SME MINING ENGINEERING HANDBOOK

THIRD EDITION

EDITED BY PETER DARLING

PUBLISHED BY
SOCIETY FOR MINING, METALLURGY, AND EXPLORATION, INC.

Society for Mining, Metallurgy, and Exploration, Inc. (SME)
(303) 948-4200 / (800) 763-3132
www.smenet.org

SME advances the worldwide mining and minerals community through information exchange and professional development. With members in more than 70 countries, SME is the world's largest association of mining and minerals professionals.

Preface

It was Robert Peele who gathered a group of 46 specialists almost a century ago to write the now classic *Mining Engineers' Handbook*, published in 1918 by John Wiley & Sons, with second and third editions published in 1927 and 1941. When Wiley declined to publish further editions, SME began publication of the *SME Mining Engineering Handbook.* SME published the first edition in 1973 and a second edition in 1992.

From that initial publication in 1918, the handbook has been acknowledged as the repository of all essential information and useful, practical detail relating to virtually every aspect of mining.

From the beginning of my mining career, I have relied heavily on this book as a source of inspiration and information. With the honor of being asked to take on the somewhat challenging role of managing editor for this third edition, I owe a debt of professional gratitude to several generations of managing editors, authors, and technical reviewers who set the seemingly impossible high standards in the previous editions of the handbook.

From the onset, several objectives were established. These objectives included (1) to produce a book that would stand shoulder to shoulder as an equal alongside previous editions, (2) to maintain its tradition of being the "handbook of choice" for every practicing mining engineer, (3) to be practical rather than theoretical in its content and approach, and (4) to be international in its appeal and examples.

Mining is an international business, and the importance of sharing experiences, knowledge, and examples from around the world cannot be overemphasized. A water "problem" in one part of the world may be considered "normal" in another. A "deep" mine on one continent may connote "very deep" on another. Tailings dams in some countries need to be earthquake proof, whereas in other countries they must be free draining.

This edition attempts to take the best of the best from around the world and package it in a standard and logical format for the benefit of the global industry. This internationalism is shown by the subjects covered in each chapter as well as by the nationalities of the world-class authors and technical reviewers represented. It is noteworthy that most significant mining operations have graciously shared their knowledge, techniques, experience, and alternative viewpoints.

The handbook has moved with the times to cover the issues that are exercising the industry, the innovations that are exciting, and how the industry is dealing with changing attitudes toward a number of its constituents such as energy (both electrical generation and carbon/petroleum based), water management, resource maintenance, and the whole subject of sustainable development. One of the significant areas in which this handbook differs from previous editions is that it includes several chapters on both the social and environmental issues often associated with mining, and, more importantly, how these issues and their impacts can be mitigated and managed.

It is important to note that this is a handbook and not an encyclopedia of everything mining. Several subjects previously included as dedicated chapters are now covered in less detail within other chapters. This move was not designed to marginalize or dilute the importance of certain subjects but was done to acknowledge the significant shifts in the way mining has changed as a result of new technologies. It also reflects how the work and the responsibilities of today's mining engineer have changed and developed.

Attempts to encapsulate the essence of so diverse a discipline as mining engineering could not have been possible without the unselfish contributions of the hundreds of authors, coauthors, technical reviewers, and mentors who are very much the unsung heroes of this publication. Much gratitude and thanks are due to the many talented and world-class professionals who have given so freely, patiently, and enthusiastically of their time, hard-earned experiences, and masterful knowledge on a plethora of mining and related subjects to ensure that this handbook was produced on time and to the meteoric standards that the industry has come to expect.

One of the many delights of managing this project has been the acquaintance (usually electronically) of so many helpful, patient, enthusiastic, and friendly people from within the various mining associations, academic establishments, mining companies, and consultancies, as well as retired engineers and specialist editors—everyone an expert in their field. Without their cooperation, steady guidance, constructive comment, and encouragement, the managing of this edition would have been an impossible task. I cannot name them all, and to mention some but not others would be ungracious, but tremendous appreciation is due.

These experts are headed by the authors themselves, almost every one of whom is a world leader in their specialist field. Often with the briefest of guidance and without any form of remuneration, they have passionately undertaken their writing tasks. Their enthusiasm, commitment, and professionalism formed the bedrock on which the handbook has been based, and, as a result, they have produced superb and exceptional texts. I salute and thank you all.

Next, I acknowledge the many technical reviewers who, often at short notice and, as this project progressed, with an ever shortening lead time, have been called on to read through many drafts before articulating and listing their comments, suggestions, and observations. It typically was not an easy task and often may have been a marathon requiring skills, diplomacy, and knowledge that went well beyond their original brief. I apologize and thank you.

Thanks are extended to SME's book publishing team who have been thoroughly professional and efficient in their handling of this edition. This team has checked every comma, word, phrase, sentence, and illustration. They have ensured that copyright rules have not been flaunted in the quest for expedience, checked and rechecked references, standardized units of measure, and performed a hundred and one other tasks to ensure that this finished product is a source of information in a format that at best pleases and at worst does not annoy. Their attention to detail in this exacting task is very much appreciated.

I also thank SME for affording me this opportunity to repay some of the debt that I believe is owed to an industry that has kept me fed, watered, enthralled, and enthused for more than three decades.

Finally, I trust that any errors in opinion, facts, or perceptions in the handbook are few in number and will not overtly detract from the usefulness of and, I dare say, enjoyment of this third edition of the *SME Mining Engineering Handbook*.

Contents

Foreword ix
Preface xi
About the Managing Editor xiii
Contributing Authors xv
Technical Reviewers xxi

PART 1: MINING: SETTING THE SCENE
1.1 Mining: Ancient, Modern, and Beyond 3
1.2 Current Trends in Mining 11
1.3 Future Trends in Mining 21

PART 2: MARKET ECONOMICS
2.1 Economics of the Minerals Industry 39
2.2 Pricing and Trading in Metals and Minerals 49
2.3 Market Capitalization 65
2.4 Investment Analysis 73

PART 3: EXPLORATION
3.1 Geological Features and Genetic Models of Mineral Deposits 83
3.2 Minerals Prospecting and Exploration 105
3.3 Geophysics Prospecting 113
3.4 Geochemical Prospecting 127

PART 4: DEPOSIT ASSESSMENT
4.1 Geological Data Collection 145
4.2 Geologic Interpretation, Modeling, and Representation 173
4.3 Sample Preparation and Assaying 187
4.4 Ore-Body Sampling and Metallurgical Testing 193
4.5 Mineral Resource Estimation 203
4.6 Valuation of Mineral Properties 219
4.7 Mineral Property Feasibility Studies 227
4.8 Cost Estimating for Underground Mines 263
4.9 Cost Estimating for Surface Mines 281

PART 5: MANAGEMENT AND ADMINISTRATION
5.1 Mine Economics, Management, and Law 297
5.2 Economic Principles for Decision Making 309
5.3 Management, Employee Relations, and Training 317
5.4 A Global Perspective on Mining Legislation 331

PART 6: MINING METHOD SELECTION
6.1 Evaluation of Mining Methods and Systems 341
6.2 Mining Methods Classification System 349
6.3 Selection Process for Hard-Rock Mining 357
6.4 Selection Process for Underground Soft-Rock Mining 377
6.5 Comparison of Underground Mining Methods 385
6.6 Comparison of Surface Mining Methods 405

PART 7: ROCK BREAKING METHODS
7.1 Mechanical Rock Breaking 417
7.2 Blasthole Drilling 435
7.3 Explosives and Blasting 443

PART 8: GROUND MECHANICS
8.1 Introduction to Ground Mechanics 463
8.2 Soil Mechanics 471
8.3 Slope Stability 495
8.4 Rock Mechanics 527
8.5 Geotechnical Instrumentation 551
8.6 Hard-Rock Ground Control with Steel Mesh and Shotcrete 573
8.7 Soft-Rock Ground Control 595
8.8 Ground Control Using Cable and Rock Bolting 611
8.9 Mine Subsidence 627
8.10 Tailings Impoundments and Dams 645
8.11 Waste Piles and Dumps 667

PART 9: INFRASTRUCTURE AND SERVICES
9.1 Electric Power Distribution and Utilization 683
9.2 Compressed Air 705
9.3 Mine Communications, Monitoring, and Control 717
9.4 Mine Surveying 731
9.5 Dewatering Surface Operations 743
9.6 Dewatering Underground Operations 765
9.7 Physical Asset Management 781
9.8 Automation and Robotics 805
9.9 Mine Infrastructure Maintenance 825
9.10 Systems Engineering 839

PART 10: SURFACE EXTRACTION
10.1 Introduction to Open-Pit Mining 857
10.2 Open-Pit Planning and Design 877
10.3 Mechanical Extraction, Loading, and Hauling 903
10.4 Selection and Sizing of Excavating, Loading, and Hauling Equipment 931
10.5 In-Pit Crushing 941
10.6 Design, Construction, and Maintenance of Haul Roads 957
10.7 Surface Ore Movement, Storage, and Recovery Systems 977
10.8 Strip Mining 989
10.9 Strip Mine Planning and Design 1013
10.10 Highwall Mining 1027
10.11 Quarrying 1031

PART 11: HYDRAULIC AND PIPELINE MINING
11.1 Hydraulic Mining 1049
11.2 Placer Mining and Dredging 1057
11.3 Heap Leaching 1073
11.4 Surface Techniques of Solution Mining 1087
11.5 In-Situ Techniques of Solution Mining 1103
11.6 Coal-Bed Methane Production 1121

PART 12: UNDERGROUND DEVELOPMENT
12.1 Introduction to Underground Mine Planning 1135
12.2 Hard-Rock Equipment Selection and Sizing 1143
12.3 Soft-Rock Equipment Selection and Sizing 1157
12.4 Underground Horizontal and Inclined Development Methods 1179
12.5 Subsurface Mine Development 1203
12.6 Construction of Underground Openings and Related Infrastructure 1223
12.7 Tunnel Boring Machines in Mining 1255
12.8 Underground Ore Movement 1271
12.9 Hoisting Systems 1295

PART 13: UNDERGROUND EXTRACTION

13.1 Room-and-Pillar Mining in Hard Rock 1327
13.2 Room-and-Pillar Mining in Coal 1339
13.3 Shrinkage Stoping 1347
13.4 Sublevel Stoping 1355
13.5 Cut-and-Fill Mining 1365
13.6 Backfill Mining 1375
13.7 Cave Mining 1385
13.8 Longwall Mining 1399
13.9 Sublevel Caving 1417
13.10 Block Caving 1437

PART 14: MINERAL PROCESSING

14.1 Introduction to Mineral Processing 1455
14.2 Crushing, Milling, and Grinding 1461
14.3 Classification by Screens and Cyclones 1481
14.4 Gravity Concentration and Heavy Medium Separation 1507
14.5 Fundamental Principles of Froth Flotation 1517
14.6 Magnetic and Electrostatic Separation 1533
14.7 Dewatering Methods 1547

PART 15: HEALTH AND SAFETY

15.1 Mine Safety 1557
15.2 Health and Medical Issues in Global Mining 1567
15.3 Mine Ventilation 1577
15.4 Gas and Dust Control 1595
15.5 Heat, Humidity, and Air Conditioning 1611
15.6 Radiation Control 1625
15.7 Noise Hazards and Controls 1633

PART 16: ENVIRONMENTAL ISSUES

16.1 Site Environmental Considerations 1643
16.2 Mining and Sustainability 1665
16.3 Impacts and Control of Blasting 1689
16.4 Water and Sediment Control Systems 1705
16.5 Mitigating Acid Rock Drainage 1721
16.6 Waste Disposal and Contamination Management 1733
16.7 Closure Planning 1753

PART 17: COMMUNITY AND SOCIAL ISSUES

17.1 Community Issues 1767
17.2 Social License to Operate 1779
17.3 Cultural Considerations for Mining and Indigenous Communities 1797
17.4 Management of the Social Impacts of Mining 1817

APPENDICES

A Web Sites Related to Mining 1827
B Coal Mine Gas Chart 1833
C Conversion Chart 1835

PART 1

Mining: Setting the Scene

CHAPTER 1.1

Mining: Ancient, Modern, and Beyond

Peter Darling

The extraction and processing of minerals is an essential part of the way the world and its various civilizations function and interact. To forget the contribution that mining has made (and continues to make) is to take for granted the significant progress that civilization has made since the last Ice Age. It is also to ignore the fact that the very structure upon which we depend is built on—and with—the products of mining.

ANCIENT MINING

The extraction, smelting, and refining of metals date from the onset of the Bronze Age, if not before. Unfortunately, no manuscripts concerning mining from this early period survive, and we are left with only fragments discussing mining in the works of the classical Greek and Roman authors. For example, Pliny the Elder (1984), in his *Naturalis Historiae* (Natural History), discusses the mining of gold, silver, mercury, and lead and mentions the use of pillars as well as fire-setting and quenching with vinegar in order to break rock. Strabo (1988) mentions the mining of tin in the British Isles as well as the copper mines of Rio Tinto in Spain and the silver mines of Laurium in Greece.

Indeed, it is thought that tin has been mined continuously in Cornwall, Great Britain, from ancient times until the closing in 1998 of the South Crofty mine, which incorporated the long-lived and famous Dolcoath, Carn Brea, and Cook's Kitchen *setts*. Other mines dating from the Middle Ages or earlier include the Falun copper mine in Sweden, which was mined from the 11th century until 1992; the Wieliczka salt mine in Poland, which was mined from the 13th century until 2007; and the Rio Tinto mine in Huelva, Spain, which has been mined periodically since Roman times.

POST-RENAISSANCE MINING

Modern mining is considered by many to date from 1556 when Georgius Agricola (Georg Bauer), the city doctor in Chemnitz, Saxony (Germany), published his famous monograph, *De Re Metallica* (Agricola 1950), which documented contemporary mining practices in the Erzgebirge ("ore mountains") mines in Saxony. Other mining-related works by Agricola include *Bermannus*, a dialogue by a learned miner; *De Ortu et Causís Subterraneorum*, a work on physical geology; and *De Natura Fossilium*, the first systematic mineralogy. Among the equipment documented by woodcuts in *De Re Metallica* are hand- and horse-operated rope hoists, piston dewatering pumps powered by large water wheels, and ventilation systems consisting of pipes fed by large air bellows. Rock breakage was by fire-setting, with gads and mauls hammered into cracks to expand them.

Mining as described by Agricola changed little until the introduction of gunpowder about 1670 and Thomas Savery's fire engine in 1698. Savery's engine, however, could only lift water about 15 m (50 ft) (Barton 1969), and it remained for Thomas Newcomen in 1712 to develop a pumping engine, consisting of a cylinder and piston connected via an overhead beam to a pump rod. James Watt's patent in 1765 consisted of two improvements to Newcomen's design (the use of a separate condenser and utilizing steam at slightly above atmospheric pressure) that resulted in the Cornish pump. The ability to pump out water extended significantly the depths to which mines could be exploited.

The introduction of gunpowder made it easier to break rock, but the process remained slow and dangerous. Powder was poured by hand into the blastholes and could be ignited by a spark. The inventions of the safety fuse by William Bickford in 1831 and dynamite by Alfred Nobel in 1867 did much to improve the safety of rock breakage. The introduction of steam- and compressed-air-powered drills in the 1860s increased productivity considerably. Refinements in drill steels and bits and the development of mechanized loading and haulage equipment bring us to the present.

ECONOMIC DEVELOPMENT AS A RESULT OF MINING

The quest for minerals has without doubt brought wealth and civilization and accelerated development to many parts of the world. Mature industries need resources for sustainability, and, once they have been depleted in one location, more must be found (usually elsewhere). Although one may question the motives and methods of those involved in early mining operations, their tenacity and determination should never

Peter Darling, Managing Editor and Freelance Technical Writer, Aylsham, Norfolk, UK

be underestimated. For once the initial enthusiasm of being a pioneer miner had given way to the dull but enduring glow of reality; progress followed quickly in the footsteps of these first buccaneers.

The U.S. gold rushes in California and later Colorado did as much for the opening of the American West as the railroads or agriculture did. Moreover, towns such as Deadwood, South Dakota, and Tombstone, Arizona, which were made famous by dime-store novels and later the movies, were actually mining towns. West and southern Africa were opened up by the slave trade, later by Christian missionaries, and then farmer-landowners. However, it is the mining industry and agriculture that have sustained these regions ever since. Indeed, such is the nature of the ultra-deep mines in South Africa that even today this country's mining engineers are considered the real pioneers when it comes to solving the problems associated with deep-level mining.

Latin America, often considered a relative latecomer to the pursuit of mineral wealth, has nevertheless contributed significantly to the world's riches. Indeed, the gold and silver of the Incas was the basis of Spain's preeminence in the 16th century, and the gold mines in Morro Velho, Brazil, and copper–silver mines of Cerro de Pasco, Peru, have been mined since the 18th century. Indeed, immediately after World War I, Argentina was the third richest country in the world (after the United States and Great Britain) based in part upon, as its name suggests, silver mining.

Australia, a vast continent in its own right, is not without reason called the "Lucky Country," due in part to its vast mineral wealth. Mining was as responsible for the opening of much of Australia's vast interior as were the sheep and cattle stations. Copper mining began in the 1840s in the South Australian towns of Moonta, Kadina, and Wallaroo. The 1850s saw gold rushes in Ballarat and Bendigo, both in Victoria. Flotation was adopted early at Broken Hill, New South Wales; and Mount Isa in Queensland has been responsible for many innovations in underground mining. Even today, barely two centuries since the initial settlement at Botany Bay, New South Wales, in 1770, mining still contributes much to the nation's fortunes, as well as to the economic and industrial expansion of so many of its Asian neighbors.

MODERN TRENDS IN MINING

Although current trends in mining have been covered in considerable detail in a subsequent chapter, several aspects of this topic deserve further examination here.

Ore-Body Characteristics

The industry has already accepted the fact that the majority of the world's future minerals will come from low-grade, super-large, high-tonnage, and ultra-mechanized operation. This trend already started with the move toward high-tonnage longwall operations for coal, huge open pits for copper (and sometimes gold), and the mining of ore that 50 years ago would be considered interesting but uneconomical to extract and therefore virtually unexploitable. Smaller operations will still have a place, but the trend toward massive block caving operations, high tonnage, and automated mining will only increase in tempo.

Indeed, with the quickly disappearing likelihood of discovering a new and easily mined high-grade ore body, the time may soon come to view in-situ leaching of certain low-grade and high-tonnage mineral deposits as attractive. Although host materials must be relatively permeable and the mineral readily extractable by acid or alkaline leaching for this method of extraction to be practical, nevertheless it may be attractive to mine some mineral deposits of low grade and relatively large tonnage by this method, where traditional methods would prove uneconomical. Although it is evident that not every mineral can be extracted in this way, in many instances such deposits will respond to economic in-situ leaching.

Social and Environmental Factors

Unfortunately, it may appear to some that gone forever is the notion that mining is an honorable adventure, often played out in inhospitable and distant regions, that aims to produce the very building blocks upon which world civilization advances itself. Today, mining is often portrayed as a beast that destroys everything in its path and creates wealth for the few and ongoing misery for the many. This portrayal is unfair, although mining companies often do little to refute it and then reinforce it through their opposition to environmental regulation.

Critics accuse the mining industry of having ignored environmental and social issues. Such criticism ignores the fact that technologies for addressing environmental problems such as acid drainage did not exist a generation ago. Moreover, factories, chemical and food processing plants, and thermal power plants, which are generally closer to population centers than are mines, sometimes produce more pollution than do mines. Nevertheless, we no longer live in an age where mining can take place in splendid isolation. Mining engineers should take heart from the fact that *engagement* rather than *confrontation* is the watchword when it comes to the future. Although it may be too much to expect the world at large to respect mining engineering as a profession, its citizens may in time acknowledge the essential role that mining performs and the constraints under which it operates.

While the majority of the industry already believes that mining must develop and operate in harmony with the environment, the real challenge is to convince the social structure, government agencies, and nongovernmental organizations that mining can (and will) be done in a safe and environmentally compatible manner. Mining's acceptance of its responsibility relating to environmental and social issues is now engrained into virtually every aspect of the industry, in much the same way as safety has become. This reeducation has paid dividends in terms of reversing the image of the mining industry, which had acquired the significant negative press irrespective of what it did. A great deal of credit needs to go to those executives of senior mining companies who grouped together several years ago to foster the Global Mining Initiative. This was certainly an idea whose time had come, but to have grasped the nettle and financed its launch and (more importantly) its implementation took a great deal of foresight and courage at a time when it seemed that nothing the industry tried could stem the tidal wave of negative opinion.

The majority of mining companies have made massive advances to address both environmental and social issues. Nevertheless, the extraction of natural resources now attracts the sort of responsibility and scrutiny that few other global industries are subjected to. The mining industry has evolved (and continues to evolve), although it is perhaps too much to expect those outside the industry to wholeheartedly acknowledge what the industry does in difficult circumstances.

Still, outside the realm of the legal/governmental license to operate, mining has nevertheless accepted the general

obligation of a social license to operate with the community at large in the areas in which it operates. Such informal contracts are being increasingly accepted as a must-have commodity whose goodwill value cannot be underestimated.

Economic Uncertainty

The first quarter of 2008 saw a series of global economic disasters that combined to create a financial tsunami that affected virtually every country and every industry, irrespective of their importance and how well they were being run. As this crisis began to unfold, there was a short-term belief that mining, as an essential industry, would escape the majority of the fallout. However, a contraction in manufacturing industries inevitably results in reduced demand for raw materials such as metals. Thus, it was inevitable that the mining industry would also follow a downward financial trajectory of its own.

Despite the fact that this brutal and surprisingly swift lurch toward the economic abyss was totally unexpected, the mining industry has fortunately survived and appears to have returned to its precrisis level. Nevertheless, there have inevitably been some considerable impacts. Confidence in this primary industry has been shaken with major layoffs implemented at some operations, others put on care-and-maintenance, and planned expansions at others postponed or cancelled altogether. Although confidence has suffered a temporary battering, the underlying economics of mining remain sound.

The anticipated amalgamation of several of the larger mining companies came perilously close to becoming a reality. In several high-profile instances, shareholders who saw no need for any new conglomerates were skeptical and uncharacteristically vocal. Customers saw such mergers as a dangerous trend that would weaken their bargaining position, as it gave too much leverage to an even fewer number of raw material providers. Financial institutions and analysts saw several mergers as a logical rationalization, and when none materialized appeared to be content that these would happen once ready money was again available to finance such acquisitions.

Personnel Assets

Virtually every industry claims that its personnel are its major asset, and the mining industry is no exception. As recently as a generation ago, mining offered a career that combined a kaleidoscope of trades (explorer, adventurer, pioneer, and engineer) while also providing a potential for overseas travel and long-term career prospects in a profession that was both respected and essential. However, a number of factors have combined to relegate mining to a career of lesser option for many who, although voicing a preference for something "less ordinary" than a nine-to-five, bureaucratic-bound existence, appear to have no desire for the type of lifestyle that mining has to offer.

The industry is, and always has been, keen to ensure that its engineers are properly taught and prepared, and has quite rightly believed that traditional university education and on-the-job training provides the best preparation for a safe, efficient, and productive working life in mining. However, the number of educational establishments providing mining engineering as a formal undergraduate-level course has diminished considerably since about 1990. Indeed, even the world-renowned Royal School of Mines in London and the highly regarded Michigan Technological University in Houghton, Michigan (United States) no longer offer mining engineering as an undergraduate subject. In many other mining institutes, the number of graduates has dropped alarmingly.

The permanent loss of knowledge as experienced artisans leave the mining industry before their skills can be passed on to others is becoming a concern in many parts of the world. The lack of skilled mining personnel has begun to emerge, at various mining conferences and similar high-level meetings, as a major concern for the industry. Although the current poor economic situation has seen workers laid off and operations, projects, and expansions mothballed, the overall trend is for fewer professionals in positions of responsibility, as well as a more casual and migratory workforce. The impact upon safety and productivity is not to be dismissed so lightly.

The significance of this issue is not in itself the need to keep up numbers but it is (1) the loss of knowledge before it can be passed on, (2) the amount of time and effort required to bring new employees up to speed so they can perform their various tasks efficiently, and (3) more alarmingly, the high number of injuries and accidents associated with new hirings. The lack of replacement miners, technicians, artisans, and qualified engineers entering the industry in sufficient numbers must be addressed before it causes the closure of marginal ongoing operations, the shelving of expansion plans, and the abandonment of seemingly viable prospects. However, it is the permanent loss of knowledge that should cause trepidation for the industry's leaders.

Fortunately, the news is not all bad: The industry is trying (and succeeding) to drastically reduce the number of personnel actually involved in ore extraction (both underground and in pit). In addition, the industry is moving (or rather being forced to move) toward exploiting mines that are larger in terms of daily tonnages with automation playing a significant part in what may rather casually be described as simply a "rock moving operation." Unfortunately, we are many years away from the totally automated, unmanned mine.

Automation

Advances in automation and robotics, nevertheless, have the potential to significantly change the way mining is conducted in many current and future operations. The major advantages of, and drivers for, automation are in hazardous, repetitive, and/or labor-intensive tasks. Although automation has not yet significantly impacted global mining and processing, it has, however, started to show its value in terms of improved safety to the point that the industry has a real sense that it will be a significant factor in the future.

Automation is particularly suitable for a number of key operations: production drilling, the real-time recognition of material being drilled, automated loading, accurate and automatic movement of equipment (be it drill rigs, loading shovels, or haul trucks), monitoring of moving parts for maintenance purposes, and diagnostic intervention. The emerging view is that automation can (and will) lead to immediate improvements in productivity. Dragline operations are in the vanguard for research aimed at remote and fully automated working. By limiting operational variations, a consistent input will ensure maximization of shovel loads, for example. In addition, improved precision means that mining tasks are consistently performed at their required location, exact rate, planned orientation, and precise time. Finally, because automation enables production consistency (especially in consistent and regular ore bodies), it means that the mine design does not need to be updated on an ongoing basis because of production variations.

With the advances being made in certain aspects of technology (e.g., wall profile recognition), the time has come when repetitive tasks, such as multiple vehicle haulings from large underground operations, are a reality and are being run from a control cabin at the surface. This facility not only removes an operator from underground but means that an 8-hour shift means 8 hours at the controls. In addition, operator fatigue is negligible. However, it is not all positive news. Side-impact incidents, which are a significant issue for load-haul-dump traveling at speed in narrow tunnels, have still not been eliminated, while productivity per hour is still lower than for manned machines. Obviously, more work still needs to be done.

Tar Sands

The world seems to have a love–hate relationship with oil: It loves the freedom that petroleum provides (i.e., instant power in a barrel) but dislikes the environmental issues associated with its extraction, refining, and burning. Tar sands, which are mixtures of sand and bitumen, are found in about 70 countries. They are distinct from oil shales, which are sedimentary rocks containing kerogen and kerabitumen, a mixture of organic compounds (from which the extraction and conversion of oil is much more expensive than tar sands).

Some tar sand deposits are accessed by drilling, after which superheated steam is used to melt and migrate the tar to a collecting chamber from where it is pumped to the surface. However, most of the *economically* viable tar sand deposits are accessed from the surface and mined conventionally. By far the largest surface tar sand deposits are found in Alberta and Saskatchewan in western Canada and contain an estimated 1.7 trillion barrels of oil. Of the Canadian oil contained in tar sand, approximately 173 billion barrels are considered economically extractable using current surface or subsurface technology, with 20% of this volume being recoverable by surface mining.

Although the cost of extracting oil from surface tar sands is high, the process does not contain any of the high risks associated with traditional oil drilling (i.e., dry holes, blowouts, hydrogen sulfide [or sour gas], explosions, and high equipment rental costs). The technology and equipment originally employed to mine these surface tar sands were borrowed from the brown coal surface mines of Germany. However, bucket-wheel excavators have by and large given way to traditional truck-and-shovel operations.

One of the major issues associated with tar sand extraction is that the oil content tends to be low (of the order of 10% to 12% by volume) and that one of the by-products of tar sand production is usually vast quantities of coarse sand. Indeed, the world's largest dam is a tailings dam associated with tar sand production in Alberta, Canada. In addition, the rock formations surrounding the tar sands tend to be heavily water bearing and require depressurization. Water-saturated organic deposits of peat material, known as *muskeg*, are also present in bogs and poorly draining creek systems. Thus water management, which also includes treatment and storage, pose significant mining engineering challenges, although the biggest issue is the operational carbon footprint, which is much bigger than traditional petroleum exploration and production.

Of course, the subsurface exploitation of tar sands is also of interest to the mining industry, although the technology employed is more akin to the methods of directional drilling and hydrofracturing, which are the mainstay of today's petroleum exploration and production industry. Solution mining is an established extraction technique and is as applicable to the subsurface extraction of tar as it is for sulfur or uranium.

This is a relatively new industry, and it will be interesting to see how and in what direction it matures. However, while the quantities of oil involved are huge, the cost of extraction will always be an issue. The fact that oil can fluctuate by as much as US$10 a barrel in a single day does not provide the degree of stability that this important (and emerging) mining sector deserves.

Alternative Uses of Coal

The 1992 edition of this handbook covered the subject of in-situ burning of coal (Chaiken and Martin 1992), and although this method holds many prospects for the industry, perhaps its greatest potential is to extract power from narrow, deep seams. However, with the near-universal requirement for clean coal, the opportunity to burn any type of coal irrespective of its rank, heating value, and ash or sulfur content has passed. Nevertheless, another potential means of extracting energy from coal has emerged: coal-bed methane production. In the near future, the pre-mining extraction of methane from coal beds will become common practice, especially from seams which are small, narrow, deep, or near populated areas. The energy potential for coal-bed methane production is enormous.

The method of drilling into and the extraction of methane gas from coal beds use well-established oilfield directional drilling, reservoir hydrofracturing, and production technology. As this method of pre-mining gas capture becomes more common, its greatest usage has and will continue to be on coal seams deemed too small, too narrow, too deep, or too close to centers of population to warrant traditional coal extraction.

BEYOND THE HORIZON

Chapter 1.3 looks at the anticipated direction for the industry in the next decade or so. However, what will this industry look like at the start of the next century? Although no one knows for certain, many subtle indicators highlight what mining in the 22nd century will encapsulate and the direction it will take.

Climatic Variation

Over time, the hysteria associated with *global warming* will have matured to the universally accepted term *climatic change*; however, the debate will continue as to the level of anthropogenic contribution. Nevertheless, in the meantime, a common-sense approach to resource husbandry and the advantages that can go hand in hand with such a widely encompassing strategy will have altered the mining/minerals extraction and processing industry forever.

Nowadays, manufacturing businesses, industrial concerns, and even corporate headquarters are being encouraged to reduce their carbon footprint. Mining, processing, and refining organizations are no exception in being pressured to reduce their environmental impact. In the future, the need to further reduce their impact will have become a way of life, utilizing considerable imagination and thinking outside the box. Mining companies hitherto concerned with providing coal for power generation will now be known as *power providers*, and their businesses will consist of supplying methane from in-situ coal bed production and generating power from nontraditional sources such as geothermal, solar, wind, and wave/tidal hydropower sources.

Electricity Generation

In the 1970s and 1980s, it was not uncommon in Britain or Continental Europe to see a Citroën 2CV car being driven in the slow lane of a motorway, with flowers and rainbows painted on its side panels. There was often an "Atom Kraft—nein danke" (liberally translated as "atomic power, no thank you") sticker displayed prominently. Many people from this era developed a no-compromise view that nuclear power was an abomination. Admittedly, they were only one generation removed from associating the power of the atom with the devastation of Hiroshima and Nagasaki, while the disaster at Chernobyl was too real to be dismissed as a once-in-a-million-year occurrence. Nevertheless, to put matters into context, the reactors at Chernobyl were of an antiquated design without containment and were poorly constructed.

