization methods) and in pointing to alternative risk-treatment options such as periodic replacement or contingency planning. RBI complements RCM, therefore, by providing an expanded level of detail in the methods and criticality of condition monitoring for static equipment such as pipes and pressure vessels. Both methods, however, fail to address the business case (financial cost/risk justification) for the proposed actions—for which cost/risk optimization methods are needed (see the "Cost/Risk/Performance Decision Making and Optimization" section).

Total Productive Maintenance

TPM encourages attention to detail, shared responsibility between operators and maintainers, and a holistic overall equipment effectiveness (OEE) measure of success.

$$\text{OEE}(\%) = \text{availability}\% \times \text{utilization}\% \times \text{quality}\%$$

Emerging from the Japanese automotive industry, TPM has largely transformed the asset-responsibility culture of the manufacturing sector. Stimulating a culture of "right first time," cleanliness, and autonomous maintenance (getting the operators to do the obvious diagnosis and first-line maintenance actions), it changes attitudes and delivers many quick wins. It falters, however, on the specific tools needed to determine which tasks are worth doing in the first place (where RCM is strong), in some aspects of risk management (low-probability, big-consequence events slip through the net of OEE calculations), and in consideration of sustainability or equipment life expectancy (OEE focuses only on the short term). TPM (and the OEE measure) focuses predominantly on these main sources of loss and inefficiency:

- Downtime
  - Equipment failures
  - Setup and adjustment time
- Speed losses
  - Idling and minor stoppages
  - Reduced speed and underutilized throughput capacity
- Defects and quality losses
  - Scrap or rework
  - Reduced yield rates

Total Quality Management and Six Sigma

Total quality management (TQM) and Six Sigma (6σ) are proven and thoroughly respected bundles of continual-improvement techniques. From Deming via Japan and from Motorola, respectively, TQM and 6σ represent the push for quality in processes, for fact-based continual improvement, and for greater client focus and teamwork. They work through multi-disciplinary quality circles and improvement activities, and they are excellent catalysts for communication, clearly focused objectives, and analytical decision making. They

bring with them a host of data-centric analytical tools for diagnosing patterns, root causes, and trends. However, they are most suited to high data volumes and repetitive activities to provide the raw material for analysis. They also lack some of the teeth of the RCM and RBI methods (to link the diagnosis of a problem to the best solution, and the right amount of that solution). Again, like TPM, they are good for revealing some quick-win opportunities and, if supplemented by appropriate complementary tools, they can form a valuable framework for sustainable continual improvement.

Root Cause Analysis

Root cause analysis covers a family of methodologies (many of which are also embedded in TQM and 6σ) for investigating anything from major single incidents to repetitive equipment failures. Most companies have procedures for the former, but few have really established a "why?" culture in which employees routinely drill down to the underlying causes of observed problems to solve them properly. The basic methodologies are excellent for the fact-based consideration of why critical events occurred and for learning how to prevent reoccurrence. They force a multi-disciplinary, open consideration of the evidence and all possible interpretations or conclusions before potential improvement actions are selected. However, the sustained *habit* is difficult to establish and maintain without the enablers of motivation and recognition and a continual-improvement culture.

Example: Root Cause Analysis Used in Improvement Program

A vanadium pentoxide mine consists of three main asset systems: the open cast mine; the crushing, screening, and milling plant; and the kiln. Since commissioning 5 years previously, this particular mine had struggled to produce a profit. Major reliability problems were still being encountered, despite an RCM study that had moved the mine from a mainly on-failure (corrective) maintenance strategy to a preventive and predictive program.

Step 1. Diagnosis of the problems (root cause analysis)

Input, process, and output (IPO) mapping. The IPO method was used to identify weak links, bottlenecks, and vulnerabilities in the mining and treatment processes. Four IPO studies were performed, with the following results:

- Theoretically, the whole mining operation should have been able to produce profits and have a sustainable output.
- The kiln was the bottleneck in the whole process.
- The crushing, screening, and milling operation had more capacity than the kiln. Because most of the equipment was in series, breakdowns frequently interrupted kiln production. Planned shutdowns to overhaul the troublesome plant feeding the kiln also interrupted kiln production.
- The open cast mine could boost output by hiring loaders and trucks at short notice, if necessary, to make up any lost output and build the 48-hour buffer stock once more.
- A vulnerability to flooding also needed to be investigated for appropriate risk management.

Review of current maintenance strategies. RCM had introduced improved condition-monitoring techniques and preventive maintenance overhauls of the jaw crusher, screens, cone crushers, and ball mill. This resulted in an improvement in uptime, but the workload for fitters, riggers, and electricians required additional staffing, and contractors were engaged to fill the resource gap. However, poor workmanship from inexperienced contractors then resulted in some recommissioning failures shortly after each start-up. The net result was that the improved output was still insufficient to secure sustainable profitability of the plant.

Review of operational flexibility (interprocess buffer stock). (1) Ball mill to kiln: The stock level of milled vanadium-bearing ore in the two existing silos between the ball mill and the kiln averaged 8 hours of kiln production. (2) Mine to jaw crusher: The stock level of mine ore between the mine and the jaw crusher was 48 hours.

Step 2. Improvement options

Maintenance strategy. Further improvement in maintenance strategy (preventive and predictive) could possibly produce further marginal benefits, but this would take 2 to 3 years to materialize.

Buffer stock. (1) Ball mill to kiln: An increase of up to 2 weeks in process stock was identified as possible by installing a bypass conveyor belt in an adjacent unused area. This could be added to the kiln feed system at short notice with a rented front-end loader to maintain feed to the kiln. Savings from this improvement could be validated and investment in a new loader considered in the future. (2) Mine to jaw crusher: An increase of 1 week in an area outside and adjacent to the pit was identified as possible.

Step 3. Implementation

Ball mill to kiln. Improvements to the buffer-stock facility did not require capital investment and were soon implemented.

Mine to jaw crusher. The additional stock of mined ore was only necessary over a period of 3 months in the rainy season. The improvement was organized to be implemented prior to the next rainy season, as a heavy rain could put the mine out of operation for a week (this occurs approximately once a year).

The net result was that the mine produced its first clear profit within the first year of implementation.

Cost/Risk/Performance Decision Making and Optimization

Good decision making lies at the heart of good asset management. Yet the priority concern of many organizations has instead often been efficient delivery—trying to do the same thing more quickly and/or more cheaply. Investment projects, for example, are pressed to deliver on time, on budget, irrespective of downstream consequences for performance, value, risk, or sustainability. Cost/performance/risk optimization, particularly over different time horizons, is a crucial part of asset management (see Figure 9.7-18). This is invariably a cross-disciplinary process, involving compromise between budget holders and beneficiaries, between technical excellence and affordability, between the interests of the customer (or public) and the asset owner. The optimization process can be complex and dynamic, often involving data uncertainties and convoluted mathematical relationships. Nevertheless, this area yields some of the biggest fruit of all—by remixing the priorities for capital investment or maintenance activity and challenging what is worth doing in the first place (i.e., doing the right things) before ensuring that such activities are delivered as cost-effectively as possible.

Optimization opportunities exist in almost all aspects of asset acquisition, development, operations, maintenance, modifications, spares, upgrades, replacements, and decommissioning. The process requires multi-disciplinary inputs of any relevant data, tacit knowledge and assumptions, math

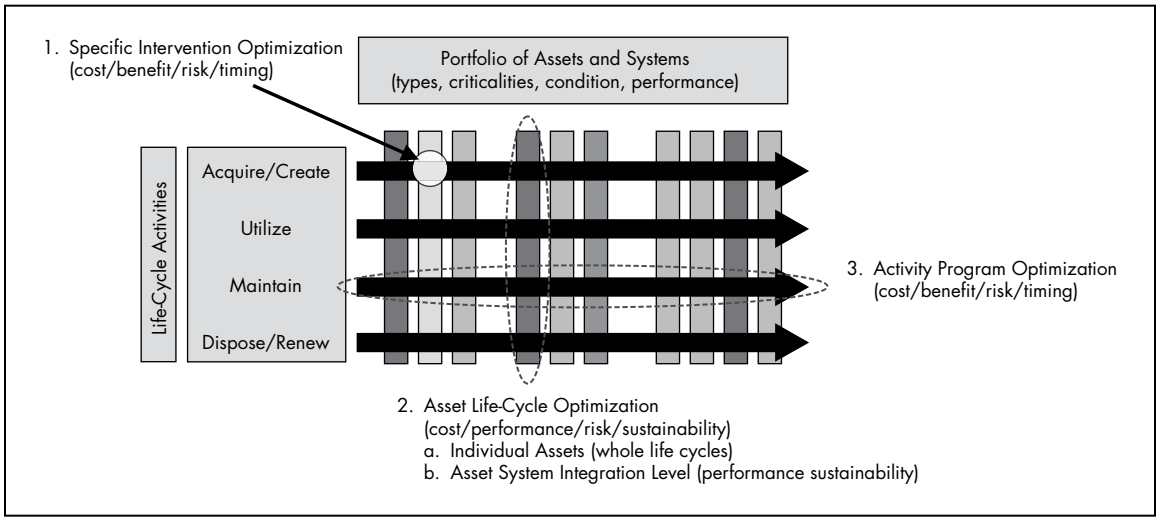

Figure 9.7-18 PAS 55 requirements for optimizing asset management activities

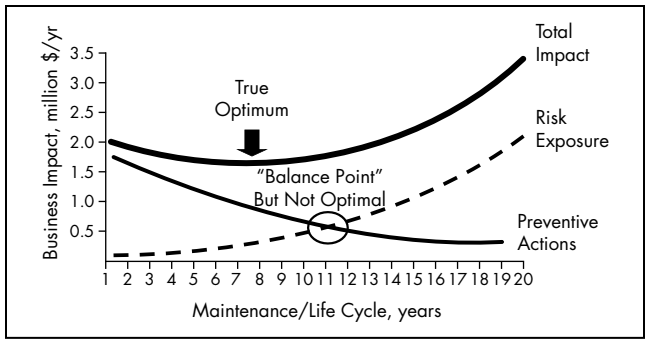
calculation of the business impact for different options, and the selection of the best combination (minimum total business impact; see Figure 9.7-19).

Two practical challenges are encountered in the effort to identify this optimal compromise—the lack (or poor quality) of data available and the mathematical complexity of determining how much risk (or performance, or asset life) will result from what level of expenditure. The first of these problems can be handled to a large degree by estimating ranges and testing for sensitivity: This reveals the key assumptions that have the greatest influence on the decision and the areas where future data collection should therefore be focused. Meanwhile, the correct mathematical treatment of assumptions, in determining the total business impact of different options, is increasingly viable and practical with the availability of modern software tools. For example, the MACRO project (MACRO 2000), a 20-company European research and development program carried out in the 1990s, yielded seven bundles of analysis calculators to tackle 42 types of common asset management decisions, ranging from "How many spares should I hold?" to optimal inspection/maintenance intervals, shutdown strategies, capital investment options, and optimal asset replacement timing (see www.decisionsupporttools.com).

The examples shown in Figures 9.7-20 and 9.7-21, for instance, involved optimizing major overhauls of an air compressor and determining critical spares requirements. Compared with the vendor's recommendations, this revealed a 25% longer interval between overhauls and a 15% reduction in costs and risks. Although not yet common in the mining sector, such techniques are now being successfully applied in oil and gas, petrochemical, electrical and water utilities, rail and air transport, defense, and manufacturing industries. Typical results range from 25%–40% reductions in maintenance costs, 3%–15% increases in production systems' uptime, and up to 30% savings in asset whole life costs. Furthermore, such methods are explicitly designed to work with incomplete information, using range estimates and exploring sensitivity to different assumptions. Thus they also provide a clear indication of the robustness of the decision and a quantified value for money, allowing better data to be obtained in the future.



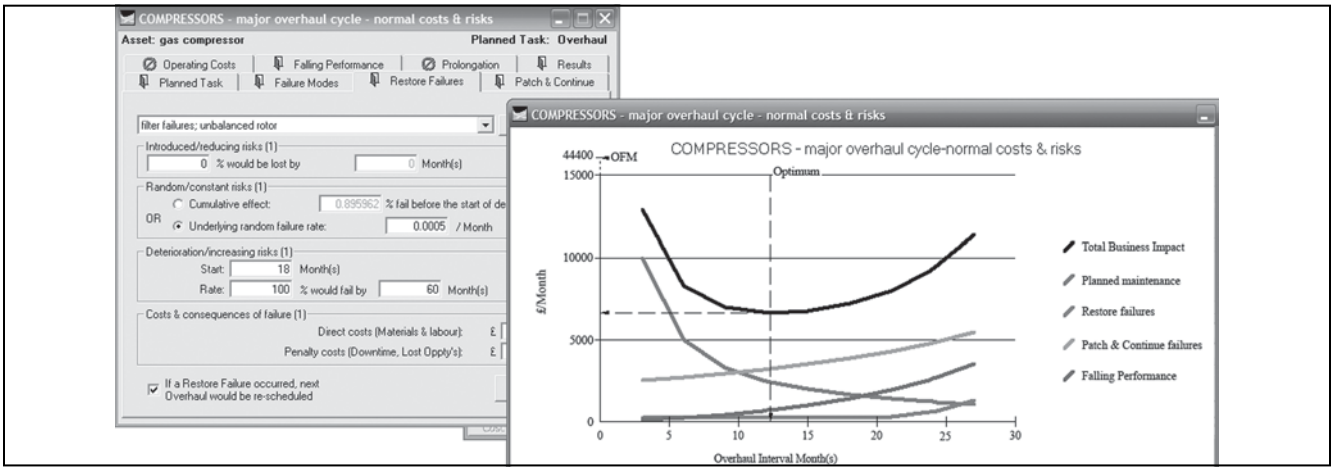


Figure 9.7-19 The true objective of cost/risk optimization

Managing Aging Assets

A great deal of attention is rightly paid to initial investment decisions, major capital projects, and capacity improvement opportunities during the life of a mine or asset. The "managed decline" phase, however, can also yield significant opportunities to influence mine performance and longevity. Secondary production and development opportunities can obviously extend a mine's profitable life span, but so too will an appropriate program of reducing operating and maintenance expenditures as the end of mine life approaches (see Figure 9.7-22). This is sometimes possible as the criticality of production systems lessens (i.e., as failure consequences are declining). Changes to maintenance intervals, nonreplacement of spares, and decisions about optimal timing for facilities decommissioning can provide significant scope for savings, thereby deferring the inevitable ultimate point of economic mine abandonment.

Similarly, as the production or processing equipment ages or deteriorates with use, changes to maintenance regimes, spares policies, refurbishment options, and equipment replacement considerations must be considered (see Figure 9.7-23).

Equipment renewal is, however, often mishandled in terms of objective total business impact: there is a tendency to push equipment to the limit, often into areas of degradation and risk well beyond the economic refurbishment or replacement point.

Figure 9.7-20 Optimizing maintenance intervals

Courtesy of Decision Support Tools Ltd.

Figure 9.7-21 Optimizing slow-moving spares

Extending Economic Life by

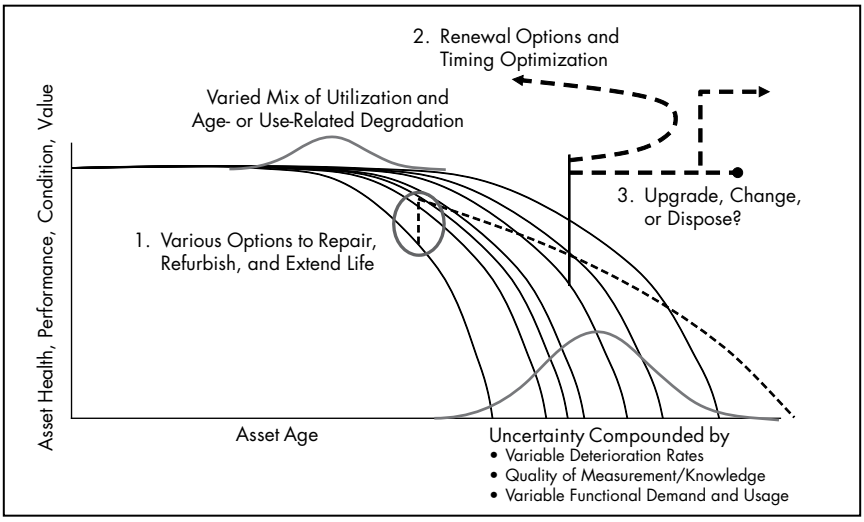
A. Production Enhancement (e.g., secondary recovery)
B. Operating Cost Reductions (as systems criticality reduces)

Figure 9.7-22 Extending mine life by increasing production and/or reducing costs

This is partly due to the perceived effect on cash flow; renewal can be a major capital expense, whereas periodic patch-and-continue repairs are individually tolerable. There are no natural trigger points that signal the need to review the cumulative cost (and projected increases) of such repairs, to review the financial value of growing risks or of degrading performance, or to calculate the total business impact for different intervention timings. The correct asset management decision, on the other hand, should evaluate alternatives: doing nothing (continued use/maintenance), refurbishing (life extension), opting for like-for-like and design change renewal (if possible), and choosing from among risk/impact mitigation options. The best choice, and optimal timing, will be identified by minimum total business impact (with appropriate discounted cash-flow considerations for intervention and expenditure timings—EAC is the most flexible financial method for doing this). Such evaluations and business-case justifications for appropriate action should also demonstrate the net impact of delay, or premature intervention, thereby quantifying the urgency or timing sensitivity for the activity (see Figure 9.7-24).

CONCLUSION

Asset management has clearly grown to become a lot more than just looking after the hardware (maintenance). During the years since 1990, it has emerged to become a core business framework for industries such as the mining sector that have a preponderance of physical assets. At a corporate level,



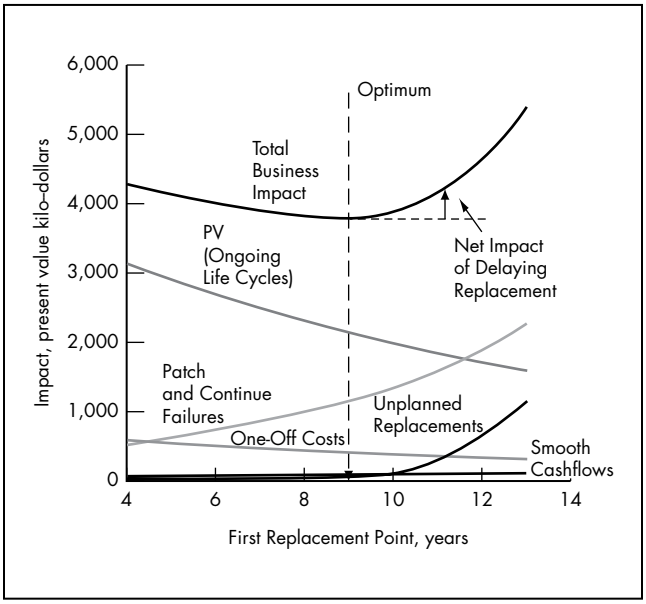


Figure 9.7-23 Options and uncertainties faced in connection with aging equipment

Courtesy of Decision Support Tools Ltd.

Figure 9.7-24 Justifying optimal asset replacement timing

it provides a model for coordinating and optimizing cross-departmental activities toward common value-for-money goals. At the level of the discrete mine, production system, or equipment, it provides language, processes, and tools for determining what is worth doing when and where. The PAS 55 standard (which is now evolving into a full ISO standard, as 21 countries have already endorsed this proposal) provides a generic and well-proven checklist of good practices, offering help in determining existing strengths and weaknesses, planning improvement programs, and demonstrating competent governance to various stakeholders. More importantly, asset management is consistently proving to yield very substantial performance, cost, and risk benefits compared with traditional siloed functional departments with their conflicting objectives.

Clearly, significant challenges are involved in adopting a joined-up, whole life-cycle asset management model, not least in the education, culture change, and leadership styles that are needed. However, the prizes are so great, and the logic (once demonstrated) so evident, that all mining enterprises can be expected to develop and/or adopt such an approach to their activities during the coming years.

ACKNOWLEDGMENTS

CHAPTER 9.8

Automation and Robotics

Paul Lever

INTRODUCTION

The need to improve the productivity, safety, and profitability of mining is driving the widespread application of automation technologies in mines. Automation in its many forms is something that miners interact with on a daily basis but may be unaware of its existence. The current implementation of mining automation and robotics has not yet significantly changed mining processes. It has, however, begun to demonstrate its potential value to improve the productivity and safety of these mining processes and associated unit operations. This has lead to a growing vision within the industry that fully automated/robotic mining will be a major part of mining in the near future. This vision includes mines that have the following capabilities:

- Automated personnel and equipment tracking
- Automated materials handling—trucks, loaders, conveyors, sizers
- Smart drills—automated drilling of holes and recognition of material characteristics
- Accurate and automated movement and positioning of all mining equipment
- Automated mechanical mining systems
- Remote supervision from distant locations
- Intelligent and integrated control over all mining processes to optimize resource value

Benefits of Mining Automation

Why does this vision of a fully autonomous mine exist today? Traditionally, the main perceived benefits for introducing mining automation have been

- Improved safety—Removing operators from hazardous and stressful mining environments;
- Higher productivity—Through the improved performance of individual machines (more metric tons per hour) and reduced downtime (automated machines see less duty than human-operated machines); and
- Reduced labor costs—Automation removes operators from machines. Penman (2002) suggests labor accounts for approximately 20% of the cost of operating a large haul truck.

Although these benefits are still appropriate today, the current renewed interest in automation and robotics in mining is related to the following perceived additional benefits:

- Limiting operational variance. Automation allows machines to be controlled so that their output is well defined. For example, an automated shovel would load more consistent bucket payloads. This allows a truck size to be selected for the shovel that will be consistently loaded to its target payload.
- Improved precision. Automation means mining tasks are executed at their planned locations and times. For example, an automated blasthole drill will drill blastholes at their precise location and specified depth as designated by the blast pattern (Holmes 2006). This means the outcomes of blasts are more consistent and generate the desired rock fragmentation, which has significant downstream benefits.

The more significant benefit of limiting operational variance and improved precision is that they enable production consistency. This means that mine designs and, more specifically, mine plans, as well as production and schedules can be generated where there is a valid expectation that they can be achieved. Automation allows mining processes to be controlled more effectively (more like manufacturing facilities) where individual processes as well as the complete mining process can be optimized. The introduction of automation is expected to serve as a catalyst for new credos for mining similar to those that have evolved through introduction of total quality management methodologies to manufacturing.

Definitions

To understand what mining automation and robotics are and what potential impact they have on mining operations, it is important to define the basic terms:

- **Mechanized:** Operations performed by machines
- **Automatic:** Does not make decisions but completes task by following well-defined rules
- **Semiautomatic:** Partly automatic and partly manually controlled

Paul Lever, Professor and CRCMining Chair, Mechanical and Mining Engineering School, University of Queensland, Brisbane, Australia

- **Automation:** Mining tasks completed by machines without human workers
- **Autonomous:** Functions independently without human supervision
- **Robotics:** Machines with high-level capabilities to sense and reason about their environment. Such machines are required for successful automation of tasks in high variable and unpredictable mining environments.
- **Intelligent:** Machines with the ability to learn, understand, and deal with new situations

What Makes Mining Automation Challenging?