In the last few years, a new generation earnestly searching for alternatives to power produced by the burning of coal or natural gas is looking at nuclear power generation anew. Unfortunately, there is still some lack of public confidence in an industry that has been shown to have safety issues. A second factor relates to waste management, which poses a different set of safety issues, but which has an engineering solution, although a different one than building safe atomic power stations.

The generation of power at an atomic plant (under normal circumstances) leads to little pollution but does result in the creation of three levels of waste:

1. **Low-level waste:** contaminated clothing, tools, paper, filters, and rags, which are known as contact waste and contain limited amounts of low-level radioactivity.
2. **Intermediate-level waste:** fuel casings and reactor components, graphite from reactor cores, and sludges from radioactive liquid effluents.
3. **High-level waste:** spent reactor fuel and transuranic residues from reprocessing spent fuel into weapons.

Although the high-level waste is automatically destined for recycling, thereby providing yet more energy, it is the intermediate- and low-level wastes that are proving to be a burden. Both are currently being stored in vast secure temporary facilities in anticipation that engineering will finally resolve the issue of how to recycle (at least partly) this growing mountain of radioactive waste. The alternative is to produce an internationally acceptable means of reducing this waste volume into a manageable size, bind it up with a medium that is inert and stable, and then devise a means of storing this in an environment that is both secure and yet allows the material to be easily retrieved. In comparison, building safe reactors is a relatively simple question of belt-and-braces design and construction, incorporating fail-safe systems, strict controls, and a strict adherence to operating procedure. On the other hand, the storing and recycling of intermediate- and low-level waste will require the combination of numerous engineering disciplines, skills, and thus far unheard of innovations. We are not so far away from wrestling this waste problem into a manageable issue, and from that point on this major hurdle to the long term and (more importantly) the sustainable implementation of nuclear power will finally have received the well-deserved fillip it needs.

Except in areas of abundant water or high relief, where hydropower is a possibility, nuclear power is probably the best the world can expect in terms of clean, effective, predictable, controllable, nonseasonal, high-volume, and efficient power generation. It would be unfortunate to squander this gift for any longer than necessary by continuing to look to the burning of coal and gas as the first, and often the only choice, in terms of power generation.

Conspicuous Power Consumption

Regardless of the way that power is generated, it will remain a strategic issue and in the future will govern the way the industry operates in certain regions. In 1980, it was estimated that in certain regions almost 40% of the energy consumption was directed toward mining, crushing, grinding, and milling. Although things have changed considerably since then, it is a fact that many of the larger mills still operating were installed decades ago. Though these mills remain (within engineering limits) as efficient as they ever were, the question has been posed of whether there is a better way to extract the "goodness" out of the ore.

As the majority of ores now being extracted will be low grade, deep, and chemically challenging, the in-situ leaching of massive blocks will become commonplace. Such operations will now fall into four categories: already fractured, self-fracturing, easily fractured, or those that require help in order to create the fracture-rich environment that will enable leaching to occur.

While today only eight minerals have been commercially mined by in-situ or solution mining (sulfur, salt, trona, nahcolite, potash, boron, uranium, and copper), by the progressive technology of bioleaching, other minerals may become commercially available in the future. Nevertheless, the practice of bringing ore to the surface to enable processing to take place will not disappear altogether. Such practices will now be confined to long-established operations where the infrastructure and processing plant have long since paid for themselves, operations that are high grade and low volume in nature, or operations where the geochemistry of the minerals and host rocks is such that leaching has failed to establish an effective means of producing pregnant liquors in sufficient quantity or at a rate that justifies embracing a new modus operandi. However, the potential environmental impacts on shared groundwater resources are likely to affect the places where in-situ leaching can be used.

Value of Water

In much of the world, fresh water is a scarce commodity. Because of the quantities of water required for drilling, crushing, grinding, and aqueous processing methods, the availability of sufficient water is critical to mining. Even in many nondesert parts of the world, water has become a matter of life and death. Indeed, Israel, Cyprus, and the Yemen are among the countries that, for the first time, have acknowledged fresh water as being a strategic commodity and have elevated its capture, "creation," and storage to a level akin to other national security items. In many other parts of the world, water is a serious issue but has yet to be elevated to a strategic commodity.

In the future, however, the use of water in mining and processing will become a real issue. The salvaging of water from processing will become, after an initial period of rapid growth and innovative thinking, an established part of everyday mining operations. Water, often a never-ending problem in underground operations, could well be the starting point for a symbiotic relationship with nonmining surface activities such as farming. Elsewhere, finer initial rock breakage and dry milling/grinding similar to that employed by the aggregate and

cement industries will become normal practice, and wet processing will be confined to fewer operations.

Nevertheless, water may also become one of the ways by which mining can be seen as a net contributor to the community in which it operates. It is a dichotomy that many mining operations (whether they operate from the surface or from underground) still pump millions of gallons of water out and away from their operations every month. Therefore, the dewatering of workings to allow development and mineral extraction will be seen as a positive by-product of mining and indeed a positive legacy in those arid and semiarid parts of the world where agriculture is an ongoing struggle against drought.

Materials' Stewardship

The Doe Run lead operations in Missouri (United States) have been in production in one form or another since the U.S. Civil War. One of the interesting aspects of the current operation is that the company has been actively practicing the notion of *commodity stewardship* for more than 30 years. The company took the long-term view that their responsibility to the United States was to see that the nation's needs for metallic lead were catered for in every sense of the word. We all understand the notion of mining, refining, and marketing raw metallic lead, but the company also assumed the mantle of collecting and recycling lead once the components in which it had been employed had reached their end of life.

Doe Run set up a nationwide collection network at which used car batteries (the major and most readily available source of secondhand lead in the United States) could be deposited free of charge. These batteries were then drained of their acid, which was sold back to the industry; the plastic battery housing was likewise recycled; and the lead metal was returned to the Doe Run processing plant where it was recycled to produce new lead. The logic behind this strategy is that the company knows about lead processing, it already owns the necessary plant and equipment to recycle the metal, and as such it is an integral part of the whole lead market.

This concept of stewardship has been used to varying degrees within the nuclear industry, which recycles its own products. It will only be a question of time before other metallic industries take on (or are forced to practice) the notion of commodity stewardship, which is the logical next step forward in recycling.

Ethics and Good Neighbors

In the future, mining organizations, and especially the larger ones, will see themselves as being resource and service providers. Whether this involves power, water, forestry goods, or the mass recycling of metals and glass, they will view their business in a holistic way. What shareholders will make of this arrangement has yet to be tested, but in recent years we have seen a shift away from shareholder positions based purely on financial returns. For example, hedge funds that invest in enterprises based on a particular ethical position (be it green, nonpolluting, good neighbor, anti-apartheid, or nonmilitary) have been available for many years.

The next logical step for mining companies is to ensure that in addition to their core business of finding, mining, and refining minerals, they also engage in other associated activities. A mining company could, therefore, find itself farming large tracts of land that it had reclaimed after strip mining had passed through the area, running offshore wind farms, or providing hydroelectric power and agricultural irrigation services.

The fact remains that today's society cannot exist without mines and the products of mining. It is no good simply saying that we will allow others to run roughshod over environmental and social issues as long as these issues do not impact us. Alternatively, by simply outlawing the consumption of metals and minerals, a resource-scarce global environment would be created that would relegate large areas of the world and its peoples to zero advancement, while ensuring that developed countries remained on the plus side of the inequality equation.

Beyond the Pale

Many would consider that future mining trends must encompass an appreciation and inclusion of two further untapped regions that are ripe for exploration and exploitation: marine mining and mining in space. However, neither of these frontiers holds much in the way of either economical or realistic possibility within the next hundred years.

The offshore production of sulfur from the Gulf of Mexico using the Frasch process is one of the few marine mining success stories. Marine mining (with the exception of creating large, near-shore coffer dams for the exploitation of diamonds in southwestern Africa, and the offshore extraction of sulfur) does not hold anything like the attraction that surface mining does. Although manganese nodules and other sea-floor mineral deposits contain huge tonnages of metals, they are unlikely to be mined for the foreseeable future for political reasons. Though the technology for mining the nodules was demonstrated in the late 1960s by the *Glomar Challenger* and others, as the deposits lie in the depths of the ocean beyond the territorial limit of any coastal nation, international agreement is required before development can occur. The failure of the 1972 Law of the Sea conference and many subsequent discussions have aptly demonstrated the unlikelihood that seafloor mining will occur anytime soon. Indeed, the only potential for a further advance in marine mining is in the winning of sand and gravel for construction purposes.

Any potential for mining in space is bound to be hampered by four fundamental issues:

1. Excessively high costs of transportation
2. Delivery and maintenance of mining equipment
3. Allowable processing methods and their requirements
4. Ownership of a planet or star and the willingness (or otherwise) of the owner to allow mining

The only reason to mine in space would be to acquire metals and minerals not available on earth, but would the excessive cost for such a high-risk project (in what would be, after all, a scientific adventure) ever be justified? There is no doubt that the major advantage that space can offer mining is as a spinoff in technological improvements, in much the same way that space and military technology and materials have already provided for a plethora of other high-level industries. In the longer term, space mining *may* provide raw materials for use in space itself (water, hydrogen, metals, etc.) to overcome the "gravity well" of Earth.

CONCLUSION

Although some may believe that mining is a sunset industry that is beginning a slow decline into oblivion, this is simply not the case. There is no doubt that the industry is a mature one,

and that, like many industries, it has had to adapt to changes in technology and perceptions. Unfortunately, it has not always been as quick to respond to public opinion as perhaps it should have. Nevertheless, mining, particularly that conducted by the larger companies, has moved with the times, and while no one is pretending that things have not always been done well in the past, no one is claiming any reason to be complacent now.

Of course, any discussion that attempts to focus on mining and mining companies under the working title of "past, present, and future" must acknowledge that mining companies are not equal in terms of their means and manner of operation. The markets they cater for are numerous, the regions where they operate are various and varied, and their attitudes toward their own personnel and those with whom they work can differ significantly.

It would be pointless to attempt to paint every mining company, minerals magnate, or corporation executive as perfect. Mining is a tough profession and frequently attracts those of similar mettle. Neither does this engineering discipline wish to lower the bar of acceptability concerning what mining companies can and should be able to do to a point that encourages a free-for-all vis-à-vis standards. There are many mining companies, most of which are large, international, and multi-commodity in character, that strive daily to raise the bar of acceptability, and it is to them that the industry often looks for continued inspiration and leadership.

ACKNOWLEDGMENTS

Tribute is given to Doug Hambley (associate with Agapito of Golden, Colorado), Peter McCarthy (chairman of AMC Consultants of Melbourne, Australia), Peter Balka (chief mining engineer with Tigers Realm Minerals of Melbourne), and Dick Bullock (professor emeritus, Missouri University of Science and Technology in Rolla, Missouri), all of whom at various times provided advice, assistance, guidance, and balance to the author during the preparation of this chapter.

CHAPTER 1.2

Current Trends in Mining

Marcus Randolph

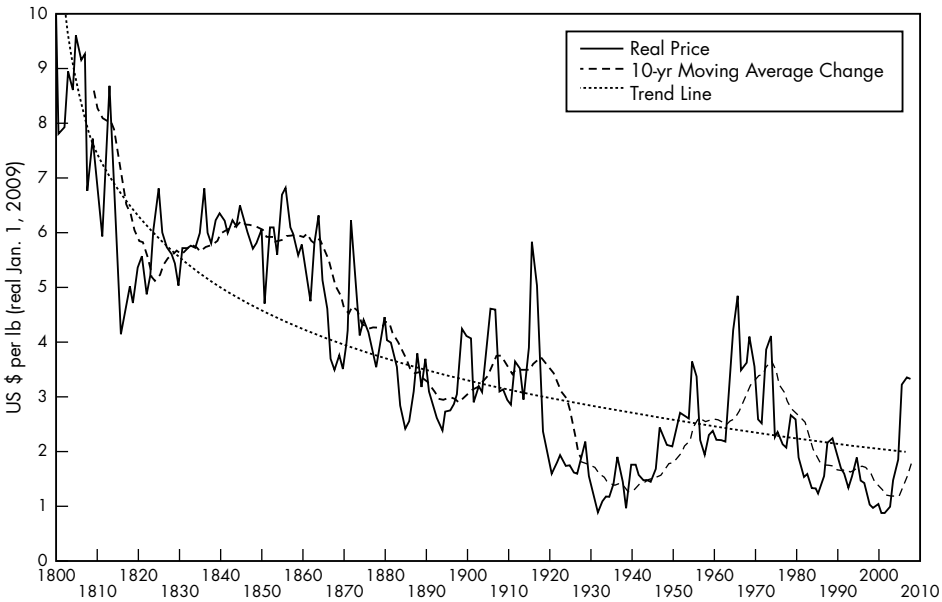
SUPPLY AND DEMAND

Two words dominate current discussions about the supply and demand of minerals: *globalization* and *supercycle*. Globalization's application is much wider than mining, although a shrinking world has profoundly impacted the mining industry. Supercycle has recently come into use because rapidly industrializing, less-developed countries have stimulated minerals demand. Fifty years ago the mining industry was dominated by local companies supplying single products to local customers. High transportation costs, poor communications technology, and a lack of companies that had the capability to invest outside their national boundaries led to an industry dominated by small producers operating on either a local or national scale.

Globalization changed all this. Easy telephone calls, long-haul planes, and huge ships meant that mining companies could develop mines and sell their output globally. At the same time, the technology used in production became more efficient—generally by getting bigger. Plants and earth-moving equipment became larger and underground longwalls got longer. Increasingly, the low-cost source of supply was huge, high-quality deposits, the product of which was shipped all over the world. The result was the cost of supply went down and mineral prices declined.

This trend was enhanced by the post–World War II reconstruction of Europe and subsequent growth boom plus the rise of major Asian economies with little or no indigenous metals resources. It also fueled the segregation of basic raw materials supply and processing, as raw materials became sourced where the best resources were located and processing occurred in countries where materials were in high demand.

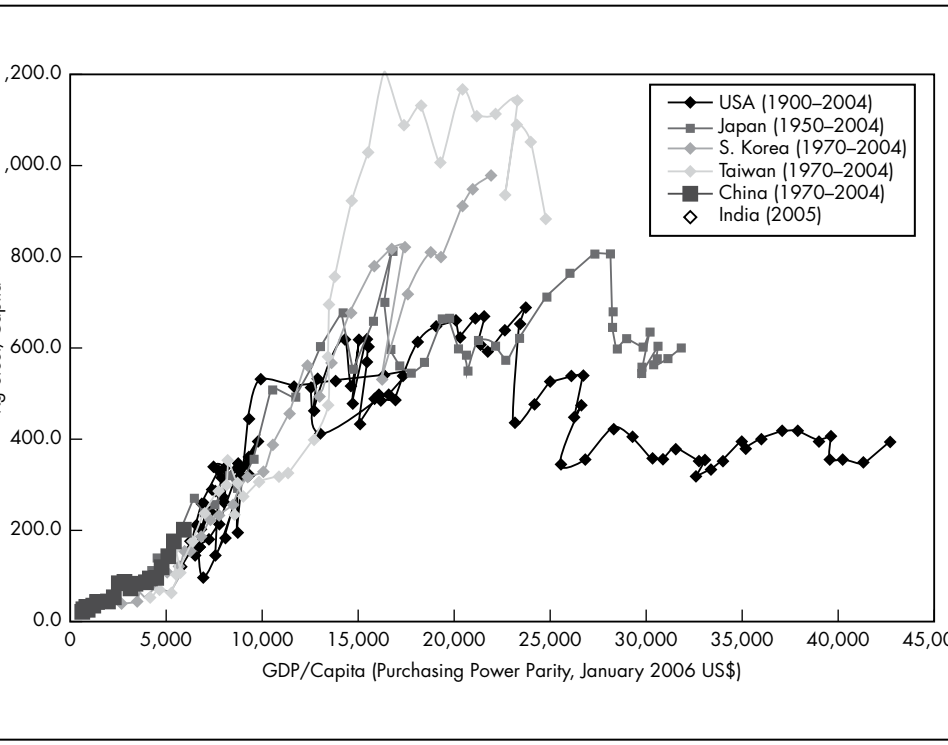
Figure 1.2-1 tracks the price of copper for the period 1800 to 2008 in U.S. dollars per pound, in real 2008 dollars. In this graph, the effect of inflation has been removed.



The first observation on Figure 1.2-1 is that the general price trend is downward, due to the impact of globalization and, to a lesser extent, technology. It is much less expensive to produce lots of copper from a few large mines in Chile than it is to supply it locally from many small mines—and, as extraction costs fall, so do prices.

The next critical observation is that, while the overall trend is clearly downward, during periods of up to 50 years prices have steadily risen. The current buzzword for these periods is supercycles, and they generally follow a major event. The largest of these was the post–World War II period when much of the world was rebuilding and metals demand grew strongly. A substantial body of experts currently believes we are in another supercycle. This period of strong demand growth is driven by the industrialization of the BRIC (Brazil, Russia, India, and China) countries. The people in these countries, which number approximately 2.7 billion (40% of the world's total population), are seeking a better way of life, which they have learned about through television, the Internet, and global tourism, and believe that this better way of life is increasingly achievable to them.

Industrialization does not affect the demand for all products equally. One of the early beneficiaries was the raw materials that go into making steel, which is an essential input in the construction of roads, buildings, and general infrastructure. Figure 1.2-2 shows the steel intensity per capita at various levels of gross domestic product (GDP). As this graph shows, steel usage rises rapidly until the economy has grown to about US$15,000 per person. During this early industrialization, iron ore and metallurgical coal, the two primary raw materials in making steel, have seen demand growth (and price) exceeding long-term averages. Should the BRIC countries continue to industrialize, the large population bases of these countries would support another supercycle. Over the next 10 to 20 years, this future growth (or not) of the BRIC countries will be the issue that will have the biggest impact on the mining industry.



The large growth in natural resource requirements is causing debate now, as it did following the substantial expansion of demand after World War II, about the adequacy of the world's resource base to meet the world's needs. The earth has a large storehouse of minerals, and nearly all mining products are much more common in the earth's crust than petroleum. As the requirement for mining products grows, the issue will not be whether we will run out, but how much will these minerals cost? The answer to this question will be determined by

the ability of mining and mineral processing technology to stay ahead of demand growth.

Marketing

No assessment of current trends would be complete without commenting on the major changes that have occurred in how mining products are sold. In the 1970s, producer prices (where producers unilaterally declared the price) were commonly replaced by auction prices. Effectively, producers of copper and aluminum began to sell to warehouses operated by the London Metal Exchange. Buy and sell prices were agreed upon through an open platform/open outcry system, similar to early stock exchanges, through auction prices. After these prices were announced and published, they became the basis for setting the price of raw materials.

The use of an auction process has two major benefits. The first is that prices change rapidly with demand. Effectively, the price is continuously set at a level where there is a willing buyer and a willing seller, which effectively represents true supply and demand fundamentals of that product in real time. Second, the auctions allowed the creation of financial products that are valued by both the buyer and seller. These financial products allow prices to be agreed upon for future sales, effectively allowing companies to reduce their exposure to changing raw materials prices. They also made it possible for companies to manage pricing risk between the purchase of raw materials and the consequent sale of the product (matching input cost and revenue).

The current trend is toward greater use of screen-traded, open auction pricing for an ever increasing range of raw materials. The early adopters were commodities that could easily be delivered to a single, consistent specification. Increasingly, screen trading is expanding to include a wider range of specifications and products, such as coal and iron ore, which have substantial variations in quality.

MINERALS EXPLORATION

Location

Mines have a single characteristic that is different from most other industries: Development, and investment, must occur where the resource is located. As miners, we don't have a choice about where to locate our mines; they need to be where the deposits are. We do, however, have a choice in how much we are willing to trade mining higher-grade and higher-quality resources in higher-risk countries for lower-grade and lower-quality resources in stable countries with developed infrastructures. This trade-off between discovery risk and political risk is the history of minerals exploration and has driven a recent trend toward exploring in less-developed countries.

Figure 1.2-3 illustrates this shift of exploration expenditure into less-developed countries. In the 1950s, nearly 80% of the world's exploration expenditure went into the United States and Canada. By the year 2000, the United States and Canada were attracting barely 25% of exploration dollars. Instead, the major beneficiaries were Latin America and Africa, with Australia and Chile developing major mining industries after early exploration success.

What is clear is that, while there is a trend away from the highly developed countries, there has not yet been a major increase in exploration in the highest-risk countries. Although many of these extreme-risk countries offer easier-to-find, high-quality deposits, they have not yet received substantial attention from the global explorers. The reason for this is the long-term nature of finding and developing a mine combined with the limited risk appetite of investors and significant operating and fiscal challenges. From the start of exploration until a mine is in production generally requires around 10 years. Recovery of the initial investment frequently takes another 10 years, effectively meaning that 20 years of operational and fiscal stability is required for a mining project to pay back its initial investment. Higher-risk regions may be geologically

attractive, but their political stability is usually believed by mine developers to be insufficient to support 20 years of exploration, development, and mine operation.

Exploration Technology

During the last 50 years, the exploration sector has moved from reliance on observations of geologic features exposed at the surface to an ability to detect hidden mineralization at increasing depths. This has largely been achieved through developments in geophysical exploration tools. Advances in microelectronics in the late 1950s supported the development of smaller equipment that could quickly measure and process large amounts of data. This smaller equipment was mounted in planes and helicopters and produced a quantum leap in the industry's ability to cost-effectively screen large areas of land.

Additionally, refinements in both passive (magnetics, gravity) and active (electromagnetics) methods provided increasing depth penetration potential. Direct detection methods are now capable of outlining larger targets buried at depths of up to 1 km. While this depth is still short of the economic limit of mining, it is a vast improvement in capability versus 50 years ago, and ongoing improvements will ensure the industry can increasingly detect mineralization that is deeper and covered by post-mineralization sediments.

In the last 25 years, targeting capability has also been enhanced by satellite spectral scanners. Dedicated satellites are now providing geologists with a substantially improved ability to map topography, structure, and alteration. The development of faster processing capability linked to computer chip speed means that an individual geophysicist carrying a laptop computer has the ability to process complex inputs from a variety of sources.

Exploration Competitors

The starting point for a successful minerals exploration program is to obtain access to highly prospective ground. This access is typically granted in the form of an exploration license by the government where the ground is located. Effectively this means that a good explorer must have a combination of relationships, capability, and reputation, which makes it attractive to the government granting the license.

This structure has resulted in four competitors in the minerals exploration arena:

1. Local public or parastatal companies that have good relationships with the host government
2. Junior exploration companies, typified by small Canadian and Australian exploration companies, that are willing to take high risks to generate a discovery and then usually on-sell it to a large producer with operating and financial capability
3. Global mining companies that are exploring for deposits they hope to develop
4. State-owned enterprises (SOEs), supported by national governments, that are seeking to acquire natural resources globally to support their countries' development

The development of group 4, the SOEs, is a recent trend and is typified by China. Under this model, the government sponsoring the SOE manages a coordinated program that frequently ties together government-to-government soft loans, infrastructure development, and access to resources for the SOE. The goal of this strategy is to ensure a supply of critical natural resources to support country growth and development.

ORE RESERVES AND VALUATION

The fundamental source of a mine's value is its potential ore reserve. The word *potential* is used because rarely is the full extent or quality of an ore body known until it is fully mined out. One of the key decisions that the developer faces before building a mine is therefore the level of certainty required about the ore body's size, quality, and shape before the commitment of funds is made. In estimating the potential, most good analyses will consider the probability that various sizes and grades of ore bodies will ultimately be found and mined.

Reporting requirements mandated by stock exchanges are requiring companies to disclose their ore reserves to standards set in codes, such as Australia's Joint Ore Reserves Committee Code. The reporting of ore reserves is generally an external exercise to provide investor assurance and governance and is different from the assessment of ore potential that is required to support an investment decision. Investment decisions need to factor in the likely outcome for the total resource size and quality, as well as the order in which it will be recovered. The critical difference is that investments and valuations are based on what is expected, whereas reported ore reserves are based on what is known.

Investment decisions establishing ore reserves and/or expected reserves also need to consider the ore-body structure, processing recoveries, and impurities. The single biggest physical factor that causes mining projects to produce lower-than-expected investment returns is misunderstanding the ore body's characteristics. The biggest errors occur in geological continuity, ground conditions, and metallurgical recoveries. Either the ore body isn't continuous, it has unexpected faults or other geologic features, the ground conditions (in the ore or the adjacent waste) are harder or softer than expected, or assumptions of recoveries and payable product are overly optimistic. All result in higher costs, and several high-profile operations had to close after start-up because of unexpected and structurally unsustainable costs resulting from serious errors in predicting one of these issues.

Unfortunately, companies do not appear to be getting better at understanding the ore reserves supporting their investment decisions. The possible explanations for this are the following:

- Drilling and sample testing are typically the slowest and most expensive parts of feasibility studies. When corners get cut, drilling gets underdone.
- Understanding the adequacy of a drilling program is complex, and the people approving the project rarely have the time or capability to judge the appropriateness of the estimated resource.

Despite the importance of understanding ore-body structure and metallurgy, the biggest unknown in mine valuation is mineral prices. This is also the factor that has the biggest impact on the project's returns. Companies are improving their capabilities in this area, with virtually all midsize and larger producers investing substantial efforts into understanding the likely direction of their key markets. However, as the movement of mineral prices are heavily driven by demand, which flows from global growth, prices are volatile and price estimates remain substantially subjective. This is especially

true over the long term, which is the time frame that is relevant to virtually all mining development projects.

MINE OPERATIONS

Most mine operations have two separate activities: mining and mineral processing. The high capital cost and long life of a mining operation necessarily lead to relatively lower rates of technological change, broadly shared with other industries with similar characteristics. The activities currently used in the mining and processing areas of most mines look similar to those used 25, even 50 years ago. Drilling and blasting, the use of trucks and shovels, crushing, grinding, flotation, smelting, and refining are all still core elements of the industry. As is the case with most technologies, however, the extent of perceived change depends on how high a helicopter view is taken. One of the most pervasive overall changes is the size of the equipment and the scale of the operations in which they are used.

In 1970, the average truck purchased for use in an open-pit mine was 90 t (metric tons). By 2008, the average size of a newly purchased mining truck had doubled to just over 180 t. Plant size has followed a similar trend. The Escondida mine in Chile has been either the first or the second largest copper mine in the world since it started operating in the late 1980s. Since construction, it has undergone multiple expansions, as shown in Table 1.2-1.

Table 1.2-1 Escondida's expansion history

Metric	1990	2008
Daily ore production, t/d	35,000	240,000 concentrator feed, 60,000 oxide leach feed, 300,000 sulfide leach feed
Total material moved, t/d	280,000	1.4 million
Annual copper production, t/yr	320,000 in concentrate	1.1 million in concentrate, 300,000 million in cathodes
Average copper grade	2.9%	1.5%
Processing technology	Concentrate flotation	Flotation, oxide leach, sulfide leach, electrowinning
Mining technology	Drill, blast, truck, shovel	Drill, blast, truck, shovel, ore conveyors

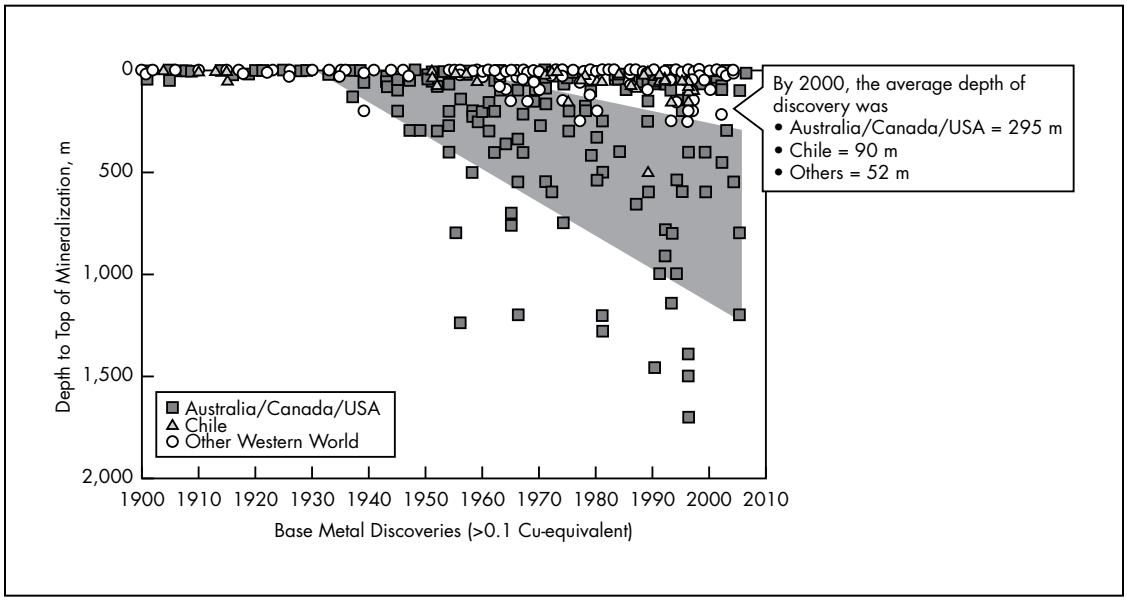
The path that Escondida has followed would be a typical one for a large mine. The initial project was designed to mine the easy-to-access, high-grade ore. The limitation on initial plant capacity was the ability to sell the concentrate, as Escondida does not have an associated smelter and was an early mover in supplying raw materials to nonintegrated processing facilities in Asia. Since its initial start-up, substantial value has been added through a series of expansions that used the same infrastructure footprint as the original construction. As these occurred, each generation of larger equipment was added, and incremental processing technologies were introduced to optimize recovery.

Escondida also reflects the general trend in mining toward large open pits. At the beginning of the 1990s, more than 90% of mine production was by underground means. By the year 2000, 85% of mine production was from open-pit mines. Current indications are that the percentage of production from open-pit mines has peaked. Large open-pit mines create big, permanent holes, leave large piles of waste rock, use large quantities of water, produce large amounts of noise and dust, and consume vast amounts of petroleum to power the mobile equipment. The tolerance of society for activities such as these is declining.

At the same time, the ore bodies that remain to be exploited are becoming deeper as existing mines deepen and improved exploration technology finds deposits under deeper cover. Figure 1.2-4 shows the depth to the top of mineralization by year. Between 1930 and 2000, the depth of the average discovery in Australia, Canada, and the United States increased from surface outcropping to 295 m. This depth to the top of the ore body requires more prestripping than any but the largest mines can support.

Additionally, the current mega-mines are reaching the economic limits with their stripping ratios. The world's great open-pit copper mines, including Chuquicamata (Chile), Grasberg (Indonesia), and Bingham Canyon (United States), are all nearly 1,000 m deep. The amount of waste removal required to continue to access the ore body is becoming extreme. All of these operations either have begun to develop and/or operate underground mines underneath their current pits or are in the later stages of engineerinsg studies to do so. To meet the tonnage requirements of these large mines, all of them are considering bulk mining methods, with block caving being the mining method of choice. In South Africa, the Palabora copper mine has already made this transition. The combination of environmental pressures and depth is expected to further this trend toward increased development of large underground mines.

Remote and Autonomous Operation



The technology shift in mining that merits close monitoring is the increased operation of equipment either remotely or autonomously. Remote operations, where the operator is not proximate to the equipment, can dramatically improve safety performance. This method of operation started to become more common in the early 1990s. By the mid-1990s, equipment suppliers were presenting the potential of autonomous equipment, where no operator was required. Since then, technology changes, including a high-resolution Global Positioning System, wireless technology, remote sensing, and robust pit management software, are making autonomous operations increasingly viable.