Automation is used extensively in many other industries and has demonstrated great value in improving productivity (Gaimon 1985; Carlsson 1995). Its successful use in the manufacturing sector is in the automation of well-defined manufacturing cycles of identical components in a well-known and well-structured environment. Mining is typically conducted as a series of discrete steps, or unit operations, by groups of equipment types working in tandem, such as drilling, blasting, loading, hauling, ground control, and materials processing. Here the highly variable and unpredictable mining environment affects the successful execution of each or sequences of unit operations. Thus, automated mining systems must be able to sense, reason, and adapt to this unpredictable environment in order to function effectively. In addition, these systems need to operate for 365 days per year in very harsh mining environments. For these reasons, many existing automation technologies from other industries are not readily transferred into mining.

The growth of robotics, driven primarily by the military, has provided the tools necessary to develop autonomous mining systems. These developments have been driven by low-cost increases in computing power; new algorithms for signal processing, perception, and control; and in particular, new sensing technologies such as Global Positioning Systems (GPSs) and radar and laser systems (Durrant-Whyte 2009). These tools are essential to accurately locate, control, and coordinate the activities of robotic machines. Onboard sensors can generate real-time maps of the mine environment (geometry and geology) around these machines so they can be optimally controlled. This spatial control information is essential to plan and schedule the complete mining process (including machines). This will make mining operations more precise and predictable (like a factory) and ultimately dramatically more productive.

Fully autonomous mining that encompasses the complete spectrum of mining processes will be expensive and require significant technical development. More importantly, it will only be achieved through significant change management of mining culture to accept these innovations. Mine automation technologies will achieve the highest probability of success using a multistep implementation program. The resulting early introduction of technologies can provide mining benefits such as

- Operator aids that improve machine performance and reduce machine damage,
- Improved mine sensing systems that can provide managers with better information about the state of the mine,
- New mine models that allow managers to execute operational decisions,
- Semiautonomous and remote-control capabilities that remove operators to safer environments, and
- Collision-avoidance technologies that prevent accidents.

Mining Robotics—The Science

Field robotics is now well established in the research, commercial, and military arenas. Mining robotics is a stream or application within field robotics. The basic science (with associate sensors, computing hardware, etc.) that drives the technology in this field is not being developed by the mining industry; however, mining robotics is using and reengineering this technology. Several good textbooks and journals explore the extensive science and technology of field robotics. Buehler et al. (2010), Siegwart and Nourbakhsh (2004), Everett (1995), and Ge (2006) are excellent references for more detailed information.

Evidence of the close link between researchers in field robotics and mining equipment manufacturers is Caterpillar's sponsorship of the Carnegie Mellon University (CMU) participation in the Defense Advanced Research Projects Agency (DARPA) Grand Challenge competition. This competition tests the performance of autonomous ground vehicles in a series of different outdoor environments and demonstrates the state of the art in mobile robotics. CMU won the last competition in 2007 and has been in a longstanding partnership with Caterpillar to develop automated mining equipment (Binning 2009).

A very large body of basic research into the development of autonomous vehicles includes major themes such as route planning (Al-Hasan and Vachtsevanos 2002; Frazzoli et al. 2002; Salichs and Moreno 2000); obstacle detection and avoidance (Azouaoui and Chohra 2002*)*; close maneuvering strategies (Gomez-Bravo et al. 2001); and autonomous vehicle control system design (Pereira 2001).

MINING AUTOMATION AND ROBOTICS IN PRACTICE

This section provides an overview of selected automation solutions for the mining industry. Some are commercially available, others are being trialed at mine sites as precommercial technologies, and some are still in the research and development (R&D) stage. Detailed published information about many of these systems is difficult to find as manufacturers and mines are reluctant to release information that might hurt their competitive advantage.

Autonomous Haulage Systems—Technology

Autonomous haulage systems are generally divided into two major divisions: site-level systems, sometimes called the office site manager, and machine-level systems, sometimes called the onboard controls.

Site-Level Automation

The site-level systems provide an interface between the human (and software-based) mine planners, provide data for business tracking, and provide optimization and control over the haulage system machines. *Mine planning* is defined as determining the goals and priorities and communicating them to the mine management tools, and *mine management* is defined as optimization of existing resources to accomplish the goals.

Mine planning. This requires significant human interaction to set goals such as prioritizing production volume versus

cost factors (fuel usage, risk of machine damage) or prioritizing short-term production versus long-term mine efficiency. The challenge in mine planning is to ensure that both explicit and implicit goals are accurately translated to the more automated mine management system.

Mine management. Fortunately, there is a large body of experience with mine management systems. However, a new generation of mine management systems will be required to address the requirements of autonomous systems. The next generation of such systems will require much more detailed mine models and many new features to manage autonomous equipment.

Machine-Level Automation

Machine-level automation requires the ability to

- Understand what tasks need to be accomplished (high-level planning);
- Determine location (positioning);
- Perceive the environment based on the location (perception);
- Based on the environment and position, plan future tasks to achieve the desired goals (task-level planning);
- Execute the planned primitives (primitive execution); and
- Handle exceptions.

High-level planning. High-level planning is the ability to interpret directions from the mine management system and to select the appropriate behaviors. For example, if an autonomous truck is directed to a load area, it needs to understand the path, validate the path, and ensure that it has the required behaviors and capability to execute the plan.

Positioning. Positioning is the ability to determine the machine's pose, meaning its location and orientation. For autonomous machines, an accurate reliable pose is critical. Although absolute accuracy is actually not as critical, the ability to accurately register the machine's pose to the mine model is a requirement. Multiple types of positioning must be considered:

- For aboveground applications, the most common real-time kinetic Global Navigation Satellite Systems (RTK GNSSs) are
  - RTK GNSS + machine sensors (such as odometers),
  - RTK GNSS + machine sensors + inertial,
  - RTK GNSS + machine sensors + inertial + perception-based positioning, and
  - RTK GNSS + machine sensors + inertial + pseudolites (ground-based satellites or reference stations).
- For belowground applications, the most common types of positioning systems are
  - Radio frequency (RF) based distance measurement,
  - Perception-based positioning + machine sensors, and
  - Perception-based positioning + machine sensors + inertial.

These positioning systems are well known in the industry. Perception-based positioning systems have been used in restricted environments such as factory settings for more than two decades (Caterpillar 1991) and in underground mining applications for nearly a decade (Ferret 2003). RTK GNSS-based positioning systems have been used to provide centimeter-level accuracy in construction applications for a decade (Saghravani et al. 2009). RTK GNSSs are susceptible to poor GNSS coverage and must be augmented to provide very high levels of availability. Unfortunately, specific areas (near the poles) and areas with blockage to the east and west can have significant problems with GNSS coverage. However, governments around the world have pledged strong support to the GNSS infrastructure; and as more satellites are put in service, the GNSS coverage should continue to increase substantially. The most well-proven technology to augment GNSS for short durations is using inertial sensors plus odometry. Unfortunately, this technology only has short-duration accuracy. Other possibilities for augmentation include pseudolites, often called ground-based satellites, or RF-ranging beacons. These systems allow individual mines to establish their own ground-based positioning system, which, unfortunately, can be very expensive to install and maintain.

Clearly, the more types of independent positioning sources that are available, the more robust the positioning solutions will be.

Perception. Autonomous machines generally need a good understanding of their surroundings to accomplish object detection and sometimes assist with positioning. The perception system usually requires information from the mine model and the positioning system to accurately determine and report the location of objects. Perception sensors can come in several different forms: radar, laser, vision, and sonar (not discussed here).

Radar has been used since the early 1900s to detect ships and large metal objects. More recently, millimeter-wave radars have been developed to detect objects for adaptive cruise controls and autonomous machines. Radar has the advantages of long range and "seeing" through dust and fog. However, radar suffers from relatively poor resolution when compared to laser-based systems. The size of an object that can be detected depends on the object's radar cross section (RCS), defined as the projected area of a sphere that would return the same signal to the transmitter. The most effective means to increase the effect of RCS is to install corner reflectors. Commercial units are sold for small boats to improve their detection ability by radar. Corner reflectors can be thought of as "tail lights" for radar transmitters.

Laser systems provide the best resolution but suffer from obscurants such as dust and fog. Newer lasers overcome much of this limitation by using multiple reflections from each point or from time gating the return to ensure that small, diffused particles (dust, fog, rain, and snow) do not obscure other objects. As the density of particles increase, the effectiveness of this method diminishes. As with radar, retroreflectors (such as tail lights or reflective tape) can be added to targets to greatly enhance their visibility to laser.

Vision has significant promise for low-cost object detection and object recognition that is most like human perception. There has been a tremendous amount of work in this field and rapid progress is being made, but so far, vision is limited to relatively short-range applications. Vision also is sensitive to shadows, dust, fog, rain, snow, and reflective surfaces (e.g., a reflection in a puddle may be confused as a real object).

Combining multiple spectrums has significant advantages. For example, combining radar and laser gives the longer range and improved penetration of radar with the laser's ability to detect smaller obstacles and improved object classification. As another example, combining laser and vision allowed the TerraMax team (in the Grand Challenge competition mentioned previously) to recognize tumbleweeds in the desert that stumped a vision-only system in earlier tests (Broggi et al. 2010).

Unfortunately, there are currently no practical standardized tests by which to easily determine the capabilities of object-detection systems under all conditions.

Another consideration for the practical use of autonomous systems is that none of the obstacle-detection systems available today have the ability to differentiate a pile of small loose rocks (e.g., a windrow left by a motor grader) from a single large rock that could damage tires.

Task-level planning. Task-level planning is defined as establishing a sequence of task or behaviors to accomplish a goal and is generally rule- or constraint-based. As expected, task planning varies significantly based on the type of goal, the number of constraints, the variability of the environment, and the flexibility of the automated system. One of the common machine-level planning tasks is object avoidance.

Primitive execution. Executing planned primitives is the fundamental machine operation; some examples include drilling, tramming, loading, grading, stability control, dumping, and ripping. These operations generally require continuous closed-loop control and are probably the closest machine operation to a human skill.

Exception handling. Handling exceptions is the ability for an autonomous machine to recognize that it does not have the means or required primitive ability to handle the existing situation, and thus it resorts to fail-safe behavior—usually stopping and asking for help.

The building blocks for autonomous haulage system technology have been developed over the past two decades to the point where commercially viable automation systems for underground mining are now available, and commercially viable haulage systems for surface mines will be available within the next few years. In the near future, autonomous and intelligent remotely operated machines will provide the opportunity for remote operations centers that allow miners to work in the relative comfort and safety of an office environment. These first-generation systems should rapidly evolve to provide continuous improvement in efficiency, productivity, and machine availability.

Autonomous Surface Dump Trucks

One of the principle benefits from using fully automated dump trucks (ADTs) is the direct reduction of labor costs. Penman (2002) found that for two-axle dump trucks in the 220-t (metric tons) class, labor accounts for approximately 25% of operating costs, fuel approximately 45%, and tires approximately 30%. For the larger, 300-plus-t class truck, Penman found the approximate cost split is labor 15%, fuel 30%, and tires 55%. Other benefits include improved safety through the removal of operators from hazardous areas and reductions in machine duty (rate of accumulated damage), and fuel consumption through more consistent operation. For example, the world's first fully automated straddle carrier system at the Port of Brisbane has reduced energy costs per container move by 40% (Kalmar Industries 2007).

The enabling technologies (navigation, truck control, and collision detection) for ADTs exist in a semimature form, and prototype ADTs integrating these technologies have been developed and tested. Commercial ADT systems are not yet available. Of the major haul truck manufacturers, Komatsu and Caterpillar have both developed and demonstrated autonomous dump truck technologies.

Komatsu currently has two sites operating its ADT technology, called FrontRunner. Codelco, at its Gabriela Mistral mine in Chile, has been operating 11 autonomous haul trucks since 1997. More recently, Rio Tinto, at its West Angelas mine in Western Australia, has been operating five trucks since late 2008 (Cribb 2010). Both sites are using 930E-4 electric-drive trucks with a payload of 300 t, and the trials are intended to test autonomous trucks in high-production scenarios. In both cases, the ADTs are not working on the same haul roads with manually driven trucks.

Komatsu's FrontRunner autonomous haulage system operates as a comprehensive fleet management system for mines. The haul trucks are equipped with vehicle controllers, high-precision GPS, obstacle-detection technology, and a wireless network communication system. The system has the capability to navigate a haul route, dump automatically to hoppers or to the ground, and work with some (but not all) loading equipment. The system leverages off several mature technologies, notably the GPS and inertial navigation systems for navigation, and millimeter-wave radar and laser systems for safety and collision detection.

These technologies are integrated using largely fixed automation strategies. Trucks navigate from a so-called pit database, which serves the purpose of a haulage map and contains largely geometrical information, notably the boundaries of the haul road, the truck's travel path, and the boundaries of the loading and dumping areas. The boundaries represent the extent of the ADT's allowed safe operation and are established by driving a light vehicle fitted with high-precision (differential) GPS around the haulage perimeter. The safe-working-area boundaries in load areas are updated as the shovel moves. As an ADT is manually driven along the required haul route at the required speed, the truck's control computer records position, speed, and direction, defining the truck's travel path. The truck's control system (steering, braking, engine, and dumping functions) has the truck "replay" this path to navigate from the load area to the dump zone and back again. The use of the teach–replay approach used in current ADTs simplifies the problem of planning the truck's course or path. The truck doesn't need to plan its path; it knows its path having learned it in the training run. The repeatability of the replayed paths under this approach is high, but it is necessary to add "dither" (a small error in truck path control so that the truck does not always follow the exact same path on the road for every trip, thus causing wear over a broader surface of the road) to the steering action to distribute road wear.

A central control computer manages the ADTs on a particular haul. Each ADT continuously communicates key data (position, speed, and heading) back to the central control computer, which provides general haulage management including tracking each truck's trajectory and anticipating collisions. An onboard safety and collision-avoidance system based on millimeter-wave radar and laser-sensing technologies is used. This system has an overriding authority to bring the truck to a stop if an obstacle or safety hazard is detected.

Automated Underground Loading and Haulage

In underground mines, the restricted environment in which equipment operates has aided in its automation. In addition, some of the greatest potential hazards to miners occur when operating in and around underground mobile equipment. This was an early driver to automate primary underground mobile materials handling equipment. Load-haul-dump units (LHDs)

and trucks operating underground follow well-defined routes in repetitive operating cycles. These, coupled with a well-structured underground operating environment, made deployment of early autonomous vehicle technologies feasible. As early as 1988, King (1988) predicted a positive economic return for the use of semiautonomous LHDs. Caterpillar Global Mining (2008) describes recent trials of automated LHDs at the Malmberget mine in Sweden showing an increase in productivity of between 10% and 20%.

Autonomous LHDs and underground trucks are now available from several manufacturers. These are the Caterpillar MineGem system (Caterpillar Global Mining 2008), Sandvik's AutoMine system, and Atlas Copco's Scooptram Automation system. At this time, more than 10 mine sites worldwide are operating or plan to operate either or both autonomous LHDs and underground trucks. These include De Beers' Finsch diamond mine in South Africa (Faurie 2007), Codelco's El Teniente mine in Chile, and the Stalwell gold mine in Australia (Caterpillar 2007).

Both systems have the underlying premise of removing the operator from the machine to a remote operating station, where the machine can be teleoperated. This station could be located underground, on the surface at the mine site, or at some distant location. Operation requires onboard cameras, computer control of machine functions (steering, braking, acceleration, bucket motions [LHDs], etc.), high-speed network communications, and associated safety systems. However, simple teleoperation is stressful for operators and less productive than manual operation.

The solution is operator-assisted automated steering during teleoperation. Here the operator does not physically steer the system but views the machine's location in real time on a mine plan (typically on a computer screen) and then uses a joystick to give the machine the direction of travel. In Caterpillar's MineGem system, this is called copilot mode.

Finally, in autonomous mode the remote operator provides a goal for the machine (LHD or truck) and the self-guidance system controls the vehicle. In Caterpillar's MineGem system this is called autopilot mode. Typically, the operator fills the LHD's bucket in remote mode and then enters autopilot mode to tram to the dump point, empty the bucket, and return to the loading point. Thus, in autopilot mode, several machines can be operated by a single operator. For safety reasons, remotely controlled and autonomous machines need to operate in exclusion zones that strictly control access.

The key to operator-assisted automated steering and autonomous navigation for LHDs and trucks is the use of a laser–radar range-sensing system. This system maps the location of objects (typically walls) around the machine and determines their location by comparing the measured profiles to an existing database provided from the mine map. This technique is known as simultaneous localization and mapping. Thus, knowing the location on the map relative to the nearest walls, the control system can drive the LHD to the desired location.

Automated Dozers

Dozers are typically used for a wide range of applications in mining. These include profile construction, cleanup around other machines, ripping, and utility work. Thus the level of complexity required to automate a dozer is very much a function of the individual task needs, such as the following examples:

- Adjusting ripper depth and angle, and dozer speed and direction, to ensure good ripping performance is key for an automated ripping dozer. Here, interaction with other machines is often limited.
- In many cases, dozers create structured profiles for other machines to work on or from. Here, material movement accuracy may be important.
- Dozers that undertake utility work such as dragging pipes and cables, moving power boxes, and pushing scrapers may have dedicated sensors and automation capabilities. Here, the dozers require the ability to rapidly move from one application to another.
- Interaction with other machines, and detecting where and what to clean up, is important for dozers required to undertake cleanup tasks. An automated dozer would have to detect when and what to clean up and interact with other machines (shovels, trucks, etc.) in a variety of modes.

The automation of dozers to remove operators from machines appears feasible for dozer operations where interactions with other machines is limited, and complex sensing and recognition of subtle changes in the machine's environment are not required. These cases do not require development and use of complex sensing systems, advanced automation infrastructure, or control of complex machine–material interactions.

Automated dozers are not commercially available today. Several original equipment manufacturers (OEMs) and third-party providers have GPS-based dozer operator aids. These include, from Caterpillar for example, "an in-cab display that gives operators easy to understand color diagrams of where to cut and fill. The system uses onboard computers, software, data radios and centimeter-level GPS receivers to constantly monitor work and update the plan" (Caterpillar 2006b). Remote-control solutions have also been available for dozers for many years. These are typically retrofits by third parties.

Research into better solutions for remote-control dozers continues. A recent project funded by the National Institute for Occupational Safety and Health in the United States developed a remote vision system for dozers on coal stockpiles. The project involved Consol Energy and Caterpillar as participants. This work is described in Schiffbauer et al. (2007).

Many of the enabling technologies (dozer control, positioning, and navigation) for automated dozers have been used in remote-control applications for some time and therefore exist in a semimature form. It is expected that automated dozers with the complete capability to build profiles, clean up, and rip will be achievable in the next 5 to 10 years.

Dessureault et al. (2007) and Holmes (2006) describe an automated dozer project at Freeport-McMoRan's San Juan (Arizona, United States) test site. The target application for this dozer is ripping. The dozer sensors include GPS, Sick lasers, and cameras (for teleremote operation).

Automated Blasthole Drills

Automated blasthole drills (ABDs) have the potential to generate a number of benefits. These include

- Reductions in machine duty (rate of accumulated damage) through smoother computer-controlled operations, and

improved blasting performance through more accurate and consistent drilling;
- Reduced labor costs; and
- Improved safety through removal of the operator from a hazardous and dusty environment.

Automation can also optimize drilling performance through control of bit loading, drill rpm, and torque parameters. Increased penetration rates, lower bit wear, and reduced drill costs will result. It is also desirable that holes are drilled at locations specified by the designed blasting pattern. Inaccurate holes can lead to poor blasting fragmentation, inappropriate muck-pile shape for loading, and so on.

ABDs also have the potential to generate benefits that include implementing drill-based, high-level rock recognition systems to provide detailed rock type and structure information that can be used in blast design. Consistent drill operation through computer control of the drilling process enables these systems to operate effectively.

Thus, the enabling technologies (navigation, drill control, and remote control) for ABDs have existed in a reasonably mature form for some time. Prototype ABDs integrating these technologies are currently under development. Holmes (2006) describes the development in 2005 of an automated blasthole drill called the Advanced Rotary Drill Vector Automated Radio Control (ARDVARC). Holmes states, "Preliminary results of ARDVARC trials as compared to normal manual drilling operations has shown a +15% productivity gain, improved pattern and hole quality, and lower machine duty cycle. Additional gains achieved from hole-to-hole positioning are expected." The technology was tested on a BE49R drill but has been transferred to the Atlas Copco PV271 drill.

Rio Tinto has also been developing an automated blasthole drill that is currently operating at its West Angelas iron ore mine. (The outcomes of this project are described in detail later in this chapter.) This machine is designed to drill automatically in both rotary and rotary-percussion modes. In addition, the drill is capable of performing rock recognition during the drilling process in order to build a rock mass description of the area to be blasted. This description is then used in the blast-design process. This drill also has full video remote-control capabilities.

The typical attributes of autonomous blasthole drills currently under development are

- Automatic drilling of the hole from collaring though pipe removal when either manned or autonomous;
- Navigation from hole to hole within a drill pattern;
- Completion of drill pattern autonomously including accurate setup, relocating holes (due to hole failures or impossible collaring), inclined holes, and drill bit changes;
- High-level task instructions from a drill-and-blast management system;
- Monitoring of self-condition (e.g., airflow and pressure, oil pressures, rpm, component failures) and appropriate reaction (e.g., report bit failure back to drill-and-blast management system);
- Monitoring of drill parameters (thrust, rpm, vibration, and other active and passive geosensors) and using this information for rock-recognition information that can be fed into a drill-and-blast design system; and
- Video remote control of all drilling functions.

Remote Operations Centers

A remote operations center (ROC) enables supervision, control, analysis, and data acquisition from afar. In simplest terms, an ROC can be regarded as a platform for enabling process automation and business integration. An ROC enables

- Enhanced occupational health and safety by removing operators and maintainers from risk exposure;
- Reduced labor costs by relocating high-cost, knowledge-intensive labor away from mine sites to urban centers;
- Increased productivity through
  - Identification of inefficiencies at operating interfaces,
  - Collaborative planning between functions (operations, maintenance, and procurement),
  - Sharing of experience and knowledge across mine sites,
  - Process visibility along the process chain; and
- Potential to lock in benefits through knowledge capture and reuse.

Implementing an ROC provides an important catalyst for change within an organization. Current workflow patterns must be evaluated and modified or adapted. Implementing ROCs therefore provides an important stimulus for changing work practices and driving an organization to achieve higher levels of labor productivity.

Interest in applying ROCs is growing within the mining industry. Examples of early adopters within the mining industry are Rio Tinto Iron Ore (RTIO) in Western Australia and Freeport-McMoRan in their Arizona (United States) operations.

Schweikart (2007) outlines the business drivers for RTIO's implementation of an ROC:

- High cost of supporting remote staff
- Desire for increased staff retention
- Business integration
- Faster, better decisions

The ROC will also supervise the autonomous systems operating at RTIO's West Angelas iron ore mine site. A fleet of five autonomous 320-t Komatsu haul trucks are operating at West Angelas, as well as one automated blasthole drill rig (Trounson 2007).

The removal of the need to maintain a large work force on-site saves ancillary camp expenses; remote working allowances; and fly-in/fly-out expenses, which can account for significant costs. Additionally, integration of operations (site, transport, and infrastructure) in one center removes "silo mentality," where people are focused only on the component of the operation they are involved in and fail to see the effects on the whole mining process, creating bottlenecks at interfaces.

Improved telecommunications infrastructure, in particular telephone networks and fiber-optic links, are cited by Dicker (2007) as key technology enablers for the ROC development. RTIO is evaluating the remote support of maintenance personnel via head-mounted displays and wearable computers. Support would make extensive use of video conferencing, remote desktop access, and voice-over IP technologies. RTIO is also evaluating remote collaborative planning via the use of augmented reality (virtual reality based on real sensor information) and touch tables (Schweikart 2007).

Schweikart outlines a 4-year plan to achieve remote-integrated operations. The first step of this plan is to integrate disciplines (planning, operations, and maintenance functions) at site level, and to begin the transfer of people from site to ROC. The second step is integration per asset (site operations integration) through the transition to remote operation and deployment of operations models. The third step is integration across sites. Because of safety concerns and relatively static operating environments, it is likely that ROC technology will be implemented first on fixed assets, such as beneficiation plants.

RTIO is investing particular attention to aspects of change management and reevaluation of workflow. Scweikart emphasizes that changing to a remote supervision and operations model necessitates a change in the way that work and information flow is managed, and that replicating existing workflows may not improve productivity.

Coyle and Holmes (2007) indicate that the installation of Freeport-McMoRan's ROC on-site was justified on the elimination of inefficiencies across operational boundaries. The ROC is also seen as playing an important role in "institutionalizing the knowledge" of maintenance and operations experts. Here, the vision of the future has tactical operations personnel co-located in a "room of truth." Verified information is made available on a real-time basis so that subject-matter experts can assist less-skilled operatives in the field. Crosspollination of ideas and shared operational awareness are forecast to lead to significant efficiency gains for the organization.

Automated Digging

Large-capacity shovels and hydraulic excavators (called diggers in this section) with bucket capacities to 70 m^3 are critical production units at most open-cut mine sites, and there is an ongoing imperative to improve their productivity. Automation is seen as one of the strategies by which improvements can be realized.

The automation of diggers presently stands at an interesting nexus. Most of the technology needed to realize the automated digger exists (albeit at varying levels of maturity), and developments in other sectors, including industrial robotics and the automotive and aerospace industries, are delivering further advances that enhance technical feasibility.

However, the cost and risk of introducing automated diggers to mining operations currently outweighs the perceived benefits. An automated digger must operate as part of the overall operation of a mine with implications on mine infrastructure, operational practice, work-force skills, and site culture. The gap is significant and no mining company is actively pursuing the introduction of automated diggers to their operations, notwithstanding the several significant mine automation initiatives taking place worldwide (e.g., Rio Tinto's Mine of the Future at the West Angelas mine site).

The transition to automated diggers will likely occur over the next 20 years. It will almost certainly be staged through incremental stepping-stone technologies that, in themselves, bring productivity and reliability benefits and allow the risks to be understood and controlled and the technology to mature and be proven and accepted in mining environments.

This section attempts to identify, at a fairly high level, automation capabilities that might serve as planks in the bridge to realizing the autonomous digger over the next two decades.

Capabilities of the Autonomous Digger

The autonomous digger

- Excavates material and loads trucks with minimal human intervention;
- Plans and executes repositioning moves using high-level mission statements referenced to the mine plan;
- Feeds up-to-date information garnered from onboard sensors back to the mine plan including terrain information, material diggability, and productivity indicators;
- Manages the dig face and floor to optimize productivity and maintain favorable bench structure;
- Automatically executes ancillary functions including management of the trailing cable (on electric shovels), machine park-up for access, and so on;
- Has advanced status monitoring capabilities to identify situations associated with the machine or the environment requiring attention. This includes monitoring structural and electrical heath trends for early prognostication of events and failures;
- Manages overall activity in the load area including the scheduling and dispatch of trucks, cleanup activities, and so forth; and
- Provides an information-rich teleoperation mode that allows recovery from exceptional situations to be completed remotely.

Benefits of the Autonomous Digger

The benefits of the automated digger stem from the increased consistency and reduced variation that automation brings to equipment operation, resulting in productivity and reliability improvements and the ability to have the machinery operate under its most favorable conditions. Ultimately this translates to increased productivity with lower production costs and energy consumption.

The business case for the autonomous digger is likely to be built around the following benefits:

- Consistent and accurate loading of haul trucks. When trucks are loaded to their rated payloads and the load is correctly distributed across the tray, then the chassis, transmission, and tire life are significantly improved and operating costs reduced.
- Increased digger availability. Automation brings consistency that stands to increase equipment availability through lower duty loadings.
- Safer operation. Most safety incidents associated with diggers are linked to operator error (e.g., digger–truck collision). By marginalizing the root cause, automation has the potential to reduce the frequency of accidents and near misses.

Technology Gaps

Four broad technology gaps must be bridged to realize the autonomous digger:

1. Control strategies must be developed to enable automated machines to operate interdependently with other equipment (manned and automated).
2. Situational awareness capabilities must evolve to the point where they can replace the many and varied functions

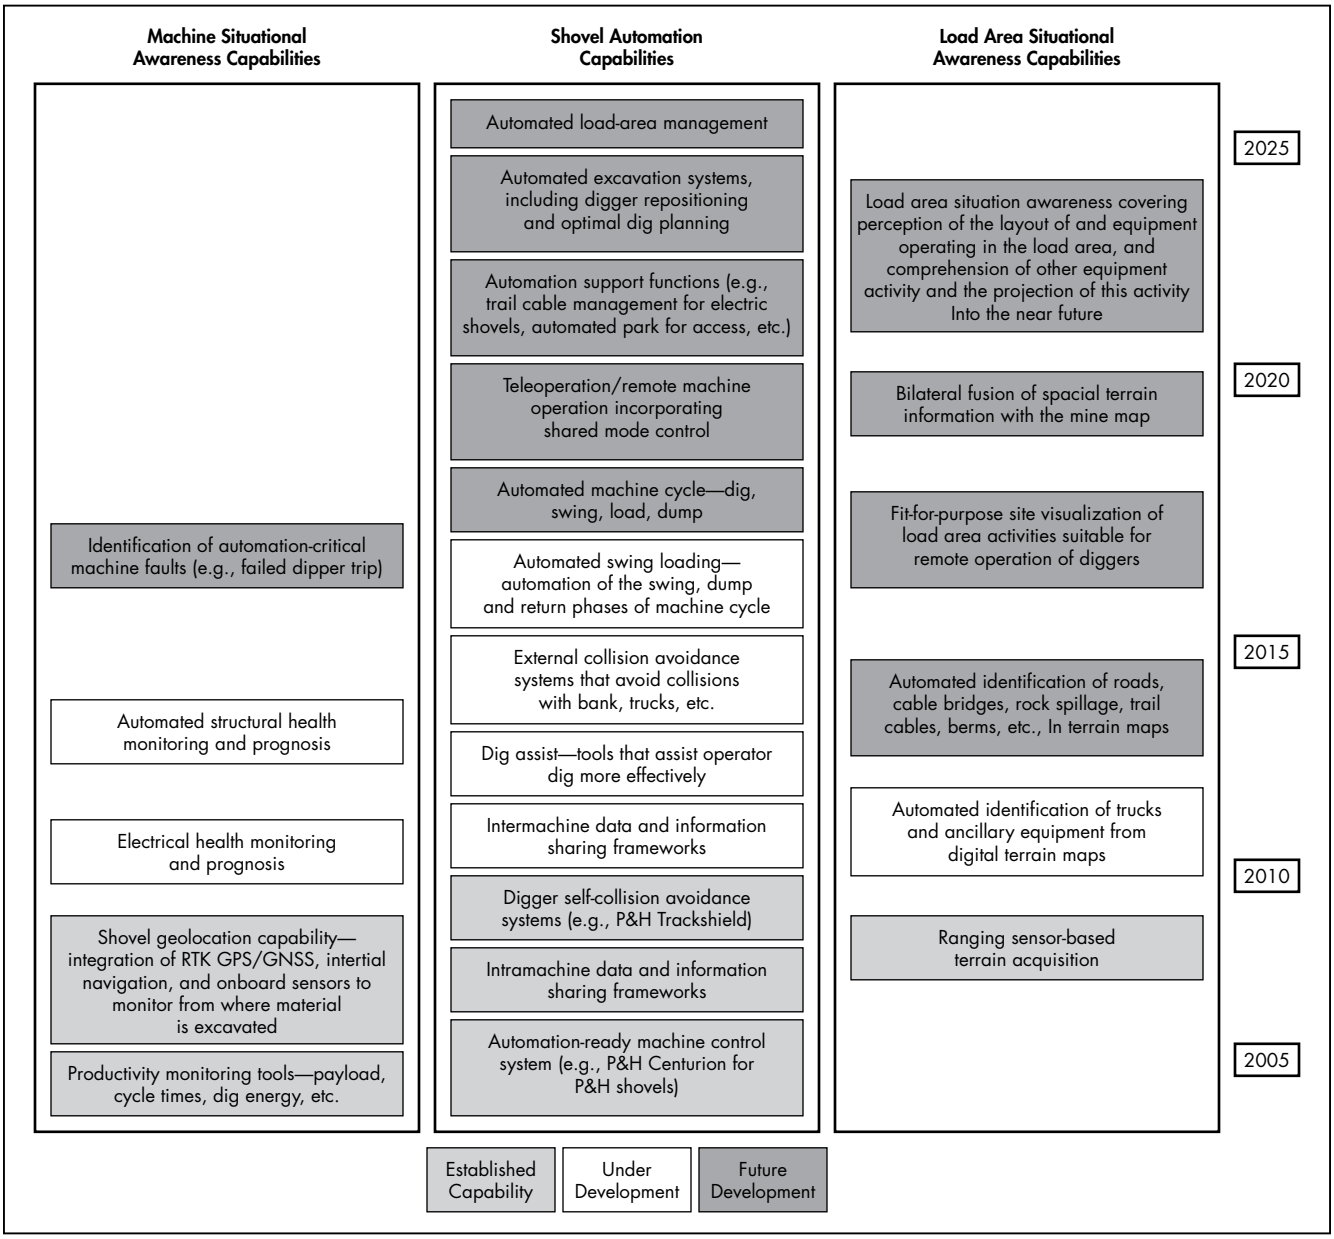

Figure 9.8-1 Autonomous digger capability plan to 2025

currently performed by human operators in planning and actions, and monitoring the status of the machines.
3. Technologies are required that enable effective integration of automated machinery into mine systems.
4. Work-force skills must be enhanced to support deployment of high-end automation technologies.

A significant component of the shovel automation problem is systems integration, including management of interactions with trucks and other equipment and integration of the autonomous shovel into the mine plan. Although in the long term there will, almost certainly, be multiple technology providers working to agreed automation standards, at this time the problem is not sufficiently well defined for effective standardization efforts. The likely scenario for the short-to-medium term is that various equipment and technology providers will integrate their proprietary systems by ad-hoc methods on an as-needed basis under pressure applied by the end user (the mining companies), or one provider will come to dominate the market and set a de facto standard for integration.

The long time horizon for achieving a fully automated digger system mandates a multigenerational technology plan with commercial outcomes that prove technology components and support and maintain the development effort toward its end goal. Figure 9.8-1 gives a digger automation capability plan to 2025 with capabilities divided into three categories:

1. **Machine situational awareness capabilities.** These include such things as machine performance monitoring, functional safety capabilities support automation requirements, electrical and structural health monitoring.

2. **Shovel automation capabilities.** These incrementally build from operator assists such as collision-avoidance tools through automated digging to management of the load area.
3. **Load area situational awareness capabilities.** These build an evolving richer situational awareness model of the load area with knowledge of digger and truck positioning at the lowest level, building toward the full perception of elements in the load area, the comprehension of their meaning, and the projection of their status in the near future.

Implicit in this capability map is that machine and load area situational awareness capabilities feed into shovel-automation capabilities. The timeline is indicative as is the ordering, but it is generally expected that capabilities will flow in this order.

The plan has been organized so that each identified capability could, in principle, serve as a commercialized outcome. The continual delivery of technology products that have productivity or maintenance benefits in their own right and contribute incrementally to the autonomous digger represents the only practical strategy. R&D-based innovation at all levels of the plan is strongly needed, and the most likely scenario is that R&D will be completed by consortiums made up of an equipment manufacturer, the end user, and one or more third-party technology providers including research organizations and universities.

Current State of Automation

Fully automated shovels are not commercially available. However, shovel automation has been the focus of extensive research over the past few years. Dunbabin and Corke (2006) describes automation work completed on a 1/7-scale model cable shovel that demonstrated the ability to automatically perform multiple truck-loading passes that included excavation of the dig face, swinging with obstacle avoidance, identifying an awaiting truck tray, determining an optimal loading strategy, and dumping the material.

McAree et al. (2007) describe collaboration between the Cooperative Research Centre for Mining (CRCMining) and P&H to develop advanced technologies leading toward shovel automation. A P&H/CRCMining laboratory has been set up in a quarry north of Brisbane, Australia, and includes a full-sized P&H 2100BLE electric cable shovel. This laboratory is used to develop and evaluate technologies that increase the productivity of electric mining shovels.

The Australian Coal Association Research Program (ACARP) is currently funding a project to develop, to proof-of-concept, an automated swing-loading technology for electric mining shovels at this facility. A joint CRCMining and Australian Commonwealth Scientific and Industrial Research Organisation (CSIRO) team are developing technologies for a shovel that cycles the swing, dump, and return functions. This includes automatically identifying the location of a truck or in-pit crusher–conveyor to be loaded; planning and executing a minimum path from dig to dump location without the dipper colliding with the truck, crusher, or bank; and dumping without spillage and swinging back to tuck position for the next dig.

Automated digging is probably the most complex component of loader automation. Automation technologies to assist digging are commercially available for several of the autonomous LHD products, but not for large-surface loading machines. A considerable body of research in automated digging exists. Singh (1997), Hemami and Hassani (2009), and Lever (2001) provide reviews of this research area.

Longwall Automation

Two basic control systems exist in a longwall operation. One control system operates in the horizontal plane to control the plan-view geometry of the longwall face, and the second operates in the vertical plane to control the roof- and floor-cutting horizons within the coal seam. Added to these functions are systems for armored face conveyor (AFC) control, including chain tensioning and load sharing, and shearer haulage control.

In simplest terms, in plan view, the longwall face should be straight and perpendicular to the gate roads. If the face is straight, both mechanical stresses on the armored face conveyor and roof support geotechnical issues are minimized. The process to achieve this situation is known as face alignment. As the longwall retreats, the assembly of supports should not creep toward either main or tailgates. To achieve this result in practice, often the face line is angled, introducing so-called tailgate lead or lag with respect to the main gate so that in sloping seams, the same creep-minimizing result can be obtained. Managing the lateral position of the longwall equipment in the panel is called creep control. Automatic face alignment and automatic creep control are two functions that can be applied to effectively provide automation of longwall plan view geometry. Available systems are discussed in this section.

In the vertical plane, the automation situation is more complex. The goal of the longwall, similar to any mining operation, is to maximize extraction of product and minimize extraction of waste. This means the longwall shearer should operate so that roof- and floor-cutting horizons are entirely within the seam, or in some cases within a selected band within the seam. Achievement of this goal is known as horizon control. Automated horizon control needs to at least emulate and at best entirely replace human-operator strategies for steering the shearer within the seam. Again, the available automation solutions for horizon control will be discussed.

Undeniably, longwall automation has the potential to deliver significant advantages in both productivity and safety (Henderson 2007). Interruptions to the mining process are basic causes of decreased productivity. Continuous automatic face alignment, for example, can virtually eliminate stoppages caused by current string line–based manual alignment processes, and optimal alignment of AFC components minimizes wear and reduces consequent equipment breakdown or change-out delays. Close control of face geometry can also improve geotechnical performance of the roof-support system where an automation system can ensure that shields are set consistently.

Automatic horizon control can more effectively steer the longwall in the seam to minimize product dilution and can also contribute to more-effective strata control by accurately leaving coal on the roof and/or floor to protect weaker strata. In the safety context, automation provides the ability for the mine to remove people from hazardous areas, minimizing exposure to dust, heat, noise, and danger from roof and face falls.

Automatic Face Alignment and Creep Control

Automated face alignment is now a mature technology, and all longwall roof support manufacturers offer systems that

deliver effective face alignment automation solutions. These systems allow desired face profiles to be entered into shield-control systems through appropriate graphical user interfaces, and shield-control systems are capable of moving individual shields by calculated distances and are thus also able to coordinate the motion of assemblies of shields to achieve desired profiles along the entire face. Shield hydraulic control systems have been enhanced to allow accurate control of double-acting (D/A) ram motion, and sensors to reliably measure D/A ram travel have been incorporated into shield designs.

Until recently, the major defect in automatic face alignment has been the inability to automatically and reliably measure the actual geometry of the longwall. True closed-loop control of face alignment can only be achieved by comparing the physically measured location of the face with the target location and then minimizing the resultant error. Previous methods were largely based on measuring the accumulated motion of shield D/A rams to indicate face geometry, which gave only an approximate solution with increasing accumulation errors. This situation has been remedied recently through the development of the LASC (Longwall Automation Steering Committee) technology, which measures three-dimensional shearer position directly through an inertial navigation-based SPMS (shearer position measurement system). Because the shearer actually cuts the face, direct measurement of shearer position is the best indicator of face geometry. Open specifications for SPMS data outputs have been devised enabling LASC technology to be applied to any combination of face equipment. The reader is referred to www.lascautomation.com for details of LASC specifications and more-detailed LASC technology descriptions. All face equipment manufacturers now offer LASC technology to the market.

Sensors that measure the position of longwall face equipment relative to the gate-road ribs can be used to provide a measure of automatic creep control. If motion of gate-end equipment relative to the ribs is detected, appropriate lead or lag of the face can be introduced into the basic face geometry input to the automation system. Although LASC laser-based creep sensors are now available to provide this measurement, transformation of this information directly into tailgate lead or lag values is highly site dependent and requires operator input.

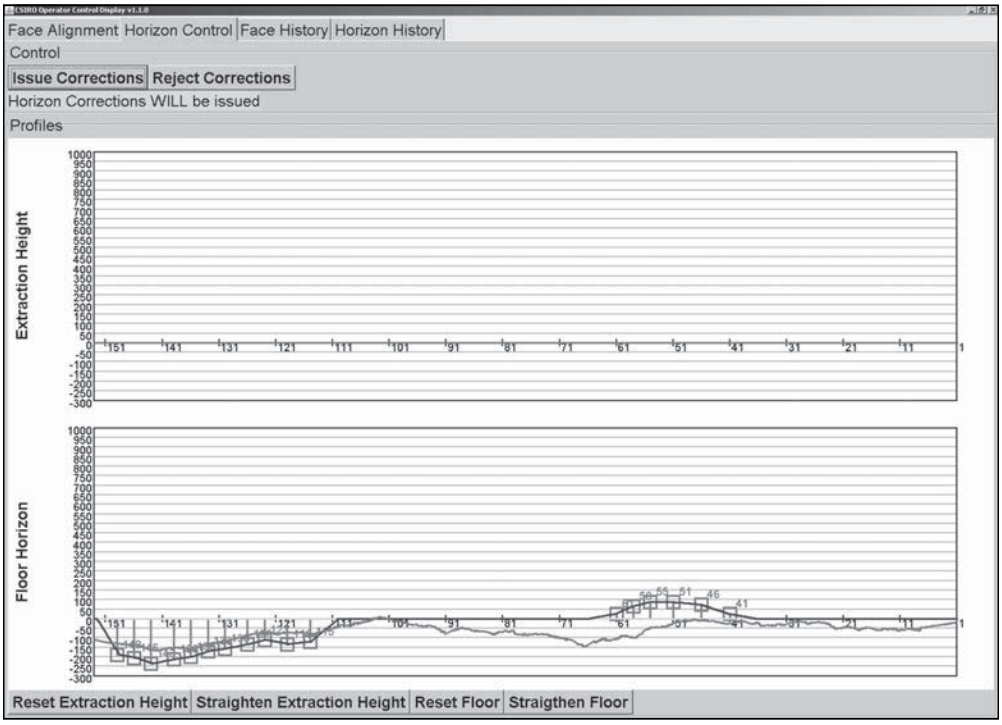
Face Alignment Control System Example

Contemporary graphical user interfaces (GUIs) for longwall roof support control systems can be used to display the state of sections of a complete longwall face that can exceed 200 shields in current operations. They can also display the leg hydraulic pressures. This display gives immediate information regarding the hydraulic performance of the supports and can also show through color change when particular shields are not set correctly or are being excessively loaded by the roof strata.

When the face has become misaligned with respect to the target face line, it is seen as an uncut wedge developing between the desired profile of the unmined coal and the AFC. To realign the face, a wedge cut must be executed in the current shearer run to realign the supports perpendicular to the longwall block. This is achieved by making proportional changes in the shield advance distances programmed to introduce a compensating wedge shape in the face, eliminating the misalignment as the shields advance after the shearer passes. The success of this kind of control depends on accurate measurement of face profile and D/A ram extension as outlined in this chapter.

It is difficult to accurately quantify productivity benefits due to contribution from specific automation system elements. However, in the case of LASC-based face alignment, sustained productivity improvement of 130 t/h was reported (Reid 2008). Other productivity improvement information is company-confidential to individual equipment suppliers.

Automated Horizon Control



Longwall horizon control—manual or automated—is a challenging task. Whereas the overall goal of horizon control is to ensure that as far as possible only coal is extracted, there are a multitude of site-specific considerations that detract from a mine's ability to achieve that goal. It might not be possible to detect seam boundaries effectively in order to prevent the shearer drums from cutting surrounding rock. In the case of thick seams where visible or other cues to indicate seam trajectory are absent, it is difficult to steer on a consistent path between the gate roads. In other cases, seam undulations along the face or into the panel might mean that equipment cannot articulate sufficiently to track the actual horizons, and roof or floor is cut as a consequence. Problems in detecting fault conditions ahead of mining could mean it is necessary to mine through the faulted zone at short notice.

Automation of horizon control is in the developing stages. The most successful strategy so far has been based on training an automation system using a human operator employing traditional manual cues for horizon detection and control to steer the shearer. The learned extraction process is then repeated automatically until some departure from the horizon-control strategy is observed, such as roof or floor being cut. The training process is then repeated. The advantage of this process is that operator exposure to face conditions is at least reduced. The accuracy of this process has been improved by the availability of the LASC technology, which gives high-accuracy floor-horizon measurements. All shearer manufacturers offer systems that are variations on this basic strategy.