Productivity improvements and reduced equipment wear and tear are driving the development of autonomous technology for mobile mining equipment. Safety and the possibility of relocating staff away from remote and unattractive locations are driving the development of remote operations technology. Both remote and autonomous operations are technology trends that should be watched closely as they can materially reduce mining costs.

Mineral Processing Technology

Mineral processing changes have also continued to evolve. As in mine operations, mineral processing equipment has become bigger. Larger grinding mills, flotation cells, and furnaces have made for simpler plant layouts and have brought down costs.

One of the high-level drivers for other technology changes has been the overall trend toward lower ore grade and/or the need to match processing routes to other ore-specific challenges. As grade declines, the focus is on increasing recovery and tonnage throughput, with less metal value ending up in the tailings impoundment. This has led to measures that provide a greater understanding and control of processes. The development of computer-automated quantitative mineralogy, on-line

Courtesy of BHP Billiton.

Figure 1.2-4 Average depth of newly discovered ore deposits

materials monitoring, in-line process monitoring, sophisticated process modeling, and centralized control have all contributed to improved mineral recoveries and lower costs. Indeed, it is now a rare plant that does not have a central control room with substantially computerized controls.

Large step-change or revolutionary innovations are rare in most industries, and this is also the case for mining and minerals. Nevertheless, they have happened. The most notable change has been the shift from pyrometallurgy toward hydrometallurgy in nonferrous processing. For example, the advent of solvent extraction electrowinning (SX-EW) technology in the 1970s has steadily led to the growth of leaching in the copper industry such that SX-EW now accounts for more than 20% of world copper production. Escondida is a good example of this trend, illustrating the key drivers of ore-specific processing, resulting in chemical heap leaching of oxide ores; and the need to treat low-grade sulfide ores, resulting in biologically assisted heap leaching. Carbon-in-pulp technology had a similarly wide impact on the gold industry.

Of course, many innovative processes or subprocesses are scattered across the industry, and, although these are sometimes significant in novelty and impact, they tend to be applicable to a smaller subset of ore bodies or ore types rather than being generic. A path of process innovation has been followed for some decades by the end user of energy coal, the power industry, in pursuit of advanced combustion and gasification technologies, as well as carbon capture and storage approaches. The desire to reduce greenhouse gas emissions is a strong driver and remains a work in progress.

Major investments have also been made in new technologies for hydrometallurgical nickel laterite processing and the pyrometallurgical production of direct reduced iron. The development of laterite processing technology has been resource driven as a result of the dearth of new nickel sulfide discoveries and the easy availability of large nickel laterite deposits. In both cases, the technologies are still evolving and have not yet become sufficiently simple or predictable to substantially change the economics of their industries. Major technology shifts in nickel and direct reduced iron have struggled to be successful, in part because

- They are competing against technologies that have been optimized over many decades;
- Development time is long and implementation comes at a high capital cost; and
- The products (nickel and iron) have highly volatile pricing, making it difficult to stay committed to an uncertain technology that, in its early stages, is missing cost and performance targets, and is therefore cash negative during much of the price cycle.

Although it is often difficult to predict where major change is likely, a trend to watch is the continued displacement of pyrometallurgy with hydrometallurgy in the nonferrous area and particularly the continued evolution, and ultimate success, of leaching technologies across a wider range of minerals.

VERTICAL INTEGRATION

By definition, mines need to be located where the ore bodies are located. Whereas the mine location is fixed, the level of processing attached to the mining operation is not. Historically, mines have been associated with the minimum level of processing to produce a concentrated product. The goal of concentration has been to minimize transportation costs.

The minimum level of processing required at a site has varied substantially according to the product mined. Largely this is because some products do not have sufficiently developed markets to allow intermediate products to be sold at full value and because locations away from the mine site can facilitate lower total production costs. As an example, there is only a small international market for bauxite and a moderate-sized market for alumina, and prices for these products tend to be fixed as a percentage of the aluminum price rather than the fundamental supply–demand balance for bauxite and alumina. This lack

of freely traded markets for intermediate products has generally resulted in bauxite miners producing alumina at the mine site, and then transferring it to distant, but owned, aluminum smelters, which are generally located in areas that can provide inexpensive power. This structure minimizes production costs but also makes it difficult to be a substantial participant in the bauxite mining industry unless your operations are vertically integrated through alumina refining and aluminum smelting.

Two current trends are pulling parts of the mining industry into or away from vertical integration. Pushing the industry toward vertical integration is the desire of governments to capture maximum rent from ore bodies and maximize job creation. As a trade-off for allowing access to mineral rights, governments are increasingly demanding construction of processing facilities in-country. Effectively, governments are looking to force mine developers to substantially increase investment and job creation as a trade-off for awarding mineral rights, even if this means processing facilities are not optimally located.

The stronger force is toward less integration caused by decreasing transportation costs, the generally lower construction and operating costs available from locating plants in Asia (especially China), and the opportunity to build larger processing facilities in central locations that can aggregate feed from multiple mines. This trend toward disintegration is expected to continue and will make it increasingly easy for mining companies to focus on mine-only operations, with processing handled by a separate company at a distant location.

SUSTAINABILITY

Environment, community, and safety are major issues for the mining industry and the trend is for increased scrutiny in these areas. The reasons for this are the following:

- **Historic:** Improperly operated and/or closed mines are still a legacy of our past. Old mines with major contamination and/or environmental degradation problems are all too common.
- **Social:** Communities, lifestyles, and even social fabric are all substantially impacted by nearby mine development.
- **Emotional:** The natural resources of a country are initially the property of the people of that country. A company, and particularly a foreign one, profiting from the extraction of natural resources is a sensitive issue.
- **Real:** The purpose of mining is to concentrate elements (minerals) for use by society. While the production of concentrated minerals (copper, gold, lead, etc.) is desirable, a side effect of mining tends to be the concentration (and release) of some undesirable elements (lead, arsenic, sulfur dioxide, radioactivity, etc.).
- **Progress:** Society expects ongoing improvements in industrial performance across all industries, and the mining industry must keep pace with progress in other industries.

The mining industry has been well aware of these issues, and its performance in the areas of environment, community, and safety is improving. In part this change is driven by higher levels of social awareness within the companies themselves. However, much of the change is also due to recognition by senior management that a good track record on environmental, community, and safety issues is a requirement for getting (and holding) access to resources.

Simply put, it is increasingly difficult for a mine operator with a bad track record on environmental or social issues to obtain or hold the license to operate that it needs to be successful in most developed and many developing countries. Governments, communities, financial institutions, and investors do not want to support or facilitate actions that are perceived to be unreasonably harmful to people. This has resulted in stronger regulation, higher levels of community involvement in the approval process, strengthened laws regarding indigenous rights, and the adoption of voluntary principles of sustainability and human rights by most large mining companies.

It has also resulted in a bifurcated industry structure whereby large, public companies are heavily scrutinized and typically seek to meet or exceed minimum legal requirements. They also tend to work closely with nongovernmental organizations (NGOs) and governments. The scrutiny and standards that apply to smaller companies are typically less than for a large one. However, governments and partners in less-developed countries are not always happy with the big company approach. This desire for quick investment supports the faster approach that smaller companies typically adopt.

The International Council on Mining and Metals (ICMM) was established in 2002, and most leading mining companies are members. Through the ICMM, the industry has put forward its proposal on sustainable development, including climate change, and has undertaken to report its progress and have its reports verified. Additionally, progressive companies have been engaging directly with their key stakeholders and making progressive decisions to enhance their licenses to operate. In many instances this involves commitment to environmental management strategies that go beyond strict legal compliance and have resulted in increased costs.

Climate Change

While there are some contrarian views, most of society believes that human-made climate change is causing harm and that carbon emissions are the primary cause. Society has therefore demanded that the subject of climate change receive maximum government and industry attention. Through the consumption of its products (primarily the burning of coal), the mining industry indirectly accounts for about 32% of global greenhouse gas emissions (IEA 2008). Given the industry's large contribution to carbon emissions, shareholders, regulators, and society at large expect the industry to reduce its footprint.

Although many mining companies have made commitments to reduce carbon emissions, this issue is expected to become increasingly contentious. The likely focus will be coal and uranium mining. Through its consumption, coal is the single largest contributor to increased levels of carbon in the atmosphere. Nuclear power, which uses uranium, has long been out of favor, largely due to issues associated with the disposal of nuclear waste and society's long memory of early nuclear incidents and accidents. However, nuclear power does not generate carbon, and, as a result, it is increasingly coming back into favor as a source of carbon-free power. Technology improvements, including carbon sequestration at coal-powered generating stations and the development of nuclear reactors with reduced levels of waste generation, will be key trends to follow.

Although it is not clear how the balance between climate change and low-cost energy will evolve, it is obvious that the

mining industry must be part of the solution and that energy produced from the mining of coal, uranium, and tar sands will continue to provide a major part of the world's energy supply.

Safety

The mining industry has historically had a poor safety record, and the industry is viewed as a dangerous one. While injury rates and fatalities continue to be unacceptably high, the industry overall has dramatically improved its safety performance. For context, the construction of the Panama Canal in the early 1890s involved the movement of 300 Mt of material and cost 26,000 lives. BHP Billiton's Escondida mine moves 360 Mt every year with the expectation that this will be achieved without the loss of a single life. Safety performance is still an issue, but dramatic improvements have been made and must continue to be made.

HUMAN RESOURCES

The design and material flow sheets for modern mines are complex and unique, the equipment is large and expensive, and operations are frequently remote. Capable people, at all levels of the organization, are therefore essential to operating a successful mine or mining company.

Despite this requirement for large numbers of capable people, the mining industry has faced and is facing a global skills shortage. The best evidence of this is the decline in university graduates in mining engineering, earth sciences, and metallurgy. In Australia, the supply of mining engineering graduates declined to just 100 in 2005, down from 200 as recently as year 2000. In the United States, there were only 86 mining engineering graduates in 2005. Similar acute skills shortages have developed for mechanical and electrical tradespeople and to a lesser degree for skilled equipment operators.

The reasons for this shortage of skilled people in mining include the following:

- **Remote locations:** Mine locations are frequently rural and remote. This lifestyle is generally less attractive than living in large cities, particularly to unmarried new graduates and families with high-school-aged children.
- **Industry unattractiveness:** Particularly in developed countries, the image of mining industry work is (incorrectly) of low-skilled, dirty jobs in an outdated, boom/bust industry. This image does not attract high-quality entrants.
- **Lack of awareness:** As the relevance of the mining industry has declined in the developed world, potential entrants are increasingly unaware of the opportunities the industry offers.

Increasingly, the trend is to fill the void left by a lack of new entrants in the developed world by recruiting skilled workers from developing countries. In 2007, the mining industry employed 8% of Australia's skilled migrants but only 1.3% of its native workers. A number of companies have started recruiting new graduates in less-developed countries with strong mining or manufacturing cultures. As a result, South Africa, Russia, and China have started to become targeted countries for recruitment of new graduates with technical degrees. These steps will help, but they are not enough to attract the talent the industry requires. To lure skilled workers, the industry is increasingly promoting the benefits of a career in mining, including career development, high pay, the ability to choose between an urban and rural lifestyle, and substantial opportunities to travel.

Finally, there is a strong trend toward fly-in/fly-out (FIFO) operations for new development projects. These FIFO operations are an alternative to creating remote residential towns to support nearby mining activities and are seen as a more attractive lifestyle alternative for many potential employees. This move toward FIFO operations also supports a sustainability agenda, because when the mine is depleted, the towns that were built to support it are frequently left without an economic base.

GOVERNANCE

There is unquestionably a trend to increased governance of public companies in general and mining companies in particular. These come from many sources:

- **Unions:** Although union membership has been falling worldwide, the statement that "you get a union when you earned one" is still valid and provides an important check on the management of industrial relations.
- **Nongovernmental organizations:** NGOs are passionate about their individual issues, and they are growing. Areas such as human rights, protection of indigenous people, biodiversity, and the environment all attract strong funding and provide a voice on mining issues that is widely heard and considered. The trend is for these groups to become more pragmatic in their approach, and many NGOs have moved from simply being against mining to engaging companies in substantial discussions about how mining can be done more sustainably.
- **Regulators:** Stricter reporting requirements and unbiased verification are clear regulatory trends through legislation such as the Sarbanes–Oxley Act of 2002 in the United States. Industry groups such as the ICMM are also substantial forces for self-regulation through their members' commitments to codes of conduct and reporting. The trend is for industry to increasingly rely on self-regulation and voluntary compliance to standards that exceed legal requirements.
- **Financial institutions and shareholders:** Equity analysts are increasingly independent from their lending institutions, and banks and investors have much better access to information about the companies they choose to financially support. For these reasons, it is harder for bad companies and projects to attract funding.
- **Society:** The volume of information and speed with which it is transmitted through sources such as the Internet are making it harder for unacceptable actions to go unnoticed.
- **Boards of directors:** Members of the boards of directors of public companies strongly dislike being associated with any type of scandal or perceived violation of a company's "social license to operate." Most boards devote large amounts of time to ensuring that high standards of governance are upheld.

Lastly, there is a clear trend toward more disciplined management decision making. As mining companies have become larger and more global, the costs of the decisions they are making, particularly to build ever larger individual mining projects, are increasing. This has brought with it a higher level of discipline to operating and capital decisions that have benefited all aspects of operation, including safety and environmental performance.

This discipline includes a more sophisticated approach to analyzing future price scenarios, assessing investment and operating decisions, and understanding risk. It also includes aggregating purchases of consumables, measuring and reporting performance in key operating areas, and requiring adherence to minimum standards of operation across entire companies. Evidence of the success of these actions is the general reduction in capital cost blowouts by the leading companies, improved investment decision making, and the ability to establish and report against a wide range of operating targets. Ten years ago BHP Billiton could not track its company-wide energy use, its carbon emissions, its usage and the prices paid for key spare parts, its instantaneous financial exposure to its key customers, or its equipment uptime. Nor could it easily dig into the quality of the supporting data for fundamental documents such as its ore reserve statements or its financial results. Today it routinely measures (and reports) all of these and much more.

However, the resources required to complete this work are large and therefore tend to be within the domain of the larger companies. This disciplined approach will need to be increasingly adopted by smaller companies or the industry will face increased regulation, which will further increase the value gap between the industry leaders and the rest of the industry.

INDUSTRY STRUCTURE

In the mining industry's evolution, the winner is clear. Lower transportation costs, bigger equipment and projects, higher standards for operating and ethical performance, and strong demand growth have all favored big, global companies with deep financial and operating capabilities. The gap in size between the leading mining companies and the rest of the pack has become quite large. In 2009, the world's largest mining company (BHP Billiton) is 40% larger than its nearest competitor (Vale), which is itself 40% larger than its next largest competitor. As a group, the large companies are active in multiple products and countries and could credibly claim to have the capability to efficiently build and operate mines in any of the major minerals, anywhere in the world.

The industry leaders also dominate the ownership of the best mineral deposits. A few midsized companies have large, high-quality deposits, but they tend to be companies that are protected from large acquirers by either their ownership structure or their potential liabilities. Companies in this group include state-owned miners such as Chile's CODELCO and companies with two-tiered ownership structures such as Teck Resources (previously known as Teck Cominco).

SUMMARY AND CONCLUSIONS

The mining industry is going through a period of rapid change. Globalization and a potential supercycle, caused by strong demand from newly industrializing countries, are permanently changing the industry. The industry-leading companies that have emerged are bigger, financially stronger, and much more capable than their predecessors. They operate across borders, produce a wide variety of mining products, and generally seek to operate in a manner that exceeds minimum compliance with international standards.

Although the companies within the industry have substantially changed, most mining operations and the technologies they apply are similar to the practices in the 1960s to 1980s. Although similar technologies are employed, individual mines are much larger, and the percentage that are open cut is higher. Operations are also increasingly moving to hydrometallurgical recovery processes and de-integrating themselves from downstream activities.

The industry is also receiving a high level of scrutiny. Resources are increasingly scarce and securing access to sufficient resources to facilitate economic development has become part of government policy in some countries. Catastrophic "unsafe events" continue to be unacceptably common and are heavily reported. Lastly, mining activities consume and alter large quantities of water and terrain and, as mining operations become larger, the scale of such alterations is becoming increasingly visible.

Society demands more from the mining industry, and the industry is responding. Increased raw material demand has brought with it growing recognition that the mining industry can be an attractive employer and that it does meet an essential need of society. This new status is increasingly attracting a new and more capable set of industry leaders, and ones that are increasingly focused on not only providing essential resources to society but doing so in a manner that is socially and environmentally sustainable.

CHAPTER 1.3

Future Trends in Mining

Tom Albanese and John McGagh

INTRODUCTION

Imagine for a moment the mine of the future, where knowledge of the ore body, its mineralogy, size, and value are known precisely, based on a range of three-dimensional (3-D) geological images captured nonintrusively long before mining commenced. The mine plan covers not only the initial target ore body but all future extensions until the reserve is exhausted. Nothing is left to chance. Imagine a mine with a zero environmental footprint and zero net energy consumption, where all processes are continuous, with process control systems that monitor and optimize performance, and where all moving equipment is autonomous and controlled from afar. Few people are visible on or under the ground, and the work environment is safe and healthy. Highly skilled workers operate the mine from air-conditioned control rooms in major capital cities. These jobs are well paid and highly prized.

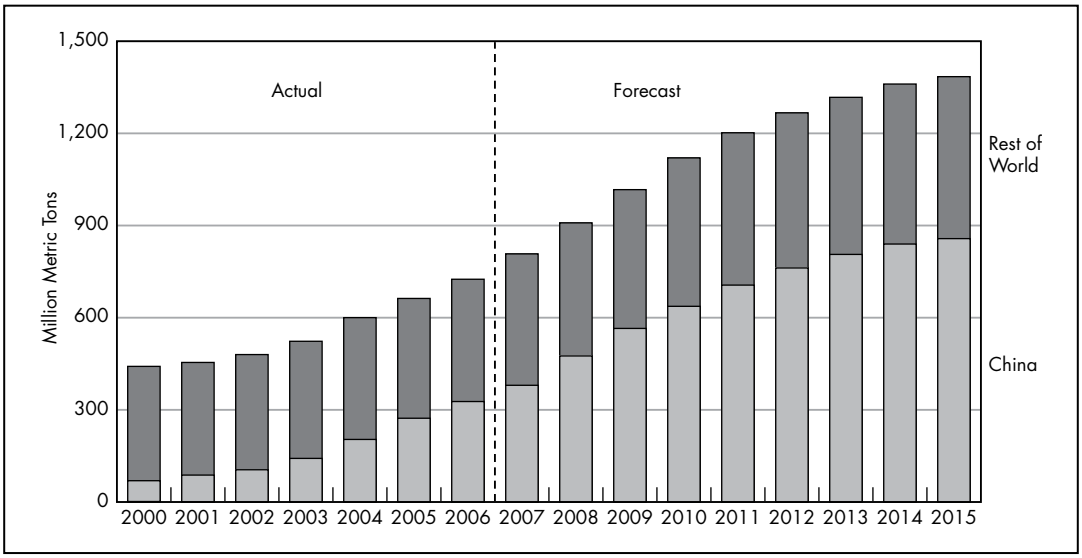
Can we imagine this future, and is it that far away? The pace of change in the industry has increased dramatically, with strong market pull and strong technology push. The mine of the future may be closer than we think, and many of the enabling technologies exist today. The trends likely to shape our future will be explored through this chapter.

Demand

Although the pace of change continues unabated, the nature, rate, magnitude, and impact of change are not constant and know no boundaries. No one predicted the coming of the information age and the enormous global impact of the Internet. The mining industry is changing in step with global demands, but the challenges of supplying minerals and metals to a world experiencing exponential change are great. The future will be very different.

The mining industry is experiencing a dramatic change, one that profoundly affects our industry, an unprecedented change that creates an enormous challenge and an immeasurable opportunity. The world is rapidly becoming urbanized, with an additional 1.4 billion people predicted to move into cities within 20 years. Although the population shift will be universal, it is being led by China and India. People who move to cities require houses, roads, schools, power stations, and stadiums, and they gain the wealth to purchase consumer goods, such as refrigerators, cars, and air conditioners. With urbanization comes a greater demand for metal. It is estimated that the average per-capita requirement for metal products is 155 kg for China's rural communities and 817 kg for China's urban dwellers.

Demand for all base metals, particularly iron, copper, and aluminum, will likely double from 2010 to 2025, due largely to this population shift. Putting this in perspective, the additional demand for iron ore in that time period is equal to the capacity of five Rio Tinto Pilbara operations, which produce close to 200 Mt per year. It is also estimated that the world will consume as much copper from 2010 to 2035 as it has during the last century.



China's iron ore imports are expected to double from 2010 to 2016 (Figure 1.3-1), following many years of growth that has made China the world's largest consumer of traded iron ore, copper, and aluminum (Table 1.3-1), together with nickel, steel, and coal. From 1990 to 2006, China's steel production more than tripled, with iron ore imports increasing 20-fold during this period. China is clearly the new force in commodity demand. The industrialization of China and India is changing the economic world order.

Supply

Satisfying this huge growth in demand is the mining industry's greatest challenge, and one that must be confronted head on. The industry must think and work differently to keep pace with this burgeoning demand. The old ways will not be good or fast enough. Change is essential.

Mine output rates must increase. Existing assets must be extended to yield more. Lower-grade reserves must be tapped. Exploration and discovery must become more efficient. The search for new high-value reserves must accelerate. These outcomes must be delivered during a global industry skills shortage and against a background of diminishing surface deposits and rising costs. Moreover, in today's society, everyone wants more for less. Higher outputs must be achieved at lower unit costs. Working against this need for lower costs are increasing energy costs, the threat of climate change, and the higher cost

Tom Albanese, Chief Executive Officer, Rio Tinto Ltd., London, UK
John McGagh, Head of Innovation, Rio Tinto Ltd., Brisbane, Queensland, Australia

Source: Albanese 2008.

Figure 1.3-1 Seaborne iron ore imports

of mining deeper ore bodies and lower ore grades, possibly in more challenging geopolitical environments.

Efficiencies must be found in all operational areas, from exploration to extraction. The solution to efficiency improvement lies in the development and implementation of new and innovative technologies. Companies that innovate are more likely to be rewarded with lower costs, improved competitive positions, superior returns to shareholders, and sustainable businesses.

And the mining industry must deliver these outcomes in an environmentally sustainable way. The planet is warming because of human activity. Atmospheric levels of greenhouse gases are increasing. The mining industry is not insulated from the effects of global warming, and we must play our part in dealing with it. As miners, we must take sustained action to reduce the environmental impact of our operations. We have no choice. If we do not reduce the size of our footprint, those who are in a position to give us a license to operate will no longer do so. Our aim must be to achieve both zero emissions and zero net energy consumption. A suite of technologies that could support such a vision is under development.

All of this must be achieved in a world where stakeholder consultation is assumed and affected communities benefit from mining activities through and beyond the life of a mine. Consultation with local communities and other stakeholders must continue to evolve through all stages of a project, including the ultimate mine closure. This necessity increases as the search for new tier 1 reserves takes exploration to less accessible and more sensitive remote areas, often in Third World countries.

The mining industry works under intense scrutiny, and rightfully so. We live in the information age. People are more informed, and information is available to many people at the touch of a button. They are aware of the environmental challenges confronting this and future generations. They are more likely to act on what they see and take action against those who do not accept that the risks to our future are real and against those who act irresponsibly. We must deal with the intense scrutiny that comes with this new age. Not only must our house be in order, but we must ensure, through better communication, that the wider community knows it is.

Table 1.3-1 Growth in China's share of global consumption of metals (%)

*E = estimate.

Finally, while innovation may hold the key, today's new technology could well be next year's standard practice, so innovation must be a continuous process through the economic highs and lows. A cultural change is needed. The goal is an environment in which workers constantly seek new and better ways of doing things and in which innovation is rewarded. New ideas must be continually developed and nurtured. The same systems and cultural changes that brought the world higher quality, better customer service, and improved safety can drive innovation in the mining industry.

The challenges are universal and demanding—the increasing demand for commodities; grades and their decline with time; mineralogy and the need to handle more complex ores; the need to find new reserves; disposal and minimizing of wastes; and the availability of water, power, and skilled labor. These challenges are combined with increasing expectations from the community and concerns about sustainability and safety and climate change, forcing a more targeted

approach on energy. The opportunities and the rewards are great. Those mining companies that meet the challenges will be in a stronger competitive position. A vision for the future is provided in the following sections.

EXPLORATION AND GEOLOGY

Logic would suggest that it is easy to find things that have already been found. In the mining world, it is hard to argue the point when just about every square kilometer of the developed world has been surveyed to some extent. It follows that if we are to keep pace with demand, exploration and discovery must become more efficient and the technology used to detect and characterize mineral deposits on and below the earth's surface must become more capable. Vast amounts of money are being spent on exploration. In 2002, global exploration expenditure was in the region of US$2.5 billion, and by 2007, it had risen to more than US$10 billion. The identification of the geologically rare tier 1 deposits is the highest prize. Such deposits grow with exploration, commonly have other tier 1 deposits nearby, and support production expansions. Their discovery is a necessary part of the total solution to satisfying growing global demand for minerals and metals.

Exploration

The aim of exploration geology is to find mineralized target areas for development into profitable mines. To define an economic deposit involves a number of steps—from initial small-scale sampling to larger-scale characterization. History has repeatedly shown that the probability of converting exploration targets into economic deposits is low. In the future, therefore, the key challenge for exploration geology is to increase this probability of success by identification of

- A wider range of deposit types, including lower-grade ores, deposits with different mineralization styles, and ores with greater variability, possibly in areas already explored;
- Deposits that do not occur at the surface or are covered and possibly in areas already explored, near existing ore bodies, or even below existing mine sites;
- Targets that are potentially more remote;
- Deposits in more politically sensitive or unstable regions; and
- Deposits in more environmentally sensitive regions.

The discovery of ore bodies or mineral resources in any of these categories will present financial, political, and scientific challenges.

Interestingly, Davy analyzed all kimberlites/lamproites discovered from 1966 to 2003 (excluding those in Siberia and Russia) and observed the following (Davy 2003):

- The frequency of discovery doubled through the 1990s compared with the 1980s as more money was spent on exploration and more junior diamond explorers were active.
- More world-class projects were discovered in the 1990s, lending support for the view that, with improved methods and new technology, world-class deposits are still there to be found.

Before discovery, however, the rights to explore a prospective area of land must first be acquired, and this is not without difficulty, especially in a competitive market. Company reputation will influence the outcome, and financial considerations are also critical. Different skill sets will be required. After government approval is given, exploration in remote, unstable, or environmentally sensitive regions must be efficient, and less-intrusive methods for detecting minerals must be employed.

Geology

In addition to target identification, geology has to better predict how ores are expected to behave during the stages of mining and metals extraction. To optimize cash flow, such ore knowledge is applied throughout the value chain. In the medium to long term, ore characterization methodologies will be improved through better measurement techniques, predictive capability, and early decision making.

Improved Measurement Techniques

New technology allows for higher-quality results that can be provided in a shorter time frame, hence increasing resolution. Such improved characterization will allow for better definition of the reserve, which impacts the economic value of the deposit.

Increased ore-body knowledge and associated technical developments allow more complex ore bodies to be potentially exploited. And better characterization of the resource is used strategically; that is, which ore bodies need to be progressed through the prefeasibility, feasibility, or order-of-magnitude stages.

In normal circumstances, confidence in data collected during project development from exploration to feasibility study increases as the project progresses. Some of the measurement and testing technologies that are likely to be further developed in the future include automated core logging, core imaging, and on-line and near-online analyzers.

Improved Predictive Capability

Improvements in 3-D modeling capability will increase the ability to predict both mining and processing behavior from measured primary data. Key elements that need to be known for base and precious metal mining operations include blasting, crushing, grinding, liberation, and recovery characteristics. Other related issues include tracking deleterious elements and minerals, providing inputs into the environmental management of waste rock, and increasing the energy efficiency of processing equipment:

- **Improved prediction of ore-body behavior in mining.** More knowledge at the early stages of projects improves decision making on mining methods; for example, for the prediction of fragmentation, crushing, and grinding and for the optimization of blending strategies. In underground mining, improved cave models can be used to optimize draw strategy.
- **Improved prediction of processing behavior.** Metallurgical data in the block model improve decisions about processing methods and allow for the prediction of performance for specific ore types and ore blends. The data are also used for concentrator optimization and metallurgical accounting.
- **Improved prediction of behavior into the environment.** It may be possible to minimize the environmental impact of mining and predict environmental impact and cost by incorporating environmental data in the block model.

Improved Early Decision Making

Higher data density (but lower cost) and increased predictive capability will enable the industry to more confidently reject exploration targets that are deemed uneconomic. Exploration provides a significant return on investment. Despite that, the cost is high and future tier 1 assets will be harder to find, so technological advancements and process improvements that shorten the discovery cycle and increase the probability of success need to be developed and implemented.

SURFACE MINING

The advent of surface mining stands, arguably, as the most significant change to the fundamentals of the mining process. The move to open-pit mining, which started in the 1890s with advancing mechanization, has dramatically simplified the process of extracting minerals. A rich history of innovation has brought surface mining to where it is today, with mine output rates that were unimaginable even a few decades ago. But what does the future hold? Surface mining is subject to a wide range of internal and external pressures, so change is essential to meet the challenges ahead. It is no longer just about moving as much rock as safely and cheaply as possible. Recently, automation and remote control of mine processes have taken center stage, and this is likely to continue into the foreseeable future as advances in communication systems, measurement systems, and computational power provide unlimited scope for development. As well as these technologies, there are still many areas where both step-change and incremental improvement can add tremendous value to the surface mining sector, and the industry appears to be poised to pursue these opportunities.

Fragmentation

Fragmentation in hard-rock surface mines is almost entirely dependent on explosive rock breakage, and this is unlikely to change in the foreseeable future. In terms of effectiveness and cost, blasting provides the ability to liberate large quantities of material to a size that can be moved using standard excavation and transport equipment.

Given that blasting lies at the core of the mining process chain, it is not surprising that considerable research has gone into explosive formulation, initiation techniques, and simulation. The Hybrid Stress Blast Modeling research project is an example of current research that is exploiting the increase in computing power to apply sophisticated numerical modeling codes to the process of blasting (Batterham and Bearman 2005). The knowledge of fragmentation and muckpile formation that can be yielded by this approach will enable blasting to be better matched to downstream requirements. This is part of the move toward an optimized mining process, free of disruptions from poor blast performance.

Alternatives to explosive fragmentation in surface mining are limited by the amenability of the ore body, in terms of both material properties and geological structure. The barrier to widespread use of mechanical excavation is the difficulty of cutting hard rock and the high cost of machine wear and tear. In mines where material is amenable to mechanical cutting, significant proportions of production are being delivered without blasting. In these instances the driver tends to be selectivity, linked to the fact that the ore thickness is significantly thinner than the normal blast-sized smallest mining unit. Therefore, if mined using traditional open-pit bench heights, the degree of dilution would be excessive. If selectivity is not a prime driver, then factors such as reduction of diesel consumption or environmental sensitivities that preclude blasting or adverse pit floor conditions could support mechanical cutting and continuous material movement.

Blasthole Drilling

Blasthole drilling offers the opportunity to gather more information on the strata and rock encountered during drilling. Today, the data associated with drilling—torque and pull-down force—are either not logged or are used in a fairly basic manner. In some instances, rock, or strata, recognition is performed by correlation of drilling parameters with rock hardness, but the technology's acceptance is not widespread despite numerous positive applications and case studies. The most often cited reason for the lack of acceptance is the need to retrain the algorithms at the heart of the system as the drill moves into different domains.