The next stage in the process is to use sensors that can replace the horizon-sensing capability of human operators, or bring to bear new horizon-sensing results. Coal interface detection (CID) sensors based on natural gamma emission by surrounding strata, thermal infrared detection, ground-penetrating radar, optical marker band tracking, and other methods have been developed with varying results. The only commercial CID sensors currently available are based on natural gamma radiation and detection of electromagnetic propagation differences between coal and surrounding strata; several of the other methods are still in the research stage.

Figure 9.8-2 shows a GUI for an interactive automated horizon control system based on the LASC technology. The GUI accepts and displays horizon information over the full face length. The upper screen enables an operator to enter adjustments to a nominal extraction-height setting that has been independently set in the shearer control system. The flat line shows that no operator adjustments have been selected.

The lower screen enables the operator to view recommended floor profiles and to input adjustments manually. The system then automatically generates LASC-recommended floor-height adjustment for the next complete shearer run. In its simplest form, this adjustment is generated by extrapolating the average floor profile from the previous five shears. At this stage of development of automated horizon control, the operator is in the loop. The operator has the ability to input manual floor-height adjustment on a per-shield basis.

Courtesy of CSIRO Division of Earth Science and Resource Engineering.

Figure 9.8-2 A prototype automated horizon control system user interface

The operator's task is to input manual horizon inputs to match the recommended profile as closely as possible. The operator is also able to take into account off-system inputs such as physical observations along the face or known conditions that would preclude the shearer being able to execute the automation system's recommended track. Close matching of manual to automatic settings is shown on the left-hand side of the display in Figure 9.8-2. On the right-hand side, the operator has chosen a floor profile that does not closely follow the predicted floor alignment.

Figure 9.8-2 shows the smooth profile that the automation system generates compared to the manual inputs. This profile then becomes the floor-height adjustment target for the OEM's shearer-control system.

"State-Based" Shearer Automation

In recent years, one of the most successful initiatives has been the development of programmed shearer automation on a logical state basis. The concept is similar to the training method of horizon control described earlier. The operating parameters required for the shearer to completely execute a single pass of a particular cutting sequence are defined as a series of logical states that encompass combinations of ranging arm positions, haulage speeds, and various sensor outputs including motor currents, position measurements, and so on. As the shearer travels along the face, it sequences through the previously defined states. If no anomalous states are encountered, the pass will be executed successfully and the machine will commence the next pass. Error states can be defined to handle operational exceptions, but some errors will cause the system to halt when human intervention is required. When this system was first introduced, significant productivity improvements resulted immediately. This was attributed largely to the consistency that was possible when operation was based on a fixed programmed sequence and not subject to variable operator inputs.

Challenges to Overcome

The automation technologies described in this chapter are able to successfully automate the routine operations of a longwall. The major problems encountered in longwall automation are concerned primarily with the management of exceptions to normal operations caused by the fact that an underground mine is actually not a factory environment and is subject to the vagaries of nature. To achieve full automation and the "workerless face," many more sensors need to be developed to replace the observing roles carried out by face operators at present. Additionally, there are issues with ensuring that equipment operates to the standards required for automation in a harsh, hazardous environment.

Mine Requirements for Longwall Automation

The face alignment and programmed shearer automation systems can be implemented in most mines. In the case of horizon control, it is necessary to establish whether local seam conditions exist that allow horizon sensors to be effective. Equipment manufacturers can offer advice as to which sensors will be appropriate.

For modern automation systems, high-quality data communications links to sensors and face equipment are required. Longwall manufacturers now provide Ethernet connectivity on face equipment as a matter of course. For these systems to be effective at a mine, corresponding communications infrastructure must be available between the face, the surface, and wider into the mining company's and its service providers' data communication networks.

Optimal longwall automation results can be achieved only if all elements in the mining process are operating reliably and at peak performance. Automation systems require particular attention to engineering and maintenance standards at the mine to ensure that all components of the system are effective. An automation culture must be developed and maintained in the work force so that automated operation is fundamental to production.

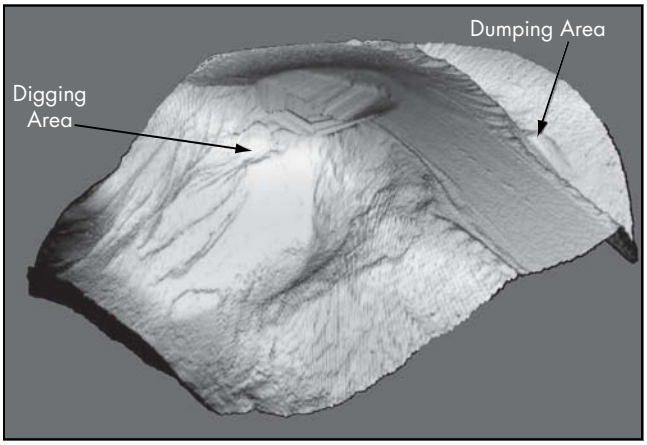
Dragline Automation

The rate of overburden removal is almost always the bottleneck in open-cut coal mining, and draglines (the most cost-effective means of overburden removal) are the tools of choice. To address this production bottleneck, various strategies have been adopted. First, manufacturers have increased in size and power over the past 40 years, but there appears to be a physical limit in just how large these machines can become before they are impractical. Second, mines have put substantial effort into operator training and production monitoring while also routinely overloading the machines. These strategies are unable to yield further improvement, but continually increasing stripping ratios (which have increased from 2–5:1 to 8–15:1 today) mean that the need is still acute.

Automation is therefore increasingly seen as the next phase in the evolution of the dragline and the industry's quest for increased production. In addition, many in the industry believe that automation can also offer the possibility of lower maintenance costs through the control of the machine within its design limits (a task that human operators often struggle with). Finally, automation systems can deliver consistency and an equivalent skill level that can result in a system that overall will outperform human operators—it may not be as fast as the best operator at the beginning of a shift, but because of its consistent operation, it will on average outperform the pool of human operators. Automation further promises a means of overcoming this skill shortage and would seem inevitable in the mining industry.

Automation Development

The history of dragline automation can be traced back to the late 1980s when BHP Billiton performed a series of trials at a mine in central Queensland, Australia (Allison 1992). These trials attempted to show that a dragline could be partially automated by replaying the control signals of an experienced operator. However, one of the conclusions of these trials was that the instantaneous swing angle of the bucket beneath the boom must be taken into account, making the simple replay strategy infeasible; that is, there must be some kind of bucket swing feedback into the control system. In 1993, CSIRO researchers funded by the mining industry began to investigate bucket-swing sensing and the subsequent automatic control of a dragline's swing motion. Initial experiments determined that vision systems, touted at the time as the solution to the bucket swing-angle sensing issue, could not operate around the clock in the adverse weather and visibility conditions typically experienced at mines. Instead, these camera-based prototypes were replaced by two-dimensional (2-D) scanning laser range finders, which became commercially available in 1995. These sensors proved to be very robust and adaptable to the weather and lighting conditions as well as the mechanically harsh environment experienced at the end of a dragline boom where they were mounted. With such a system it became possible to accurately measure the swing angle of the hoist ropes and hence the angle the bucket-rope plane made with the vertical boom plane (Roberts et al. 1999).



Automation of BE1370 Dragline Demonstration

A full-scale proof-of-concept automated swing-control system was developed on a BE1370 dragline at the Tarong coal mine in South East Queensland, Australia. It performed a fully automatic dig-to-dump-to-dig motion, whereas bucket filling remained the responsibility of the operator. A key component of the system was active controls—the joysticks and pedals were driven by small motors to affect computer control of the dragline, but the operator could override at any time and regain control by moving one of the joysticks. This system was further developed on a BE1350 at the Boundary Hill pit in central Queensland, where in 2002 a 2-week production trial was undertaken (Corke et al. 2003). In total, 12,235 cycles were performed, 3,042 using the automation system and 9,193 fully manually. More than 250,000 t of material were moved autonomously during this trial. In summary, three significant conclusions were reached. First, the system performed more than half of its cycles in better time than the average of the operators working over that period. Experienced operators observing the dragline could not tell a manual cycle from an automatic one. Second, the performance of the automation system was compromised by the system's lack of accurate terrain information. The system relied on the operators marking the position of the spoil piles, highwall, and any other obstacles. This was done by placing the bucket over these locations and pressing a button on the joystick controller. However, a safety margin was introduced to ensure that the bucket never collided with the terrain, and this typically added a 5%–10% time penalty to each automated cycle (due to overhoisting). Third, it was clear that the automation system treated the dragline more gently than the human operators. No specific maintenance benefits could be derived from such a short trial, but the time history of control outputs from the automation system were far smoother than the human operators.

The same CSIRO team between 2002 and 2006 addressed the lack of real-time situational awareness around the dragline where they developed a digital terrain mapping (DTM) system. As well as allowing an automation system with a smaller safety margin, the accurate knowledge of terrain can be used by the automation system to plan optimal bucket trajectories. The successful use of 2-D laser scanning systems for rope location (Roberts et al. 1999) inspired the CSIRO researchers to trial a longer-range scanner on the boom tip, giving it a view of the terrain immediately beneath the boom. With this arrangement, all the terrain around the dragline could be mapped as the machine rotated (Roberts et al. 2003). Initial standalone trials (without the automated swing control) proved the concept, and a 4-week production trial was undertaken in 2006 on the Boundary Hill BE1350. A DTM produced during this trial is shown in Figure 9.8-3. This trial showed that DTMs could be produced routinely in a production environment and that the DTMs themselves were useful to the mine planners and surveyors, even without an automated dragline control system. Further, a level of detail never envisaged was obtained in that the material movement of every cycle could be recorded if desired.

Automated Dragline Digging and Precision Dumping

In 2005, the CSIRO team demonstrated a fully autonomous tenth-scale model dragline that incorporated bucket-swing

Courtesy of CSIRO.

Figure 9.8-3 Digital terrain map produced during a 4-week production trial

feedback, generation of DTMs, optimal bucket-path planning, and autonomous digging (Dunbabin et al. 2006).

The practice of precision dumping has again been raised now that autonomous draglines have been shown to be feasible. The concept of a dragline being capable of accurately dumping its load into a hopper and feeding into a conveyor or into trucks could transform certain mining operations. The CSIRO team has shown how the tenth-scale model dragline can reliably dump material directly into a truck tray (scaled accordingly).

Current Status

The past 15 years have seen a number of proof-of-concepts and demonstrations in full production environments with trials lasting multiple weeks (Winstanley et al. 2007). Dragline automation is now technically possible; economics and the market will determine when it is finally introduced.

FUTURE CHALLENGES

A major challenge over the next decade is to automate the unit operations themselves, understanding that some of the equipment in a group may remain under direct human control or be semiautomated. Thus, each automated machine must be able to operate interdependently with the other machinery associated with the unit operation. The absence of this capability currently is a major barrier to the deployment of automation technologies in mining. Understanding how to achieve safe, interdependent operation in mixed fleets is the most important and significant technical barrier to the further development of mining automation technologies.

McAree and Lever (2003) provide recommendations for where investments in surface mining automation research will provide the short-to-medium-term benefits to the mining industry while making progress toward full automation. They are as follows:

- **Advanced sensing technologies for the mine environment.** This includes the processing of sensor data to extract information and sensor fusion for combining data from several sensor sources. Imaging technologies for terrain and local-area mapping are important, as current technologies are sensitive to dust, vibration, and temperature variations.
- **Use of mine-wide information systems to facilitate unit interactions.** Mine-wide information systems play a critical role in controlling the interactions of automated equipment. This task will be complicated significantly if common communications protocol is not adopted that would allow complete interoperability between sensors and mine information software from different vendors.
- **Extended use of existing and new sensors aboard equipment.** Data from onboard sensors can be used not only to monitor and report equipment status and performance, but to develop detailed understanding of equipment operations and their interaction with mining processes. Understanding these operations is an important step for successful automation.
- **Developing duty meters to manage the trade-offs between equipment productivity and damage, and to predict failures.** Automation systems must perform the many maintenance, fault detection, and isolation functions that operators currently execute. It is important to understand how machine performance and duty trade against each other to optimize the productivity of automated equipment. Poor availability poses the same problem for automated equipment as it does for manually operated equipment.

The widespread acceptance of automation and robotics technologies in mining over the coming decades will depend on a number of factors, including

- Simple and effective integration with mining processes;
- Changes to existing mining processes to simplify the use of automation;
- Management acceptance to ensure automation is seen as a benefit, not a threat, to the mining work force;
- Implementation occurring in stages starting with narrow domain or task requirements and then increasing capability and complexity (machines then systems);
- Meeting mine requirements of productivity, cost, and flexibility;
- Balancing technical complexity with robustness;
- Transparent operation wherein mine personnel must clearly understand the capabilities and limitations of the systems; and
- Turnkey systems, as much as possible.

A major threat to the uptake of mining automation is the desire for a quick success, which leads to shortcuts in technology development and poor implementations.

A VIEW OF AUTOMATION AND THE MINE OF THE FUTURE

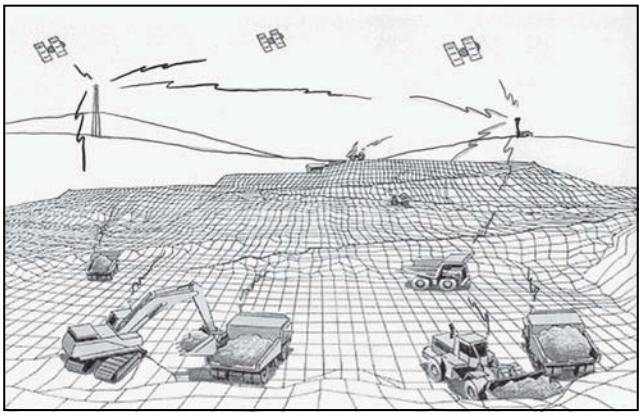
For decades, visionaries have predicted that autonomous machines would be critical to the future of mining. The major drivers have been safety, the need to work in remote locations, the lack of operators in general, long-term reliability improvement, and efficiency gains. These visions are rapidly becoming a reality.

Safety Advantages

One of the most often-cited reasons for autonomous mining is safety. Although the fatality rate published by the Mine Safety and Health Administration (MSHA 2009) shows a reduction in fatalities, significant improvement is still needed. Despite tremendous effort on the part of regulatory agencies, mining

companies, and equipment suppliers, the total number of fatalities in the United States has on average not improved substantially since 2003. Similar statistics from Australia, South America, and China show that further safety improvements are very challenging to achieve and potentially even harder to maintain. One clear strategy to reduce injuries and to easily maintain the reductions in injuries is to remove people from harm's way. For example, it is estimated that automation and ROCs offer the opportunity to remove up to 80% of haulage-system operators from surface mines. Fewer people involved in mining operations translates to fewer opportunities for safety-related incidents and fewer opportunities for long-term disabilities caused by repetitive operations.

Integrated Site Awareness



Another significant safety advantage provided by autonomous systems can be achieved through integrated site awareness or situational awareness. Probably the most easily understood example of situational awareness is the accident prevention provided by air traffic controls. By tracking most planes and controlling corridors, the situational awareness provided by air traffic controls helps reduce mid-air collisions. Studies indicate that situational awareness can lead to substantially improved performance in complex military environments (Endsley 1995). Although managing a mine or operating mining equipment may not be as complex as operating a military aircraft or as demanding as managing a battlefield, the continual, around-the-clock nature of the mine operation makes site awareness just as critical (Figure 9.8-4). A well-integrated mine of the near future will allow all machines and potentially mobile objects to be tracked in real time. Integrated site awareness will allow both automated and human machines to easily perceive and comprehend the current situation, which should lead to better decisions and a safer environment for both.

No Fatigue and Minimized Opportunity for Operator Error

Although recent estimates of the effect of fatigue in accidents vary considerably (from 2% to 41% according to De Gennaro et al. 2001), fatigue is clearly recognized as a significant contributor to mine accidents. Furthermore, operator error caused by all sources (including fatigue) may account for as much as 88% of all accidents (Heinrich et al. 1980). It is commonly recognized that the best means to avoid accidents is to design out the opportunity for the accident. Using automated systems significantly reduces the opportunity for errors and provides a means to accurately track, correct, and control any remaining issues. Automated systems never get tired, bored, distracted, or inattentive. There will certainly be challenges related to performance in all environmental conditions, but these should be well understood and will improve over time.

Remote Locations

It is anticipated that many new mines will be located in regions with low population densities. The cost to develop housing, schools, hospitals, and other required infrastructure can significantly impact the ability for a given site to be a cost leader (have a production cost below the average cost in the industry). Many remote sites are supported by a large number of fly-in/fly-out (FIFO) employees, which can lead to "FIFO fatigue" and potential higher turnover rates (due to the variability in mining, it is difficult to make accurate assessments).

Courtesy of Caterpillar, Inc.

Figure 9.8-4 Communication infrastructure for a future mine

Informal feedback from the mining industry suggests that it costs mine sites 100% of an annual salary to replace a worker and a further 50% to train the replacement to a desired productive level (Rowland Communication Group 2004). The cost to attract workers and the worker turnover at remote locations can severely impact the operating cost, production, and safety at these remote mine-site locations. Reducing the total number of workers via automation and allowing more of the remaining workers to work at ROCs could significantly reduce FIFO fatigue and may reduce employee turnover.

Availability of Operators

Scarcity of skilled operators during boom times is often cited as a major problem for mining expansion (Barta 2005). Certainly mines that follow the volatility exploitation model (essentially, mines that are only operated during times of high commodity prices) will make it difficult for the industry to maintain a stable, highly trained work force. Using autonomous systems could minimize the volatility and reduce the start-up and shutdown times of higher-cost operations.

Efficiency

Another key reason for interest in automation is the expected gains in overall relative efficiency, where relative efficiency is defined as tons moved per day relative to a nonautomated mine with the same contingent of machines. Several factors can dramatically influence the efficiency gains at any particular site including load size, cycle time (speed, queuing time, spotting time, loading time, and dumping time), accuracy (percentage of loads delivered to the right location), machine availability, and operator availability (discounted for training time, breaks, absence, etc.). For haulage systems, these can be written as

- Relative productivity = (relative load × relative accuracy × relative machine availability × relative operator availability) / relative cycle time
- Relative load = (autonomous machine load) / (manual machine load). Expect this ratio to equal 100%.
- Relative accuracy. This is the percentage of total loads (waste and ore) that are dumped in the correct location. The relative accuracy should improve slightly for automated machines.

- Relative machine availability (the percentage of time that the machine is down due to a mechanical or electrical failure). It is assumed that machine availability will improve over time with automation, due to the more-consistent machine operation.
- Relative operator availability. Operator availability can vary widely depending largely on the local mining process. This is an area of substantial potential gain for autonomous systems. For example, if an existing mine with no automation achieves 16 h/d of actual working time and the same mine with an automated haulage system can achieve 22 h/d of operation, it is a 38% increase.
- Relative cycle time. This is the average total time per cycle with an autonomous system divided by the average total time per cycle without an autonomous system. Relative cycle time includes the loading time, transporting time, dump time, and queuing time. For underground mining systems that are already using remotely controlled machines, automation should provide a significant improvement in cycle time. But for haulage systems that are currently using manned machines, the relative cycle time may be lower for initial automated systems. However, due to the expected rapid evolution of autonomous systems, it is anticipated that future generations will match the cycle times of well-controlled mines that operate machines within their design limits. In other words, the machines will be operated according to their design limits and the mine rules.

Efficiency Gains Though Process Control

Arguably, the greatest potential improvement may be in process control. The availability of machines that operate consistently and as instructed provides the opportunity for mine operators to fine-tune their operations. Future mine systems will allow every machine, person, and process to be accurately tracked. This will provide unique capabilities to accurately model all mine processes using real-time models to improve mine-planning capabilities. The autonomous machine will be the most salient change, but the real driving force for improvement will be the consistent, predictable process coordinated by an information-rich environment.

An example of a related industry is that of grade-control systems used in construction. These have shown process control–related improvements of 30%–50% and associated fuel and carbon dioxide reductions of 43% (Caterpillar 2006a). Process control is expected to be a strong area of dramatic innovation as autonomous machines begin to be deployed. Although independent data is not available, a recent article regarding the deployment of Caterpillar's MineGem technology at the Jundee gold mine in Western Australia states that "MineGem cut down on wear and tear on the machines." According to Gary Mills, Jundee's mining manager,

> What was happening previously too is that the boggers were bouncing off the walls and causing a lot of damage.…The laser-driven boggers stay off the walls, so you don't get any damage even though they can go faster.…The need for secondary stockpiles in the mine has also been removed by the faster tramming speeds, cutting down that cost as well (Haycock 2009).

Challenges and Changes Required for Successful Automated Systems

Clearly, putting an autonomous machine into an otherwise unchanged mine will not provide the expected gains. For example, in general, autonomous trucks will initially travel at slower speeds than human-operated trucks, causing significant loss of efficiency for the human-operated trucks.

Information System Improvements

One of the biggest changes will be the amount of information needed to run a mine smoothly. An autonomous mine will be very much information driven including everything from the detailed mine model to product levels, payloads, and the location of every asset. This will drive several requirements on communications and information infrastructure:

- High-bandwidth communications with quality of service capability will be a requirement. It is strongly suggested to have dedicated communications channels to avoid issues with lost or late communications.
- Tracking and communicating the location of every asset will be a key layer of the obstacle-avoidance strategy. Neither people nor machines should be allowed to operate within an autonomy zone without proper electronic tagging.
- Every asset will need to provide vital information such as its position, heading, health, status, destination, detected objects, and potential road (map) changes. In addition, it would be useful to communicate any potential changes about the road surface (wet, rough surface, soft, etc.).
- This information will be in addition to the existing productivity and maintenance information that is used for typical mine management.

Accurate Mine and Machine Model

Maintaining an up-to-date mine model will be absolutely critical to autonomous machines. Although machines should have secondary sensors to detect inconsistencies in the mine model, autonomous machines will by necessity assume that the mine model is correct. Most machines should be programmed to halt if they detect inconsistencies in the mine model. Analysis of the inconsistencies and self-correction would be the next phase of development for automated systems. The definition of the mine model will require orders of magnitude more detailed than existing mine models that are used for automated assignments or dispatching.

All mining machines will have to be modeled as well. The fidelity of the machine model will be dependent on the class of machine such as autonomous machines, interactive machines (such as loading machines), support machines, and mobile platforms (light plants, pumps, etc.). Autonomous machines, including both kinematic and dynamic models, will need to be very accurately modeled. Interactive machines (such as loaders) will need to have a very accurate kinematic model and accurate positioning. Support machines may be modeled much more simply, and mobile platforms may be modeled simply as an exclusion zone. Any significant changes to these machines will need to be tracked and modeled (e.g., a pickup pulling a trailer suddenly appears to have grown in length).