In the future, real-time feedback from the drilling rig will be regarded as routine. In addition to the drill parameters and rock recognition, sensors in the drill will perform a variety of duties ranging from elemental ore analysis to the measurement of geotechnical rock mass characteristics. Discrimination using a variety of measured and derived properties will move the industry toward greatly improved digging to ore–waste boundaries. Advanced blast design packages will become more accepted and more sophisticated, with the packages linked directly to the charge loading trucks. The linkage will be wireless and will replace the manual exchange of data, thus leading to the planned loading of a range of explosive types and densities. The correct delivery of optimized blast designs will ensure greater predictability in fragmentation and muckpile shape, which in turn will lead to improved digging conditions and reduced operating costs.

The advanced drill-blast-load loop is heavily dependent on the deployment of a variety of sensors. Every time we touch a material, we must learn something about it. The use of sensors and their integration into standard operating procedures will enable miners to increase operational effectiveness even when there is a skills shortage.

Materials Movement

A major challenge lies in how best to get material out of a mine. In early open-pit mines, locomotives moved much of the material in the larger pits such as Bingham Canyon, Utah (United States). The move to trucks was a major step forward in flexibility and has driven the increase in open-pit mining. In open-pit mining, equipment size matters and equates to productivity: more material moved in a given time. For this reason, the trend will be for ever larger equipment. Although the trend has been focused on the size of haul trucks, to load these larger vehicles the size of loading equipment has also increased commensurately. Currently, haul trucks with payload capacities of up to 365 t (metric tons) carry loads from the mine face to the tip point, a 12-fold size increase in payload capacity since 1950. To satisfy the enormous appetites of these trucks, excavators with buckets of up to 45 m^3 and payloads of more than 100 t are in use, enabling even the largest haul trucks to be loaded with four passes, thereby ensuring a quick turnaround.

But what is the ideal size of a haul truck: larger, smaller, or the current size? The answer is uncertain, but the trend toward larger vehicles shows no sign of slowing. Fewer, larger trucks reduce flexibility, increase risk, reduce mining selectivity, and drive up the size of ancillary equipment. Larger trucks and

excavators must be exceptionally reliable to improve availability and ensure that productivity targets are met. Smaller trucks drive up cost because of number, maintenance, and larger work force. The trend in size will be strongly influenced by what best suits an automated mine operation, where reduced cycle times and increased availability will deliver productivity gains. Limitations to further size increases may also come from engineering and material constraints.

Trucks, predominantly diesel-electric, provide flexibility and can move anywhere. Despite increases in efficiency, the diesel use is significant, and its reduction is a major challenge to the industry. Alternative energy sources for trucks must be developed. Driven by the need to reduce greenhouse gas (GHG) emissions and reduce dependence on petroleum feedstocks, the global automotive industry is moving rapidly to develop alternatives to the embedded internal combustion engine. Hybrids may be part of the solution. Hydrogen fuel cells offer some promise, and biodiesel based on waste biomass may be a viable alternative fuel for internal combustion engines. Certainly, the automotive industry's experience will flow onto the mining industry, and early adoption of a viable alternative can be expected.

Electrically augmented trucks fed from an electric pantograph (overhead power lines) are deployed at some sites, with their original installation driven by the fuel crisis of the 1970s. Their reduced flexibility and difficulty in changing the size of trucks due to the fixed overhead infrastructure limits their widespread application. Given the current fuel situation, development in the field could be expected.

Alternatives to haul trucks must be considered, particularly in view of ever-increasing energy costs. The obvious alternative is a conveyor system for flat areas or high-angle conveyor systems to reduce diesel-intensive uphill hauls, but there are drawbacks. A conveyor is more fixed and can transport well-fragmented material but cannot take run-of-mine blasted material, unlike haul trucks. For conveyors to be effective, the top size of material must be controlled and this can only be guaranteed currently by size reduction through crushing or mechanical cutting. In-pit crushing is a solution to this dilemma, which has been deployed at various sites over the years, but the challenge has always been such units' mobility. Recent developments in mobile crushers and the use of conveyors have created greater opportunities with future developments in this field expected to widen the application of the technology. Further, mechanical excavation could provide the consistent material flow suitable for a conveying system in amenable materials.

Long-haul, or out-of-mine transport, presents a further set of challenges in the future. Long-range overland or aerial conveyors offer some alternatives. Many significant overland conveyors have been deployed to great effect, and recent developments in aerial conveying systems could provide further alternatives where terrain is unfriendly to the overland version or where the system must traverse environmentally sensitive areas. From an energy perspective, conveyors of both types offer the option to use regenerative technology to feed power back into the energy system.

Pumping has not traditionally been considered as a material movement system, but with improved knowledge of rheological flow properties, there are moves to examine the pumping of slurries containing much larger particles.

The traditional transport option for long distance, including mine to port, is rail. Locomotives are currently the focus of considerable research into alternative fuels, including the development of a hybrid diesel-electric locomotive that not only reduces emissions but reduces fuel consumption by capturing and storing energy dissipated during braking. It promises both cost and environmental benefits. The efficiency of the overall rail network is also a major consideration, and, in addition to the application of advanced optimization models, there is a move to autonomous train operation.

Planning and Scheduling

As the mining industry moves toward more complete integration of production systems, planning and scheduling will change dramatically. Whereas plans and schedules for mining, maintenance, and logistics were once developed in relative isolation, the trend is toward whole-of-business planning and scheduling. Distinctions between long- (strategic), medium- and short-term planning may remain, if only for convenience, but business processes and software systems will evolve such that plans and schedules developed with different time horizons will influence and be influenced by others:

- Plans and schedules will become adaptive, responding to increased granularity in space and time information.
- Real-time sensing of material geometallurgical properties will influence the mining sequence and downstream processing in close to real time.
- Short-term production schedules may even respond to short-term fluctuations in market needs.

Although the next step-changes in mining methodologies may not be immediately apparent, every change introduces new challenges for planners and schedulers. Software systems for mine planning and scheduling will evolve to cater to these and other mining options.

Formal optimization algorithms have long been used to design optimal pit shells, aiming to maximize project net present value. But optimization is likely to be applied much more systematically throughout the production process, not only from mine to mill but from pit to port. Decisions that relied on experience in the past may one day be supported by almost continuous re-optimization of the production process. Genetic and evolutionary algorithms will complement parallel efforts to solve large mixed-integer linear programming techniques. Optimization algorithms will account for uncertainty in all parts of the production process, from variability in geometallurgical properties to reliability and availability of fixed and mobile plant to fluctuations and trends in costs and commodity prices.

As the mining industry moves toward automation and autonomy, the movements of individual vehicles will be planned and scheduled at ever-decreasing time scales. Some vehicles will effectively control themselves. Short-term mine plans may define the broad parameters, but conventional dispatch systems may become a thing of the past.

For the foreseeable future, explosive rock breakage and the use of haul trucks and excavators will remain an integral part of hard-rock surface mining. Dramatic increases in the use of automation and remote control of mining equipment will shape the future of surface mining. Underlying all future developments will be the ability to significantly increase the sensing, measurement, and monitoring of critical geological, geometric, and equipment-related parameters. Every time an opportunity arises to gain knowledge by taking a measurement,

this opportunity must be followed up. The effective integration and use of these data will provide the backbone of future advances in surface mining and will enhance the ability to deploy the automated systems that are such a critical part of the future.

AUTOMATION AND REMOTE OPERATION

The automation of mining processes is a technological step-change that will provide part of the solution to the industry's most pressing challenge: achieving higher outputs to satisfy the projected continuing growth in commodity metal requirements.

Automation also addresses the shorter-term imperative of maintaining a suitably qualified work force at remote mine sites, which is an industry-wide problem. Younger generations are reluctant to leave the comforts of urban life, where they see their futures. Although work forces can be maintained in mining regions, the cost of doing so is extremely high, not only in direct wages, training costs, and penalties that have to be paid to professionals and skilled workers alike, but also in housing and other infrastructure needed to support the work force.

Benefits of Automation

Automation increases the level of control in what is inherently a chaotic process by applying more stringent rules to decision-making processes and removing the randomness inherent in isolated decision making. Applying a controlled process to variable mine geology and ever-changing topography results in higher productivity and lower cost. Automation involves the collection and use of data; for example, gathering data from the blasthole drilling process, which enables hole placement and blast design to be better controlled and blast outcomes to be predictable and optimum.

Another benefit of automation comes from increasing the utilization and performance of haul trucks and other high-cost capital items. With improved control comes a reduction in the expected levels of wear and tear and breakdowns, enabling preventive maintenance to be better planned and performed. Moreover, the amount of wear and tear will be reduced because the autonomous machine is operated constantly within its design envelope. Costly breakdowns and unplanned maintenance should be avoided, as the cost of the repairs are higher than planned ones, but more importantly, the disruption to the production process cascades through the system with costly knock-on effects. Attempts to control wear and tear through driver regulation have had limited success because such regulations are not easily enforceable. Higher availability and utilization means higher productivity and lower unit costs. Another significant benefit is the large fuel savings that can be achieved by optimizing the vehicle operating parameters, a vital consideration in times of high oil prices and concern about GHG emissions.

Clearly, the time is right for automation, but it will not happen overnight. The technology for a fully autonomous mine must be developed, but it is unlikely that any one single company could take on the challenge alone. The disparate, independently developed pieces of the automation puzzle will need to be connected and synchronized. This will require the industry to adopt automation standards that allow this to happen. Even so, the cost of automating all of the functions in mining will be a lengthy and costly endeavor. If there is no sustainable competitive advantage from in-house developments, most mining companies will not want to incur the high costs and will prefer to buy technology from specialist suppliers. Mining companies will need to develop a method for overcoming this nexus because the provision of a complete turnkey automation package by a single supplier is unlikely to happen in a timely manner.

Underground mining, where the imperatives for change are much greater, was the first bastion to fall to equipment automation. Space is tight, the dangers are greater than surface mining, and health issues are of greater concern. Unmanned vehicles are now more common. Vision and guidance systems enable a remotely controlled vehicle to know precisely its location in a mine by comparing the camera view with stored images. Vision systems improve the ability of a remotely controlled vehicle to approach a rock pile and optimize the load collected. The combination of these semi-smart machines with effective communications infrastructure enables tele-remote operation of underground machinery by operators sitting in safe and benign office-like environments and allows machinery to be operated in areas where the dangers preclude human operation.

Vision for the Future

The mine of the future might include

- A mine site where automated blasthole drill rigs perfectly position every hole, conduct analysis during the drilling, and tell the explosives delivery vehicle what explosives load and blend to be charged to each hole;
- An excavator that can "see" the difference between ore and waste in the muckpile, can separate the two, and automatically load the driverless haul truck before dispatching it;
- Driverless trains fitted with an array of sensors that enable them to see beyond the horizon and that can travel in a convoy as though linked by some invisible thread;
- A haul truck that automatically reports to the workshop as scheduled maintenance becomes due; and
- A haul truck with none of the design constraints that come with having a driver—no cabin, windows, air conditioning, nor headlights; that is more symmetrical, possibly able to travel in two directions equally; and that comes with the current energy system and drive train—all-wheel drive and steering, electric motors driving each axle, power generators, and storage systems under body.

If these and other systems were put together, it is easy to imagine the mine of the future operating similar to a rock factory where all functions work in unison, more like a production mine than the variable mines seen today.

Automated Mine Site

In surface mining, "islands of automation" in haul trucks, blasthole drill rigs, shovels, surveying, and blasting are being developed. These independent developments must be integrated, which will multiply the benefits that would otherwise be achieved. Integration avoids unnecessary duplication of enabling systems such as navigation and provides operational standards and links all data sets. To avoid possible choking of the available bandwidth, developments in wireless communication are needed. Although individual pieces of equipment will need to become smarter to reduce the communications requirement, a central "brain" to conduct the disparate mining activities must be developed and implemented.

Automation will require the transfer and manipulation of huge amounts of data. Autonomous operations, such as drilling, surveying, blasting, and loading, will each link to the brain or autonomous backbone, which provides the coordination and sharing of resources that will be essential to the autonomous mine. The know-how to develop this backbone will likely be developed in-house by the mining companies in order to tailor it to the mining process. Perhaps in the future, as technology advances, it will be supplied as a turnkey system from original equipment manufacturers (OEMs).

A key capability of the backbone or brain will be the ability to effectively fuse the data from the disparate sources around a mine. Data fusion differs from data warehousing. Whereas data warehousing requires the storage and use of data to extract value, data fusion integrates data that offer a conflicting view of the world prior to the data being used. Data fusion is essential for a process that integrates and automates several functions.

An example of the need for data fusion is to precisely know the position of an autonomous moving vehicle in a mine. A Global Positioning System (GPS) provides a good indicator of a vehicle's position, but it is not fail-safe, so a backup is needed. Inertial navigation systems can provide information on position as can wheel encoders that measure the distance a vehicle has moved. A fast-moving vehicle such as a truck will likely have all three. To integrate these three sets of data and apply uncertainty theory to determine the most likely position of the vehicle, data fusion is required using algorithms. All of this data handling must be performed rapidly to ensure feedback to the vehicle and the autonomous brain controlling the array of resources in the mine. This is but one example of data fusion requirements in an autonomous system, and it heralds the future types of employees that mining companies will need to design and run information processes.

The experience from the development of an autonomous mine will impact future mine planning. For example, the precise control of haul truck movement may create an opportunity to build narrower and longer haul roads.

Technology Development

As discussed, the vision of a fully automated remotely controlled mine is deliverable but will take many years, substantial investment in research and development, and a broad collaborative network involving OEMs and leaders in automation. The creation of a fully automated mine could not be achieved by even the world's largest miner working in isolation. It will take the skills of large and patient companies to develop an autonomous haulage system. To deal with the robotics required in a fully automated mine, it requires the combined brainpower of large teams of dedicated research workers such as those employed at the Rio Tinto Centre for Mine Automation, based at the University of Sydney (Australia). Others will contribute to the development of advanced sensors. The proving ground for new technology is the mine itself. When all components are proven and the system is fully integrated, this template of the autonomous mine will be deployed. Components of the system, such as driverless trains, may be deployed earlier.

Driverless Train

Rio Tinto has announced that it will automate its iron ore railway in the Pilbara region of Western Australia. Within 5 years, driverless trains will be operating on most of the 1,300 km of track that serves its Pilbara operations. The cost is high. This will be the first time automation has been used in a heavy-haul railway of this scale, though the technology successfully operates on many metropolitan passenger railways around the world, where it is safe and reliable. Automated operations will integrate with the existing train management system and will bring efficiency gains through greater scheduling flexibility and the removal of delays. Additional safety systems are being developed to meet safety levels required for automated trains. Rio Tinto is working closely with the Western Australian Office of Rail Safety to ensure that all safety requirements are met.

Operations Center

Rio Tinto has established an operations center in Perth, Australia, to manage operations in the Pilbara mines, about 1,300 km away. This is a key step on the path toward a fully automated mine-to-port iron ore operation. At full operation, it will house hundreds of employees who will work with Pilbara-based colleagues to oversee, operate, and optimize the use of key assets and processes, including all mines, processing plants, the rail network, ports, and power plants. Operational planning and scheduling functions will also be based in the operations center, where staff will also manage power distribution and maintenance planning. Although the goal is a more efficient operation, an additional benefit of establishing an operations center within a capital city is that it will directly confront the high cost of basing employees at remote sites. This center is but one part, albeit a very important one, in a fully automated operation that includes driverless trains, autonomous trucks, and autonomous drills.

In mining, the traditional coal face is where many of the worst accidents happen and occupational illnesses are sown (Cribb 2008). An inestimable benefit of automation and remote operations is the improvement in human health, safety, and well-being as a result of moving people out of the danger zone. So although the absolute number of jobs might not change with automation, the overall safety performance of the company will improve as a direct result of worker displacement.

Computing Power

The mining industry has experienced significant growth in the utilization of computers since the mid-1980s due to widespread adoption of personal computers. For iron, aluminum, and copper mining, it is expected that the computing power required over the next 20 years will increase by an order of magnitude. The upgrading of personal computers across most sectors of the mining industry represents a major share of this growth. The remainder is driven by the needs of various applications that target improvements in productivity, cost, quality, safety, and reliability, including

- Mining and plant scheduling and optimization,
- GPS-based applications,
- Automation,
- Finite element analysis/simulation in plant design and troubleshooting, and
- Adaptive plant control based on predictive models.

Mine Workers

Automation may or may not mean fewer workers in the industry. It may be that, through automation, fewer workers are employed

at the mine site or mine output is doubled with the existing work force. Regardless of the impact at the mine site, specialist jobs in data processing, systems maintenance, electronics, and so forth will be created at locations possibly thousands of kilometers from the mine. These new workers will be housed in high-tech, air-conditioned offices or control rooms, a long way from the conditions experienced at a mine site. Mine operations in more politically sensitive regions may well be controlled by workers sitting in an operations center in a neighboring or distant country.

Automation and remote operations directly impact mine workers, and success in introducing change cannot be assumed. Much effort needs to go into planning, and communication is crucial. The work force must be prepared for such change through a well-planned cultural transformation process; if not, barriers to change will be erected. By being given relevant information, workers must come to understand that change is necessary for survival. At the same time, they must accept that the ways of the past, while good for their time, will not guarantee future prosperity. Finally, they must also understand and accept alternative ways and must embrace the process of change. Although the future of the industry or their employer may be important, to most workers, income stability is all that matters, so this must be addressed in any change process. Perhaps automation's most exciting potential, though, is its power to win a new generation of gifted youth to mining through the marvels of mechatronics and artificial intelligence (Cribb 2008).

While automation in the mining industry has been littered with many false starts, the challenges facing the industry today demand autonomous solutions. The rewards for being at the forefront of automation are great, but the penalties for inaction are far greater. Mine automation will take leadership, resources, good planning, cooperation between suppliers and users, and a lot of patience.

UNDERGROUND MINING

A number of large mining companies pursue a strategy of owning and operating large-scale world-class mines, typically in the form of large open pits. However, the depth at which open-pit mines can be developed is limited. Although larger and more efficient trucks will enable open pits to operate to greater depths, it is likely that the economics of strip ratio and large-scale waste management will be the prime control on depth. For example, it is anticipated that an increasing share of Rio Tinto's production, particularly in the copper and diamond groups, will come from underground operations (Clayton 2008) and that the majority of investment in the future will be in the form of large tonnage block cave mines.

The challenges of block caving include high capital costs; long lead times before revenue generation; and complexity in design, construction, and operation. These projects should be conceived of as rock "factories"—mines built to a specified quality and schedule—and then operated in a predictable manner in terms of production rate, grade, and costs.

Knowledge

The industry's block caving experience has driven a number of new development concepts, which are different from those for a more typical mine. However, the rate of development needs to increase rapidly. This change in concept requires a change in project definition, planning, and implementation. In particular, an early and deep understanding of ore-body (and waste rock) characteristics, design, and constructability are critical.

Improving resource and reserve knowledge can provide substantial competitive advantage. It is important to identify at an early stage those resources that fit the required extraction profile and are amenable to bulk mining. Ore-body knowledge is critical to the overall design and construction plan. Block caves require greater upfront ore-body knowledge, because the final extraction level needs to be planned in detail before construction can commence.

Design

Past block cave design has mainly been based on application to weaker rock masses than those proposed today and will be required in the future, and, as such, much design work is currently based on inappropriate rules and outdated experience. Current design methods in block caves are largely based on empirical techniques developed in the 1970s and 1980s, and more advanced techniques are still in their infancy. There is a clear need for a superior understanding of how a rock mass will cave and the characteristics of caved material, particularly the fragmentation. As the key driver of block cave mines, fragmentation determines bulking and rock flow characteristics that must be understood for optimal mine layout, infrastructure, and operational design. Fragmentation determines optimal drawpoint spacing, which, in turn, strongly influences recovery, dilution entry, and conditions.

Customized Development Design

Improved characterization of the rock mass through which the drift will be developed, via a more rigorous approach to site investigation and face mapping, will yield benefits. For example, ground support techniques have not evolved substantially since their inception in early 1970. Better design and products could reduce costs by 10%, saving many millions of dollars. Such savings could also be achieved in the other caving-type operations. In order to support the substantial levels of investment associated with block caves, functional and reliable design tools are required, which will result in more reliable cave designs.

Reliability in Constructability and Construction

Block caves require large initial capital investment before revenue is generated. As such, they are similar to civil construction projects such as road tunnels where revenues are not realized until the project is complete. The construction of three block caves with a capacity of 110 kt/d will require

- Approximately 16 shafts (8 to 10 m in diameter) 1,500 to 2,000 m deep with four to five in various stages of construction per year over 12 to 15 years, and
- Approximately 900 km of horizontal development over 12 to 15 years.

The quality of mine construction is critically important, as repairing and retrofitting the footprint after production starts is expensive and interferes with operations. Therefore two significant drivers are

1. Time to construct, related to time-cost of money; and
2. Quality of construction, related to operating availability and effectiveness.

Because of the long lead times to cash flow and the construction costs, time to construct the development is vital to a block cave. When projects miss their plan rates of development, this seriously impacts the overall project economics.

The importance of construction quality cannot be overlooked. Lack of attention to quality is a major contributor to slow production start-ups and ongoing operational issues. Quality is much more critical to block cave operations than to other underground operations because of the costs associated with retrofitting. It is 10 times more expensive to repair after the fact than to specify fit-for-purpose during design. More importantly, as repairs are undertaken, production delays are incurred.

If ore bodies are adequately defined and designed, and constructed to perform to plan, the reliability of production will almost certainly be greatly enhanced. Reliable production requires reliable systems and, importantly, automation. The construction to plan must include the ability to develop the mine to plan.

Construction of Underground Infrastructure

Traditionally, underground development has been regarded as an ongoing operating expense. The key driver was the unit cost, and advance rates tended to be a secondary consideration. This led to a general acceptance of rates that were below par and were substantially less than those achieved in the civil industry. Real mine data show that, although equipment technology has improved, performance has deteriorated. The value of a proposed block cave mine is heavily influenced by the speed, cost, and quality of the development work to put the mine in place. Currently, in these circumstances, the key driver is the advance rate of the primary access and critical infrastructure, while unit cost, although important, is secondary.

A major portion of future copper and diamond production will be from underground mines. These block cave mines require a significant portion of all development to be completed before production can commence. As a result, future production will require many kilometers of development each year over a 15-year period.

Today within the mining industry, a single end tunnel is typically advanced at an average rate of about 5 m/d, which has decreased threefold since the 1960s. Over the same time period, equipment performance has increased fivefold and cost per meter of tunnel has increased tenfold. Conversely, the civil tunneling industry has seen a steady increase in advance rates in recent years, and this begs the question as to why mining projects achieve 5 m or less while civil projects achieve 10 m/d.

Five major reasons contribute to this variance:

1. **Knowledge:** A substantial site investigation is undertaken prior to developing any civil tunnel.
2. **Planning:** Civil tunnels are planned in detail.
3. **Face size:** Larger faces in civil tunnels usually allow multi-tasking.
4. **Resources:** Civil projects are focused on developing tunnels, and more money is spent per meter of development in order to achieve schedule.
5. **Technology:** A system approach is applied that includes different equipment than the conventional mining drill-and-blast.

Future significant step-change improvement in the rate of construction of underground infrastructure will require the following initiatives:

- Speed and quality of underground infrastructure construction, including successful implementation of new mechanized excavation technologies and shaft logistics
- Development of innovative support system for different excavation systems and ground conditions
- Reliable prediction of rock behavior to properly select and implement construction technologies
- Use of smart approaches of working with the rock mass to minimize risks and uncertainties

Output Rates

The goal in mining is to achieve planned output rates in a safe and environmentally responsible way. With moves from open-pit to underground mining as one option for extending the life of a mine, or with a preference for underground mining because of its lower environmental impact, output targets will undoubtedly be influential. While this may, at first, seem unreasonable in view of the greater technical difficulties accompanying underground mining, output maintenance may be crucial to the viability of any mine extension project. The cost of developing a high-output underground mine as an extension of an existing open-pit mine may well be lower than the cost of finding and developing a new tier 1 reserve.

As mentioned, achieving economic output rates via block caving methods provide numerous challenges. The difficulty lies in operating sufficient drawpoints to create the required muck mass and having a materials handling system capable of moving that amount of rock. Here, the development work is all related to the mine plan and the layout of the production block. For example, preliminary plans for the Grasberg block cave in Indonesia (Brannon et al. 2008) suggest that 1,100 drawpoints are required to deliver an output of 160,000 t/d.

Planning

When planning an underground mine it is important to have detailed knowledge of the ore body, the ore grade, its mineralogy, its shape and dimensions, intrusions, and contamination. Knowing how a mine will behave during mining operations is fundamental. The conversion of an open-pit mine to a block cave mine adds even greater complexity because of the potential for pit failure and the dilution effects that come with ongoing deterioration of the pit wall. In addition, the extent of the underground mine network inevitably causes higher stresses that must be considered in the mine planning to ensure a successful transition from open pit to underground. The timing of the transition is not negotiable, because caving can cause instability in a pit, so all surface mining activities must cease before ore can be taken from a block cave mine. Such timing issues are considered in plans for two major transitions to block cave mines currently being investigated, namely the Grasberg (Indonesia) and Bingham Canyon copper mines.

The technology used in block cave mines is not new. What is new is the scale of the mines now being planned, which takes the industry into uncharted territory. For this reason, the planning process for the conversion of an open-pit mine to an underground mine is measured in decades rather than years. Improved modeling of the mine would deliver immeasurable savings in development costs, but to create such models, the learning from existing large-scale projects must first be captured.

Bingham Canyon

As an example, studies of Bingham Canyon (Brobst et al. 2008) and what option to choose (open pit, underground, or closure) when the current pit mining operations finish around

2019 provide an interesting insight into the time and effort needed to ensure that all possibilities are considered and the best option is chosen. The study timeline follows.

- 1997: study commenced.
- 2006: order-of-magnitude study complete.
- 2006: prefeasibility study commenced.
- 2009: prefeasibility study for expanded open pit due for completion.
- 2013: prefeasibility for block caving methods due for completion.
- 2019: current operations due to cease.

As well, the following tests have been conducted during the studies:

- 160 km of drilling
- 500 unconfined compressive strength tests
- 500 tensile strength tests
- 300 triaxial tests
- 250 direct shear tests

In parallel with this, more than 15,000 individual structures along 44 km of exposed bench in the pit have been measured and logged. This work provides knowledge of the ore body and surrounds and enables plans to be continually refined. One can only imagine the worth of having, at the outset, more detailed underground knowledge that might be delivered via an advanced, nonintrusive sensing process.

Operations

Studies have been conducted into drifting speed (Nord 2008) and the impact of tunnel cross-sectional size and shape, shot length, and the optimum timing of support activities versus activities at the mine face. This knowledge is of great value when linked to productivity and equipment utilization objectives.

The key to the future lies, firstly, in developing sensing technologies that will provide a better picture of the subsurface structures, and, secondly, in using advanced computer modeling (a) to predict the broader impact of mining an ore body and (b) to optimize all processes to achieve planned outputs at lowest cost. Because there is only one opportunity in developing and implementing a plan, the uncertainty must be removed during the planning process as much as possible. The only certainty is that the growing global demand for minerals will stimulate changes in underground mining methods, some of which will be predictable and some will not be foreseen.

ADVANCED PROCESSING

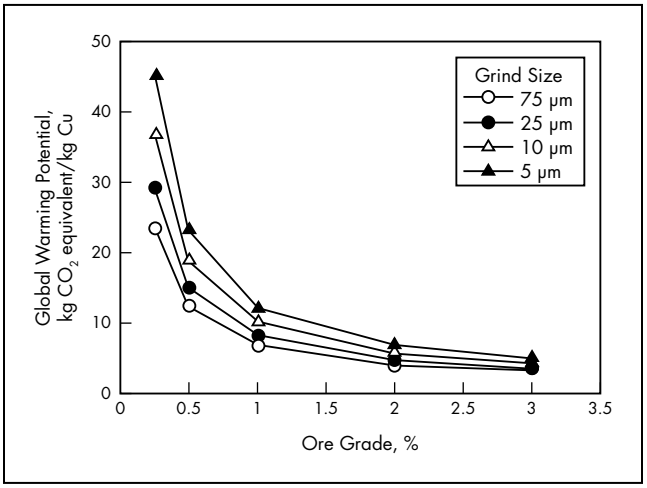
The science and practice of mineral processing have been and continue to be driven by the same internal and external pressures that have shaped other facets of the mining industry. At the forefront is strong global demand for virtually all minerals and metals, and this situation is set to continue.

Of greater relevance, given diminishing surface reserves, the industry is required to mine ever-deeper deposits and to process ores of lower quality and more complex mineralogy. This, together with increasing requirements for zero environmental emissions, reduced energy consumption, and sustainability, will require even more sophisticated processing methods.

However, underground mining is traditionally more energy intensive than surface mining. Deeper, lower-grade ore bodies will require more energy to mine and process. Larger quantities of gangue material need to be brought to the surface and then disposed. Against this background, and with higher energy costs and the need to reduce GHG emissions to combat global warming, efficiency improvements and less-energy-intensive processing technologies are essential. Automation, remote control, improved sensors, and real-time analysis will play a key role in mineral processing developments as they will in other mining operations.

Comminution and Energy Usage

Large amounts of energy are needed to crush and grind rock finely enough for subsequent separation of the minerals of interest. Comminution is the most energy-intensive activity in the current mineral concentration flow sheet, consuming around 30% to 50% of the total energy requirement. In plants required to grind a very hard ore (nominally Bond work index in the range of 15–25 kW·h/t) to finer liberation sizes, this requirement can be as high as 70% (Cohen 1983). In the broader perspective, it has been reported that comminution activities in the United States account for as much as 1.5% of U.S. total energy consumption (Charles and Gallagher 1982). In the context of typically quoted energy efficiencies of less than 5%, comminution is an obvious focus for improvement for tumbling mills that represent a majority of downstream size reduction.



Compounding this situation are industry trends toward lower ore grades, which translate into even more intense comminution processing, hence even higher energy usage to recover the same quantity of mineral. As ore grade decreases, process energy requirements rise rapidly, even for the same liberation size (Figure 1.3-2).

However, the grind size is not a static target. In an effort to increase recoveries, today's grind size target is much finer than it was 50 years ago. At one time, a grind size for lead–zinc processing of <70 μm was regarded as fine, whereas today the grind size is more likely to be <7 μm. This is due to the requirement for subsequent processing, including froth flotation, where finer sizes result in increased recovery. Therefore, despite the development of more efficient grinding mills, there has still been a significant increase in the overall energy consumption.

It may well be that high-pressure grinding rolls (HPGRs) will become a key technology for hard-rock comminution, providing high capacity at lower energy intensity. Recent results (Anguelov et al. 2008; Michael 2007) suggest that replacing semiautogenous grinding mills with HPGRs in a circuit can reduce comminution energy requirements by about 25%.

Flotation and Larger Particles

Like comminution, flotation remains a key technology in mineral processing and one that has seen steady improvements over many years. Flotation performance is highly dependent on particle size. For best performance, a particle size in the range of 20 to 100 μm is required. Poor recovery of fine particles is typically associated with entrainment, whereas poor recovery of coarse particles is associated with inertial forces that prevent the large particles from being recovered. With increasing pressure to reduce the energy and costs associated with comminution, the desire to increase the particle size in flotation increases. Research will be needed to develop improved froth flotation processes that enable these coarser

Source: Norgate and Jahanshahi 2007. © CSIRO Australia 2006.
Figure 1.3-2 Relationship between ore grade and embodied energy

particles to be separated and to ensure that metal recovery is not compromised.

The trend is toward larger flotation cells to reduce capital and operating costs associated with flotation (Outotec 2007). Cell sizes have increased from around 50 m^3 in the early 1990s to 300 m^3 in 2007, and all signs are that this trend will continue. These large cells present challenges to adequate mixing and suspension of solids. Larger cells can require higher shear rates to maintain the solids in suspension, which can exasperate recovery of coarse particles. The use of computational fluid dynamics has become an essential tool for understanding the detailed performance and for designing devices to optimize flow profiles in the cell.

Because water is becoming a scarce resource in many regions, pressure is mounting to manage this resource more carefully. This will undoubtedly serve to stimulate process development wherever water is consumed in the mining industry. One likely emerging trend will be the so-called dry processing, where water is replaced by air as the separation media. For example, the rotary air classifier has an action similar to that of a conventional wet jig and has been successfully applied to gold ore processing (Piggott 2000). Another example of dry mineral processing is the rotary classifier developed by Australia's Commonwealth Scientific and Industrial Research Organisation (CSIRO 2009).

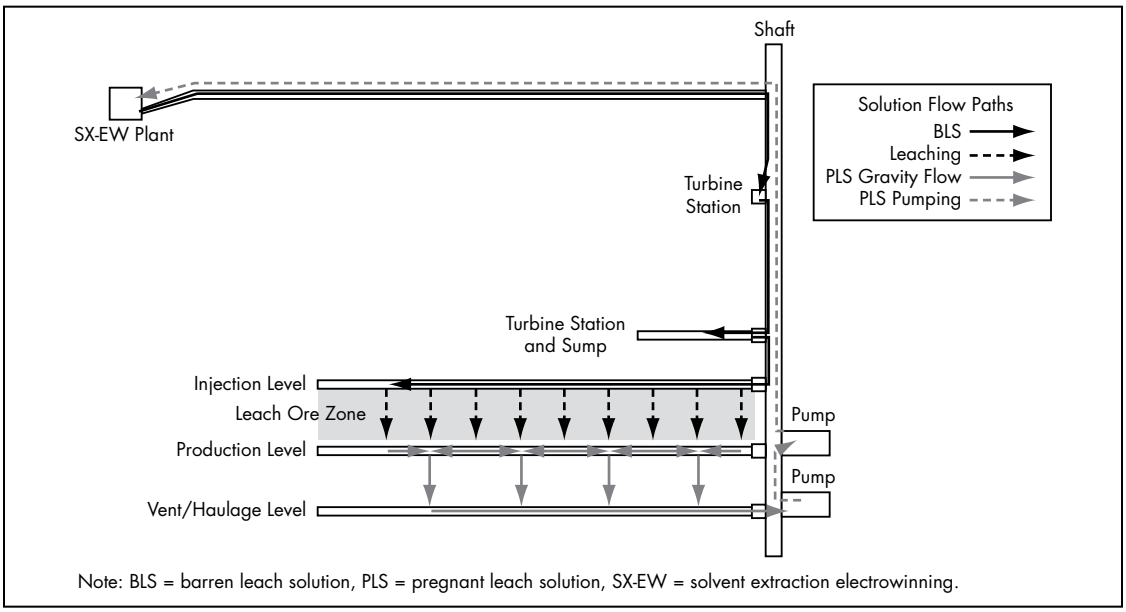
Mining and Reducing Materials Movement

Two other trends will affect mineral processing. Mechanical miners using rotating cutters have shown promise in rocks up to 200 MPa, but they produce a quite different size distribution than blasting and excavation. The use of mechanical cutters opens the possibility for sorting before final comminution, which would reduce energy usage significantly. An added benefit is that mechanical mining and excavation is more amenable to automation than conventional blasting and excavation.

New ore-sorting technologies will automatically sense and optimize conditions according to the composition of the host rock. This process will reject gangue minerals and hence significantly reduce the mass of rock required for processing to yield the same amount of product. New sorting technologies will

- Dramatically increase the ore grade before processing,
- Make low-grade ore deposits more economical to mine, and
- Reduce the comminution of gangue minerals. This will significantly reduce the energy consumption per metric ton of product and reduce quantity of tailings generated per metric ton of product, thus reducing associated environmental and community impacts.

New ore-sorting and grinding techniques in the future will enable ores to be processed underground, further reducing waste movement and potentially compounding the benefits already mentioned. Underground processing will require equipment that is smaller, lighter, and more mobile, possibly made from advanced composite materials.



Heap and In-situ Leaching

The ultimate extension of reducing material movement is to leach the ore in the host rock (in place) and not take any waste material to the surface. This technology would be applied to deep ore bodies that are initially developed for caving using fully automated methods to ensure high health and safety standards. The mineralized material is leached in place using acids or solvents chosen according to the metal to be extracted. The dissolved metals are then pumped aboveground and extracted. The acid/solvent works in a closed loop, and the system would be designed in a way that prevents escape from the mining zone. A conceptual approach to in-situ leaching is shown in Figure 1.3-3. This method is expected to have much lower capital and operating costs and use significantly less energy. It would also allow for minerals to be extracted from harder to reach places and would eliminate the need for people to enter the mine altogether, dramatically increasing operational safety.

In-situ leaching is already used to extract water-soluble salts such as sylvite and halite. The application of commercial scale in-situ leaching to sedimentary uranium deposits has also been around since the 1960s. Effectively, the in-situ leach process leaves the ore in the ground and recovers minerals by pumping a leachate solution into boreholes drilled into the deposit; the pregnant solution from the dissolved minerals is then pumped to the surface. The key to successful leaching of uranium is the identification of suitable, below-water-table sedimentary deposits in which uranium is confined in permeable rock by impermeable layers.

In the future, it is expected that the uranium industry's experience will lead to technology developments to enable extraction of other metals—for example, copper—in this way. For copper, however, the nature of deposits poses a significant target, because a key requirement is for the ore body to be permeable to the liquids used. Because porphyry copper deposits have low permeability, future challenges include economic mine development and sufficient initial fragmentation, as well as subsurface control of the leach solution.

In-situ processes could potentially deliver the highest goal: a zero environmental footprint. They would enable land close to or even under cities or in environmentally sensitive areas to be mined without any adverse impact. In the case of copper, 99% of the rock mass is left intact and only the valuable material is transported to the surface.

Source: Rio Tinto 2003.

Figure 1.3-3 In-situ leaching

Leaching technology also lends itself to the extraction of minerals from heaps that, with low head grades, have previously been seen as uneconomic to process. Purpose built, fully automated plants would allow extraction rates and yields to be optimized. Solvents would be within closed loops, and heaps monitored and managed with advanced sensor systems.

Energy Supply

Energy issues discussed more fully elsewhere in this chapter apply equally here. Low-emission energy sources must be pursued and regenerative technologies utilized where possible. Of particular relevance for deep underground mines, geothermal energy sourced in situ may be used to power all mining processes.

In summary, the growth in demand for all minerals will continue for the foreseeable future. If the industry is to keep pace with this growth, improved mineral-processing techniques must be developed in parallel with improved mining processes. This demand, together with cost, sustainability, and skills issues combine to drive toward ever larger, automated mining operations. Mineral processing will be altered by the change in scale, particularly the use of ore sorting and advanced comminution technologies. However, the growing scarcity of new high-quality surface deposits is pushing the industry toward a greater dependence on underground mining. Here, underground sorting and comminution will reduce the energy consumed in transporting waste from the mine. Alternatively, in-situ leaching will lead to the elimination of waste movement and allow extraction to occur with almost zero environmental and community footprint.

SUSTAINABILITY AND ENERGY

According to the United Nations Brundtland Commission, sustainable development "meets the needs of the present without compromising the ability of future generations to meet their own needs" and covers a diversity of issues that continue to evolve (Skinner 2008).

Good management is managing a business with an embedded sustainability culture delivered through senior management commitment and documented strategies, procedures, and goals, with benefits far outweighing the costs (Skinner 2008). These benefits include:

- Reputation,
- Access to resources,
- Access to talent, and
- Access to capital.

Mining companies must put sustainable development at the forefront of their operations and future developments. They must work closely with host countries and communities, respecting their laws and customs. It is important that the environmental effects of their activities are kept to a minimum and that local communities benefit as much as possible from these operations through employment, capacity building, personal development, and poverty reduction (Lenegan 2007). Higher local employment reduces risk to the business. The mining industry often operates in remote locations, so it makes great business sense to increase the availability of local goods and services.

Society's expectations of mining companies include reducing the footprint of activities so that habitat and species conservation is compromised as little as possible. This means leaving as much natural variety in place after operations finish as existed before (Slaney 2008). The discipline and management tools that underpin sustainable development provide a mechanism for continually increasing efficiency and productivity in the business, generating long-term returns to shareholders. It is this willingness to think in terms of economic, social, and environmental sustainability that separates us from the past and gives us a pointer to the future.

Social License to Operate

Working closely with local communities and indigenous groups to understand and respond to their concerns and

aspirations develops the social license to operate that is essential to successfully developing and managing a long-term mining operation. Mutual respect depends on our understanding the issues important to our neighbors and on our neighbors' understanding what is important to us. Wherever we operate, we must do our best to accommodate the different cultures, lifestyles, heritage, and preferences of our neighbors, particularly in areas where industrial development is little known. Our community and environmental work is closely coordinated and takes account of peoples' perceptions of the effects and consequences of our activities. Obtaining the social license to operate is a key requirement for mining companies in the future.

Acid Rock Drainage and Waste Disposal

Determining the inherent acid rock drainage (ARD) potential of solid and liquid samples will continue to gain significance in the mining industry as more complex ore bodies are discovered and more complicated processing methods are employed. The key elements for future predictive classification based on ARD will include mineralogy (i.e., characterization of acid-generating vs. acid-neutralizing minerals), mineral surface analysis (i.e., availability of reactive mineral surfaces to water and/or the atmosphere), and mitigation strategies. Trade-offs between these elements will also be relevant throughout the life of the mine.

The potential effects of ARD will impact brownfield, but possibly even more so greenfield, exploration in the future. Indeed, exploration targets with high ARD potential or likely waste treatment issues may be classed as nonprospective. For example, it is well known that tailings from sulfide mineral extraction processes are likely to have high ARD generation capacity. Deposits of this type will therefore require active management in tropical environments but less so in less reactive terrestrial settings. For future exploration targets in reactive environments to be prospective therefore, demonstration of ARD prevention through treatment and disposal or by successful containment through the application of barrier technologies will be necessary.

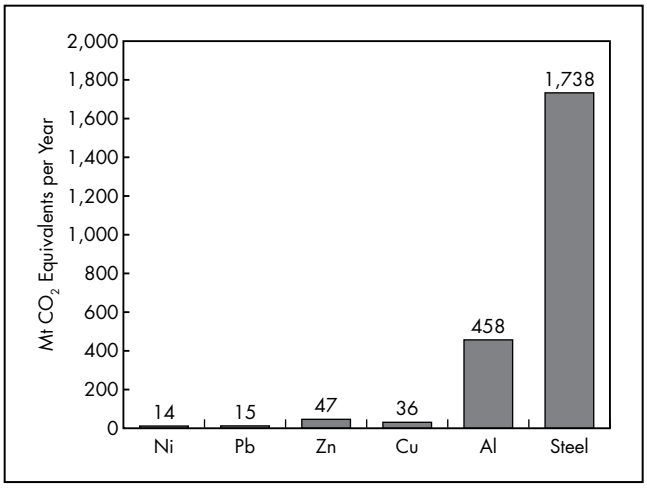
Current minerals processing methods often include fine grinding, which generates fine-grained acid-generating minerals and leads to potential ARD issues. The large amounts of tailings, albeit of low grade, that are generated by these processes are also likely to become less environmentally acceptable. These environmental concerns will make in-situ processes to reduce mining waste and contain acid-generating minerals in-ground more attractive in the future.

Clearly, there are some obvious environmental advantages of in-situ mining, including a much smaller footprint, significantly reduced amounts of waste generated during mine life, simpler closure and rehabilitation procedures, more effective water treatment, and ARD prevention. Significant challenges, however, remain for in-situ processes to become a reality—preventing leakage of the leach liquor into the groundwater and isolating the system from water ingress through the development of suitable barriers, improving geomechanics to induce fragmentation, and controlling the chemical environment at depth.

The ARD potential of metalliferous deposits opens significant challenges for managing terrestrial waste rock dumps, including long-term geotechnical stability, long-term drainage and hydrology (particularly in high-rainfall areas), locating appropriate sites to place the waste dumps, and placement methods such as riverine and marine tailings.

Product Stewardship

Rio Tinto defines product stewardship as an action program that recognizes the need to ensure that products are produced, used, and managed at end of life in a socially and environmentally responsible manner in order to support societal goals of sustainable development and commercial goals of sustainable markets. A coherent and comprehensive approach to product stewardship contains the following elements:



- **Life-cycle assessment:** using life-cycle methodologies to gain value and to understand the benefits and impacts of products along the full value chain and to explore shared responsibility beyond the production gate
- **Eco-efficiency:** ensuring that processes are as eco-efficient as possible and the mineral and metal resource is used wisely
- **Product disclosure:** disclosing information on product health and environmental effects as well as providing information on safe methods of handling and disposal
- **Customer/supplier engagement:** engaging with customers and suppliers to identify opportunities and to assess and manage risks. This knowledge can be used to better meet the needs of customers and (where the risks are justified) protect existing markets, grow sales, develop new markets, and also to leverage supply arrangements.
- **Market protection:** participating in scientific, regulatory, and political arenas to influence policy and regulation that have the potential to limit market access or restrict product uses in ways that constrain sustainable development
- **Research:** identification and filling data gaps on issues related to product and process health and environmental effects

In our changing world, new paradigms are emerging about the sale of products so that continued access to markets cannot be assumed. A timely and proactive strategy designed to address issues that threaten both our license to mine and market our new and existing products will be required. Additionally, it is evident that product stewardship will help identify and manage the safety, health, environmental, social, and economic risks and benefits of our products across the value chain (i.e., from mineral extraction to end of life).

Energy and Climate Change

Of greatest importance today is the issue of climate change and global warming, which will remain center stage for decades. Even with immediate action, it will take generations to reverse a trend that has been gathering strength since the industrial revolution. This global issue requires a decisive global response through coordinated local actions. While the developed countries must show leadership through action, there is no global solution without the participation of India and China.

Climate change will mean many things depending on the extent of global temperature rise and the extent to which the ice caps thaw, but for the mining industry, a reduction in available water and a greater incidence of extreme weather events could impact mine planning and operations.

Source: Norgate and Jahanshahi 2006. © CSIRO Australia 2006.

Figure 1.3-4 Global greenhouse gas emissions for selected metals

The activities of human beings and companies are contributing to climate change through GHG emissions, particularly carbon dioxide (CO_2) (Chiaro 2007). Most analysts predict that world energy demand will increase significantly over time and that coal will continue to be an important contributor in the energy mix, particularly as the emerging economies rely heavily on coal-fired generators. The International Energy Agency predicts that by 2030 world energy demand will increase by 66% and fossil fuels will remain the primary energy source.

Given growing energy demand, stabilizing CO_2 levels to 550 ppm in the atmosphere (to limit global temperature rise to 2°C) will require a significant reduction in GHG emissions. A "business as usual" approach to energy generation and consumption will likely result in accelerating and unsustainable levels of CO_2 in the atmosphere. Technology gaps must be filled by the development and adoption of low or zero CO_2 generation technologies and step-change improvements in energy efficiency.

Emissions from the mining, refining, and smelting of metals are a major contribution to global CO_2 emissions. Global emissions for a number of metals are shown in Figure 1.3-4 (Norgate and Jahanshahi 2006). Global trending of GHG emissions are not showing any signs of improvement, and climate-change challenges represent a significant threat to the global minerals industry. Because GHG emissions are dependent on the management of energy supply and use, energy audits are a useful tool for identifying energy-saving opportunities.

Energy Consumption in the Minerals Industry

Energy costs are a significant proportion of total cost inputs for the global mining industry. The Mining Association of Canada completed a series of mine benchmarking studies (Mining Association of Canada 2005a, 2005b) to determine the energy consumption for both surface and underground mining operations. Extracting the raw data from the Canadian studies and averaging them across mines and commodities, a general picture of energy consumption can be formed for different operations, as shown in Figure 1.3-5 (Batterham and Goodes 2007). Not surprisingly, underground mining operations are significantly more energy intensive. As surface ore deposits become more difficult to find and the requirement for more and deeper underground operations increases, energy consumption is therefore expected to increase.

A number of opportunities for reducing energy consumption are evident:

- New technologies for reducing grinding and comminution energy, switching from processes that are known to be inefficient
- More efficient conveyor and transportation systems, particularly in automated mines
- Improved ventilation systems for underground mining (totally automated underground mining operations could negate the need for any underground ventilation)
- Advances in mineral flotation and concentration
- Development of in-situ leaching processes for minimizing or eliminating the environmental footprint
- Improved on-line analysis to minimize the amount of gangue material that is processed
- Underground or in-pit sorting to reduce the amount of material moved

In addition, technologies aimed at reducing energy consumption in the production of metals, for example, iron and aluminum, will be critical.

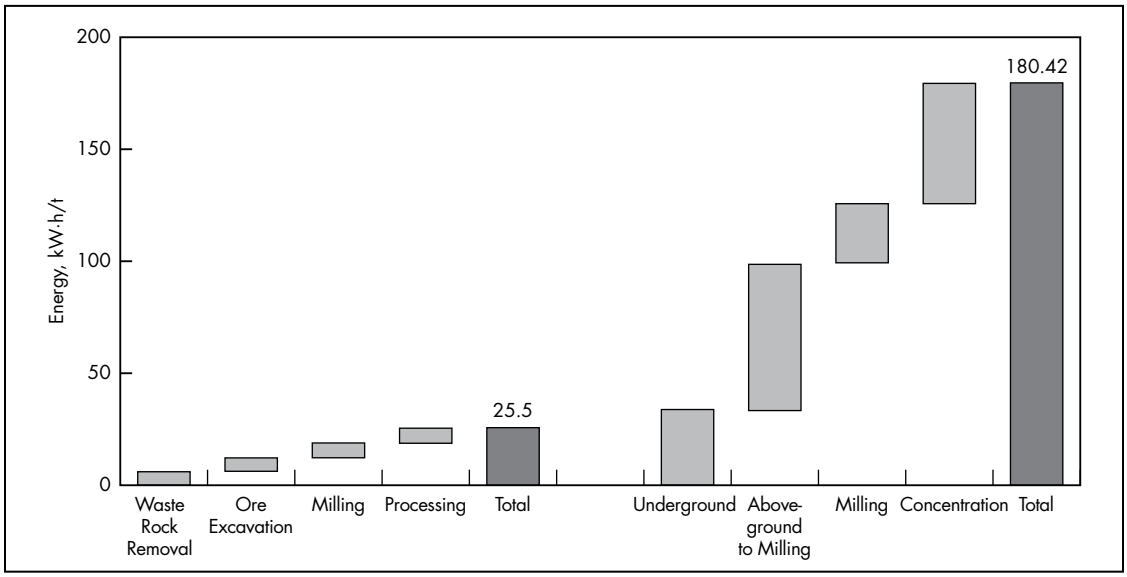
The second crucial element in reducing GHG emissions relates to electricity supply. The emissions arising from the generation of electricity need to be minimized to reduce the overall footprint. A range of carbon-free alternatives exist today and a number of advanced energy technologies for electricity generation are being developed.

Existing alternate power generation technologies include

- Nuclear,
- Wind,
- Solar,
- Solar thermal, and
- Hydroelectric.

New power generation technologies include

- "Clean coal" technology involving carbon capture (as CO_2) and storage (CCS),
- Energy from advanced biotechnology and biomass,
- Geothermal power, and
- Hydrogen-based transportation and electricity systems.



The application of these alternative energy technologies can have a significant impact on reducing GHG emissions. More remote mining operations operating on discrete electricity grids can employ a range of these energy types optimized for local circumstances. End-use technologies to improve energy efficiency and reduce energy demand must also be developed.

Examples of Emerging Energy Innovations

Many large mining companies are actively involved both in identifying and implementing short-term energy efficiency improvements and in developing step-change technologies to significantly reduce energy consumption. Both activities are critical. The following step-change energy opportunities are given as examples of industry developments.

Novel Comminution Approaches

Comminution energy efficiency is known to be low, and often less than 1% of the energy consumed goes into the breakage process. However, the understanding of comminution processes has markedly increased with recent computer

Source: Batterham and Goodes 2007.

Figure 1.3-5 Energy consumption in surface and underground mining operations

modeling. The results point to significant improvements being possible, in the order of 10%–15% energy consumption and corresponding increases in mill throughput.

One opportunity for improving energy efficiency lies in the pretreatment of the ore, with the aim of introducing microcracks into the system. The development of next-generation industrial microwave delivery systems offers a pathway to implement this approach. With these technologies, it may be possible to deliver microwaves to tonnage quantities of ore at economic rates.

HIsmelt Process

HIsmelt is a new technology developed by Rio Tinto to enable the direct smelting of fine iron ore and coal into molten iron. By avoiding the coking process, it offers significant technical and environmental advantages over existing iron-making techniques. Construction of the first 800,000-t/yr HIsmelt plant, owned by a joint venture company, was completed at Kwinana in Western Australia in 2005 and has been progressively commissioned since then. Iron ore from Western Australia and low-volatile coal are injected as fines into the molten bath of the smelt reduction vessel where they are directly smelted to molten iron.

Coal Initiatives

FutureGen is a U.S.-sponsored research project that aims to install a large gasification power station with integrated hydrogen production, carbon capture, and storage as a prototype demonstration of zero emission coal-fired technologies.

For amenable coal seams, underground coal gasification (UCG) is an energy technology likely to feature prominently in the future. By initiating and then controlling combustion autonomously within the coal seam, UCG produces a syngas (typically H_2 [hydrogen], CO_2 [carbon dioxide], CO [carbon monoxide], CH_4 [methane] and H_2S [hydrogen sulfide]-dry basis) that can be further refined aboveground to produce a relatively clean, affordable, and versatile source of energy. Although not a new concept, products from UCG compare favorably with alternatives in the context of today's more mature whole of life oriented assessment criteria, culminating in its recent rediscovery.

Clean coal initiatives are also being promoted by regionally based programs such as Coal21. This Australian-based program is a collaborative partnership between federal and state governments, the coal and electricity generation industries, the research community, and unions, that aims to promote and facilitate the demonstration, commercialization, and early uptake of clean coal technologies in Australia.

Hydrogen Energy

Hydrogen Energy is a joint venture between Rio Tinto and BP, created to further develop the hydrogen economy. Hydrogen-fueled power plants with CCS combine a number of existing technologies in a unique way to create low-carbon energy. It works by "decarbonizing" a primary fuel such as coal, oil, or natural gas. This decarbonization technique separates the hydrogen and captures the carbon from the fossil fuel as CO_2. The clean hydrogen is then burned in a specially modified gas turbine to produce clean electricity, and the CO_2 is stored securely deep underground in depleted oil and gas oil fields or natural saline formations. CCS technologies will be a key component in the fight against climate change.

Each of the component CCS technologies is proven and has been practiced within the oil and gas industries for decades. At this scale, their combination and integration is innovative, providing Hydrogen Energy with a real opportunity to generate large-scale clean electricity using existing fossil fuels.

Emissions trading is key to the development of a market-based carbon price that will help drive the lowest-cost pathway to a low-emission future. The target must be a zero net energy mine, and a technical pathway to achieve that objective can already be envisioned.

PART 2

Market Economics

CHAPTER 2.1

Economics of the Minerals Industry

Phillip C.F. Crowson

Mining is like any other economic activity in that its contribution to the gross domestic product (GDP) is measured by its value added—that is, its worth based on the sum of wages, salaries, rent, royalties, direct taxes, interest payments, and gross profits involved in producing its final products. However, its modest share of the global gross product greatly understates its importance. Like other primary industries, it produces the raw materials that form the essential basis of all other economic activities. Mineral products perform the same function for the global economy as the vitamins and trace elements in the human diet. Without their continuing supply, economic activity would gradually wither and die.

BOUNDARIES

The minerals industry embraces a wide range of different products with differing methods and structures of production and with diverse markets. Its boundaries are conventionally defined to exclude petroleum, natural gas, and water, although hard-rock mineral fuels such as coal and uranium are included. Distinctions are also drawn between mining and quarrying for sand, gravel, and construction materials, although those share the characteristics of other mineral products. The downstream boundaries of the industry are imprecise as it merges, in many instances, into processing and manufacturing industry. That is especially true of some industrial minerals, particularly those used in chemical manufacture, but it also applies to metallic minerals.

Where the division is made is largely one of convention. The production of pig iron and steel, for example, is regarded as manufacturing, so the boundary with mining is the output of iron ore. For copper the division is less clear-cut, with some mines producing copper metal on-site and others selling ores and concentrates. Conventionally primary nonferrous metals are grouped as mineral products, but their semifabricated shapes and wrought products are grouped as manufactures. That raises questions about a metal like aluminum, for which the major input is not the mineral raw material but energy.

Mines produce ores rather than finished salable products. With few exceptions, most run-of-mine output requires some degree of processing before it can be sold. In some instances that may be no more than simple washing and sorting, but, at the other extreme, complex metallurgical or chemical processing may be necessary. Mineral producers aim to maximize the profitability of their operations and will balance the costs of additional processing against any advantages gained from selling higher-value products.

DEMAND

Few mineral products are demanded for their intrinsic worth but instead for their various properties. Most are intermediate goods used as raw materials or processing aids for more finished products. The main exceptions are precious gems and precious metals in some but not all of their uses. Whereas each mineral has a specific set of properties, whether physical or chemical, few of those properties are unique to any one mineral product. End users of the finished product may be completely unaware of what minerals are used in its manufacture and are merely interested in whether the product meets their needs satisfactorily. In short, demand for minerals is derived from demand for finished products, and in many instances the minerals used account for a relatively small proportion of the product's total cost.

This derived nature of demand means that it is difficult for producers of many mineral products to differentiate their material from that of other suppliers, except concerning its inherent properties. While the properties of a specific mineral product may make it ideally suited for some end uses, most uses will normally have substitutes of varying degrees of effectiveness. The fertilizer minerals are a partial exception in that regard, because growing plants require potash, phosphate, and nitrogen in varying combinations, but even the consumption of fertilizers is dictated by the demand for agricultural products and by farmers' cost structures. Demand for mineral products is always at the mercy of fashion, of technological changes in end-use markets, of governmental regulations, and, above all, of relative prices. These characteristics are not unique to mineral products but set them apart from the general run of manufactures.

Phillip C.F. Crowson, Hon. Prof. & Professorial Research Fellow, Centre for Energy, Petroleum & Mineral Law & Policy, University of Dundee, Scotland

Substitution and Prices

That substitutes exist for most mineral products in many of their uses circumscribes their producers' market power. A marked shift in a product's relative price will impact the size of its market. Some substitution may be straightforward, as in the use of different minerals as fillers or extenders in the plastics industry, or of different materials in the manufacture of refractories. Sometimes the most effective substitutes are abstinence, as in a farmer's decision not to apply phosphate to his fields one year, or a change in processing technology, such as heat treatment to replace the addition of alloying elements. It will often involve process adaptations or investment in new technology and equipment. In those cases substitution will be spread over a period, rather than instantaneously, but when it has occurred, it is unlikely to be reversed quickly. Changes in relative prices often drive irreversible technological change.

Often demand for a specific mineral product will be affected not by changes in its own relative price but by the prices of the products in which it is incorporated or used in processing. For example, the demand for fillers and coating clays is driven by changing demands for paper, and for zinc in galvanizing by markets for steel products. Changes in end uses and in consumers' spending patterns, driven by demographic and technical change, and sometimes merely by fashion, can open up new markets for individual minerals and wipe out existing markets.

Markets for Mineral Products

Most types of economic activity, including trade and services, depend on mineral products, but their use is biased toward the goods-producing sectors. Demand for many mineral products, and for metals in particular, is heavily reliant on construction, capital goods industries, and the manufacture of vehicles and consumer durable goods. Because these markets are responsive to changes in expectations and to movements in interest rates, they are typically the most volatile segments of overall expenditure. Even where mineral products are used for processing or in goods for immediate consumption, their demand can fluctuate by far more than overall economic activity and is at the mercy of variations in work in progress and in the holding of inventories of all types throughout the production chain—from mine to final consumer. In general, therefore, demand for mineral products is more volatile than economic activity, as measured by changes in industrial production or GDP.

Demand, Incomes, and Intensity of Use

Typically an economy's demand for goods rises with per capita incomes. When these are near subsistence levels, and only the most basic needs can be satisfied, the usage of minerals per unit of output tends to be low. Initially, many of the needs for mineral products will be met by imports of finished goods rather than by domestic manufacture. As per capita incomes rise, the demand for more sophisticated products will also expand, thereby raising the economy's intensity of mineral use per unit of output. Rapidly growing demands for investment in modern infrastructure of all types will further boost the intensity of use (IU). The demand for mineral products, and especially for the building blocks of steel, cement, and construction materials, will tend to increase far more rapidly than the GDP. Eventually, the nation's basic infrastructure will be developed and individuals will devote an ever increasing proportion of their growing incomes to services of all types rather than to products. The goods that are purchased will tend to be less materials intensive than those purchased at lower levels of income. Consequently, the economy's IU of mineral product per unit of GDP will eventually peak and then fall back. Although its absolute demand for mineral products may continue growing with expanding per capita incomes, a point may be reached where even that ceases to rise and even weakens.

Smaller economies with limited populations and/or inherent geographical disadvantages may never develop their own materials-based manufacturing industries but continue to rely on imports. This means their IU of many mineral products will never rise substantially, regardless of the levels of their per capita incomes. By contrast, some economies may develop large export-oriented manufacturing capabilities so that their apparent IU not only rises rapidly but also reaches atypically high levels. Densely populated countries with limited land area will have different consumption patterns than more sparsely populated bigger countries, even at similar levels of per capita income. In short, each country's IU of mineral products depends on far more than per capita incomes alone, but those provide the main impetus for change.

The basic pattern of changing intensities over time as incomes rise can be traced in the historical experience of the mature industrial economies and is still being written in the newly industrializing and developing countries. Continuing technological change, both in products and production processes, and shifts in relative prices, especially of energy, mean that newly industrializing countries do not slavishly follow the path of their predecessors. Each country will naturally adopt the cheapest and most effective set of technological options available, which will probably, but not necessarily, be less materials intensive. Global demand reflects both the sum total of the component economies' varying patterns of IU and their GDP rates of growth. To the extent that some of the final output of the rapidly growing economies, such as China and India, is based on exports to the mature economies, their rising demands for materials will be partly at the expense of the mature economies rather than merely additional to them.

Demand, Supply, and Prices

Since production is relatively slow to react to swings in demand and tends to be more stable in the short run, supply and demand are seldom in precise balance. There is normally a dynamic equilibrium over time, with capacity moving in step with demand, but market balances can quickly veer from shortage to excess with little warning. The consequence is volatile prices for most mineral products. In some instances, a buildup or reduction of inventories can cushion the immediate impact, but many products are not amenable to large-scale stockpiling. Producers are therefore forced to reduce their output when demand falls, but they can seldom react quickly enough when demand surges. Even the mere existence of accumulated inventories can adversely affect expectations and depress prices.

Demand and Recycling

Quite apart from changes in inventories, supplies of many mineral products are not met by newly mined material. Even some of the minerals used as processing aids may be recyclable, although most are dissipated in use. Where mineral products are processed into capital goods and consumer durables they become part of the global capital stock and potentially available for recycling when the goods are scrapped. Products

used in packaging can also be recycled. The extent to which recycling supplements primary production depends on the nature of the original end uses, the lives of the finished goods, the available technology, and governmental regulation. It is also governed by the rate of demand growth. Even in mature markets, recycling alone cannot meet new demand, but its ability to satisfy part of that demand does constrain the commercial freedom of the mining industry. Much recycled material will be supplied for environmental reasons as a result of governmental regulation or fiscal incentives. Its supply is thus fairly insensitive to price, a contrast to the supply of newly mined material.