Required Operational Changes

Successful installation of an autonomous system will require operational changes in several key areas:

- **Working environment.** Obtaining consistent predictable productivity will require a reasonably predictable working environment. Anything that alters the working environment such as water trucks will need to be accurately controlled and monitored.
- **Improved information system maintenance.** Maintaining the electronic infrastructure will include positioning systems and dedicated high-bandwidth communications systems. In general, automated systems will require either a dedicated network or a redundant network with quality of service assurance. In addition, a backup network should be installed for emergency and autonomy stop functions.
- **Avoiding mixed fleets.** In general, autonomous machines will travel at different speeds than human-operated machines (faster in some cases and slower in others), and mixing manned and unmanned machines may cause significant loss of efficiency for the human-operated trucks. Automated equipment may be programmed to be more "sensitive" to human-operated machines, potentially slowing down to avoid any risk of an accident, and will, therefore, tend to be less efficient.

Machine Health and Maintenance

Site-level machine-health monitoring will become more critical as autonomous machines become more prevalent. In addition, there are still items that are only detectable by human operators (some vibrations, noises, etc.). Development of new prognostics and diagnostics will be required, and maintenance procedures will become much more critical.

CASE STUDY: AUTOMATED SURFACE BLASTHOLE DRILLING AT THE WEST ANGELAS IRON ORE MINE

This section provides an overview of blasthole drilling automation and uses the data associated with the implementation of this application at Rio Tinto's West Angelas iron ore mine.

An automated surface drill is generally considered one that can tram, level, and drill automatically. Automated blasthole drilling is considered easier to adopt into an existing mine fleet than other large, automated mobile equipment due to its relatively slow movement and generally isolated operation.

The automation of surface blasthole drilling has made significant advances into the mining industry since 2005. Some of the cited benefits are

- Repeatability of drilling process
- Lower total cost per meter
- Increased production per drill
- Longer use of assets
- Lower labor needs
- Better hole stability
- Better predictability of blast fragmentation

Issues with Implementation

During the implementation of a new automated drill system, there can be an expectation that the system will perform at a level at least comparable to the existing system. If the system is not performing within expectation, the technology may not be adopted.

Table 9.8-1 Basic sensors for an automated drill

Description	Typical Sensors Used
Drill-rig position	High-precision Global Positioning Systems, ground-based satellites, inertial measurement units, lasers
Drill-hole depth	Lasers, string encoders, wheel encoders, magnetic pulse
Drill-rotation velocity	Magnetic pickup on drill-drive gearbox, flowmeter on rotation hydraulic circuit
Drill-rig roll and pitch	Tiltmeters
Track speed	Track encoders

Source: McHugh 2009.

To plan for implementation success, mine operators should consider the following elements:

- **Drill automation approach.** If the drill automation approach is different from the current manual drilling approach, this must be clearly explained to the stakeholders. Some degree of customization of the automation to suit the ground conditions should occur before the drill is used in full production.
- **Automation sensors.** The automation system critical sensors must be accurate and able to survive in a mining environment. Sensors that detect the surrounding environment (e.g., vision systems) must be of sufficient resolution to determine changing conditions such as collapsed faces or large boulders to prevent catastrophic damage to the machine. Typical sensors required to automate a large blasthole drill are displayed in Table 9.8-1.
- **Communication infrastructure.** If the drill is to be remotely supervised, the communication system selected must be suitable for the application. This will require site surveys and consideration of future requirements.
- **Service support and training.** A sustainable production system requires service support and training. The model of service and support must be clearly defined before implementation.
- **Other dependent mine processes.** The drill automation will affect other processes such as normal drill servicing, sampling, and charging due to more restricted access to the drill area. New procedures will be required before implementation.
- **Safety.** Mine operators may choose soft procedural safety controls rather than more expensive engineering controls that are difficult to maintain in a rapidly changing mine environment. The automation of blasthole drilling may not require interaction with other mine equipment, thus reducing system complexity. The use of remotely operated automated machines provides a much safer environment for drill operators, removing the operator from potentially hazardous areas such as unstable pit walls, unstable pit floors, hazardous airborne dust, and hazardous noise.

  The use of an independent emergency shutdown system that can stop the engine as fast as practicable would provide a level of redundancy in the case of uncontrolled movement. This is very important if a remote operator is supervising the automated drill or drills.

Table 9.8-2 Comparison of drill accuracy for automated and manual operation

Automation Capability

The automation of the large-surface blasthole rigs has advanced at a faster rate than the smaller articulated boom rigs. Larger rigs are considered easier to automate as they have fewer degrees of mast movement. They are generally located in mines with large, simpler patterns with generally vertical rotary holes. The benches are generally well maintained and provide the ideal environment for navigation and leveling. Automation of rotary drilling is considered easier than hammer drilling. Hammer drilling requires a precise rotation speed that must adapt according to the penetration rate. Rotary drilling, on the other hand, will generally have a fixed rotation speed that does not vary as much with the geology.

Mine operators will always encounter different drilling environments, and the more accepted automated drill systems are the ones that allow intervention either manually or remotely to deal with exceptions. This feature is important as it generally allows little loss in production over completely manual systems, aiding in system acceptance.

The automation of some ancillary functions of the drilling process will require significant engineering changes to occur such as bit changing and mode of drilling. Since these processes use consumables of the drill that wear quickly, in the near term they are probably better handled in a semiautomated mode.

To make the drill ready for automation it is generally considered that the drill must be set up for electronic control. Many of the new surface drills use the controller-area network bus that was developed for the automotive industry.

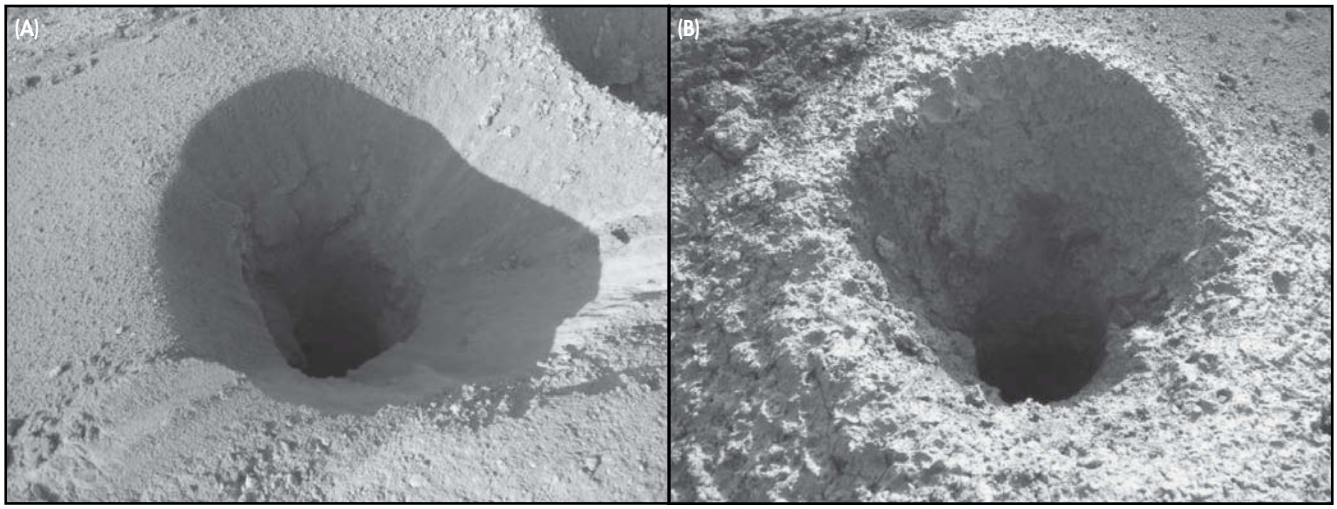
Advantages of Drill Automation

Automation of surface blasthole drill rigs has demonstrated greater accuracy and repeatability with similar rates of productivity compared to manual operation. Remote supervision of automated drills has allowed one operator to control more than one drill.

Field trials of a proprietary automated system on an 80-t Terex SKSS16 rotary and percussion blasthole drill at the West Angelas iron ore mine demonstrated significant improvements in accuracy over manual operation. The summary of the results are displayed in Tables 9.8-2 and 9.8-3.

Table 9.8-4 compares the same automated drill performance against five other same-model drills operated at the mine in manual mode over a period of 9 weeks. The remotely supervised drill was able to drill more than 90% of all holes in automation mode.

The high degree of repeatability of the automated drilling process allows mine operators to choose a drilling approach that best suits their operation with a high degree of confidence that the drill will achieve it. The selected drill approach should ultimately help achieve the overall mine strategy. The repeatability also helps mine operators to better understand the trade-offs in different approaches. The mine geology can have a significant impact on which approach is required at different areas of the mine, and therefore it is unlikely that one single approach will be optimal in achieving the mine strategy. Approaches may include



- Trading off production performance for improved drill bit wear rates,
- Drilling the straightest hole,
- Maintaining hole stability to prevent redrilling, and
- Lowering overall stress and vibration on the drill mast and chassis.

In a manual drilling operation, expert drillers are those who can best follow the approach selected by management and adjust the strategy according to the changing geology and condition of the drill. The automation of these approaches will generally reduce the time required to train a new operator to perform like an expert driller. Figure 9.8-5 is a comparison of a manually drilled hole and an automated hole drilled 5 m apart in the same geology. The automated drill shows the correct amount of water injection to maintain a stable collar in that geology.

Disadvantages of Drill Automation

Although the advantages of automation are significant, there remain some disadvantages:

- The automated drill is best-suited to stable geology.

Source: McHugh 2009.
Figure 9.8-5 Comparison of drill collars between (A) manual and (B) automated drill holes

- It can be slower than certain parts of the drill cycle as it maintains the level of accuracy required.
- Sensor failure on the drill is common and could stop the whole system.
- Without significant sensors and processing, the drill may not detect the changing drilling environment such as
  - Collapsing collars,
  - Collapsing holes,
  - Collapsed bench edges,
  - Obstacles such as rocks fallen on the bench, and
  - Potential interaction with other equipment such as explosive-charging carriers.
- Detection of worn bits or drill-string failure can be difficult.
- High-precision GPS may be difficult in deep pits and may require ground-based satellite augmentation.

Challenges to Overcome

To improve the function and reliability of automated systems, several factors need to be addressed:

- Provision for reliable sensors capable of withstanding extreme conditions experienced on the drill
- If operating remotely, reliable wireless communication with significant bandwidth
- The use of prior geological knowledge to adjust the automated settings
- Adequate vision coverage to supervise the rig remotely
- Complex movement path planning between rows
- Integration with other mine equipment such as explosives trucks

Advances and Productivity

Wireless communication for supervision of automated drills enables the use of other real-time sensors for purposes such as rock recognition, automated sampling, and downhole sensors. Prior knowledge of the rock behavior could be incorporated into the automated function design.

The use of remotely supervised automated drills enables the operation of at least two drills at once. As automation becomes more reliable and remotely supervised, it should be possible to run more than three units with one operator.

ACKNOWLEDGMENTS

Special acknowledgments are given to Ken Stratton, a senior technical steward for Site Systems and Automation at Caterpillar, for contributing "A View of Automation and the Mine of the Future" and the "Autonomous Haulage Systems" sections; and to Charles McHugh, a principal mining engineer of Automation, Technology, and Innovation at Rio Tinto, for authoring the case study of the surface blasthole drilling automation program at the West Angelas mine.

The author also thanks David Hainsworth and David Reid, CSIRO Division of Exploration and Mining, for their writing of the longwall automation section; Jonathan Roberts and Peter Corke, Robotics Autonomous Systems Laboratory, ICT Centre, CSIRO, for their writing on the dragline automation section; and Ross McAree, professor of mechanical engineering, Mechanical and Mining Engineering School, University of Queensland, for his writing on the automated digging section.

CHAPTER 9.9

Mine Infrastructure Maintenance

Uday Kumar, Peter Knights, and Mahinda Kuruppu

INTRODUCTION

This chapter is about maintenance of mine infrastructure so that a mine can safely and economically operate at or above design capacity without unscheduled stoppages or disturbances.

The term *mine infrastructure* refers to major capital installations at surface and underground mine sites. Mine infrastructure is very site specific and depends on the mine location, size, mining method, equipment used, and work force. It includes access roads and declines, hoisting and ventilation shafts and equipment, drainage and pumping facilities, backfill preparation and delivery systems, power generation plant and distribution systems, workshops, service and warehouse facilities, offices, changehouse, chilled-water plant, wastewater management systems, and construction facilities. Other on-site infrastructure includes ore treatment plant and laboratories, communication networks, and equipment for automation of mine operations.

The primary objective of mine infrastructure maintenance is to ensure that production targets are met on time, safely, and economically. Modern mining is mechanized and automated, requiring a high level of availability and reliability of mine infrastructure and maintenance preparedness to ensure that operations are maintained at designed (mine) capacity. The mine production system is critically dependent on the availability, reliability, and capacity of mine infrastructure. The substantial level of system integration in modern mines has elevated the criticality of mine infrastructure. Furthermore, mechanized and automated mining systems are expected to safely perform at designed capacity around the clock, making access difficult for maintenance workers and complicating the task of maintenance scheduling.

Because of the diversity of solutions to specific infrastructure requirements, this chapter will not detail maintenance requirements for all types of infrastructure. Rather, it concentrates on general principles of infrastructure maintenance management and presents some of the critical issues and challenges related to maintenance of the following systems:

- Hoisting systems
- Underground roadways
- Electrical power distribution systems
- Mine dewatering systems
- Maintenance workshop facilities

PERFORMANCE OF INFRASTRUCTURE

Availability and reliability performance is the commonly used measure of infrastructure performance. Maintainability performance is the universal measure of the maintenance friendliness of the infrastructure. Availability and maintainability are not only measures of system performance, but they also have considerable influence on the financial performance and success of mining businesses.

Availability

Designing and using infrastructure systems that are maintenance friendly significantly improves safety and system availability. Availability of infrastructure means that infrastructure is available for delivering the services for the specified period of time. In general, infrastructure availability can be defined as

$$\frac{\text{available time for service}}{\text{total scheduled time for service}}$$

The International Electrotechnical Commission (IEC 2010) defines *availability* as follows: "The ability of an item to be in a state to perform a required function under given conditions at a given instant of time or over a given time interval, assuming that the required external resources are provided."

Availability performance is described by the collective term *dependability* and is a function of reliability performance, maintainability performance, and maintenance support performance as illustrated in Figure 9.9-1.

Reliability and maintainability are design characteristics of the infrastructure that are determined during the design and development phase of the system's life cycle. Maintenance support, on the other hand, is dependent on the users' organizational

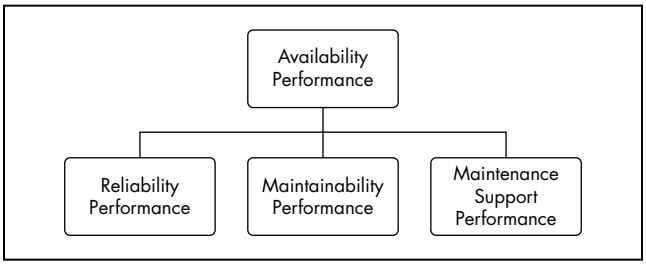

Figure 9.9-1 Dependability and availability concepts

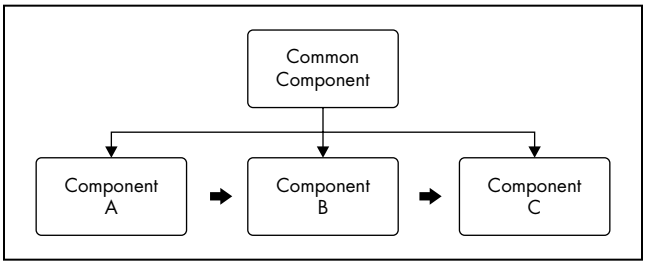

Figure 9.9-2 Reliability block diagram showing common infrastructure component

and operational need, including their operating environments. These factors influence the risks (or uncertainties) related to the availability and capacity performance of the mining infrastructure. A high availability performance level is an important and critical requirement for most of these systems. The factors influencing availability and capacity performance of mining infrastructure include reliability, maintainability, and maintenance support (Figure 9.9-1). Even though high operating reliability characteristics are desirable to reduce the costs of maintenance and maintenance preparedness, the benefits of improved maintainability should not be overlooked in achieving the required availability performance. High maintainability performance makes a system easy to maintain and repair, resulting in high availability performance (see Kumar and Akersten 2008).

Reliability

The reliability of a system is a measure of the probability of its survival as a function of time. In the mining industry, mean time between failures (MTBF) is often used as a proxy for measuring system reliability, where *failure* is defined as unscheduled downtime due to equipment (not process) malfunction. Block models are often used to model the reliability of systems. Systems can be characterized according to whether their principal components are series or parallel connected. In series-connected systems, the failure of one component causes the entire system to fail. This is typical of longwall systems, where, for example, the failure of the face or main gate conveyor disrupts coal production. Parallel systems are designed with some redundancy. For example, a mine dewatering station should include at least one standby pump. Should the main pump fail, the standby can be activated to prevent flooding.

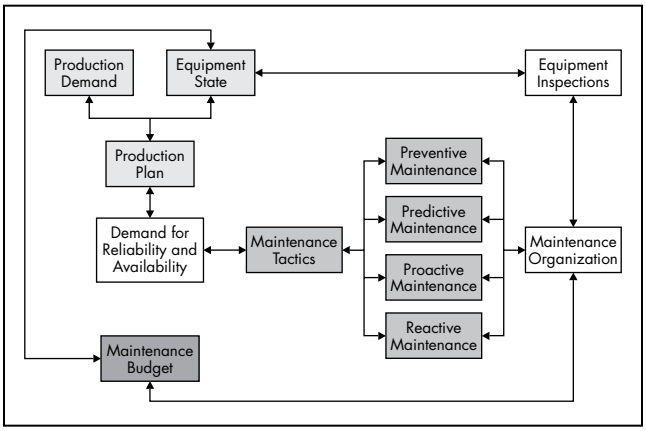
The mine infrastructure elements listed previously are either common components to production systems (see Figure 9.9-2) or are series connected, and so many items of mine infrastructure rate highly on the scale of critical systems for maintenance purposes. For example, every component in a longwall mining system requires power to function. Failure of the power distribution system will cause all components to fail. A mine hoist is a very important series-connected element in the productive system. Loss of hoist capability will result in production losses and could jeopardize the future of a mine depending on the extent of the downtime required to restore functionality.

Maintainability

High maintainability performance and, in turn, high availability performance is obtained when the system is easy to maintain and repair. In general, maintainability is measured by the mean repair time, often called mean time to repair (MTTR), which includes the total time for fault finding and the actual time spent carrying out the repair. The way in which an infrastructure system is designed and built has a direct bearing on the maintainability of the system.

Capacity

Many of the mechanized and automated mining operations are expected to perform safely at designed capacity most of the time or around the clock, making it extremely difficult for infrastructure engineers and managers to get a time slot to maintain them so as to guarantee a high level of reliability, availability, and capacity. The issue of possession of mine infrastructure for maintenance is critical in a mining system operating 24 hours a day and seven days a week.



It is also important to define the capacity of infrastructure. It is possible for infrastructure to be available, but the prevalent operating condition or physical condition may restrict capacity. For example, a mine hoist may be forced to operate below rated capacity because worn guide rails restrict hoisting speeds. Similarly, a poorly maintained haul road can restrict speeds and lower transport capacity. Roads may be filled with potholes, or a lack of water for sprinkling may mean a lot of dust is generated, reducing visibility for truck drivers and forcing slower operations. Maintenance of roads, haulages, and other infrastructure systems directly affects their capacity.

Therefore, it is important to measure the performance of mine utilities and infrastructure in terms of both availability and capacity. To ensure adequate availability and capacity, high levels of reliability, maintainability, and maintenance system support.

MAINTENANCE TACTICS

Maintenance tactics, sometimes called maintenance policies or maintenance strategies, are defined on the basis of failure type and consequences of failure. Four basic classes of tactics are available for implementation:

1. Reactive tactics are run-to-failure policies—that is, repair only on breakdown. This approach is also known as corrective maintenance.
2. Preventive tactics are interval or time-based maintenance activities and include inspections, lubrication, adjustment, calibration, cleaning, component replacement, and overhaul.
3. Predictive tactics are condition-based maintenance and repair activities. Predictive maintenance techniques rely on a measure of performance deterioration to intervene prior to failure and include oil analysis, vibration monitoring, and thermography.
4. Proactive tactics are based on a root cause. They include design-out maintenance (design modifications), reliability in procurement and warehousing, operator-driven

Source: Nilo 2004.

Figure 9.9-3 Integrated maintenance activities

reliability, and operating restrictions designed to eliminate the root cause of problems.

A tactic is defined by the type of maintenance and repair action to be realized and the criteria for determining when to apply that action. Unscheduled maintenance work arises as a result of reactive tactics. Scheduled maintenance comprises preventive, predictive, and proactive maintenance work (see Figure 9.9-3).

The production plan is formulated based on estimated sales demand and the current state of the productive equipment and infrastructure. The production plan drives the asset management plan, which specifies availability, reliability, and capability targets for productive equipment and infrastructure assets. These targets drive the selection of maintenance tactics within the infrastructure maintenance plan. These choices in turn determine the maintenance workload, which dictates the level of resources (labor, equipment, and tools) required. In the real world, the maintenance budget restricts the extent of these resources. The maintenance plan must be adjusted by reviewing the type and frequency of tactics to accommodate the budget.

Selection of Maintenance Tactics

Infrastructure assets are constructed to fulfill a useful role or purpose, known as the *primary function* of the asset. The purpose can be defined by answering the question "What do we want the asset to do?" For example, the primary function of a hoist system might be stated as "to lift 5,000 t/d of ore from the 300-m level to the surface stockpile."

However, *secondary functions* often must also be fulfilled. These include environmental integrity, safety, structural integrity, control, containment, comfort, and appearance. A secondary function of the hoist system is that the skip must decelerate to a creep speed before each station. *Protective functions* are a subset of secondary functions and provide protection against environmental damage or risks to health or safety.

In his book *Reliability-Centered Maintenance*, Moubray (1997) defines a functional failure as "the inability of an asset to fulfil a function to a standard of performance which is acceptable to the user." Reliability centered maintenance (RCM) attempts to guide the selection of maintenance tactics by

- Preventing loss of functions that might lead to health, safety, and environmental risk exposure; and
- Preserving functions necessary for operating capability.

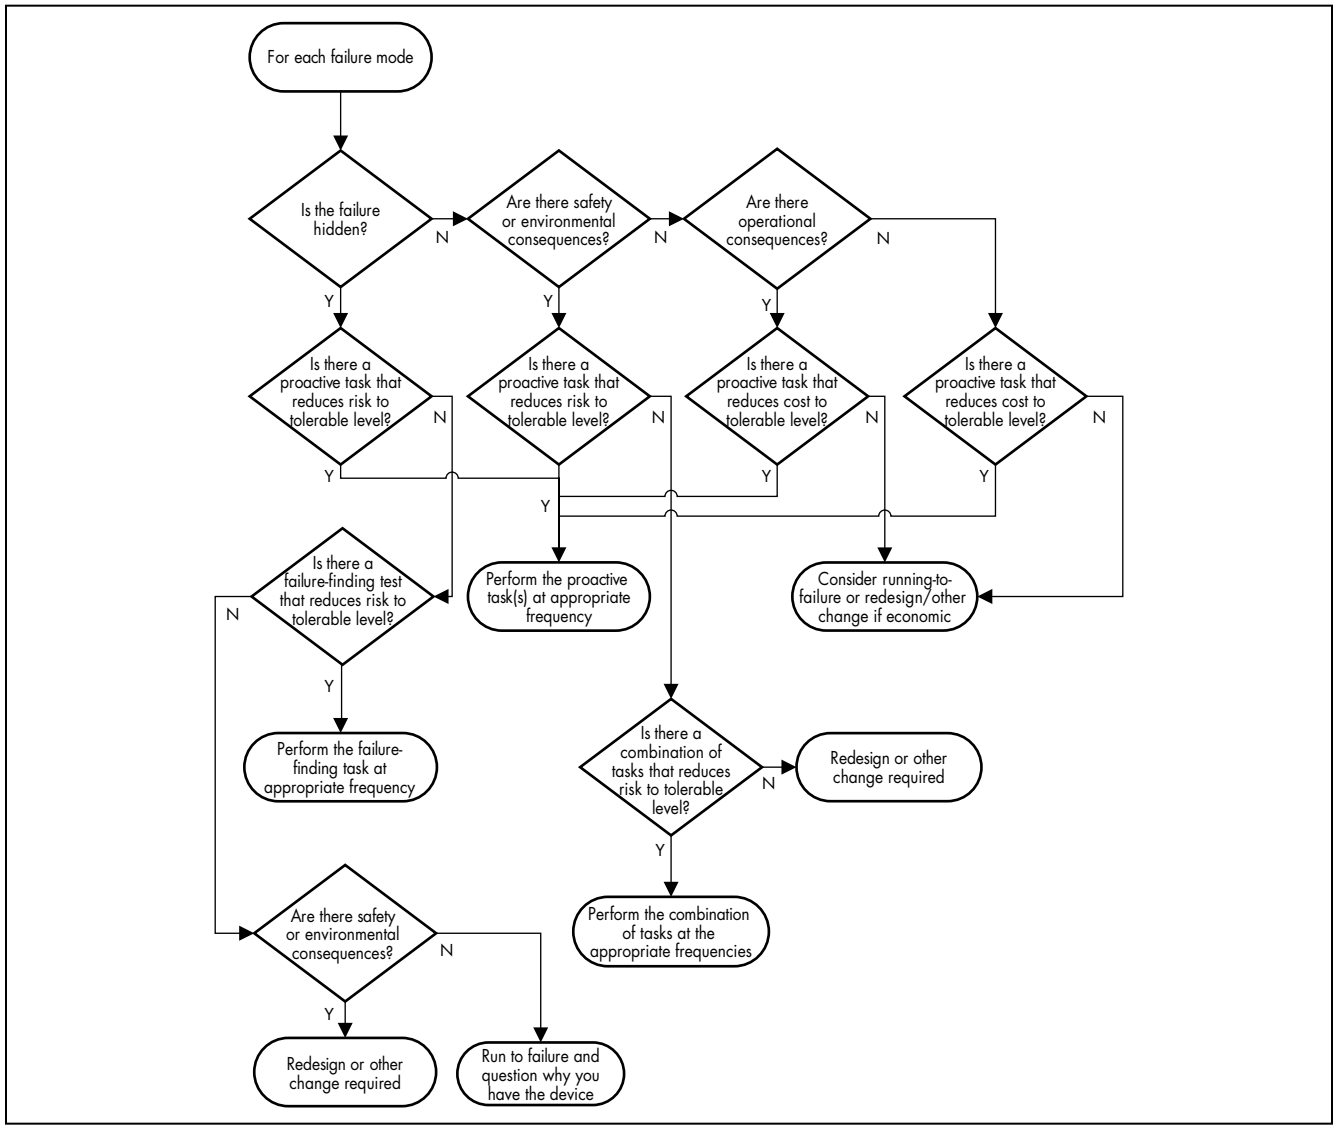
In the RCM methodology, the following questions are asked in order:

1. What are the functions and associated desired standard of performance of the asset in its present operating context?
2. In what way can it fail to fulfill its functions? (Functional failure)
3. What causes each functional failure? (Failure modes)
4. What happens when each failure occurs? (Failure effects)
5. In what way does each failure matter? (Failure consequence)
6. What should be done to predict or prevent each failure? (Proactive tasks)
7. What should be done if a suitable proactive task cannot be found?

Figure 9.9-4 shows a simplified RCM decision tree for selecting maintenance tactics. For each failure mode being evaluated, maintenance tactics are defined by beginning the logic at the top left corner of the decision tree. It can be seen that maintenance tactics are defined first on the basis of the consequence of the failure and second on the failure type (wear out, random, burn-in, or early life failures).

RCM decision trees such as that shown in Figure 9.9-4 are extremely useful for defining the type of maintenance activity to apply. However, they do not help to define the frequency with which these activities should be applied.

A trade-off exists between the frequency with which preventive maintenance is scheduled and the cost of lost production incurred. If maintenance is insufficient, the result is a high likelihood of breakdown and significant production losses. At the other extreme, overmaintaining an asset also results in production losses. As Figure 9.9-5 shows, there exists an optimal frequency with which to schedule preventive maintenance activities. Determining this optimum, however, is not a trivial task and will not be dealt with in this chapter. Readers are referred to Jardine and Tsang (2006).



LIFE-CYCLE COSTS AND MAINTENANCE STRATEGIES

The root causes of reliability problems (Figure 9.9-6) are not just due to the maintenance process. The way infrastructure assets are specified and designed, the price and quality criteria adopted during the purchase process, the way certain assets are stored (e.g., shafts of electric motors must be regularly rotated to prevent flattening of ball and roller bearings), the way in which installation and commissioning are controlled, and the way equipment is operated all contribute to potential failures during operation. World-class maintenance organizations use root-cause analysis techniques to pinpoint the potential causes of failures. They then design specification, purchasing, warehouse, and operating procedures aimed at reducing the incidence of failure during operation. Maintenance activities that involve design modifications are known as design-out maintenance.

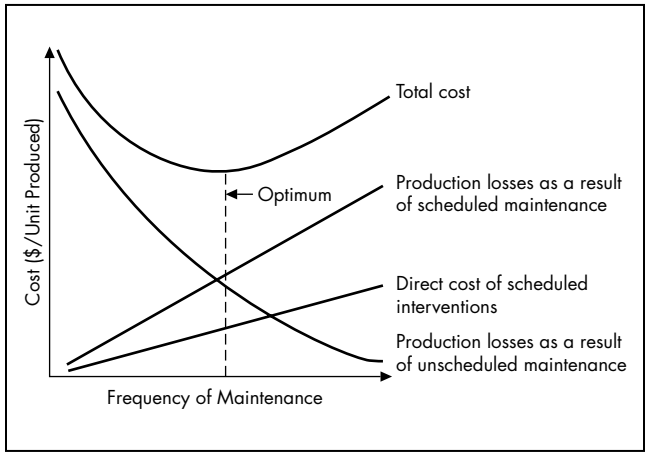
SYNCHRONIZING THE MAINTENANCE PLAN WITH THE PRODUCTION PLAN

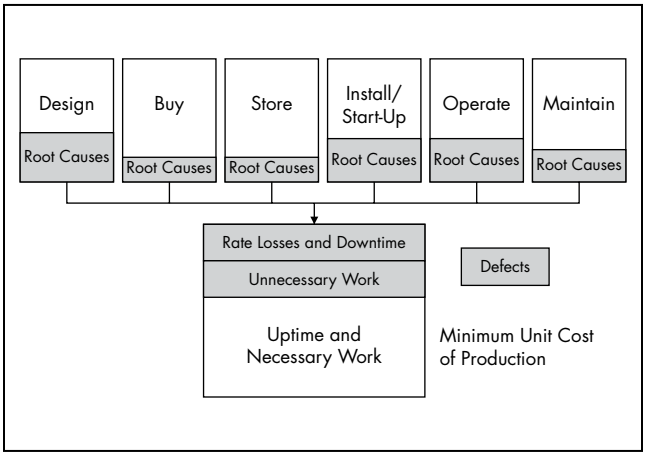
It is important to synchronize the mine infrastructure maintenance schedule to that of the mine production plan and the production equipment maintenance schedules. Key to this is the implementation of a process to determine maintenance and repair priorities. Such processes are usually dependent on the evaluation of the effects and consequences of failure modes.

One way to determine the criticality of each failure mode is to quantify the expected frequency and impact of the failure

Source: Reyes-Picknell 2005.

Figure 9.9-4 Simplified logic for reliability centered maintenance





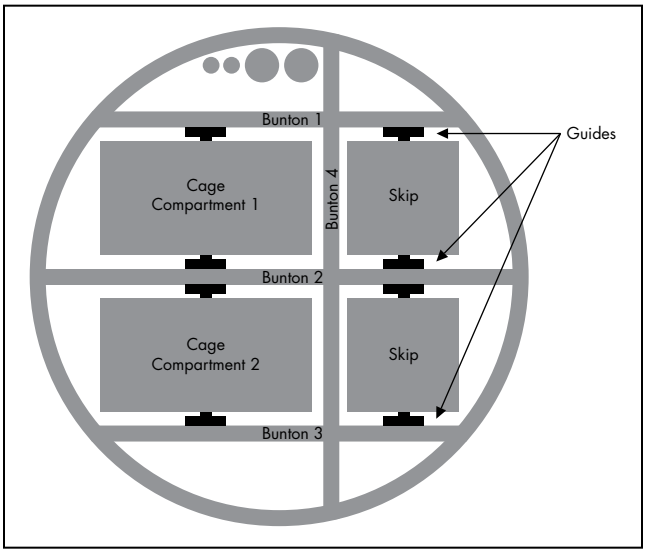


Figure 9.9-5 Optimal frequency of preventive maintenance

Source: Moore 2008.

Source: Northcote 2004.
Figure 9.9-7 Typical shaft cross section

and determine whether, during normal operating conditions, the failure will be evident to an operator. Quality Standard QS-9000 guidelines assign a rating using an integer scale of 1 to 10 to the frequency, severity, and detectability of each failure mode (Stamatis 1996). The severity rating needs to consider safety, environmental, and economic impacts. A risk priority number (RPN) can then be calculated for each failure mode by multiplying the three assigned ratings.

Grouping of the resulting RPN values allows low-, medium-, and high-priority maintenance and repair tasks to be determined. This in turn helps in scheduling. High-priority tasks have greater reason to interrupt production for immediate attention. Medium-priority tasks can be grouped and completed during the next scheduled preventive maintenance, whereas noncritical tasks can often be deferred until the next overhaul window.

MAINTENANCE PERFORMANCE MEASUREMENT

The cost of mine maintenance and its influence on the effectiveness of the total system can be significant. Mine managers need to know how outputs from investments in the maintenance of infrastructure will contribute to business goals. Without any formal measures of performance, it is difficult to plan, control, and improve. The main purpose of performance measurement is to determine whether systems and organizations are performing as they should. This helps determine resource allocation and subsequent control of outcomes.

One way to compare outcome measures with performance targets is to benchmark performance with competitors. *Maintenance performance indicator* (MPI) is the term used to describe an indicator that is a product of several metrics and is used to measure maintenance (Wireman 1998; Parida and Kumar 2006). Mining companies use many different forms and types of MPIs to measure the performance of maintenance processes. MPIs show the value of the contribution of maintenance process toward the ultimate objective of the company as a whole.

MINE INFRASTRUCTURE EXAMPLES

The following discussion deals with specific applications of mine infrastructure maintenance related to the provision of safe access to the ore body via shafts and roadways in underground mines. It also addresses the maintenance of electrical distribution and dewatering systems in underground and surface mines.

Mine Hoisting Systems

Access to ore reserves in underground mines is achieved either by declines or by shafts. The economic cutoff depth for decline haulage depends on a multitude of factors including production rate, ore grades, metallurgical recovery factors, truck capacity, and haulage speeds. Deeper underground mines are serviced via shaft hoisting systems. Apart from providing access to the mine's ore body, the shaft also serves as an opening for mine ventilation and a conduit for mine services such as water and compressed air systems. Shaft availability is invariably at a premium, as downtime required to inspect, maintain, and repair shafts directly translates to an opportunity cost of lost production. Engineers charged with shaft maintenance are tasked with achieving an appropriate balance between downtime costs and shaft integrity.

This section describes the fundamental maintenance management requirements of hoisting systems for underground mines.

Major Hoist Components

A hoist system consists of a winder, headframe, shaft steelwork and guides, ropes, conveyances, and counterweights. Shafts are typically divided into several compartments. Figure 9.9-7 shows a typical shaft cross section with cages for personnel and equipment access and skips for the conveyance of ore and waste. The winder plant consists of winder drums, a braking system, drive motors, and control system.

Shaft Structures

This section draws heavily on the work of G.J. Krige (2005).

The maintenance of shaft structures is becoming an increasingly important factor in the operation of underground mines. Because profit margins in deep underground mines are tight, the life of old shaft infrastructure is increasingly being extended.

Two key parameters are strength and functionality. Shaft guides must have sufficient strength to resist the impact forces resulting from the passage of conveyance and they must be functional in guiding a conveyance without derailment.

Shaft Structure Deterioration Mechanisms

Engineers charged with the maintenance of hoisting infrastructure are frequently called on to assess the suitability of shaft equipment with various levels of deterioration for safe hoisting. Thus it is necessary to be able to identify, measure, and manage the principal deterioration mechanisms. These mechanisms are caused by operation of the shaft or by rock movements due to mining or seismic activities.

Deterioration from Shaft Operation

The following deterioration mechanisms are related to the operation of shafts.

Steel corrosion. The most common deterioration mechanism in deep shafts is corrosion of steel comprising shaft buntons and guides, pipes and pipe support brackets, and station or platform structures. Generalized corrosion affects the entire exposed area of all steel structures, and localized corrosion affects specific areas of the structure.

Generalized corrosion results from ambient atmospheric conditions within the shaft, including the gaseous content,

humidity, and temperature of air. Typically, shafts with upcast air are more prone to generalized corrosion than shafts with fresh downcast air. Generalized corrosion uniformly reduces steel thickness and leads to a uniform reduction in the residual strength of steel components.

Localized corrosion results when corrosive chemicals and moisture are trapped in pockets where spillage can accumulate—cable trays, flat horizontal surfaces, or at the ends of buntons—as a result of water running down the shaft lining. Localized corrosion results in the reduction of strength of the steel member at a particular point.

Mechanical damage. Mechanical damage may be caused by falling objects in the shaft or by collision of shaft conveyances and shaft steelwork. Minor mechanical damage may also be caused by spillage, but it seldom causes significant loss of strength or functionality of steelwork. Major mechanical damage often causes complete loss of functionality without significantly impairing strength.

Fatigue damage. Fatigue damage of steel shaft structures is caused by repeated loading cycles during the operation of the shaft. The loading cycle results from the passage of conveyances within the shaft. Load magnitude is determined by guide misalignment, bunton stiffness, hoisting speed, and conveyance effective mass. Fatigue cracking at welded joints is a real possibility, usually occurring at or close to connections. Loss in strength and functionality is similar to that caused by localized corrosion.

Wear. Wear is a deterioration mechanism usually confined to conveyance guides. Wear does not compromise strength, but it may affect functionality. Localized wear may be indicative of misalignment of buntons due to rock movement.

Deterioration from Movement

Deterioration mechanisms related to rock movements or seismicity within a mine include those described in the following paragraphs.

Vertical strain. Ongoing mining can progressively reduce the area that has been supporting the weight of overlying rock, resulting in vertical compressive strain. This vertical strain in the rock can be induced into the shaft guides. A compressive strain causes bowing of the guides between bunton levels. Strain limits should not exceed the closure of permissible gaps left between shaft guides.

Horizontal ride. Some shafts are constructed to pass through the ore body. This is typical of reef mining as practiced in South Africa. Redistribution of stresses following orebody extraction can result in horizontal dislocation of the shaft above and below the reef. It may lead to severe distortion of the buntons installed between the hanging wall and footwall of the ore body.

Vertical closure and squeezing. Changes in rock stress caused by mining can produce vertical and horizontal displacement of the shaft. Unless adequate provision has been made for vertical closure during the design and construction of the shaft, shaft steelwork can become severely distorted. Redistribution of horizontal stresses as a result of mining activities can cause inward pressure on shaft walls, squeezing or distorting the shaft section. This leads to cracking or crushing of concrete in the shaft lining, buckling of shaft steelwork and piping, and misalignment of guides. Changes in horizontal stress state have also reduced clearance between shaft conveyances and shaft steelwork or walls, increasing the likelihood of impact of the conveyance with steelwork.

Shaft Structure Maintenance

A three-step strategy is proposed for defining the maintenance strategy for deep shaft structures:

1. Define limits and requirements using analytical techniques. This means that the misalignment and deflection of deep shaft structures must not exceed the specified maximum. Analytical techniques based on well-established shaft design procedures (e.g., SANS 10208-3 [2001]) can be used to establish acceptable limits to deterioration.
2. Implement measurement and inspection procedures. Information must be captured, recorded, and reported on a regular basis by mine personnel working in the shaft who know the shaft well. The deterioration condition should be described within a limited number of categories. There should be enough categories to enable meaningful trending while still allowing memorization and simple categorization. Table 9.9-1 lists six shaft categories developed by Anglo American Corporation (Krige 2005). Color coding can be used as an effective reporting means, with green indicating structural members classified as category 0 or 1 condition, yellow categories 2 and 3, and red categories 4 and 5.
3. Monitor trends and schedule maintenance. Most shaft deterioration takes place slowly, so changes may not be noticed. It is important to track deterioration over time (Table 9.9-2). Gradual movements of bolts in slotted holes and gaps between structural members may be observed, and, quite suddenly, further ground movement can result in buckling of buntons. Corrosion can progressively reduce the stiffness of conveyance guiding systems over many years. Again, quite suddenly, with no specifically observed, changes, conveyances may start to derail because reduced stiffness has led to dynamic displacement of the conveyance exceeding the upper limit.

Condition Monitoring of Guides

Hecker (2005) provides a useful summary of predictive maintenance techniques used to assess guide alignment. These methods include the following.

Plumb lines. The most common method of aligning shaft steelwork is based on vertically suspended plumb lines. Often the distances to be measured are large, causing plumb lines to sway because of air movement in the shaft. To overcome this, steady-state brackets can be installed to hold the lines still at the points in the shaft, and the plumb bobs can be suspended inside oil pots. Because lines have to be suspended outside of compartments, distances often have to be measured at awkward angles. Both factors can lead to measurement errors.

Laser beams. Calver (1982) described a method of mounting a laser onto a guide. A target is placed on the same guide at a distance away from the laser. This distance is chosen such that refraction caused by water in the air and temperature gradients is minimized. The target is then moved progressively closer to the laser and fixed to the guide at intermediate positions. At each position, the target is adjusted so that the laser beam coincides with the center of the target, allowing a deflection profile of the guide to be established.

Table 9.9-1 Shaft condition categories

Condition Category	Description of Steelwork Condition	Use of Shaft
0	New condition; no deterioration	No precautions necessary
1	Good condition; some deterioration but no loss of strength	No precautions necessary
2	Reasonable condition; less than 5% loss of strength	No precautions necessary; minor maintenance advisable to retard rate of deterioration
3	Poor condition; loss of strength of between 5% and 20%	No precautions necessary; planning of major maintenance advisable to protect asset
4	Severe deterioration; loss of strength of between 20% and 50%	Reduced speed hoisting advisable; planning and execution of major maintenance necessary
5	Critical deterioration; loss of strength exceeding 50%	Expert assessment of shaft use necessary; execution of major maintenance critical

Inertial platform. Inertial platforms were first developed in Belgium and South Africa. Such a system consists of a platform suspended from a conveyance. Proximity transducers on the platform measure the distance between the platform and the guides. Accelerometers, and sometimes gyroscopes, measure platform motion. Double integration of the accelerometer signals can be used to calculate the path that the platform follows down the shaft. The deflection profile of each guide can be calculated by adding the distance between the platform and the guide to the amount by which the platform deviates from the vertical in each direction.

Moving-beam systems. Moving-beam systems consist of beams running along the guide rails. Guide curvature can be measured by recording the distance between the center of the beam and the guide face, or by measuring the inclination of the beam. The guide shape can then be calculated from the successive curvature readings obtained (Hecker 2005).

Hoist Ropes

Wire hoisting ropes are constructed of an assembly of steel wires that operate at high stress levels and are almost invariably subjected to fluctuating rope loads. A significant source of stress fluctuation is the repeated bending and straightening of ropes as they run over sheaves.

Greenway (2005) provides the following list of factors affecting the life of winding ropes:

- Manufacturing standards and quality
- Rope design and selection for envisaged duty
- The provision and selection of a satisfactory operating environment
- The control of loading of in-service ropes

Rope safety is affected by the following factors (Greenway 2005):

- Control and limitation of manufacturing defects
- Effective assessment of rope condition to identify the optimal moment to discard the rope
- Detection of abnormal rope damage
- Control and limitation of severe peak rope loads

Chaplin (2005) lists the following factors that contribute to degradation and fatigue of hoisting ropes.

Tensile fatigue. Tensile fatigue results from the fluctuation of axial tensile loading. Changes in the attached mass and acceleration are the primary sources of axial load fluctuation. For this type of fatigue, dominant parameters are the tensile load range, mean tensile load, rope construction and wire grade, environment (including lack of effective lubricant or exposure to corrosion), and manufacturing quality.

Bending-of-sheaves fatigue. This form of fatigue involves repeated bending while under constant tensile load. The primary sources of stress fluctuation in this mechanism are the local changes in wire curvature as the rope adjusts to the radius of the sheave or the drum. Restriction of the source of fatigue stresses to change in wire curvature requires that individual wires can slide with respect to one another. Any constraint to this freedom, or ineffective lubrication or internal corrosion, will impair fatigue endurance.

Free bending fatigue. Free bending fatigue involves fluctuating bending deformation that does not involve contact with another body and that is typically excited by system dynamics. In fixed-rope applications, this type of bending often takes place adjacent to a termination.

Torsion fatigue. A consequence of the geometry of many ropes is that they generate a torque in response to a tensile load when the ends are constrained. Some rope constructions are designed to minimize this tendency to rotate, but these can have other disadvantages such as not being as robust. Under certain applications of wire ropes, such as moorings of offshore systems, torsion fatigue can be a dominant mode of failure.

Combined modes. In practice, life of a hoisting rope is dictated by a combination of fatigue modes, usually tensile and bending-of-sheaves fatigue. Briem (2005) provides a

useful method for estimating the fatigue life of wire hoisting ropes on drum winders as defined by a limiting number of single bending cycles.