SUPPLY

Attention is normally focused on minerals supply, and in particular on its nonrenewable nature and site specificity. These are extremely important but over a rather longer time span than the immediate characteristics of supply and demand. It is often overlooked that the mining industry exists solely because there is a demand for its products rather than because ore deposits exist. Unless there are potential end uses for the products of their exploitation, ore deposits would be not much more than interesting geological phenomena.

Geographical Location

It is a truism that viable deposits of most minerals are not scattered evenly across the globe but that their geographical distribution is uneven. The lower a mineral element's crustal abundance, and the higher the concentration factor required for economic mining, the scarcer and less evenly spread geographically it becomes. In sharp contrast to manufacturing and to mineral processing, the location of mines is dictated by a combination of geology and geography. Yet the contrast can be overstated because the existence of known ore deposits does not necessarily guarantee that they will be mined. That will depend on a wide range of technical, economic, social, environmental, and political factors.

Mining is not the only type of economic activity whose location is geographically predetermined. Others include, for example, certain forms of agriculture, the generation of hydroelectric power, and even tourism. It is, however, unquestionable that mining can only occur where mineral deposits exist, often in places that are remote and inhospitable. Historically, mining was regarded in nearly all locations as having a prior claim on land use and taking precedence over alternative uses, almost regardless of where the mineral deposits were located. That is increasingly less likely today, with mining having to compete with other potential uses. This applies not just near urban centers in densely populated countries but also in populated regions where the preservation of the natural landscape may take precedence over any form of development.

All forms of mining involve some, often irreversible, disturbance to the physical landscape. When today's advanced economy countries were industrializing and needed minerals both as raw materials for industry and to create infrastructure, such disturbance was accepted as an unavoidable consequence of accessing mineral wealth. Moreover, mines tended to be relatively small and not too obtrusive on the landscape. Metallic minerals were largely extracted from underground workings, which produced limited amounts of waste. By contrast, much modern mining is carried out on a large scale, often through open-pit workings that both scar the landscape and create substantial volumes of waste rock.

Ore and Waste

The product of all mines is ore. Even where it is mined underground from rich veins or seams, its extraction will necessarily require the removal of waste rock. Historically, miners followed the often narrow veins using muscle power to extract the ore with pick and shovel, and the amount of waste was kept to an absolute minimum. With the introduction of ever more complex machinery and equipment, mines produce a greater proportion of waste. The underground workings now have to be large enough to provide access for and to accommodate modern equipment. Open-pit mines have to remove any overburden and sufficient surrounding rock to ensure the stability of the pit walls. The deeper the mine, the greater the volume of waste removed.

In most instances, the run-of-mine product requires treatment and upgrading before it can be profitably sold. Even coal may require washing. Most industrial minerals are subjected to a variety of physical or chemical processes in order to maximize their market value. Metallic ores usually contain only modest proportions of commercially valuable products whose extraction generates large amounts of tailings. Today a typical mine covers a much larger land area than it did in the 19th or early 20th century, and it alters the landscape irreversibly. That makes the mine a much less desirable neighbor than in earlier times, to the extent that local communities are often unwilling to trade the environmental and social costs for the benefits. Even so, mining of all forms accounts for a modest proportion of the earth's surface.

Depletion and Transport

The mining industry's substantial need for supplies of energy, power, and water—both in the extraction of raw ore and in its subsequent processing—partly governs its location. These requirements certainly help dictate the form in which mineral products are transported and the nature and extent of upgrading on the mine site. So too, crucially, does the availability of transport. Indeed, there has been an almost symbiotic relationship between the development of transport systems and the mining industry.

That relationship has been fostered by the main characteristic of the mining industry: its dependence on the extraction of nonrenewable resources. Individual ore deposits are strictly finite, either because they are physically bounded or because the costs of extracting the remaining ore become prohibitive. Naturally, any society will first exploit the most accessible and easily worked ore deposits. As these become worked out, it will develop technologies to extract more ore from the existing workings, whether by going deeper or by process innovations. These productivity improvements will be accompanied by a search for new ore deposits, which will probably be increasingly distant from population centers and their markets. Hence, the imperative is to improve transport links and reduce transport costs in order to enable the development of more distant mines at acceptable costs.

Mineral deposits will only be exploited if the mines based on them can profitably ship their products to the marketplace. With relatively few exceptions, mines are primarily developed with the expectation of earning profits, over and above their operators' capital costs. If they are persistently unprofitable, they will close down, even if the underlying mineral deposits are not depleted. The emphasis is on *persistently*, as explained later. The cost of transport relative to the price of the final product dictates the geographical reach of each mine's market

and strongly influences the nature and degree of processing at the mine site. Those products with high value-to-volume ratios, such as gemstones and precious metals, can be transported long distances easily and will have global markets. At the other extreme, products with high volume-to-value ratios, such as sand and gravel and construction materials, will secure only local markets. Marked reductions in the costs of deep-sea shipping since World War II have widened the geographical markets for bulk products, such as iron ore and coal, from the national to the regional and even to the global.

Where mineral deposits are located deeply inland, remote from major markets for their products, they can only compete if their products are upgraded locally in order to minimize transport costs. Such upgrading will, in turn, rely on the proximity of sufficient competitive sources of energy. Whereas Chile's copper mines are fortunate in being close to the sea, which can be used to profitably ship concentrates, those of central Africa depend on local smelting and refining to minimize the volumes being transported to ports.

Competitive Influences

A mine's ability to compete mainly depends not on relative transport costs, important though those are, but on the characteristics of its mineral deposit, on the mining method used, and on the nature of its processing plant. These inherent influences will inevitably be modified by the political, social, and economic conditions of the host countries, including such factors as wage inflation, energy costs, and exchange rates, which are outside the mining company's control. Such factors tend to be relatively more important for manufacturing industries, including mineral processing plants such as smelters and refineries, than for mines.

The nature of each ore deposit normally dominates the inherent influences on relative costs. Since few mineral deposits are identical in all respects, their costs, and hence their profitability, will tend to vary. Some will be close to ample supplies of water and energy, and easily accessible, while others will be more remote. Some may outcrop at or near the surface and be amenable to surface mining through open-cast methods, whereas others may be so deep as to require extraction through shafts or adits. The nature of the host rocks and of the minerals themselves will vary from the easily worked to the physically demanding. In some instances, the commercially valuable components may be easily liberated, whereas in others, complex physical and chemical processing may be needed. Perhaps the major factor is the grade of a deposit—the proportion of salable materials it contains. Other things being equal, which they seldom are, the higher the grade of a mineral deposit, the lower its relative costs compared with a similar but lower-grade deposit.

For many raw minerals, the average grade is less important than the extent to which a mine can maximize its output of the higher-priced types of the basic product without expensive processing. Typically the higher-value uses offer sizable premiums over the more common uses. Metallic ores are seldom pure, but they contain a variety of different elements and compounds. Obviously, the higher the content of the main metal, the more attractive the deposit, but the nature and importance of co- and by-products are also relevant. Some are highly desirable and raise the potential value of the ore, whereas others are toxic and reduce the marketability of the mine's products. Sometimes the costs of their removal and safe storage outweigh any mining benefits. Where mines yield a range of by-products, their production decisions can become complex, especially where, as is usually the case, the grades of the constituent elements vary throughout the ore body. Sometimes those decisions may appear perverse, as when maximizing profitability may involve concentrating on by-product recovery at the expense of the main product's output, irrespective of shifts in its demand and prices. This merely emphasizes that the underlying objective of mine managements is usually creating value for shareholders rather than ensuring supplies of raw materials.

Ore Grades and Exploration

The relative grades of ore of different deposits, even allowing for the contributions of all the salable products, are not necessarily reflected in the relative costs per unit of product. The higher the grade, the more a deposit is able to support deep underground mining, which usually costs far more per ton of ore than open-pit mining. Also higher grades may be able to offset the additional costs of complex treatment and processing.

In theory, the higher-grade, more easily processed, and more accessible deposits are mined first. Certainly, the average grades mined of some metallic ores such as copper have tended to decline over time, being substantially lower today than in the 19th century. The tendency toward declining grades has in many cases been countered by falling transport costs and by improvements in the technology both of extraction and processing and of exploration. The average iron content of ores mined in Western Australia and Brazil today is much higher than the typical grades of iron minerals earlier processed in most of Western Europe. The uranium deposits of Ontario exploited in the 1950s had much lower average grades than the latest generation of Canadian mines.

Ore Depletion and Technological Change

In essence, each generation will tend to exploit the best deposits of which they are aware with the technologies at their disposal. As geological knowledge increases, both through a better understanding of the nature and genesis of mineral deposits and through continued exploration with ever more sophisticated techniques, the number of known mineral deposits also rises. Some may have higher ore grades than the deposits already being worked but in many cases will suffer from offsetting disadvantages, such as remoteness from markets or poor accessibility. Simultaneously, the technology of ore extraction and processing is continuously changing and enabling the economic development of previously sterile mineral deposits. Such technological changes can be driven both by end-use requirements and by a need to remove existing constraints and bottlenecks in supply.

Over time, changes in the costs of producing mineral products result from a continuing tug of war between the cost-raising effects of ore depletion and the cost-reducing impact of technological change and rising productivity. That leaves aside such general economic influences as movements in general price levels, wage rates, energy costs, and exchange rates. The result is never a foregone conclusion. There have been periods where the forces of depletion have prevailed and inflation-adjusted costs of production have tended to rise, as in the 1950s and 1960s. There have also been lengthy periods, as in the 1980s and 1990s, where those forces have been outweighed by productivity improvements and real costs have tended to fall. That the real prices of most mineral products have not shown any marked trends over long periods suggests

that the opposing forces have been fairly evenly balanced. In that regard, however, the past is not necessarily a good guide to the future, if only because there have been wide and prolonged fluctuations around the long-term averages. While all mineral products are subject to some common influences, the historical behavior of their prices has differed widely, reflecting both their different end uses and the varying influences on the nature and locations of their production.

Capital Expenditure Requirements

The industry's requirements for capital spending vary with the location and nature of each mineral deposit. In addition to construction of the mine itself and of the associated processing plant necessary to produce a marketable product, usually an associated infrastructure is needed. This will naturally be less when the mine is situated near an established town or an existing mining district, with existing supplies of water and power and established transport links, than when located in virgin territory. Even in the former instance, existing facilities will probably need supplementing and upgrading. Although mining may not be the most capital intensive of industries, it is one of the leaders.

The lead times before a mine produces any income can be considerable, especially if full account is taken of the period from initial exploration to commercial production. Even the lead time from first discovery to a decision to invest will normally exceed a decade for a large mineral deposit. The expenses of prefeasibility and feasibility studies in fully delineating the deposit, developing a viable extraction and treatment process, and carrying out the requisite environmental assessments will normally be capitalized. Construction itself is likely to be spread over several years, and it normally takes about 2 years from start-up for a large mine to reach and sustain its design capacity. There has, however, been a near-universal tendency for the scale of mines to increase over time.

Unlike many productive enterprises, the mining industry not only has a heavy burden of capital expenditure before starting production but also large continuing needs over the life of its mines. This is an inevitable feature of the depleting nature of mineral deposits. In addition to normal capital spending on replacement equipment and maintenance, the industry has to meet the capital costs involved in extracting ore from increasing depths and more remote sections of the deposit, and in maintaining production in the face of declining ore grades. Without such continuing capital expenditure, an individual mine's output would soon tail off and decline.

So, too, replacement investment is needed in each mineral-producing sector. Although mine closures are likely to be bunched in periods of weak market conditions, some take place even when markets are buoyant. When total demand is static or even falling, new capacity is needed to offset losses from mine closures and from reductions in the output of some continuing operations. As the overall demand for most mineral products rises over time, the gross annual additions to capacity normally need to exceed the net additions—and in many instances by a substantial margin. The balance depends on the typical life and size of mines, which are a function of the nature of the underlying deposits, and on the rate of demand growth.

Additional capacity can come from expansions of existing facilities on known mineral deposits or their extensions, or from the exploitation of previously undeveloped deposits. Usually mining companies only prove sufficient ore to justify their initial capital expenditure. As mining progresses and the operators obtain a better understanding of their ore deposits' characteristics, they will often delineate additional material that can justify mine expansion. The expansion of existing mines on known ore deposits usually accounts for a substantial share of annual changes in net capacity. At one extreme, such expansions may involve no new capital spending, perhaps by the use of different explosives in the mine or a new reagent in the processing plant, while, at the other extreme, substantial capital expenditure is needed to deepen or extend the mine. A common feature is the introduction of the latest available technology, allowing improved productivity and offsetting underlying cost increases.

Economies of Scale

As mines expand and become larger, they can exploit economies of scale. The larger the mine, the more it can reduce its fixed costs per unit by spreading them over an increased output. It can justify investment in larger items of equipment, such as shovels and trucks, or in more capital-intensive mining methods than smaller mines. It can also support the mining of much-lower-grade ores than smaller operations. Indeed, it is only by operating on an ever-increasing scale that the mining industry has been able to offset the costs of extracting and processing leaner ores in more remote locations. From time immemorial there has been an inexorable trend toward more capital-intensive and larger-scale mining methods. This trend accelerated across the board from the late 1980s, resulting in reductions in the number of mines for each product and a strong rise in their average size. Open-pit mines tend to operate on a much larger scale than underground mines, and their relative expansion was favored for many years because of their ability to exploit technical economies of scale to the utmost.

That ability was enhanced by the growth of debt-based project finance in the post-war decades. Historically, the risks involved in mining inhibited companies from relying unduly on debt finance. That necessarily meant a dependence on equity markets and internally generated funds that tended to constrain companies' abilities to optimize the scale of their mines. The scope of the local market was often a further limitation when transport costs acted as a constraint. Thus mines tended to start off relatively small and expand when market conditions and finances permitted. In the past two decades, however, the availability of project finance on a large scale and the existence of a global market enabled companies to develop at a technically optimum scale from the outset.

Increasing scale is a mixed blessing. The larger the mine, especially if open pit, the greater its environmental and social impact on the surrounding neighborhood. Moreover, the larger mines' needs to minimize their fixed costs per unit of output reduce their flexibility to respond to changing market conditions. That can potentially lead to a greater volatility of prices than in markets with a larger number of smaller operations.

In practice, most mines tend to maximize their throughput during periods of low prices, often by raising the average grade of ore mined. If mining companies aim to maximize the net present value (NPV) of their ore deposits, they might logically reduce their cutoff grades when prices weaken, but their objectives are more complex. They also need to watch the profitability of their capital investment, which is different from the implied value of the mineral deposit. Corporate survival will tend to take precedence over theoretical maximization of NPV.

Closures and Cutbacks

Mines tend to remain in production as long as possible, even when prices fail to cover their costs. Experience shows that downturns do not last indefinitely, and companies hang on in the hope of improved conditions, as long as variable costs are covered and some contribution is made to fixed costs. Banks may support a loss-making mine's continued operation to ensure the eventual repayment of their loans. In many cases, the costs of closure may exceed the costs of continued production because of the need for rehabilitating the site. The continuing expenses of care and maintenance need to be taken into account. If mines are crucial contributors to the local economy, governments may be prepared to underwrite their losses to maintain a district's economic and social stability. In some cases, the mine's product may be essential for downstream operations, and the need for a continued supply of raw materials counterbalances any cash losses.

The rigidity of production in the face of falling prices is greatest in terminal markets of last resort or where the costs of stock building are low relative to the value of output. By-products have to be stored in one form or another when their market conditions weaken differentially to those of the main product. Thus the sour gas producers of Canada have periodically vatted large quantities of by-product sulfur, whose removal is essential for the sale of gas. The costs of mining and stockpiling most industrial and bulk minerals are prohibitive, and their mines will normally have to reduce their output when demand falls and prices weaken. By contrast, producers of products with terminal markets, namely the major nonferrous and precious metals, can always sell their entire output as long as they are prepared to accept the going prices. Even when users are unable or unwilling to purchase, they can place their product in warehouses.

Pricing and Barriers to Entry

The ease or difficulty of building up inventories is only one of the factors explaining the pricing of mineral products. The most important are the responsiveness of supply to changing demand and prices, and the level and nature of barriers to entry. These factors are closely intertwined. Where the barriers are high, the existing producers will enjoy some monopoly power and will be able to influence prices. In the short term, that power will be circumscribed only by the availability and effectiveness of substitutes, including recycled materials; by any countervailing power of purchasers; and by the extent to which the existing producers share similar objectives and philosophies. In the longer term, the existence of apparently attractive profits will attract new entrants, whose successful penetration of the market will depend on the causes of high barriers to entry. Where the barriers to the entry of new suppliers are low and easily surmountable, markets will tend to be competitive, with prices more closely reflecting the interplay of supply and demand.

Easily the most important constraint on new production is the availability of untapped mineral deposits. That is not just a function of a mineral's crustal abundance, vital though that is, but also depends on the number and nature of the potentially mineable deposits. The crustal abundance of platinum is slightly higher than that of gold, but the commercial deposits are few and geographically concentrated, whereas deposits of gold are much more widely dispersed. Therefore, platinum's barriers to entry are considerably higher than those of gold. Even where unexploited mineral deposits are known to exist, they may not be commercially viable with the existing technology. In some instances, the possession of proprietary technology by the existing producers sets a high hurdle for new entrants. Elsewhere the limited size of the total market and its concentration may restrict the scope for new suppliers to secure sufficient sales to justify investment.

Most of the barriers except geological shortage can eventually be surmounted or circumvented. Even that encourages exploration, which may result in the discovery of new deposits that, in some instances, may be superior in many respects to the deposits already being mined. The existence of processing constraints fosters technical research and development that often results in less expensive or more efficient processes, thereby enabling the new entrant to leapfrog over the constraint. Even the small size of an existing market is not an absolute barrier for innovative new entrants that search out and develop new uses. In order to keep prices in check, most purchasers will be keen to encourage additional suppliers. Users naturally favor a degree of excess capacity among their suppliers. Over time the role of falling transport costs in lowering the locational barriers to entry and expanding the geographical reach of markets has greatly reduced the abilities of local and regional suppliers to control their prices and market conditions.

Frequently, artificial impediments to new entrants can be as effective as technical limitations. For national markets these include subsidies and trade barriers of all types. Shielded from the full ravages of foreign competition, local suppliers can wield considerable control over their local markets. Most tariffs and similar obstacles to trade in mineral products have been eliminated or greatly reduced over the years in successive rounds of international tariff negotiations. Nevertheless, some tariff barriers still remain, mainly affecting countries that want to do more than simply extract and export their minerals without further processing. Imports of basic mineral products may be duty free, but there may be seemingly modest tariffs on downstream products, including semimanufactures. In such instances, there may be fairly heavy effective protection on the value added in the downstream products.

POLITICAL FACTORS

Trade barriers aside, most administrative and political fetters on supply are in mineral-rich rather than importing countries. Even where many known mineral deposits are awaiting development, and seemingly able to produce profitably with existing technology, their exploitation depends on a benign, or at least neutral, social, political, and economic environment. In many mineral-rich countries, the environment is anything but benign. As noted earlier, mineral enterprises commit considerable resources to developing mines over many years before commercial production starts. The prospective lives of their investments stretch many more years from start-up. At each stage, the technical and economic risks are high, with an ever-present possibility that the investment will fail. After the investor has committed resources to developing a deposit, it is a captive hostage to fortune. The company's capital is well and truly sunk, and it is impossible to transfer the investment to a more accommodating environment. Thus a mining company's bargaining power with the host country weakens considerably after its capital is invested.

This change in relative bargaining strength is not necessarily reflected in any change in the terms under which a

mine is developed. It does, however, focus exploration and mine development on countries with relatively stable political, social, legal, and economic frameworks. Where these essential preconditions are not met, many companies will tend to shun investment, no matter how geologically prospective the country. Investors in riskier countries will seek commensurately high returns and will tend to concentrate on developing mines with limited needs for expensive infrastructure and with rapid payback periods.

By no means are all the administrative and political barriers to entry confined to developing countries. For example, Australia restricted the development of new uranium mines for several decades because of opposition to nuclear power. Concern over potential environmental damage from mineral development has also led to specific prohibitions on mining in, or near to, national parks and areas of natural beauty in North America, Australia, and Western Europe.

Such environmental concerns are but a part of the strong atavistic feelings aroused by mining throughout the world. No matter that mineral deposits have little or no value until their contents are extracted by mining, there are widespread and deeply held beliefs that its rewards should accrue not to the investor but primarily to the state as the custodian of the public interest. With but a few exceptions, most mineral rights throughout the world are vested in the state. Where undeveloped mineral deposits are sold or auctioned, their prices reflect a mixture of the capital already expended in their exploration and discovery, and the expected rent accruing from their future development and exploitation.

Mineral Exploration

Like any other form of investment, mineral exploration is made in the expectation of yielding a return over and above the capital invested. Although the risks of failure are high, companies do not explore in the pursuit of average rates of return, but in the hope that they will, so to speak, hit the jackpot with a highly attractive discovery. Their return may come either from their own development of mines to exploit any discoveries or from selling the discovered deposits to other companies. Thus, guaranteed property rights that can be legally enforced are as essential for exploration as for mine development. The exploring company needs an assurance that it can profit from any discovery it makes.

Mineral Rents

The mining industry's economic contribution is measured by its value added: the sum of the rewards paid to the primary factors of production, namely land, labor, and capital. For all but the marginal producer, a proportion of the value added reflects rents accruing to the resource. In that regard, mining is like other primary industries such as agriculture and forestry where part of the annual income springs from the characteristics of the natural resources used. Rent is the difference between the value of the product and the sum of the opportunity costs of all the resources involved in making the product, including the minimum rate of return to capital required to make an investor commit funds in the first place. In the short run, it can accrue to any of the factors involved, including labor and management, but such *quasi-rents* are normally competed away in the longer term, unless there are artificially high barriers to competition for these factors. By contrast, the rent accruing to the resource reflects its inherent nature with prevailing technologies and geological knowledge.

Resource rents are only mobilized when a mineral deposit is mined. They require the application of the other production factors, notably labor and capital, before they are valorized. When undeveloped mineral deposits are sold or auctioned, those involved are making implicit assumptions about the NPV of the future rents that their exploitation will yield. Those assumptions may prove wide of the mark, whether unduly optimistic or far too cautious.

The concept of mineral rents may be straightforward, but their estimation is complex. Even where prices and demand are stable, costs and incomes will vary from one year to the next. Heavy capital expenditure is incurred before commercial production and at periodic intervals during subsequent years, and capital costs are also associated with final closure. Given the costs involved in the discovery and proving of ore, the life of the mine is unlikely to be known with certainty. Typically, companies only prove sufficient mineral content to justify their initial investment, no matter how large the underlying deposit. As mines near the end of their productive lives, their operating costs tend to rise as their grades decline and they go deeper. In practice, demand and the prices of inputs and products can fluctuate considerably, even where their underlying trend is stable. All too often it is not. For these varying reasons, the amount of rent will vary from one year to the next. That means that all incomes and expenditures should be converted to NPVs in order to ascertain a mineral deposit's rents.

This raises further complications. Should future values be discounted at the investor's opportunity cost of capital or at some other rate? In any case, what is the opportunity cost of capital? It is likely to vary among different categories of potential investor and among different countries. The minimum required rate of return will be lower for a short-lived operation requiring minimal facilities in a developed country than for a long-lived large-scale mine needing massive infrastructure in an unstable developing country. A large diversified mining company may be able to raise funds far more cheaply than a much smaller company without an established track record, but the cost of finance to governmental agencies may well be lower still. Since mineral rents ultimately arise from the nature of the underlying resource, these opportunity costs are in any case less relevant for discounting future values than the national social discount rates of the host countries. These are also likely to differ, probably being much lower in a rich advanced economy than in a poor developing country.

Rent and Depletion

No matter how future values are discounted to present values, part of the rent more properly represents the cost of the depletion of the resource rather than a genuine surplus. As such, this user cost element of the rent should naturally go to the owner of the resource, usually the state, as recompense for its exhaustion. This *user cost* is specific to nonrenewable resources, as the productivity of most agricultural land can be maintained or restored by appropriate husbandry. The precise magnitude of user costs varies from mineral to mineral and over time. Theoretically, its annual incidence should in some manner reflect the rate of net depletion of each deposit. As already noted, however, the ultimate size of most mineral deposits and the lives of the mines they support can normally be assessed only retrospectively rather than in advance.

Rent and Taxation

There is no theoretical basis for sharing among the various stakeholders any remaining rents beyond user costs. In practice, the owners of the mineral deposits, usually the state, make strong claims for retaining the lion's share through taxation. That presupposes that the potential rents of each deposit are not captured by purchasers of mineral products through prices that fail to cover full costs or are prematurely wiped out by new entrants or technological developments. Changes in geological knowledge, in mining and processing technology, and in end uses can affect the inherent profitability of operating mines and even lead to their early closure before they have extracted the full potential of their mineral deposits. In such instances, some of the potential rent will remain sterilized.

That mineral rents are both unpredictable and unstable and can only properly be assessed retrospectively make them an unsatisfactory basis for taxation. Governments want and need some degree of certainty in their fiscal receipts. Typically, royalties that are linked in some manner to output provide such certainty and are relatively easy to compute. That is a further advantage for many host nations that have limited administrative capacity and shortages of skilled labor. Companies are liable to pay such royalties as long as they produce, even when they make no profits, so that governments are guaranteed an income. Ad valorem percentage royalties based on turnover are more flexible than fixed royalties based solely on volumes of production. The great disadvantage of any output-related royalty, no matter how it is calculated, is that it is a fixed cost and consequently raises the economic cutoff grade for mining, potentially sterilizing marginal parts of a mineral deposit that might be extracted and processed in its absence. Nonetheless, governments regard that as a price worth paying for royalties that typically average in the 1%–3% range. Higher royalty rates are often applied to precious metals and gemstones. In all cases they are seen as payments to the owners of the resource and may be conceptually regarded as covering user costs.

Most governments also levy income taxes of varying coverage and complexity. Attitudes to appropriate rates and allowances change over the course of the economic cycle with shifts in product prices and profitability. During the 1980s and 1990s, there was a tendency for the overall tax burden on mining projects to fall. Competition between putative host countries to attract new investment led to a narrow range of tax incidence. Those countries with tax burdens significantly above the prevailing norm were considered unlikely to capture foreign investors. In reality, tax is only one factor among many in influencing investment decisions and is by no means the most important. The boom of the mid-2000s caused host nations to reassess their tax regimes and to seek additional revenues. Some countries raised or imposed royalties and others reexamined their income/profits taxes in order to capture greater shares of increased profits. The sharp drop in the prices of many minerals in the second half of 2008 demonstrated the volatility of the industry's profits and that host countries were chasing an elusive moving target.

Mining and Economic Management

Volatile and unpredictable earnings because of fluctuating demand and prices can be readily absorbed by a broad-based and widely diversified economy, even if the local impact may be great. They are much less manageable for developing countries with few or no alternative sources of income and employment. The problems of economic management for such countries were compounded when mineral prices appeared to be on a long-term declining trend in real terms. They were then faced with falling terms of trade so that it became progressively harder to earn sufficient foreign exchange to finance imports. Although the mid-2000s' boom apparently disrupted previous trends, it might be premature to announce their death.

For many economies, the start-up of new mining projects can cause sudden spurts in incomes, employment, and foreign exchange earnings. This lumpiness accentuates the problems caused by the underlying volatility of most sectors of the minerals industry. Unless it is appropriately managed, a surge in activity arising from new mine development can unbalance the host economy. The effects tend to be much more pronounced in the oil and gas sector than in nonfuel minerals, but they are nonetheless observable. A strong rise in exports affects the balance of payments and tends to cause the currency to appreciate. At the time, resources, especially labor, are attracted away from their existing uses into the newly expanded mining sector, and costs are bid up. The competitiveness of the existing sectors declines, leading to reduced sales and rising unemployment, so that booming mineral exports are accompanied by a shrinking economic base in the rest of the economy. These are the symptoms of *Dutch disease*, named after the experiences of the Netherlands following large natural gas discoveries in the 1960s. It is not an inevitable accompaniment of mineral development and can be countered by the host government taking timely and appropriate budgetary and fiscal action.

Institutional Capacity and Mining

Unfortunately, some host countries lack the necessary institutional capacity and administrative competence to adopt and pursue appropriate fiscal policies. Nor are they always capable of installing and operating systems for offsetting volatile tax receipts. Such systems include stabilization funds that receive all mineral tax revenues as they are earned but only release them for government spending over a period based on an estimate of likely average earnings over the business cycle. Effective stabilization funds can insulate governmental spending from extreme fluctuations in tax receipts, but they are not a universal panacea. Aside from the inherent difficulties involved in assessing future trend prices and revenues are the problems of ensuring the independence of a fund's management and operations from political and bureaucratic interference. Those are issues for mature democracies, let alone for most developing countries.

Geology knows few (if any) political or social boundaries, and mineral deposits are often located in unstable countries riven by tribal and social tensions. That their exploitation might finance civil wars, exacerbate preexisting tensions, or involve corruption is not the fault of mining in and of itself. With proper management, mineral wealth can be used to ensure economic and social development and eliminate such tensions. All too often, however, powerful interest groups seek to capture the potential benefits of mineral development for their own ends rather than for the national good. At the extreme, such rent-seeking behavior might become kleptocracy by the ruling elite.

When the obvious environmental impacts of mineral development, no matter how well and sensitively those are managed, are added to its potential adverse economic and social consequences in poorly managed countries, it is understandable that the mining industry's critics talk in terms of an

inevitable resource curse. In many instances, however, host countries have few, if any, alternative sources of potential wealth creation. They lack the luxury of choosing between mining and other economic activities. Furthermore, weak institutions and poor governance are the major causes of most of the ills that have been ascribed to dependence on mineral development. The appropriate response is to tackle those issues directly rather than abjure mining on the grounds that it might make them worse rather than help solve them.

Resource Depletion and Sustainability

Regardless of the effectiveness and competence of host governments, all mineral-rich countries have to cope with the consequences of reserve depletion. No matter how extensive a country's mineral deposits, they will eventually be exhausted. In this narrow sense, mining is not sustainable. Often the minerals extracted will have been exported rather than retained within the country and hence will not be potentially available for recycling locally. Unless new discoveries and technological developments unlock additional mineral resources, alternative means of wealth creation will be required to maintain existing living standards, let alone meet the rising needs of an expanding population. Investment of some of the proceeds of today's mining in other means of generating wealth may be economically and socially desirable, but the imperative of satisfying immediate needs may be difficult to resist, even in well-governed nations. In weakly governed states they may be irresistible.

Historically, mining has often provided the springboard for sustained economic development, both through its requirements for infrastructure, its demands for goods and services, and downstream linkages into further processing. As well as their direct employment and purchases, mining developments can create indirect demands from their workers and suppliers. The size of such multiplier effects depends on the location and nature of the initial projects, and on the extent to which those of the mine itself or all the facilities associated with the project are taken into account. Often the main, indirect benefits may be realized far from the mine itself and for many countries and regions may indeed leak overseas. Similarly, there may be little prospect of economic downstream processing in many countries that lack appropriate infrastructure or suitable labor. Compared with earlier times, changes in communications and technology have greatly reduced the potential for local multiplier effects.