Hoist Rope Inspection Procedures

To ensure safe operation, mining companies are required to inspect hoist ropes. Visual inspections are performed daily and electromagnetic induction tests are performed every three to four months. During visual inspection, rope speed is reduced so that an inspector can look for visible signs of rope defects. This typically results in the loss of about half an hour per day of shaft time.

Electromagnetic (EM) analysis of hoist ropes uses a data capture system that wraps around the head of a rope, allowing it unhindered passage. The EM head induces eddy currents within the rope, and a signal or trace is returned that is proportional to rope section integrity and thickness. Local faults are generally detected as local spikes on the EM trace, and loss of metallic area shows up as a sustained dip in the trace.

Young and Delaney (2005) describe the development of an automated hoist-rope inspection system in which an EM detection head was integrated with a vision system and hoist drum encoders. Pattern recognition software linked to the camera data picks up visible signs of deterioration. Digital signal processing of the EM traces is as outlined previously.

Underground Roadway Maintenance

Haulage roads in any mine are an integral part of the production system and make a significant contribution to the mine productivity, safety, and economics. A haulage road can be broadly classified in one of three categories:

1. Permanent haul road
2. Service haul road
3. Temporary haul road

All haulage roads need a carefully planned maintenance program. Otherwise, they can turn into a major production bottleneck.

Underground roads provide access from the shaft or decline and the ore body. Good roads are essential to moving personnel and materials around an underground mine. Poor roads result in maintenance downtime, which restricts access to parts of the ore body. The costs include lost production; damage to mobile equipment, resulting in increased tire and vehicle repair costs and lack of vehicle availability; and road-related accidents, resulting in injury and compensation claims.

Degradation Mechanisms

The following text draws heavily on a paper by Logan and Seedsman (1995).

Road defects are the result of interactions of the excavation process, pavement materials, traffic, environmental conditions, and road construction. Causes can be linked to poor floor horizon control, lack of drainage, poor compaction, or the use of inappropriate material to carry high-axle loads.

Water plays a critical role in the degradation of underground roads. Only small quantities of water are required to deteriorate pavements. Key degradation mechanisms include the following:

- *Potholes*, which form when induced water pressures cause layer separation. Areas where poor drainage has led to water retention are particularly susceptible to potholes.
- *Ruts*, which are deformations in wheel paths in parallel directions. This is a characteristic of soft clay floors.
- *Shoving*, whereby road material is moved sideways by cornering, braking, or sliding wheel forces.
- *Slippery surfaces* caused by presence of clay materials or sediments on the surface of the roadways.

Maintenance of Underground Roadways

Maintaining underground roadway surfaces has three main objectives:

1. To provide a good riding surface
2. To minimize safety hazards for vehicular traffic
3. To provide a free-draining surface

As a road deteriorates, several maintenance procedures of moderate cost can be used to prolong its life. These include grading, compaction, drainage maintenance, and resurfacing.

Grading profiles. Logan and Seedsman (1995) regard grading as the single most important function in maintaining an underground road network. Regular grading to maintain crossfalls, eliminate surface defects, and restore drainage profiles reduces the effects of surface water. Lack of adequate crossfalls is one of the principal problems associated with roads. Crossfalls should normally be in the range of 1:25 to 1:17.

Compaction. After grading, compaction of pavement materials can assist pavement performance and minimize maintenance intervals by increasing the strength of the pavement and its resistance to water.

Drainage. These maintenance tasks for drainage systems are essential:

- Checking that flow from drippers is collected and directed away from the pavement
- Cleaning roadway drains of debris to ensure free flow of water away from the pavement
- Regularly inspecting and maintaining roadway pumps to ensure effective operation and clear the inlet of debris
- Regularly cleaning settling pumps to ensure effective pump operation and prevent overflow
- Checking and flushing drain lines to prevent sediment buildup and reduce duty on pumps
- Locating and addressing new sources of water

Resurfacing. Pavement resurfacing may be required as a result of degradation of the road aggregate, incorrect selection of pavement material, traffic abrasion, shoving and mixing of the road base with weaker material, or scouring and erosion due to water flow. If resurfacing is required, the weaker material should be removed and new material should be added and mixed with existing strong materials. The pavement should then be shaped with a grader and compacted, and drainage should be reestablished.

Electrical Power Distribution Systems

This section describes the essential features of electrical power systems used in surface and underground mines and their maintenance management. Because mining operations are highly mechanized, mines and processing plants consume large amounts of electricity. The mining engineer is expected to be aware of the utility, applications, limitations, and risks involved in the use of electrical power, as well as the maintenance of electrical infrastructure.

Alternating current (AC) is the standard power supply, although direct current (DC) is used in certain specific applications such as motors requiring speed control. The transmission and distribution of AC power requires voltage variation using a network of transformers. The main transformer on-site receives grid power to the mine site. Alternatively, diesel electric AC power generators can be used in areas where the electrical grid power is inaccessible.

Mining operations require mechanical power for most work, and mechanical power is often facilitated by the use of electrical motors to drive various accessories—for example, material-handling equipment, ventilation fans, and hydraulic equipment such as rock drills. Therefore, mining engineers need to have an understanding of the maintenance aspects of motors and motor starters, transformers, and distribution cables that power mining equipment. To a very large extent, predictive maintenance methods are replacing the traditional usage-based maintenance in the management of electrical infrastructure in mines.

Stages of Power Distribution and Power Factor

Most mines are large consumers of electrical power. If the power is supplied by the electrical mains grid where the transmission voltage is 33 kV or more, the voltage is usually stepped down to 11 kV using a main transformer located on-site. Alternatively, if the power is supplied by a diesel generator, the voltage may need to be stepped up to 11 kV. Power is then distributed via a network of feeder cables to substations located on the surface facilities and in underground locations. The substation transformers modify the voltage as required by the applications. In surface mines, the main consumer is electrically driven mining equipment such as draglines and shovels. In underground mines, the main consumers are ventilation fans, large drilling machines used for mine production and rock reinforcement, and dewatering pumps. Generally a substation transformer supplies power to all the applications in its locality.

The power factor is one of the significant parameters that should be monitored in the use of electrical power. It is defined as the ratio by which the product of voltage and current is multiplied to obtain the true electrical power (Rizzoni 2007). Hence

$$\text{power factor} = \cos \Phi = \frac{\text{true power}}{\text{apparent power}}$$

where $\cos \Phi$ is the cosine of the phase angle between the current and voltage vectors. The product of V and I is called apparent power, and

$$P_T = V \times I \times \cos \Phi$$

where P_T is true power, V is voltage, and I is current.

The power factor is affected by the inductive and capacitive components of the electrical infrastructure, which includes both the distribution system and the consuming appliances. If the power factor is low, the current increases to supply true power given in kilowatts. Increasing the power factor close to unity is significant in any power distribution system to limit the current flow through the circuit. This is known as power factor correction. In practice, most circuits are inductive and as a result cause currents to lag behind the line voltage. A circuit with a leading current (capacitive circuit) is seldom found. However, these effects do occur in long-distance power lines. These are the two major causes of low power factor:

1. Lightly loaded electric motors and transformers (this equipment should be designed to run at or near full load)
2. Fluorescent lighting circuits (these lights have to be considered carefully and steps taken to improve their power factor)

Correcting the power factor is part of daily maintenance in a large power consumer. The optimum power factor achievable is about 0.85.

Safety Aspects of Electrical Power

A range of protection devices and methodologies may be applied for the safe use of electrical power. To maintain safety, it is vital that these devices be properly installed, inspected, and maintained and that correct practices be followed in their use.

Earth Leakage Protection

Earth fault protection is a crucial aspect in the use of electrical power in underground and open-pit mines where high-voltage electrical cables are frequently used to power mining equipment. The main purpose of earth fault protection is to safeguard personnel and electrical apparatuses. Unless properly controlled, the occurrence of an earth fault can be hazardous at a mine because it may cause

- Voltages from machine frame to earth, which are dangerous to personnel; or
- Electric arcing underground, which may initiate an explosion or fire.

The most common apparatus faults in mines occur in power cables, as they are susceptible to damage caused by heavy equipment. This is particularly true of flexible trailing cables that supply power to mobile mining machines. They are laid over ground or close to ground level, and it is almost impossible to prevent their damage by road traffic and during relocation of the cables. Cable construction is such as to provide every phase conductor with an individual conductor screen so that crushing would expose a single phase, creating an earth fault current. A protective device such as an earth leakage relay would then isolate the cable and contain the sparking within the cable before the occurrence of a heavy short-circuit current due to a phase-to-phase fault. Coordination among protective units is introduced to allow the unit closest to the fault to isolate the faulty circuit without causing the healthy part of the system to be deenergized.

Effect of Current Exposure to Human Body

Though desirable, it is almost impractical to provide automatic protection against electrocution as a result of direct contact with a live conductor, particularly where the electrical reticulation is exposed to a humid or damp atmosphere. To appreciate this, it will be necessary to study the effects of current values on human beings (Table 9.9-3).

As the table indicates, passage of current as low as 20 mA through the human body can cause loss of muscular control to the extent that an individual cannot disengage from the live conductor, and a current in excess of 50 mA is sufficient to produce a critical heart condition from which there is little or

Table 9.9-3 Effect of current exposure on the human body

Current Level, mA	Effect
<1	No sensation
1–8	Sensation of shock, not painful; individual can let go at will, as muscular control is not lost
9–15	Painful shock; individual can let go at will, as muscular control is not lost
16–20	Painful shock; muscular control of adjacent muscles lost; individual cannot let go
21–50	Painful shock, severe muscular contractions, breathing difficulty
51–200	Ventricular fibrillation (a heart condition that may result in death)
201 and over	Severe burns; muscular contractions so severe that chest muscles clamp heart and stop it for the duration of shock (this prevents ventricular fibrillation)

no chance of recovery. For effective safeguard against electrocution, it would be necessary to introduce earth leakage protection designed to operate with a fault current below 20 mA, which in most cases would be impractical.

Methods of Earth Fault Protection

Two main methods are used for earth fault protection. They are earth leakage protection and earth continuity protection. The earth leakage protection devices are activated by any unbalanced current of any phase of a three-phase circuit caused by an earth leakage. The leakage current should not exceed 1 or 2 A for most applications, and it is limited to 30 mA for portable apparatuses operated by personnel (Mines Safety and Inspection Regulations 1995). The principal purpose of earth continuity protection is to ensure a continuity of earth conductors throughout the length of the supply cable and associated connectors. All trailing cables have either a separate central conductor called a pilot wire or they use a pilot-wireless monitor through the cable conductors. The pilot-wire/pilot-wireless systems are connected to a solid-state frequency-controlled system to ensure the continuity of the ground conductor. In case of damage, if the signal level becomes too low (indicating excessive resistance in the pilot-wire/pilot-wireless system) or the frequency is outside tolerance, the monitor indicates a fault condition and opens (i.e., trips) the control relay. Most mine regulations specify that automatic protective devices must be tested periodically for proper operation (Mulvaney 2008).

Other protection devices that ensure safe power usage are surge diverters, which protect the circuit from overload surges such as those due to lightning; circuit breakers, which respond to overloads and quench the resulting arc in a way that will not affect other parts of the system; fuses, which open the circuit when excessive current flows through it; and manually operated isolators and switches.

Maintenance of Major Components Used in Electrical Power Reticulation

The major components that require maintenance are the transformers, switchgear, and protective equipment. The protective equipment is also used with ventilation fans, pump motors, electrically powered mining machines such as rock drills, and trailing cables. Usage-based maintenance is commonly practiced in many mines. However, predictive maintenance based on condition monitoring improves reliability and should be implemented wherever possible. The following points relevant to the maintenance management of major components are suggested:

- Transformers use air or oil as a medium for cooling and insulation. Regular monitoring of the condition of oil is useful as a predictive tool to determine the performance of the transformer. Oil analysis gives information about the integrity of insulation of the transformer windings, dissolved gases resulting from any arcing within the windings, water contamination, and the degree to which the oil itself has deteriorated. Arcing may occur as a result of breaking down of insulation properties in oil. A thorough visual examination for oil leaks, including temperature measurement and a test of relief valve operation, should be carried out periodically.
- As trailing cables are subjected to frequent movement in a harsh mining environment, they accumulate damage over time. The insulation resistance is one indicator of the accumulated damage. Hipot or megger testing are popular insulation test methods practiced by many companies. However, both methods damage the cable and reduce its operational life. It is not recommended to conduct destructive testing of cable insulation. IEEE 400-2001 (2002) states that partial discharge testing is nondestructive and more accurately gauges insulation integrity. This information is useful for timely replacement of the cable. Trailing cables should be equipped with both earth leakage relays and earth continuity relays.
- Mines have typical apparatuses such as dewatering pumps and ventilation fans. Suppliers of this equipment usually provide maintenance information. However, it is the responsibility of the mine's personnel to perform the routine maintenance.
- Dewatering pumps must be equipped with devices such as flow-sensing relays, reservoir water level sensors, and position indicators of inlet and outlet valves to make sure that the pump does not engage unless there is adequate water. The proper functioning of these devices should be checked periodically. Portable dewatering pumps are not generally equipped with all the flow-sensing devices. However, they are usually fitted with current-sensing devices that stop the pump if there is a large variation of the load such as that caused by loss of water. Also required are regular lubrication of motor bearings and switching contact maintenance of motor starters.
- Primary ventilation fans are heavy electromechanical machines. The bearings on which the motor shaft is mounted are subjected to wear resulting in increased vibration and heating. A periodic measurement of the bearing temperature and vibration monitoring of the fan reveals the condition of the bearings and the dynamics of the fan rotation, allowing prior action to be taken before a failure occurs.
- Rock drills are subjected to heavy vibration. Therefore in addition to periodic checking of the trailing cable, the electric panel should be checked for loose contacts.
- Motor starters should be selected considering the applications. For example, variable-frequency-drive starters help to regulate the motor speed, and they can be very cost-effective for use with primary and secondary ventilation fans where constant full-speed operation is not required.

Also, these starters work well with automatic and remote control systems. Other types of starters commonly used are soft starters having electronic control of starting voltage, star-delta starters, and direct on-line (DOL) starters. The DOL starters are suitable only for low power applications, as the starting current of the motor can be as much as seven times the full load current. Because of the presence of moving parts and the heavy current experienced by starters, wear is usually high, and the frequency of inspection and maintenance should be adjusted as required.

- Mine regulations usually specify that earth leakage relays need to be checked for proper operation at frequent intervals (e.g., monthly). Also, power cables and earth grounding must be checked periodically.
- The resources needed for maintaining the electrical infrastructure depends on the extent and complexity of the electrical equipment. Most mines require a lead hand who can also act as a supervisor, and other electricians. At least one electrician shoud be required to work during each shift. Specialized contractors may be needed for specialized or statutory work such as that dealing with high voltage. Also required are an electrical maintenance shop and an inventory of consumables and test equipment.

A reliability-focused maintenance plan should be developed to keep the mine electrical system in good working order. Necessary precautions must be taken to minimize the risk of earth fault, as mines use flexible power cables and associated gear for power distribution. Mine regulations stipulate the periodic testing of earthing systems, protective devices, cables, and other electrical equipment, and use of a logbook is required to maintain all testing and examination records. During maintenance of mining equipment, personal danger tags are used to communicate with equipment users that their equipment is being serviced.

Dewatering Systems

Open-pit mines vary in size and depth. Large pits can be several kilometers in length and width and up to a kilometer deep. In most instances, the depth is greater than that of the natural water table. A variety of methods are used to remove water ingress. Some mines remove water continuously via bore pumps located around the pit. Others pump away water collected in a sump at the bottom of the pit. Regardless of the method employed, it is necessary to use one or more pumps that can remove the peak water ingress that may occur during the rainy season. This will keep the drawdown level (i.e., depressed water table level) below the pit depth. Dewatering of pits situated close to lakes or nearby abandoned mines can be challenging if seepage occurs.

Selection of Pumps Used for Dewatering

Many types of pumps are used to remove water from mines. The factors that determine the type of pump are flow rate, pressure or elevation, density of water, and suction head that should not exceed a given limit. Centrifugal pumps are adequate for most dewatering applications and are commonly used for lifting water up to about 300 m (1,000 ft). Multistage pumps can be used for removing water at greater depths (Munson et al. 2006). In underground mines, positive displacement rotary pumps are popular because of their self-priming capability. Plunger and diaphragm pumps are also used.

The design of centrifugal pumps is a highly developed field. Actual pump characteristics are experimentally determined through tests and supplied by the pump manufacturers. Typically they include a graphical relationship between the total head and the discharge as well as identification of the zone where the pump efficiency is high. For a given head and a discharge, a suitable pump can be selected considering its efficiency as well. Furthermore, pump characteristics also include what is known as net positive suction head. This is useful to determine the maximum suction height of the pump while allowing for pressure losses in the pipe.

Head Loss in Pipes

Head loss in piping should be taken into account in determining the overall pressure head required for pumping. This consists of the pipe friction loss and the shock loss when the fluid passes through sharp bends and turns (which should be eliminated or minimized during construction and maintenance). Pipe manufacturers usually provide the friction losses. Piping handbooks give the shock loss factors applicable to sharp changes in the piping geometry (Crowe et al. 2008). Alternatively, losses due to bends and other geometric changes of a pipe can be expressed as an equivalent increase in the length of the pipe subjected to frictional resistance. Often it is more convenient to include the effect of geometric changes as an added length, which is provided by the pipe manufacturers.

Planning and Managing Surface Mine Dewatering

For mining to be carried out without the hindrance of groundwater ingress, many managers seek to reduce the level of the water table below the depth of the mining pit. The usual strategy for doing so is to pump from several bore water pumps before constructing the surface mine and during mine operation. Alternatively, the water collected in sumps at the pit bottom is removed in some mining operations. The following considerations can be useful during planning and operation of the dewatering system.

- The estimate of water ingress should be based on a hydrological study. The existence of nearby abandoned mines or large reservoirs such as lakes must be considered. Previous experience with groundwater in bores or drill holes in and around the location can also be useful, as can construction of test bores.
- Place of discharge should be decided considering the geology. If the ground is permeable, water must be sent to a reservoir far distant from the mine.
- Electric submersible bore pumps, which are available in a variety of sizes and capacities, can be used. Bore pumps are usually multistage centrifugal pumps. Although they are quite reliable, they can be easily damaged by letting them run without water and/or under cavitating conditions. Hence flow-sensing switches should be incorporated to ensure that pumps stop automatically when adequate water is unavailable. They may be reenergized after a preset time lapse. Pump manufacturers provide automatic pump controllers and alarm transmitters.
- In many sites, the yield of water increases substantially for weeks or months and then gradually lessens. Pumping should continue until the drawdown is below the pit bottom. The drawdown can be measured by inspecting the level of water in drill holes or well bores.

- In some cases, dewatering is done using a sump located inside the mining pit. Centrifugal pumps with horizontal- or vertical-axial configuration can be used as appropriate. However, they should be located near the sump so suction head restrictions are satisfied. Pumps driven by diesel engines are commonly used at some locations inside a surface mine if electrical power supply is unavailable. If the depth of the mine is great and/or the delivery distance is large, a transfer tank may be required on the ground level adjacent to the pit for temporary storage of water. Silt may be removed by sending it through a precipitation tank. In this case, secondary pumps are needed for delivery of water to the final destination.
- Pumps configured to operate in parallel increase the flow rate without increasing the total head. Those configured to operate in series increase the total head without increasing the flow rate.
- The main considerations in selecting a pump for dewatering are capability, reliability, portability, and wear resistance. Both reliability and wear resistance are affected by operational conditions.
- The correct grade of polyethylene pipe, one that can withstand the applied pressure, should be used. The size of the pipe should be determined considering the flow rate. A velocity of 3 m/s (9.8 ft/s) is an upper limit considering the frictional losses in a pipeline. A minimum velocity of about 1 m/s (3.2 ft/s) is required to prevent settling of solid matter inside piping. The settling velocity depends on the maximum size of the solid particles carried by water. To minimize damage to the piping and to reduce maintenance, all piping must be securely fastened. This is necessary because pipes tend to move about when subjected to internal pressure and in particular when dynamic transient pressures occur.
- If the delivery pipe passes through steep elevations, one should be aware of the possible occurrence of large negative pressure in the falling side of the pipeline. Vacuum relief valves may be required to prevent pipe collapse. Similar conditions may occur when the pump is suddenly stopped where the water is delivered through a long pipeline.
- The life of a pump, particularly if it is used for pumping saline or corrosive waters, is affected by the material it is made of. The expected mine life should be considered when pump material is being selected. Even a long-lasting and expensive pump, if it is operated under abrasive conditions, may require regular replacement of the impeller or volute chamber.
- Some important considerations in the design and maintenance of sumps and transfer tanks are to provide adequate excess capacity to cater for pump downtime, install trash screens and grit traps ahead of the pump intake, and facilitate the regular cleaning of deposited material in screens and grit traps.
- A vacuum gauge installed in the suction side of a pump gives useful information about its performance. An unusually high suction pressure may indicate a blocked suction pipe and/or cavitation occurring, whereas a low value may indicate that air has leaked into the suction pipe or that the pump has not been primed. Similarly, an unusually low reading in a pressure gauge installed in the delivery side may indicate no flow, excessive air in the water, and so on. An increase in the delivery pressure indicates a blockage or a closed valve in the delivery pipe. Excessive vibration in a pump may be an indication of an unbalanced or worn-out impeller, worn bearings, or a damaged shaft (Kuruppu 2008).

Table 9.9-4 Maintenance strategies

Type/Tactic	Details
Preventive maintenance	Interval-based maintenance including cleaning, inspection, and replacement of parts
Predictive maintenance	Measurement of performance factors such as flow rate, suction, and delivery pressures; maintenance and repair according to needs and prior to failure
Proactive maintenance	If failure is repetitive, reengineering of system to eliminate root cause of failure

Table 9.9-5 Factors to consider when selecting a maintenance strategy

Factor	Description
Reliability	At a minimum, the predictive maintenance strategy is necessary to ensure high reliability. In some cases, proactive maintenance may be necessary to eliminate the root cause of failure in the existing systems.
Availability and capability	Most equipment requires at least preventive maintenance. The service interval should depend on the demand for equipment (e.g., operational hours per week) and the recommended interval of parts replacement.

Maintenance Management of Dewatering Infrastructure

The maintenance management strategy should be designed to minimize the total dewatering cost over the planned life of the pit. This may include adding more resources such as equipment for performance monitoring, replacement of parts, routine cleaning and inspections, and reengineering of the existing infrastructure if the current system is not reliable. An optimum level of maintenance is that which corresponds to the lowest total dewatering cost. Table 9.9-4 gives a list of maintenance strategies commonly adopted by maintenance personnel. Table 9.9-5 shows the factors that should be considered when formulating a maintenance strategy. Reactive maintenance, which would be required in case of equipment failure, can be minimized by adopting these strategies.