Even in advanced countries, mine closures raise economic and social problems. There is a perennial debate between those who would create alternative employment opportunities near worked-out mines and those who would completely abandon remote mine-based settlements and move their inhabitants elsewhere. If alternatives can flourish without artificial support such as subsidies, the former may be the more sustainable approach. In other cases, it is best to tackle the social dislocations involved head on and accept that townships orphaned by mine closures are unlikely to be sustainable.

The paradox is that mineral development mobilizes wealth by using up the potential wealth inherent in natural resources. Provided that some of the wealth thus mobilized is reinvested in providing for future needs, then mining makes a proper contribution to sustainable development. An unexploited mineral deposit is completely sterile, making no contribution toward meeting either present or future needs. There is never any guarantee that its contents will be needed in the future.

CHAPTER 2.2

Pricing and Trading in Metals and Minerals

David Humphreys

PROJECT PRICE ASSUMPTIONS

When assessing the feasibility of developing a mining project, assumptions need to be made about the price which the product to be mined will bring when it is sold. Indeed, it is often the case that the price of the product has a bigger influence on the outcome of the assessment than any other single variable. Because forecasting prices is not a simple matter, this is a challenge. Commodity prices are subject to significant short-term volatility as well as longer-term cycles. Moreover, the challenge is compounded by the fact that the mine undergoing evaluation may have an expected life of 20 or more years and may not be scheduled to come into production for several years ahead.

Nevertheless, in order for the feasibility of project development to be determined, a view has to be taken on the likely price of the product over the project's life. This central case assumption will be the expected annual average price to be achieved for the mined product during each year of the project's life. No less important, those responsible for setting the price assumptions will need to understand the risks inherent in price forecasting and properly assess the range of possible price outcomes around their central case assumption in order to determine whether the project can live with the price risk it faces. This might be done by examining past patterns of price volatility and the length of previous price cycles.

Failure to do such a risk analysis potentially means committing to a project that comes on stream at a point in the cycle where it cannot cover its operating costs or that it never achieves a return for the investor. At the same time, it needs to be borne in mind that a policy of being overly conservative with one's price assumptions brings with it a contrary risk—that of missing out on a viable business opportunity. Therefore, to do their job, price assumptions for mining projects have to balance both upside and downside risks.

UNITS OF MEASUREMENT

Considerable care needs to be exercised when working with metal and mineral prices to ensure that the units for pricing have been correctly specified and apply to the product to be produced. Prices are generally set according to a unit weight of product, although for some commodities other considerations such as purity play a part. Gem diamonds are famously priced according to the four "C's"—carat, clarity, color, and cut. Talc prices take account of whiteness and grain size, while prices of coal consider calorific content and the quantity of ash present.

Prices for metals are commonly set according to the weight of a standard unit of refined product. Increasingly, the International System of Units (SI) is employed, with the metric ton (t), the kilogram (kg), and the gram (g) as key units of measurement. However, for reasons of industry convention as well as history, the use of SI continues to live alongside other older systems of measurement, such as U.S. or imperial. Since much of the world quotes metal prices in terms of U.S. dollars per metric ton, the use of U.S. dollars or U.S. cents per pound is widely used, particularly in North America. (For purposes of conversion, 2,204.622 lb = 1 metric ton.) Also in North America, one still encounters the use of the 2,000-lb short ton. Prices of precious metals are universally quoted in terms of troy ounces (oz), 1 troy oz equating to 31.1042 g.

Moving away from refined metals, things become rather more complicated. Metal concentrates and other intermediate metallurgical products, such as copper–nickel matte, are typically priced on the basis of the weight of recoverable metal they contain, with premiums earned for recoverable by-products such as gold and discounts imposed for unwanted impurities such as arsenic. Some mineral raw materials are priced according to the metal compounds they contain rather than the metallic element alone. Thus, chrome ore is typically priced according to its Cr_2O_3 (chromium oxide) content while bauxite is priced on, among other things, its Al_2O_3 (aluminum oxide) content. The pricing of iron ore is based on the weight of contained Fe. However, because these ores often contain significant amounts of water, which the buyer does not want to pay for, prices of iron ore are typically quoted on a dewatered basis in dry metric tons (dmt) or dry metric ton units (a dry metric ton unit representing one hundredth of a dry metric ton).

Because transport costs are an important component in the pricing of these bulkier, less-processed products, their prices often include reference to where the price has been

David Humphreys, Independent Consultant, Former Chief Economist at Rio Tinto & Norilsk Nickel, London, UK

established. Thus products quoted "FOB" (free on board) represent the price of a product delivered on board a ship. The cost of transport and insurance beyond this point is the responsibility of the buyer. By contrast, prices quoted "CIF" include the cost, insurance, and freight to the destination port. Prices quoted "EXW" (ex-works) signify that all costs for transport and insurance beyond the seller's gate must be met by the buyer. Occasionally, prices are quoted for a specific geographic location, usually a major port such as Rotterdam or Vancouver.

The pricing of industrial minerals represents another level of complexity because these are commonly valued as much for their physical and chemical properties as for the elements they contain. Minerals such as bauxite, magnesite, and zircon used for refractory purposes are valued and priced according to their heat-resisting qualities. Minerals used as fillers and coaters in the manufacture of paper, paints, and plastics, such as talc, titanium dioxide, kaolin, and calcium carbonates, are valued and priced according to their brightness, whiteness, and qualities as an opacifier, among other things. The fertilizer minerals, which include potash and phosphate rock, are closer to metals in that they are priced according to the elements they contain that contribute to plant growth, namely phosphorus, potassium, or nitrogen. Some industrial minerals are priced according to the form in which they are to be delivered, for example, bagged or bulk.

Because of this relative complexity and the lesser transparency of the markets for industrial minerals, the business of determining likely prices for these commodities generally involves a great deal more detailed market research, including talking to potential customers, than is the case with metals. Reference prices for industrial minerals quoted in trade journals may not be directly applicable to the particular specification of the product that the project being evaluated is going to produce, and assuming that they are could prove costly.

PRICES AND INFLATION

Several other issues must be addressed when setting the prices of mineral commodities for project evaluation. The first is the awkward fact that while physical units of measurement do not vary over time, the value of money does. Thus its use in establishing prices means that one is in effect employing a variable yardstick.

The terms used to describe changes in the value of money are *inflation* and *deflation*. Inflation signifies that the value of money in a country is declining. A 10% rate of inflation effectively signifies that money is losing a tenth of its value every year and, by implication, that one needs 10% more of it to buy a given quantity of any commodity. Conversely, deflation signifies that the value of money is increasing over time.

Inflation has been the most common experience of the global economy during the course of the last half century, although prior to this there were extended periods of deflation. In more recent times, Japan experienced deflation for many years following the bursting of its bubble economy in 1989. Since 1970, inflation in the United States, under the broadest definition of the term, has averaged around 4% a year. However, there have been some extreme cases, such as in Brazil at the start of the 1990s or Zimbabwe in the 2000s, when the rate of inflation has run at thousands, or indeed millions, of percent a year.

Market prices are what customers have to pay for a commodity on the basis of prevailing money values. Prices quoted on this basis are thus referred to as prices in money of the day or prices in current money terms. Another label sometimes applied is *nominal terms* (implying the pricing terms named). Investors, however, are generally interested in the real returns they stand to get for their investment, which is to say, returns after the effects of inflation or deflation have been taken into account. It is simply not attractive for an investor to receive a nominal 10% return on his or her investment in a year when the value of money has declined by 20%.

For this reason it is common for feasibility studies to be conducted in real or constant money terms, with the effects of inflation or deflation taken out, and all cash flows into and out of a project brought back to current money values. This is achieved by adjusting nominal prices and costs by a general index of inflation, such as the consumer price index, the producer price index, or (the broadest index of all) the gross domestic product (GDP) deflator.

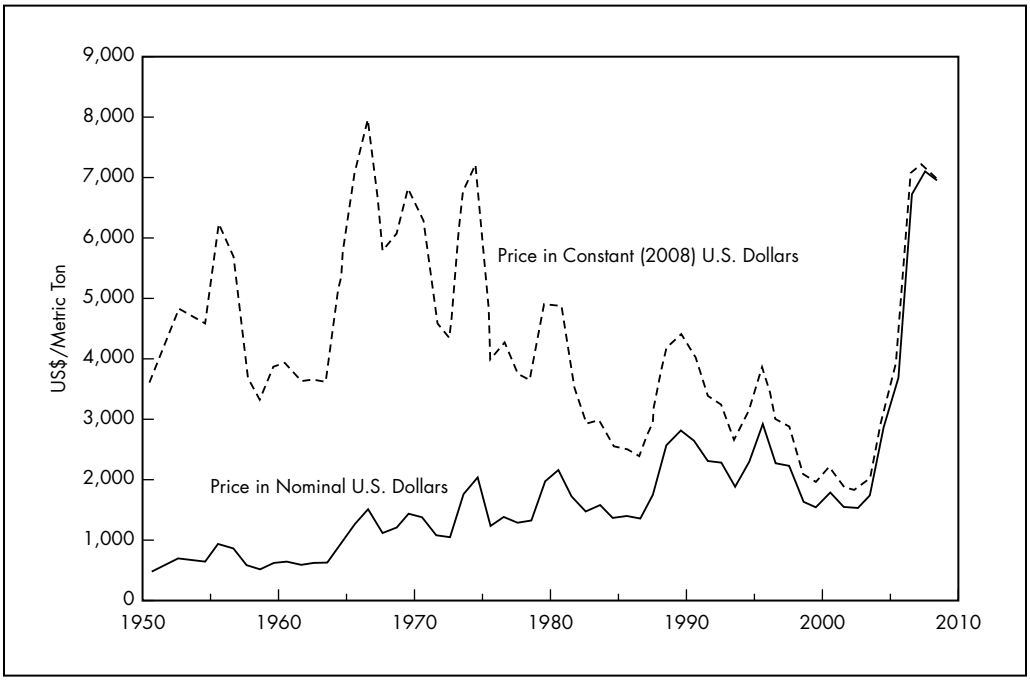

Figure 2.2-1 shows the trend in the price of copper on the London Metal Exchange (LME), quoted in nominal dollar terms between 1950 and 2008. It also shows the effects of applying to these nominal prices the U.S. GDP deflator to produce a constant dollar price series. The dollars used for this conversion are 2008 U.S. dollars. As is apparent, the trends described by these two price series over the years since 1950 are dramatically different.

PRICES AND EXCHANGE RATES

The second issue to be addressed is the currency in which the commodity price is to be quoted. Most internationally traded commodities are conventionally quoted in U.S. dollars. This was not always the case. In fact, it was only in 1992 that the LME, the world's largest metal exchange, went fully over to the dollar. Up to that point, contracts had been traded in a mixture of U.S. dollars and pounds sterling.

Commodities that are not much traded internationally—for example, bulk low-value minerals such as construction aggregates—will more generally be quoted in the currency of the producing country. The principle also applies where a market has a strong regional component. Thus, mineral sands containing titanium and zirconium are often quoted in Australian dollars, barite used as drilling mud in the North Sea oil industry is quoted in pounds sterling, asbestos ex-mine from Canada is quoted in Canadian dollars, and magnesite from Greece is quoted in euros.

For projects in the United States, the use of the U.S. dollar as the basis for pricing commodities poses relatively few problems because mining companies will typically be assessing their costs and prices using the same currency. For projects outside the United States, however, where costs may be largely incurred in another currency, dollar-based price forecasts need to be made in association with explicit assumptions about the exchange rate between that currency and the U.S. dollar. This is partly because in global commodity markets, price levels are a product of the interplay of the currency exchange rates of producing and consuming countries, just as they are a function of supply and demand. (See section on "Prices in the Near Term.") However, more importantly in a practical context, it is because exchange rate movements can have important implications for project revenues—and thus margins—in local currency terms at any given U.S. dollar price.

Source: Data from LME 2009 and BEA 2009 (for U.S. GDP deflator).

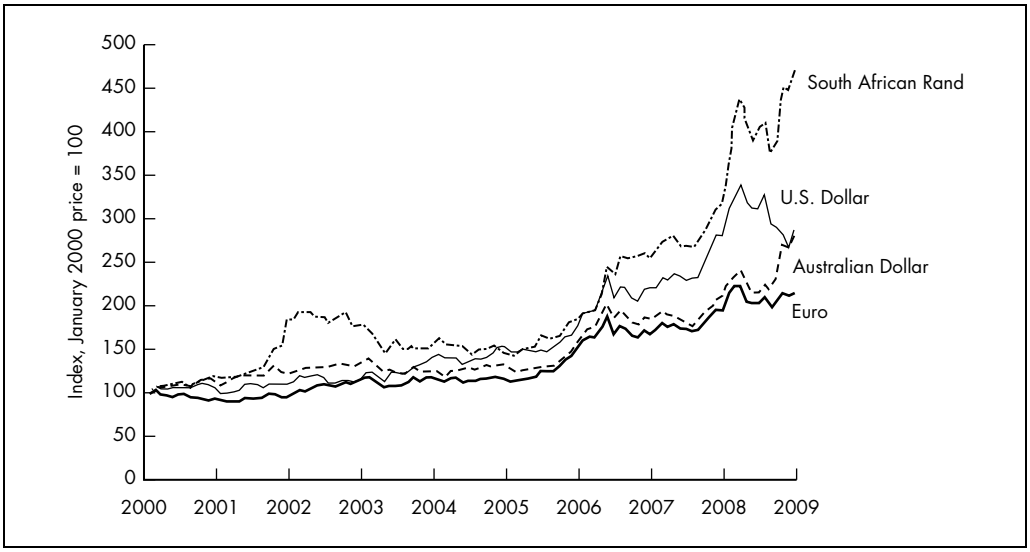
Figure 2.2-1 LME copper price, 1950–2008, in nominal and constant dollar terms

Consider what happens when the currency of the country in which a project is located declines in value against the U.S. dollar. In effect, the cost of production in dollar terms declines or (effectively the same thing) the revenues in local currency terms increase. Either way, the project margins improve. By the same token, if the currency of the country in which a project is located increases in value against the U.S. dollar, the cost of production in dollar terms also increases (the revenues in local currency terms decline). Understanding the interplay between prices and exchange rates can therefore be crucial to the assessment of a project.

The point can be illustrated by looking at what has happened to gold prices quoted in different currencies. Setting the U.S. dollar price of gold at an index of 100 in January 2000, one can see from Figure 2.2-2 that the price by the end of 2008 had risen almost 200%. By contrast, the price of gold quoted in euros had increased only 100%. Australia and South Africa, two important gold-producing countries, show rather different trends. While the price of gold in South African rand increased some 370% over the period, the price of gold quoted in Australian dollars increased only half this amount, implying, all other things being equal, that Australian producers felt the benefit of rising gold prices rather less than those in South Africa.

In reality, of course, other things are seldom equal. For one thing, exchange rates between currencies partly reflect differences in the rates of inflation in the countries concerned. Thus, if the weakening of a currency against the U.S. dollar solely reflects the fact that the country using that currency is experiencing a higher rate of domestic price inflation than is the United States, it may not be the case that a fall in the value of the currency signifies that the dollar costs of production are declining at all. For another, in countries where the export of a mined product is a major component of its total exports, there is likely to be a strong interrelationship between the price of the product and the country's exchange rate. This is the case, for example, with the copper price and the exchange rates of Zambia and Chile.

These are not easy issues to deal with, but analysts evaluating projects need to recognize their importance and address them explicitly when determining prices for projects. Because exchange rates are an integral part of the pricing equation, feasibility studies can be as easily flawed by a failure to understand the interplay between prices and exchange rates as they can by choosing the wrong price.



WHAT DETERMINES PRICE

Subject to the nature of the project being assessed and when it is expected to generate revenues, assumptions will need to be made about both near-term product prices—that is, prices over the next 3 to 5 years; and prices over the longer term—those beyond this period.

Prices in the Near Term

The volatility of metal and mineral prices makes assessments of the expected future level of a mineral product's price in the near term somewhat challenging. How important this is depends on the status of the mineral project being evaluated. For a start-up mining project, which is not due in production for several years, it is obviously not so important. But in the evaluation of a merger and acquisition target, where the cash flows from the acquisition over the next few years are expected to contribute to funding its purchase, it may be absolutely critical.

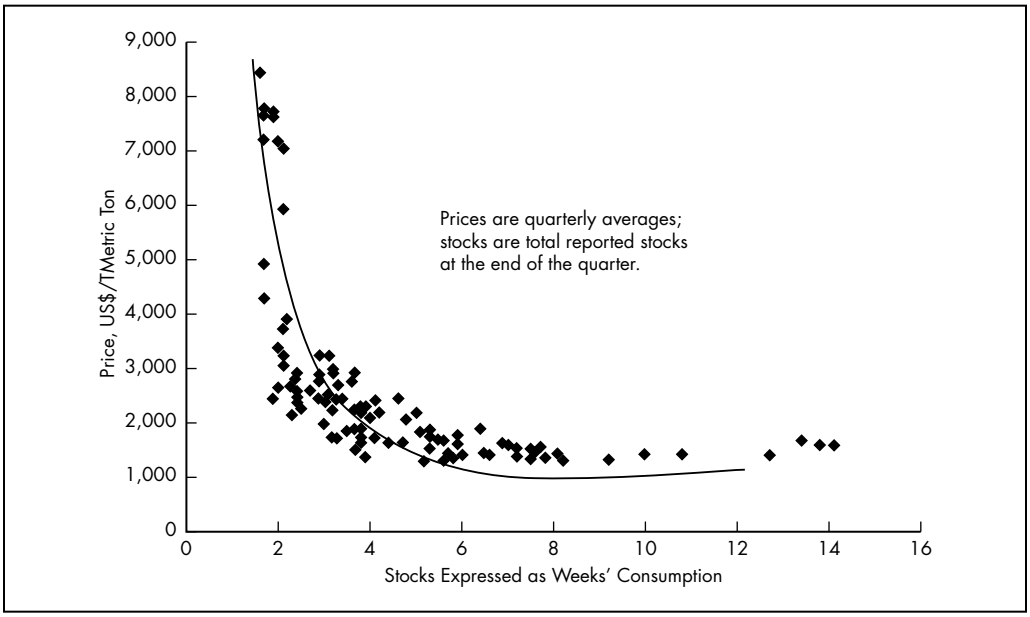
There are broadly two approaches to forecasting prices in the near term, commonly referred to as technical and fundamental. Technical analysis focuses exclusively on the price variable itself and on price behavior. It is based on the proposition that prices tend to follow identifiable patterns, which, if one analyzes price history sufficiently rigorously, can be

Source: Data from World Gold Council 2009.

Figure 2.2-2 Gold price in different currencies, 2000–2009

used to predict how prices will behave in the future. Technical analysis originated in the close observation of price charts—for which reason technical analysts are often still referred to as chartists—but today tends to be more computer based. The relatively short time scales over which this approach has the power to forecast (typically measured in weeks or even days) makes it popular among traders and speculators but rather less relevant to mining companies, which tend to think in years rather than in weeks or months. Such companies will generally favor a fundamental approach to price forecasting—that is, one focused on prospective developments in supply and demand for the mineral product concerned.

Because the demand for mineral commodities is driven by developments in the broader economy, an assessment of the economic growth environment is typically the starting point for demand analysis. However, because different minerals are used in different sectors of the economy, the structure of economic growth can be important, too. Metals such as steel, copper, and aluminum have a heavy concentration of use in investment goods such as buildings and machinery and in big-ticket consumer items like cars and refrigerators, which tend to be quite cyclical. This explains why demand for these metals tends to be more volatile than economic activity overall. Other mineral products such as titanium dioxide, which is extensively used in paper, plastics, and paints, have their principal applications in lower-value consumer goods, and therefore their demand tends to be more stable. Regional factors can also be important. China's rapid economic growth in recent years has had a huge impact on the global demand for mineral commodities.



On the face of it, supply ought to be easier to forecast because companies often make public their production plans, while the length of time it takes to construct new capacity means that production changes are usually signaled well in advance. In practice, however, producers' plans get disrupted as a result of geological discontinuities, mining problems such as pit wall failures, equipment breakdowns, labor disputes, and power shortages. Because undershooting production targets is fairly common, analysts will often factor in a disruption allowance to their projections of future supply. However, the scale of such losses can vary substantially from year to year. Moreover, production sometimes actually exceeds plans, particularly during cyclical downturns when producers are able to bring forward development projects or are boosting their productivity to reduce unit costs of production.

The idea here is that balances derived from such supply–demand analysis should provide guidance on whether markets are likely to be in surplus or deficit in the next few years and whether prices are therefore likely to fall or to rise over this period. Combined with information on existing stock levels (an indicator that market analysts watch closely), supply–demand analysis should give an idea of the scale of likely future market imbalances and thus the possible extent of price movements.

Some modest science can be brought to the exercise by plotting past imbalances against prices in a so-called pinch point chart, using the resulting relationships to predict likely future prices. Such a chart, plotting quarterly copper prices against quarterly reported copper stocks expressed in terms of weeks of consumption for the period 1983–2008, is shown in Figure 2.2-3. Indeed, one can go further and combine these prospective market imbalances (or the stock changes implied by them) into a statistical model along with indicators of economic activity, such as industrial production and the strength of the currency in which the price is quoted, to capture other price drivers, to get a still more precise fix on likely future prices.

Unfortunately, projections of prices flowing from these models are only as good as the forecast data on which they are based and, regrettably, these are generally not very good. Moreover, one has little prospect of being able to incorporate extraneous factors affecting prices into such models, such as unanticipated economic or political shocks and investor sentiment.

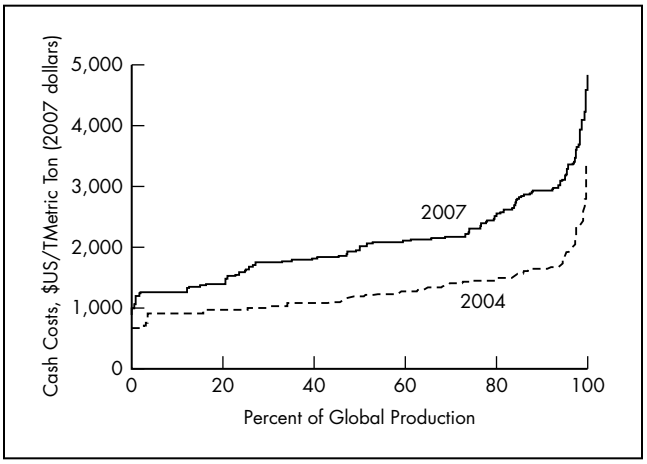
It is one of the characteristics of metal markets that they often attract significant interest from investors, in addition to those engaged in the physical trade. These investors include hedge funds, technical traders, the proprietary trading desks of investment banks, and commodity index funds. These last are funds designed to give commodity price exposure to the likes of pension funds and insurance companies, either because they believe that commodity prices are likely to go up in the

Source: Data from LME 2008 and Brook Hunt 2008.

Figure 2.2-3 Copper price and stocks, 1983–2008

future or else (and more commonly) because they believe that returns from commodity investments are inversely correlated with those from securities and bonds and thus are likely to hold them for portfolio diversification.

Quite where the line should be drawn between investors and speculators is far from obvious, since both are essentially in the business of trying to make a profit by buying and selling metals in anticipation of future price movements. Typically, investors are deemed to have a positive influence on the process of price formation because, by acting as counterparties in deals involving trade participants, they provide liquidity to the market and accept price risk. Speculators, by contrast, tend to be viewed much more negatively on the grounds that their buying and selling creates self-reinforcing upward and downward price spirals and drives prices to extremes that are unwarranted by market fundamentals.



In the absence of any objective and reliable means of distinguishing between these sets of actors, the application of the terms *investor* and *speculator* often comes down to a question of the commentator's preconceptions or the underlying conditions of the markets in which the investors and speculators happen to be operating. The matter is not, however, entirely academic. The sharp and sustained increase in prices, which began for many metals in 2005, coincided with a large increase in investor/speculative interest in metals, which produced large profits for the mining sector but also led to substitution and demand destruction for some metals. In practice, while the involvement of nontrade players can undoubtedly be an important influence on prices in the short term, most economists would take the view that over the long term—which is to say, over the life of a mine—the effect of investor and speculator behavior tends to balance out, making their net influence relatively marginal.

Prices in the Long Term

While assessments of supply and demand are a useful price forecasting tool for 3 to 5 years into the future, mining investments typically span several commodity cycles and therefore need to be based on prices that stretch well beyond the horizon of a single cycle, perhaps to 20 or 30 years. The longer-run prices used for this purpose need to be grounded in the underlying economic realities of the minerals industry and the assumption of a balanced market (because, by definition, in the long run, markets must balance). Because such underlying economic realities change only slowly with time, long-run prices for project analysis will typically be assumed either to be flat in real terms or else to trend gently—which is to say, they will not incorporate any assumptions about economic cycles.

There is no single or simple way of evaluating these longer-run economic realities, and the approach used needs to be adapted to the characteristics of the commodity under analysis. However, for many commodities, including most of the major nonferrous metals, long-run price forecasting is commonly based on an analysis of production costs. The primary tool for the analysis of production costs is the industry cost curve. This is essentially a compilation of production costs for all the producers in an industry, ordered from lowest to highest cost, and organized to create what is in effect a proxy for the industry supply curve. (It is not strictly a supply curve because the basic unit of supply used in the construction of the curve is a producer rather than a single unit of output.) As an example, cash cost curves for copper in 2004 and 2007, both of them expressed in 2007 U.S. dollar terms, are shown in Figure 2.2-4. By convention, revenues from by-products recovered from a mine are treated as negative costs.

The construction of cost curves is extremely data intensive, requiring as it does detailed information on the costs of every mining operation worldwide. Such information can be assembled from published financial statements, where these exist, or else can be generated using technical engineering models of individual operations together with generic assumptions about the costs of inputs, such as power, labor, flocculants, and parts. In practice, because of the extent of these data

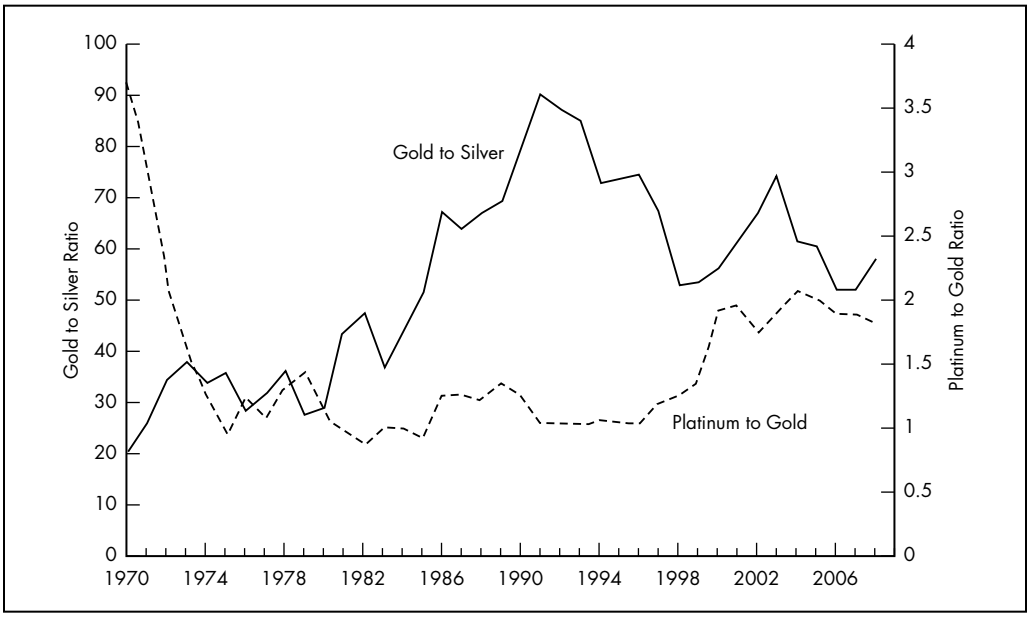
Source: Data from Brook Hunt 2008.

Figure 2.2-4 Cash operating costs for global copper mining industry

requirements, most mining companies will buy such data from consultants specializing in this sort of work.

The rationale for using costs as the basis for long-run price determination is to be found in the economic theory that the price of any commodity in a competitive market will, over the long run, tend toward the costs of the marginal producer and in the presumption that commodity markets come about as close as possible to perfect markets. The marginal producer is defined as the last, or highest-cost, producer who is needed in production to meet prevailing demand. Any tendency of prices to fall below this level will result in some producers being forced to shut down. Any tendency for prices to rise above this level will be a signal for producers to bring back into production higher-cost capacity or else to invest in new capacity. Precisely where the marginal producer is to be found on the cost curve over the long run (i.e., over the cycle as whole) is a matter of judgment and may vary according to commodity but is typically a point some 90% to 95% up the cost curve.

It needs first, however, to be determined exactly what costs are relevant to the behavior of the marginal producer. In the short run, the relevant costs are generally considered to be cash costs. So long as producers can cover their cash outgoings, they will remain in production. Over the long run, however, economic theory suggests that the costs of the marginal producer will incorporate an incentive element representing a return to investors over and above cash costs, without which they would be better off withdrawing from the sector and investing their money elsewhere.



The experience of the 1980s and 1990s, unfortunately, did not appear to conform to this theory. For much of the period, prices seemed to reflect cash costs—that is, short-run marginal costs. There was little or no incentive element, a fact borne out by the generally poor returns achieved by investors in the mining sector during these years. The implication seemed to be that the long run was little more than a series of short runs strung together. It was also generally the experience of these years that prices of many commodities appeared to be trending downward in real terms. (See, for example, the price of copper in Figure 2.2-1.)

In retrospect, it would appear that the 1980s and 1990s constituted a rather special set of conditions. Following the two oil shocks of the 1970s, demand for many commodities was suppressed, both by cyclical influences as well as by a shift to service sector activities in many developed economy countries. Supply, at the same time, was getting a boost from the opening of several important mineral-rich parts of the world (notably Latin America and Southeast Asia), in some instances from direct or indirect state subsidization, and, in the 1990s, from the flood of metals coming onto global markets following the economic collapse of the Soviet Union.

The combination of these factors produced conditions of almost permanent oversupply, making it difficult for prices to lift themselves off the short-run marginal cost curve for any sustained period. Most likely these special conditions will not apply with the same force over the next 20 years and metal markets will generally be in better balance. This being the case, prices will be able to climb above the short-run marginal cost curve for more sustained periods than during the 1980s and 1990s and, in accordance with what economic theory asserts, incorporate more of an incentive element. There is no common view on how big this incentive element is likely to be, with opinions ranging from those who use historical margins as the basis for their projections to those who believe that the incentive element will need to be substantially higher in the future than during the 1980s and 1990s in order to ensure that incomers to the industry earn a competitive market return on their capital and that sufficient investment in production capacity is forthcoming to balance the market.

For precious metals and metals produced as a by-product of other metals, such as cobalt, cadmium, or indium, the costs of production are a poor guide to long-run prices (even where it is possible to compute them, which often it is not). Therefore, the setting of long-run prices for these metals has to rest more heavily on an analysis of historical price information. This might include the analysis of averages and trends during the period over which price data are available, together with an examination of relationships with prices of other metals, especially those that have common markets or serve as substitutes. The analysis of price relativities is particularly popular for forecasting prices of, and for developing strategies for trading in, precious metals. Figure 2.2-5 shows the relationship between annual gold and silver prices and between annual gold and platinum prices between 1970 and 2008.

This analysis of historical trends needs, of course, to be supplemented with more qualitative judgments about the likelihood of the factors that have shaped prices in the past (e.g., the structure of production or developments in key markets) continuing to persist in the future. Structural breaks in price series are unusual, but they can and do occur from time to time. The price of molybdenum became a lot more volatile as a result of the breakup of its concentrated supply structure in the 1970s. (See section on "Producer Pricing.") Zircon sands, which were historically used mostly in relatively low-value foundry and refractory applications, have, in recent years, seen more and more of their market demand accounted for by the ceramics industry, in which customers are both willing and able to pay higher prices for premium-quality raw materials. This, combined with pressures on available supply, has meant that zircon prices appear to have moved onto a sustainably higher plane. Banking on structural change of this sort to generate a higher price for a project's output and thereby justify the investment in it may conceivably pay off but, in light of how rare these events are, is a high-risk strategy.