Adequate resources must be available to meet the requirements of maintenance. The resources usually required are skilled personnel such as team leaders, plumbers and fitters, parts required for pumps and prime movers (e.g., diesel engines), accessories such as piping and pipe fixtures, and material-handling equipment.

In conclusion, dewatering of pits requires proper consideration of the rate of water ingress and the total pressure head needed for suction and delivery of water. The total head depends on suction height, delivery height, and friction loss in the piping. Once the pumping system is operational, the reliability of the pump can be adversely affected by air entrapment due to low water level and by abrasive material such as sand mixed with water. The latter causes rapid wear in the impeller and the housing. Other problems are clogging in the suction and delivery pipes and the occurrence of transient pressures in the delivery

pipe resulting from sudden interruption to pumping. To minimize damage to pumps and piping and the disruption of dewatering, these issues require proper planning, monitoring, and control.

Maintenance Workshop Facilities

For a mine system to operate successfully according to specifications, there must be a variety of supporting maintenance workshops and facilities near mining activities. These can be managed by the mining companies or, if the maintenance of mining equipment and systems is completely outsourced, by a private contractor.

These facilities consist of central workshops shared by repair and service personnel. Such workshops are equipped with all the necessary facilities—welding, painting, drilling lathing, metal drilling, machine lubricants, and so on. Minor repairs for mobile equipment are often performed at the site of operation, but when a piece of equipment needs to be overhauled or needs major maintenance and repair, it can be moved to central workshops. As mining systems become more extensive, the operation and management of the maintenance facilities must be integrated into mine operation functions. Infrastructure facility management is increasingly important for reducing mining systems' operating costs and improving their reliability. Judicious location and operation of such facilities will reduce the transport- and logistics-related costs involved in operating and maintaining mining systems.

CONCLUSION

A characteristic of many of the mine infrastructure elements is that they are either common components to production systems or are series connected. Because of this characteristic, the business risks associated with stoppages or service reduction due to poor maintenance can be significant. Due to design deficiencies or to operational and environmental stresses, infrastructure systems are not completely failure free, and they are sometimes unable to meet capacity requirements. Therefore, a high degree of maintenance preparedness for the mine infrastructure is necessary to meet performance targets. In some mines, this preparedness is best achieved by integrating maintenance organization into operations departments. In others, especially mines having a high degree of process complexity, the preferred solution is to maintain a separate engineering department.

With the potential reemergence of the minerals boom, infrastructure utilization will become of critical importance. This in turn will limit the availability and extent of opportunities to perform routine preventive maintenance of mine infrastructure, requiring continuous revision of tactics employed to maintain infrastructure assets.

CHAPTER 9.10

Systems Engineering

Rajive Ganguli, Kadri Dagdelen, and Ed Grygiel

INTRODUCTION

Systems engineering is a field consisting of a broad range of techniques that can be used to quantitatively model, analyze, and optimize a system. Thus, it includes a whole range of methods, including modeling techniques such as discrete event simulation and artificial intelligence, analysis techniques such as statistical tests and Six Sigma, and optimization techniques such as linear programming and gradient methods. To a practitioner, however, the subject could be limited to the techniques that are directly applicable to their field. Because mining spans a variety of activities, the mining industry uses every systems-engineering technique available.

Because of space limitations, this chapter cannot cover the entire range of techniques relevant to the industry. For this reason the topics included were selected based on certain criteria. Topics are covered if they are relevant to large portions of the mining industry, especially if the topic can be usefully covered in brief. Most topics, however, do not fall under this category, and most are very complicated techniques that require entire books for proper presentation and are important only for a narrow application in the industry. Additionally, they may have been widely discussed in the literature (mining and otherwise). Therefore, these techniques are only introduced here, with the focus being on "good practices."

This chapter discusses data collection, modeling techniques, analysis techniques, and optimization.

CORE FUNDAMENTALS: DATA COLLECTION

Optimization is essentially an act of balancing competing constraints with the constraints being defined by data from the process. Because erroneous constraint definitions could result in gravely suboptimal optimization, it is imperative that all data be collected carefully and described accurately.

Measuring something fixed and definite, such as the length of a machine, is easy. However, measuring activities that are variable is not easy, because many measurements have to be made, with "many" not necessarily being a very clear number. Additionally, when measurements are expensive, there is a constant struggle between "how many" and "representative."

Determining Sample Size

This section discusses methods of determining the required sample size.

Minimum Number of Samples to Estimate Within a Certain Error Range

If the standard deviation, σ, of the process being measured is known, then the sample size, n, required to obtain an error range ($\pm$) of δ is calculated as follows (NIST/SEMATECH 2006):

$$n = z_{\alpha}^{2}\left(\frac{\sigma}{\delta}\right)^{2}$$

where z_{α} is the value on the normal distribution curve for a probability of α.

This equation assumes normality, and it also requires *a priori* knowledge of the process's standard deviation. If the distribution is not normal, but the number of samples exceeds 30, then the normality assumption will probably be fine. It is when the number of samples is low that a wrongful normality assumption is harmful.

Example 1. The time to cut a face was previously determined to be normally distributed in a mine, with an average cutting time and standard deviation of 43 and 15 minutes, respectively. Management would like to sample the cutting times before and after the modifications to know if the modifications did make an impact. How many samples (of cutting time) are needed if the average cutting time is to be estimated (at a 95% confidence interval) within 2 minutes of true mean?

Solution. A 95% confidence interval implies $\alpha = 5\%$, which yields $z_{\alpha} = 1.96$ (round off to 2). Given that $\sigma = 15$ and $\delta = 2$, to estimate the mean cutting time within 2 minutes of the true mean, management needs to take $(2)^2 \times (15^2/2^2) = 225$ samples.

Rajive Ganguli, Professor of Mining Engineering, University of Alaska Fairbanks, Fairbanks, Alaska, USA

Sampling Proportions

Frequently, the focus of a small sampling exercise may be to see if a given machine or process is running or not. Sample values in such cases are binary, that is, a machine is running or not running, and the ultimate measurement is a proportion (such as the machine is running X% of the time). For such cases, the minimum sample size required is given by the following equation (NISH/SEMATECH 2006):

$$n = z_{\alpha}^2\left(\frac{pq}{\delta^2}\right)$$

where

p and q = two proportions (running/not running)
δ = margin of error in estimating the proportion

A time study for sampling proportions should include at least 10 successes and 10 failures. Studies focused on equipment reliability and statistics such as mean time between failures are directed to the literature on reliability engineering (O'Connor 2002; NISH/SEMATECH 2006).

Example 2. The main belt conveyor at a mine typically runs 90% of the time. It is down the rest of the time. Management would like to buy a new motor to improve reliability. How many samples (running/not running) should management take if they wish to estimate (with 95% confidence) the proportion of the time (±2%) that the belt is running?

Solution. A 95% confidence interval implies α = 5%, which yields z_{α} = 1.96 (round off to 2). Given that p = 0.90, q = 0.10, and δ = 0.02, then $n = 2^2(0.9 \times 0.1/0.02^2) = 900$ samples.

In this case there is an additional question (not addressed here): When should one collect the 900 samples? The answer to that question lies in the 90% estimate given in the problem. If management sampled the belt every hour to obtain the 90% estimate, then the 900 samples should be obtained on an hourly basis. If the belt fails very infrequently, the Poisson distribution discussion that follows should be considered.

Poisson Distribution

Poisson distribution governs sparse data (i.e., rare events). For a Poisson distribution, the minimum sample size is given by the following (van Belle 2008):

$$n = \frac{4}{\left(\sqrt{\mu_0} - \sqrt{\mu_1}\right)^2}$$

where μ_0 and μ_1 are the estimated means of two populations that are to be compared.

Example 3. A machine breaks down approximately every 10.5 hours. A new maintenance program is expected to increase the time between breakdowns by 2 hours. How many samples should be taken to conduct the two-mean comparison tests?

Solution. The number of samples needed, n, is as follows:

$$n = \frac{4}{\left(\sqrt{10.5} - \sqrt{12.5}\right)^2} = 45$$

Working with Any Sample Size

Sampling/measurement is useful even if a large number of samples cannot be taken. Comparison of means and confidence interval for means are very valuable tools whether or not a large number of samples are taken.

Example 4. In the previous example, management could not take 225 time-study samples on the continuous mining machine (CMM). Before the changes were made, 38 time-study samples (n_1) revealed the cutting time to be normally distributed with an average of 41 minutes (μ_1) with a standard deviation of 14 minutes (σ_1). After the changes were made, 32 samples (n_2) revealed a cutting time average of 38 minutes (μ_2) with a standard deviation of 11 minutes (σ_s). Did the changes improve the CMM (with 95% confidence)?

Solution. This problem is solved by performing the following four steps:

1. Compute the pooled degrees of freedom, ν, as follows:

$$\nu = n_1 + n_2 - 2 = 68$$

2. Compute the pooled variance, s^2:

$$s^2 = \frac{(n_1 - 1)\sigma_1^2 + (n_2 - 1)\sigma_2^2}{\nu} = \frac{37 \times 14^2 + 31 \times 11^2}{68} = 161.8$$

3. Compute the t-statistic:

$$\text{t-statistic} = \frac{\mu_1 - \mu_2}{\sqrt{s^2\left(\frac{1}{n_1} + \frac{1}{n_2}\right)}} = \frac{41 - 38}{\sqrt{161.8\left(\frac{1}{38} + \frac{1}{32}\right)}} = 0.98$$

4. Look up t-table for t_{critical} for α = 0.05 (two tail) and ν = 58. This gives t_{critical} = 2.0.

Because the computed t-statistic is lower than t_{critical}, one cannot claim that the changes made any difference.

Example 5. In Example 1, what is the confidence interval (95% confidence) for the obtained average cutting time in the first time study (n = 38, μ = 41, and σ = 14).

Solution. The problem is solved by performing the following steps:

1. Confidence interval for mean = $\sigma/\sqrt{n}$ = $14/\sqrt{38}$ = 2.71
2. t-statistic for 95% confidence interval (α = 0.05, two tail) = 2.0
3. Confidence interval = $\pm 2.0 \times 2.71 = \pm 5.4$

The time study truly implied that the average cutting mean is between 35.6 (i.e., 41 – 5.4) and 46.4 (i.e., 41 + 5.4).

Time Studies

When the minimum sample sizes are known, the next step is to actually collect the samples. Time studies are a common way that processes are sampled. Simply speaking, time study is the process of measuring the frequency and duration of activities. Time studies can be very insightful, as they quantify the interaction between activities. Even though most interactions are known, the magnitude of the interaction can sometimes be a surprise. When properly designed, time studies can be used to identify bottlenecks, set performance standards, and guide system redesign. A typical sequence for a time study is as follows:

1. **Identify the goals.** Cleary spell out the goals of the study.
2. **Gather intimate knowledge of the system.** Visit the location, meet people, and identify potential hazards. Learn about factors (such as shift changes) that may compromise the integrity of the study.
3. **Plan for the act of time study.** Identify observation locations, prepare for the environment (moisture, dust, noise,

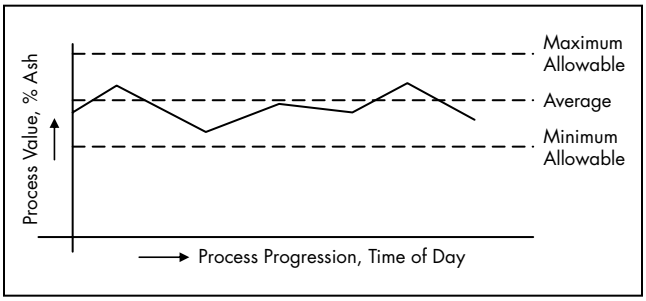

Figure 9.10-1 Example control chart for a coal washing plant

etc.), create forms or obtain batteries and software for personal computing devices. If there is more than one person involved in the time study, ensure that every member understands the definition of an "activity," especially when to start and stop.

4. **Collect long-term data.** Not all critical activities may occur during the time study. This is especially true of major breakdowns. Thus, it is important to review long-term records.
5. **Analyze or utilize time-study information.** Look beyond "averages." Do not assume normality. Explore the role of variability through simulation.

Advances in sensor and mine communications technology is eroding the role of performing time studies in areas that are popular time-study targets, such as truck-shovel utilization. Most mining equipment has sensors that measure and record basic operational data (such as cycle time, truck load, and speed) and health data (such as engine temperatures or breakdown) that can feed directly into a production-simulation exercise. While the wealth of data can vastly improve production simulation, one must be careful not to implicitly trust automatically gathered data. Errors have been known to occur, not just because of undetected malfunctioning sensors, but also due to errors in data warehousing, including conceptual errors such as different periods of aggregation for different data streams and errors in upstream databases that contribute to the corporate warehouse (such as a misspelled operator name).

MODELING TECHNIQUES

This section introduces three common systems-modeling techniques.

Statistical Process Control

Statistical process control (SPC) procedures are implemented to track a normally distributed process in real time with an eye on quality limits. The term *process* is meant as a key performance indicator of the system. Thus, while coal washing may be the process that is being tracked, the actual measurement being utilized in the tracking could be the average ash content (Figure 9.10-1) of washed coal. The intent of SPC is to identify when a process is out of control, so that remedial actions can be taken immediately. In Figure 9.10-1, the upper and lower limits for the process are shown. The process is deemed out of control whenever a process measurement strays past them. In many cases, a process may not be deemed out of control unless several process values are out of bounds.

In the simplest of forms, SPC requires a regular measurement of the process. These measurements are then plotted on a chart that has quality limits. The limits are usually either two standard deviations (95% confidence limit) or three standard deviations (>99.5% confidence limit) from the mean.

Because the mean and standard deviation estimates of the process directly impact when the process is deemed "in control" or "out of control," it is critical that these be estimated after a rigorous study of the process. An appropriate number of independent samples should be taken. However, this may be easier said than done because many mining processes are inherently correlated in time. For example, the ash content is directly related to the seam quality. When a particular area is being mined, all quality data will be similar. Thus, a 100-short-ton batch of coal may all have similar properties. The inherent correlation in processes is what makes SPC challenging.

Inherent correlation between samples close in time can be detected by plotting $P(t)$ versus $P(t + \lambda)$, where $P(t)$ is the profits received at the end of period t and λ is some lag time. For example, assume that measurements are made every minute. If 500 data points were collected, then $P(t)$ is the entire data set. If $\lambda = 25$, then $P(t + 25)$ or lag 25 data, would be the series starting at Sample 26 and ending at Sample 500; $P(t + 25)$ would have 475 points. Next, $P(t)$ is plotted against $P(t + 25)$. Of course, the last 25 points in $P(t)$ have to be discarded so that it also has 475 points, such as $P(t + 25)$. If this plot reveals no correlation (i.e., $R^2 < |0.05|$), samples 25 minutes apart should be used to draw the SPC chart.

Discrete Event Simulation

To understand discrete event simulation (DES), one must look at processes as a group of non-deterministic activities. Non-deterministic activities are those whose duration cannot be predicted with certainty. Some activities occur in a sequence, while some occur in parallel. At any given time, many activities are in progression, while some activities may start or end. For example, as one truck heads toward the mill, another is headed to the dump, while yet another may be headed to an excavator. During this time, a drill may be drilling blastholes or an excavator may be loading. The start or end of an activity is termed an "event." DES is a process simulation technique that models a process as a series of events. Simulation is controlled by a calendar of events called the "future events list" (FEL), with time jumping from one event to the next. Events are generated according to the definition of individual activities, with most activities being stochastically defined (i.e., as a statistical distribution). As events are generated, their start and end times are written to the FEL.

DES is very useful because it is able to represent a process or system with all its inherent variability. The complex interactions between events can be understood and their effects accurately quantified. The effect of probabilistic interactions is the most difficult to quantify in the methods that do not take into account the stochastic nature of most activities. Additionally, even if their stochastic nature is accounted for, it is almost impossible to quantify the combined effect of events, each of which follows a different distribution and is intertwined with other events.

The key to a successful DES model is good data. Time-study or other data that are used in the model should be representative of the activity. Maintenance and operational data beyond the time-study period should be reviewed to identify and quantify long-term trends. Distribution fitting should be accurate and should be correct for the activity. For example, for manual tasks, a right-tailed distribution is preferred (Yingling et al. 1999).

There are a variety of DES languages, including Arena simulation software (Rockwell Automation) and GPSS World (Minuteman Software). An excellent resource for mine simulation is Sturgul (2000).

Artificial Intelligence: Neural Networks

Artificial intelligence is a field encompassing a variety of tools—a popular one of which is neural networks. Neural networks are used widely in the mining industry, including in ore reserve estimation, process control, and machine health monitoring. This topic has been presented widely in the literature and, therefore, the reader is directed to standard references (Hagan et al. 1996; Sarle 1997; Haykin 2008) for a fundamental presentation. However, the many subtleties of neural networks that impact performance, but are not discussed widely in common literature, are presented here.

Neural networks are simply numerical models that describe through equations (i.e., $y = f(\boldsymbol{x})$) the relationship between a set of inputs, $\boldsymbol{x}$, and a given output, y. What makes them tricky to use is that there is little theoretical guidance on the modeling process. This is compounded by the multitude of software products, such as business intelligence tools, that make it "easy" to apply neural networks, resulting in many wrong or suboptimal applications. This is especially true in mining because mining-related data often have some amount on built-in unreliability.

Data Subdivision

As with any modeling process, neural models are tested prior to their use. Modeling and testing are done by splitting the data set into modeling and testing subsets. Typically, data are randomly subdivided (such as 75% modeling, 25% testing). However, as shown by Ganguli and Bandopadhyay (2003), random subdivision can result (with substantial probability) in two subsets that are not statistically similar. It is obvious that the modeling subset should be similar to the testing subset; otherwise it is akin to studying English but being tested on French. This problem is pronounced when the data set is sparse. A neural network requires the modeling subset to be further split into training and calibration subsets. Thus, this modeling approach requires the data to be split into three similar subsets: training, calibration, and testing (TCT). Usually, the split is 60%, 20%, and 20% between the three subsets, though there is no hard and fast rule.

Techniques such as genetic algorithms have been used to split data sets into TCT subsets (Ganguli et al. 2003; Samanta et al. 2004a). Some also first presplit the data set into multiple groups/categories, each of which contributes to TCT subsets (Samanta et al. 2004b; Yu et al. 2004). In any case, the intent is to arrive at three subsets that are "similar." It is up to the modeler to decide on what constitutes similarity. No matter what strategy is used in constructing TCT, the following two rules should be adhered to (especially in sparse data sets):

1. The training subset should contain the highest and lowest values. This way, the neural network is exposed to a broad range of data during training.
2. When data grouping/segmentation is done prior to constructing the TCT subset, it is possible that some groups may not have sufficient data for the three TCT subsets. In such cases, samples are assigned to training first, followed by calibration. Testing has the last priority.

The point of this discussion is that data should be subdivided with care rather than randomly. If data are divided randomly, one should verify that the subsets are similar.

Neural Network Design

The choice of architecture is an important neural network design parameter. The architecture of a neural network implies its size (in terms of number of neurons), number of layers, and choice of activation functions. Some of these are discussed in this section.

Size of the hidden layer, number of neurons. As a general rule, the total number of weights and biases should be less than half the number of training samples. The total number of weights and biases in a single-layer neural network, for N_{ip} inputs, N_{hl} hidden layer neurons (with associated N_{hl} bias weights), and one output (with an associated bias weight), is as follows:

$$N_{\text{weights + biases}} = (N_{ip} \times N_{hl} + N_{hl}) + (N_{hl} + 1)$$

Too many neurons result in too many neural network parameters being estimated from too few samples. Thus, the estimates may not be reliable. The most desirable neural network is the one that meets performance criteria with the least number of weights and biases.

Number of inputs. It should be remembered that even if one has sufficient data to define more inputs, more inputs might not be necessary. As Ganguli et al. (2006) discovered while modeling a semiautogenous grinding mill, not every input helped improve model performance (despite common belief on their usefulness). In other words, the modeler should experiment by eliminating some inputs so that the model has the least number of inputs, weights, and biases for the same neural network performance. When eliminating inputs, ideal candidates are those that are highly correlated to other inputs or those on which the modeler has the least confidence (in terms of quality of data). If the inputs are correlated, one could apply techniques such as Gram–Schmidt orthogonalization to remove the correlation between inputs prior to using them.

Training algorithm. The next important design factor is the selection of a training algorithm, including learning rates and momentum. Simply speaking, training involves optimizing the following nonlinear objective function:

$$\varepsilon = f(\boldsymbol{w})$$

where

ε = error
$\boldsymbol{w}$ = set of weights and biases

Optimization of nonlinear functions is a very mature field, with no clear guidance on the "best" algorithm. This includes the work of Samanta et al. (2006), who applied (and discussed) various training algorithms for ore reserve estimation and did not find any clear leaders.

However, "Neural Net FAQ" (Sarle 1997), which is an excellent Internet resource on neural networks, recommends the following:

- Use Gauss–Newton algorithms (such as Levenberg–Marquardt) for small number of weights and biases. These are resource-intensive algorithms that require a

Table 9.10-1 Suggested data descriptors for common distributions*

Distribution	Required Descriptors	Intuitive Descriptors
Normal	Mean, μ Variance, σ	expected value = μ; variance = σ
Poisson	γ	expected value = γ; variance = γ
Lognormal	Mean of lognormal data, μ_{LN} Variance, σ_{LN}	expected value = $e^{(2\times\mu_{LN}+\sigma_{LN}^2)/2}$; variance = $(e^{\sigma_{LN}^2}-1)\,e^{(2\times\mu_{LN}+\sigma_{LN}^2)}$
Beta	The shape parameters, α and β	expected value = $\frac{\alpha}{\alpha+\beta}$; variance = $\frac{\alpha\beta}{(\alpha+\beta)^2(\alpha+\beta+1)}$

*Deciles and quartiles are always helpful additional descriptors.

storage capacity proportional to the square of the number of weights and biases.
- Conjugate-gradient-type algorithms are less resource intensive and require a storage capacity proportional to the number of weights and biases. Thus, they are best for large problems.

No algorithm guarantees finding the global optima. Therefore, it is customary to train the neural network several times, starting with a different set of random weights each time.

Advanced concepts. Many different neural network models can be fitted to a given data set. Often it is very difficult to decide which model is "best"—is it the one with the best prediction correlation (r^2), the one with the best root-mean-square error, or some other measure? How does one combine competing performance measures? Additionally, what if the testing subset performance is very different from training and calibration subsets? While not all answers are easy, a common-sense solution would be to pick a network that performs equally well across all subsets.

There is no reason, however, to restrict oneself to one model to represent the data set. "Ensemble modeling" (Dutta et al. 2006) can be done where predictions from multiple neural network models are combined to obtain the final prediction. Because ensemble models reduce variance and not bias, ensemble members should ideally be low bias predictors. Other ensemble modeling concepts include boosting (Samanta et al. 2005) and modular networks (Sharkey 1999).

ANALYSIS TECHNIQUES

This section presents two common analysis techniques after a brief discussion on how to describe data.

Basic Description