Price Trends

A key problem in using production costs to determine long-run prices is that, while the physical parameters of production may change only slowly over time, the financial parameters can change quickly and sometimes significantly. Accordingly, the cost curve shifts through time—rising and falling, steepening and flattening—in response to broader economic and industry developments such as fuel prices, wage increases, and exchange rates, as well as the closures of old mines and the start-up of new ones. Ideally, for the determination of long-run prices, analysts would like to have a decycled or normalized cost curve incorporating long-run estimates for all the key input variables. In practice, however, one is always looking at these things through the lens of the current cyclical phase and having to make judgments about which changes are temporary and which are likely to persist on the basis of imperfect information.

As a result of the sustained commodity price boom which followed 2003–2004, there have been major upward revisions in mining analysts' expectations of long-run real dollar prices of mineral commodities across the board. The reasons given for these revisions generally reflect a combination of claims that global demand for commodities has shifted onto a steeper trajectory because of the industrialization of Asia and because the cost of both producing metals and of creating new production capacity has moved higher and is destined to remain higher for the foreseeable future. An additional reason is the decline in the value of the U.S. dollar, which occurred over the same period and which on its own would lead one to expect future metal prices to be higher in U.S. dollar terms.

In assessing the longer-term outlook for prices, it is critical—albeit quite difficult—to try to separate two distinct factors: (1) the effects of the business cycle and (2) a structural shift in the long-run supply curve (the underlying economic realities previously discussed).

Between 2002 and 2007, the global economy experienced an unusually strong cyclical upswing. Annual growth during this period averaged almost 5%, compared with 3.5% for the previous decade. A major role in this cyclical upswing was played by China, which was both growing extremely fast and was highly materials intensive, being heavily concentrated on investment (notably residential and infrastructure construction) and export manufactures. This resulted in an unusually long cyclical upswing, with metal demand staying stronger for longer and metal supply being slower than would normally be the case to catch up. It also resulted in widespread investor interest in metals, as previously discussed. As a consequence of these factors, metal prices stayed higher for longer than in previous cycles while costs escalated as producers were forced to absorb higher raw material costs (e.g., steel and energy) and as the prices of equipment and services (e.g., trucks, tires, and skilled labor) were bid up. While these factors are undoubtedly real and take time to work themselves through, they are, for the most part, reversible and have few implications for the long term.

The structural factors that shape the long-run supply curve for the mining industry are of a rather different nature. They include physical factors such as resource quality and institutional factors such as access to minerals, as well as the effects of improving technology and management. For 30 years, starting from the mid-1970s, these factors combined to keep production costs in the mining industry moving steadily downward. New mineral provinces were opened up, mining regimes were liberalized, the discovery and exploitation of larger deposits permitted the achievement of substantial economies of scale through the use of ever larger equipment, and energy costs generally trended downward, while labor reforms and the introduction of information technologies led to substantial increases in workplace efficiency. In short, productivity growth in the industry consistently outran the effects of resource depletion. The implications of these developments for mining industry cost curves was to depress and flatten them.

There are strong grounds for believing that this phase has come to an end. Mineral resources are not running out, but the

real cost of developing and managing them appears to be on the increase for a whole raft of reasons, including declining ore grades, more complex mineralogy, smaller deposit size, more difficult (e.g., deeper) mining conditions, and increasing geographic remoteness. Also of relevance to an energy-intensive industry, it is highly probable that the lengthy decline in real energy prices has come to an end. Indeed, in some parts of the world where mining is important (e.g., southern Africa and Chile), power shortages have become a serious problem for the industry. Similarly, in some parts of the world, water, which is typically required in large quantities by mining operations, is becoming scarcer and more expensive.

The prospective shift in the emphasis of nickel production away from ores in which the nickel occurs in the form of sulfides toward those in which it occurs in the form of oxides is part of this general shift toward the exploitation of higher-cost resources, as is the development of the lower-grade, harder-to-mine, and harder-to-process platinum–palladium deposits on the eastern limb of the Bushveld in South Africa. For copper, a high proportion of recent production growth has come from smaller deposits, which have not benefited from the economies of scale enjoyed by some of their predecessors. In the future, much more of the world's copper will have to come from higher-cost underground mines than is presently the case. Similar challenges are evident in the production of many other metals and minerals.

Structural change is also manifest in the rising barriers to entry in the mining industry. Partly this is because many of the remaining large, undeveloped mineral deposits are located in developing countries, which have poor infrastructures and where mine development implies an associated—and invariably costly—requirement to build ports, power stations, townships, and railways. This is arguably why capital costs per unit of installed production capacity in the industry have increased more in recent years than can readily be explained by purely cyclical influences. In terms of the implications for the cost curve, if the effect of rising operating costs tends to be to shift the cost curve along its entire length, the effect of increased costs of entry is to tilt the cost curve—that is, make it steeper. As illustrated schematically in Figure 2.2-6, both factors serve to raise the point of intersection on the supply curve (and thus the implied equilibrium price) for any given demand function. Specifically, as rising costs push the curve describing the amount of product that producers are willing to offer consumers at different prices from S (supply) to S^1, so the market-clearing price (P) of the product rises from P to P^1.

No less important as a barrier to entry—and having a similar impact on the cost curve—are the growing political obstacles to mine development. Recent years have seen a major revival of resource nationalism worldwide, a tendency undoubtedly aggravated by high commodity prices. This has led to the blocking of possible mine projects by governments keen to extract the maximum benefits from resource developments on their soils (or else ensure that it is done by a domestic producer) as well as to widespread increases in mineral taxation and mineral royalties. The large Oyu Tolgoi copper mine project in Mongolia, for example, was stalled for a long time because of the sponsors' inability to agree on terms for development with the host government.

Elsewhere, mining companies face tightening government regulation, often for environmental reasons, and challenges to their activities from growing local activism. All of this adds to the costs of mine development and increases the prices that mine producers and their bankers require if they are to accept the implied risks and commit to investments. Although there is a good prospect that real prices will be sustained in the future above the levels experienced in the 1990s, the extent of the price increases are far from clear. Investors' need for higher prices does not necessarily deliver higher prices, and it is important in this context to note that, while a lifting and tilting cost curve may result in higher long-run prices for the industry as a whole, the benefits of this will only flow to the lower-cost producers. Marginal, high-cost producers will remain just that—marginal.

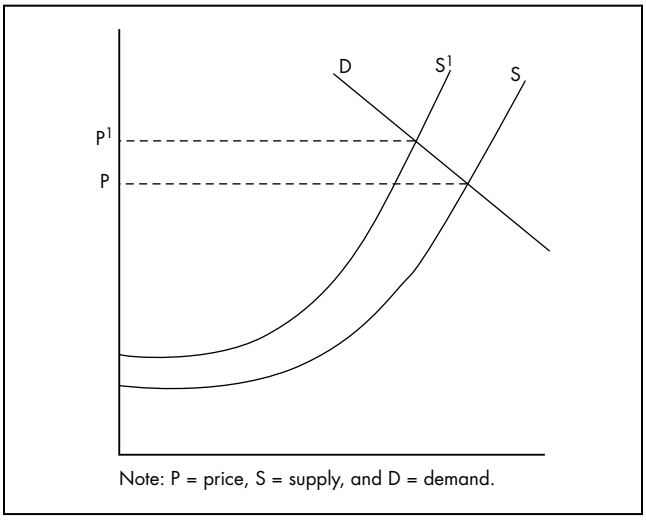

Figure 2.2-6 Price implications for increased cost of entry to industry

WHERE AND HOW PRICES ARE DETERMINED

Many factors influence the manner in which metals and minerals are traded and priced. Among these are the number of buyers and sellers in the market, the distance between them, the nature and complexity of the products being traded, and whether or not they can be stored for long periods without deteriorating. Two of the more critical dimensions are transportability of the product and its degree of standardization (homogeneity). These are used in Figure 2.2-7 to provide a rough schematic categorization of market types.

The transportability of a product refers not just to the bulk and weight of a product and the distances to be carried but to its ability to bear the cost of transport. In other words, it is about its value-to-weight ratio. Transportability is important in determining the reach of a product's market. Greater transportability will generally imply a more global market and greater potential for the involvement of many players. Gold and diamonds, because of their high value-to-weight ratio, are obviously among the most transportable commodities. Bulk minerals, such as iron ore and coal, which have a low value-to-weight ratio, have markets that are more regionally defined, with producers being primarily focused on either the Atlantic or Pacific basins. However, most iron ore and coal producers are able to supply both markets, even if only to a limited degree, while South Africa, an important iron ore and coal producer, sits equidistant between the two markets. As a result, the prices in the two markets tend to move in line with each other. Some commodities, such as construction aggregates, have scarcely any international trade at all.

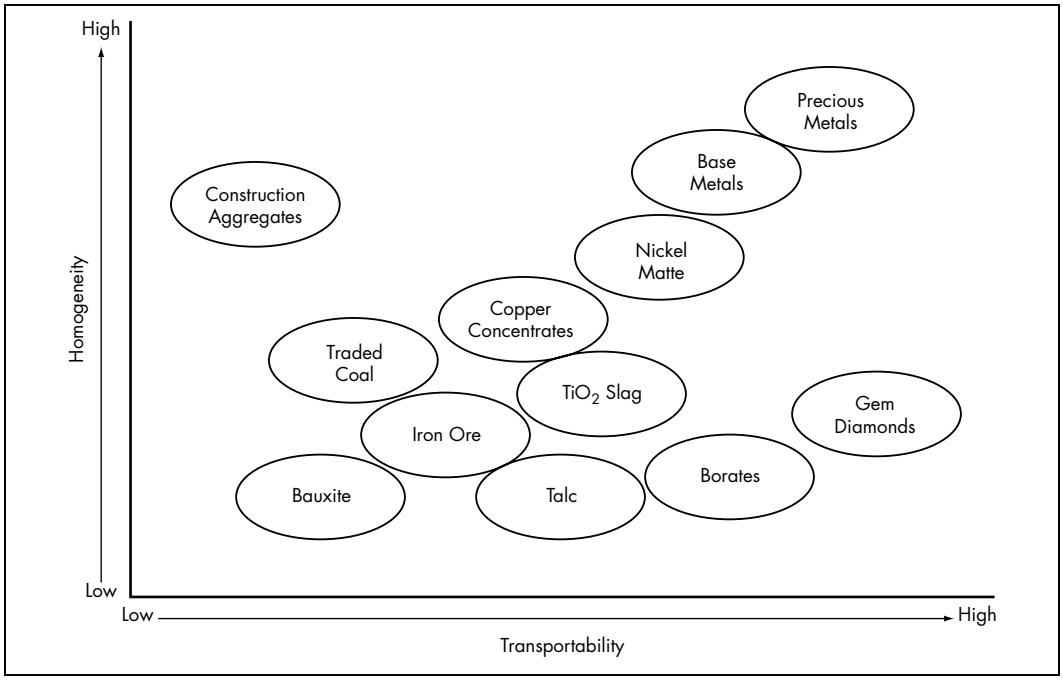

Figure 2.2-7 Dimensions of market structure: schematic representation

The second key dimension is that of product homogeneity. At one pole are commodities that meet a globally defined standard—gold bullion, for example, or copper of 99.99% purity. Such products are known by economists as fungible—that is, any one metric ton of the product is fully substitutable for any other metric ton. Such substitutability creates the potential for swaps in different parts of the world, thereby diminishing the need for transportation. A high level of homogeneity also permits paper- or computer-based trade in warrants for a commodity and makes possible the participation of traders and speculators who do not produce or use the commodity as such but who play a role in matching producers and consumers in different parts of the market and in oiling the wheels of the price formation process by trading among themselves.

Differentiated (heterogeneous) products lack fungibility. Consumers buy these products for the specific properties they possess. This requires producers and consumers of the product to negotiate directly with each other and set their prices in relation to the particular characteristics of the product being traded. For some industrial minerals these properties can be highly specific and more or less totally non-substitutable. Talc, for example, is produced to a wide range of specifications with different colors, different particle sizing, and even different mineral constituents. For other commodities, such as iron ore or coal, there may be a degree of substitutability. All iron ore is ultimately valued for its iron content just as all thermal coal is ultimately valued for its heat-generating qualities, but consumers may nevertheless have preferences for certain types of material because they have other positive attributes or are low in certain impurities. Some steelmakers are prepared to pay a premium for iron ore in lump form because it saves them the cost and effort of agglomerating iron ore fines. Other steel mills may have a preference for iron ore low in alumina. Similarly, with thermal coal, different electrical power plants have different tolerances for the ash content of coals, and some are prepared to pay a premium for a low ash product.

These factors also help determine how big a role traders play in the market. Products that are highly specific to a particular market or a particular plant will generally need to be traded directly between producers and consumers of the product. The more homogeneous a product, the greater the scope for participation in the market by traders. Distance to market is also a factor, with traders traditionally playing a more important part in markets where supply comes from producers in remote regions (particularly in developing countries) or who have a relatively small production and for whom it is more economic, or more practical, to employ the services of traders to market their products than familiarize themselves with the market or develop a marketing network of their own.

These intermediaries (as traders are sometimes called) are generally headquartered in metropolitan centers such as New York, Tokyo, Singapore, London, Frankfurt, and Zug (in Switzerland) and maintain offices or agents in the main producing and consuming regions. They generally deal with a whole range of minerals and metals and develop detailed knowledge about producers' products and consumer requirements so as to be able to match them. They will generally also be adept at organizing financing for trade transactions (a significant challenge in certain difficult countries) and managing price and currency risk. The key to their success is their access to market information and their skills in using this information to find and structure profitable deals.

Metal Exchanges

The most economically important nonferrous metals are traded and priced on metal exchanges. The two most widely known and quoted are the LME and the New York Mercantile Exchange (NYMEX). As of 2008, it was possible to trade aluminum, aluminum alloy, copper, lead, nickel, tin, zinc, and steel billet on the LME, as well as certain plastics and indexes. From early 2010, it will be possible to trade cobalt

and molybdenum. NYMEX offers contacts in copper, aluminum, gold, silver, platinum, palladium, coal, uranium, and hot rolled steel coil.

Many other exchanges exist, and this number is growing. The Shanghai Metal Exchange offers trading in aluminum, copper, lead, nickel, tin, and zinc; the Tokyo Commodity Exchange trades gold, silver, platinum, palladium, and aluminum, while on the Chicago Board of Trade it is possible to trade gold and silver. There are also metal exchanges in Moscow, Mumbai, Kuala Lumpur, and Dubai (Radetzki 2008).

Although the precise manner of trading varies from one exchange to another, in essence, metal exchanges are places for staging auctions at which contracts for a given commodity are offered for sale during prescribed hours of business each day. On the LME, these prescribed times are 5-minute rings during which trading is conducted verbally across the floor of the exchange, a process known as open outcry. Trading on an exchange is open to anyone with an appropriate credit rating, but actual transactions must be conducted through a member of the exchange. Trading can generally also take place outside prescribed hours using interoffice computer-based systems.

Exchange contracts specify a standard quantity of the metal being traded. For example, the LME aluminum contract is for 25 t (metric tons) while the NYMEX contract is for 44,000 lb. The quality of the metal constituting acceptable delivery is precisely specified. Brands produced by smelters and refiners must be approved for listing by an exchange before they can be traded.

Offerings made on the exchange floor are for delivery at a specific time. LME contracts are traded for the prompt or cash position, requiring immediate delivery of metal, or for future delivery on a specified date, while NYMEX contracts specify the month of delivery. Aluminum and copper can be traded out to 10 years on the LME, while zinc and nickel can be traded out to 5 years, although trading can be quite thin for the far forward dates. Where future prices are higher than the spot prices, the market is said to be in *contango*; where it is below future price (usually a sign of tightness in the market for immediately available metal), it is said to be in *backwardation*. Some metal exchanges also permit the trading of options—the right to buy or sell metal at a given (*strike*) price at a specified point in the future—for the payment of a stipulated premium.

Under standard exchange contracts, sellers may deliver to buyers any acceptable brand the sellers choose at any warehouse approved by the exchange. This latter option is important because the LME has approved warehouses not only in the United Kingdom but also at major ports in continental Europe, Asia, and the United States. (They are typically located near major centers of metals consumption to ensure that producers have to bear most of the costs of getting the metal to market.) NYMEX has approved warehouses scattered throughout the continental United States. If the buyer takes delivery at a warehouse location that is inconvenient, or if the brand tendered is not one that the buyer would normally choose to use, then as a rule it is possible to arrange to make an exchange for a more suitable warehouse location or a more desirable brand through an exchange member, although this is likely to involve paying a premium.

In practice, for the vast majority of exchange transactions, there is no physical delivery of metal. Instead, the buyer of a contract will sell the contract, or the seller of a contract will buy back the quantities involved in the original transaction prior to the effective date of the contract. This is because one of the central functions of metal exchanges is to enable buyers and sellers of metal to lock in—or *hedge*—prices to cover their raw material costs or their plant output.

By way of illustration, assume a secondary copper smelter buys scrap material to be delivered to its plant in 30 days. After delivery, an additional 45 days may be required for processing. The price of copper may rise or fall substantially between the date of the original purchase and the date, 75 days forward when the refined metal is available for sale. By selling the equivalent amount of copper on the exchange the day the scrap material is purchased for delivery 90 days forward, the secondary smelter has fixed the price it will receive based on the conditions in the market at the time it bought its raw material. When the refined metal is available, it is sold to the consumer at the then prevailing price and the outstanding exchange contract is bought back. These two transactions offset each other, so the net outcome is based on the original exchange sale, even though no delivery was made to the exchange. Producers of mined products can similarly use a metal exchange to lock in prices if they want the security of knowing their selling price or if they have concerns that the price of their products may be about to fall.

In addition to the large volume of exchange transactions based on this type of hedging, trades are also made by investors who believe they can profit by purchasing when a rise in price is probable or by selling when a fall in price looks imminent. (Rather confusingly, this kind of activity is sometimes also referred to as hedging. It is really the opposite of hedging because hedging is about reducing risk, whereas investing or speculating is about deliberately taking on risk in the hope of earning a commensurately higher return. Such activity is more accurately described as taking a position in the market or, perhaps, making a strategic hedge.) Such investors need not actually be involved in the metals business at all or have any interest in holding supplies of metal. In the great majority of instances, therefore, they either liquidate their positions in the market prior to maturity or, alternatively, liquidate nearby positions and roll the contracts forward to more distant dates.

Because of the large scale of these paper trades, the total amount of metal traded through an exchange is generally many times the amount of metal physically passing through it or indeed traded in the market as a whole. The amount of aluminum, copper, and zinc traded through the LME in 2007 was more than 30 times the annual consumption of those metals. For nickel it was around 20 times. Nevertheless, exchanges remain important to the physical market for metals as the place where producers who have no customers can deliver their metal and where consumers who do not have an alternative supplier can buy it. It is effectively the physical market of last resort, for which reason exchanges are sometimes referred to as terminal markets, and the stocks lodged in the warehouses and registered with an exchange are accordingly watched closely by analysts for evidence of emerging imbalances in supply and demand.

Metal exchanges are also crucial to physical producers and users of metals because their products, even if they go nowhere near an exchange, will typically be based on prices determined on an exchange. The central pivot of price determination on an exchange is the spot, or cash, price, which is the price of metal for immediate delivery. The three most important spot prices on the LME are (1) the *official* price, which is the final price from the last ring session of the morning;

(2) the *unofficial* price, which is the final price from the last ring of the day; and (3) the *closing* price, which is the price of the day's last recorded LME trade. These are rapidly and widely communicated throughout the world and used for off-exchange trading. Although differences can exist temporarily between prices on exchanges in different parts of the world, such differences provide an opportunity for traders to buy in one market and sell in another and so are quickly traded away in a process known as arbitrage, ensuring that exchange prices everywhere converge.

Trades made between buyers and sellers off the exchange will normally take place at a premium to quoted exchange prices. This premium reflects the cost to the producer of storing, transporting, and insuring the metal on its way to the consumer. Thus, for example, a metric ton of nickel might be contracted to be sold to a customer for delivery in 3 months' time, at an average of today's exchange settlement price and the price prevailing on the date of delivery, plus a premium of $150/t. The transport element in premiums means that the level of premiums in different markets often reflects imbalances in regional supply and demand. Movements in premiums sometimes also act as a leading indicator of price movements. Deliveries of metal to exchange-registered warehouses do not earn producers a premium, which explains why they are generally reluctant to deliver metal there if they can avoid it.

Bullion Markets

Although precious metals are traded on exchanges, the greater part of the trade in these metals is conducted through bullion markets. Participants in such markets include members of the London Bullion Market Association (LBMA), which covers gold and silver; and the London Platinum and Palladium Market (LPPM), which covers the metals in its title.

In contrast to the metal exchanges, where metals are traded and cleared anonymously through a common open channel and which provide clearing and guarantees for participating members, trading in bullion markets takes place directly between the members of the market and their clients on a principal-to-principal basis, which means that all risks, including credit risk, are between the two counterparties to a transaction. This is termed an over-the-counter (OTC) market. Participants in OTC markets are not necessarily obliged to report their trading volumes or their stock levels, so markets in which metals are traded in this fashion tend to lack the transparency of metal exchanges.

The London bullion market is a wholesale market where the minimum traded amounts for clients are generally 1,000 oz of gold and 50,000 oz of silver. Good delivery bars (i.e., bars that meet prescribed criteria for weight, purity, and other physical characteristics set out by the bullion market and which come from certified refiners) are 350–400 oz for gold and 750–1,100 oz for silver, while platinum and palladium are normally traded in multiples of 500–1,000 oz. Unlike a metal exchange, bullion markets permit flexibility with respect to contract units, settlement dates, and delivery specifications. And, unlike the typical contract for a nonferrous metal, which will commonly use a price formula linked directly to published LME prices, the price for a precious metal traded OTC is in principle negotiable along with everything else.

Public price quotations for metals traded on bullion markets are established in two ways. The first is through daily price fixes, which offer a snapshot of market conditions at particular points in time. The process for determining prices under this arrangement starts with a small group of member banks assembling in London each business day—twice a day in the cases of gold, platinum, and palladium; once a day for silver. The chairman of the meeting suggests an opening price, which is relayed to members' dealing rooms and then to the customers of the members. On the basis of orders received, members declare as a buyer or a seller. Provided both buying and selling interests are declared, then members are asked to state the amount they wish to trade. If the amounts of buying and selling do not match, the same procedure is followed again at higher or lower prices until a balance is achieved, at which point the price is declared fixed. The price fix is communicated to the market and used as a benchmark for trading worldwide and for the pricing of financial instruments such as swaps and options. In addition to the fix, the LBMA offers forward quotations for gold and silver, these being the rates at which member banks are prepared to lend these metals on a swap against U.S. dollars for up to a year ahead.

While the London fixes are widely used as the guide to pricing precious metals, the amounts of metal involved in the fixing processes are small compared to the total volume of precious metals traded OTC by bullion banks and dealers worldwide. The greater part of this trade is done at prices quoted with delivery in London or Zurich, referred to as Loco London and Loco Zurich, respectively. Prices quoted by dealers for these locations are updated effectively 24 hours a day and can be adjusted to cover the costs of producing smaller, exact weight bars or bars of fineness in excess of the defined minimum level of purity. Surveys of these dealer prices are collected and published on a regular basis for reference purposes by trade journals such as *Platts Metals Week*, *Metal Bulletin*, and *American Metal Markets.* More up-to-the-minute indications of price are provided by the wire services, most notably Reuters, which continually survey dealers and banks around the world on their trades and, on the basis of this information, compile reference prices, which they make available to service subscribers. The silver refiner and fabricator, Handy & Harman (part of the WHX Corporation), has traditionally published a reference price for silver in North America. With a shrinking proportion of the global use of metals taking place in Europe and North America, an increasing role is being played in the precious metals trade by centers outside these regions, notably Tokyo, Shanghai, Hong Kong, Mumbai, and Dubai.

Producer Pricing

Under the producer pricing system, the producer of a metal or mineral informs the market of the price at which it is prepared to sell its product. It is typically found in markets where production is concentrated in the hands of relatively few firms and where demand is robust. These factors combine to focus market power in the hands of sellers and permit them to charge a price that reflects their cost of production plus a suitable margin. Proponents of producer pricing have argued that the system gives stability and predictability to prices, which industrial customers like; provides incentives for undertaking research and development; and promotes the development of constructive long-term business relationships between buyers and sellers.

Producer pricing has historically been widely employed in the metals industry. For many years it was the norm for aluminum, nickel, and molybdenum, although at various times copper, lead, and zinc have also been subject to producer pricing. In most cases, however, this form of pricing

was killed off during the 1970s and 1980s when a combination of slower demand growth and a wave of new market entrants and the breakdown of protected regional markets halted the power of producers to set prices and facilitated the growth of metal exchange trading. The LME contracts for aluminum and nickel both date from this period.

Variants of producer pricing nevertheless continue to exist, generally in sectors where the range of suppliers is relatively limited or where markets are small and products have a high degree of specificity. Sometimes prices issued by producers are described, more neutrally, as list prices rather than producer prices to avoid the suggestion that producers are somehow imposing prices (and in practice it may well be the case that there is scope for negotiation around the prices quoted). In the market for gem diamonds, the Diamond Trading Corporation (DTC, part of the De Beers group of companies), which handles almost half of all the world's gem diamonds by value, sells uncut diamonds to authorized buyers from a list of prices laid out in the DTC price book. Johnson Matthey and Engelhard publish daily the prices at which they are prepared to sell platinum group metals. BHP Billiton and Norilsk Nickel have for several years posted on their Web sites the prices at which they are prepared to sell cobalt, along with prices realized in recent sales. For more complex products, such as borates, for example, producers make available to their customers a list of the different chemicals they can offer with associated prices. In all these cases, of course, while it may serve everyone's purposes to have a list to work from in what otherwise can be a rather nontransparent markets, producers cannot escape the laws of supply and demand and inevitably have to adjust their prices from time to time in light of actual or prospective market imbalances.

Negotiated Pricing

The term *negotiated pricing* is used here to describe the various pricing systems that lack a formal institutional focus and are typically the product of bilateral contracts made directly between buyers and sellers (i.e., principal to principal). It includes a wide range of trading and pricing types, with variable degrees of sophistication, and tends to apply to products that are either too differentiated in their nature to permit exchange trading, too bulky, or too unstable chemically to be stored for long periods in warehouses, or to products for which the markets are too small scale and fragmented to warrant exchange trading.

At one pole are the bulk commodities iron ore and coal, the prices of which are the subject of annual, formal, high-profile negotiations between buyers and sellers. The scale of the trade in these commodities and its importance to the economies of the participating countries make these negotiations almost political in nature. After several months of preparatory meetings, conferences, and subtle public maneuvering, negotiations on seaborne iron ore prices typically begin in earnest early in the calendar year. For historical reasons, contracts in Europe tend to run over the calendar year and those in Asia over the financial year starting in April, though both tend to be negotiated simultaneously. Although most producers and buyers of seaborne iron ore participate in this process, attention inevitably focuses on the larger producers (currently BHP Billiton and Rio Tinto out of Australia and Vale from Brazil) and the larger steel mills in Europe, Japan, and China. Although negotiations can often drag on for months, after a deal has been struck between any two companies, the convention is that all participants in the market automatically adopt this as the "benchmark" for pricing during the remainder of the year, with discounts and premiums to the benchmark grade of ore applied according to the precise form in which the ore is to be sold (lump, fines, or pellets), the mineral type, and the iron content and impurities (e.g., sulfur and phosphorus). Allowance for freight costs between seller and buyer may be treated as part of the discount structure or else may be subject to direct negotiation, depending on whether the product is being traded FOB or CIF. With FOB, the buyer pays for the transport; with CIF, the seller pays.

Seaborne trade in coking coal and steam coal is subject to a similar process of negotiation but with a slightly different cast of players. While the steel mills are the primary purchasers of coking coal, seaborne steam coal is brought by electrical power companies. In common with iron ore and coking coal, the buyers are heavily concentrated in Europe and Asia. Prices for iron ore and coal in North America are settled independently of these processes but nevertheless track those in the seaborne market quite closely because North American companies are active participants (albeit not generally large ones) in these seaborne markets.

Although this process of annual negotiation has undergone severe strains over the years, notably during periods of substantial shortage or surplus, it has generally served the interests of producers and buyers to persist with it and to lock in multiyear contracts with only the price to be negotiated annually. The operators of large continuous-process plants such as steel mills and power stations like to have secure and consistent supplies of known-quality raw materials and to know what they expect to pay for them. For the producers, the same predictability is useful for planning production and evaluating growth opportunities. Indeed, without the certainty of long-term contracts, mining companies have often in the past been reluctant to commit to major investment in the expansion of capacity for bulk commodities, given the capital-intensive nature of their production.

However, change is beginning to come to the trade in bulk seaborne commodities. In the important Asian market, the rapid growth of China's steel production has been shifting the focus from Japan, the traditional leader of negotiations in the Asian theater. The severe shortages of iron ore experienced in the first decade of the century by the rapid growth of China led to the emergence and then rapid growth of a spot market for iron ore, based on production from small producers in China and India. In turn, this gave rise to proposals for the development of an official index of spot trades to provide a more sensitive and timely indicator of market developments. The intention was that this should inform negotiations on longer-term contracts and permit some movement away from pricing as a once-for-all annual event. At the end of 2008, after months of discussions with industry participants on methodology, the journal *Metal Bulletin* launched a price index for iron ore fines imported into China.

Trade in steam coal has gone further down this path. The growing spot market in steam coal led a number of large coal producers and power utilities in 2001 to set up an Internet system for trading cargoes of steam coal, called globalCOAL. Based on trades among companies using its Internet platform, globalCOAL generates indicators of spot and forward prices of coal, which can be used to benchmark trades outside the market as well as permitting hedging and price risk management in the industry. Although annual contracts are still

widely used in the industry, there is a close interplay between spot and contract prices.

Raw materials used for the production of refined nonferrous metals are often traded on a hybrid basis, containing elements of both terminal market pricing and negotiated pricing. When a copper mine contracts to sell copper concentrates to a custom (i.e., third-party) smelter or refinery, it will typically do so based on the LME price in the 3 months after delivery, applied to the copper content of the concentrate being sold, less a deduction intended to reflect the negotiated cost of smelting and refining. Most such concentrates are sold on multiyear frame contracts with the terms for smelting and refining negotiated annually or biannually according to market conditions. These negotiations are quaintly referred to in the trade as the "mating season." Additionally, a smaller spot market acts as an indicator of the near-term balance of supply and demand.

The deduction from the copper price, which the smelter refinery must accept in order to acquire a supply of concentrate and which is the focus of the negotiations with the miners, is based off the percentage of metal in the concentrate that is considered recoverable (known as payable metal) and consists of two principal elements: (1) the treatment (or smelter) charge (TC), which is applied per metric ton of dried concentrate (dmt) on payable metal and (2) a refining charge (RC), which is applied per pound of payable copper. Collectively these are referred to as TC/RCs and are sometimes expressed as a percentage of the refined metal price. The level of TC/RCs is determined by the balance of supply and demand in the concentrates market (which may or may not be in step with the balance of supply and demand in the market for refined metal); the tighter the market for concentrates, the lower the TC/RCs.

By way of a worked example, take the case of a 30% copper concentrate in which the payable metal content is deemed to be 29%, the TC is $70/dmt, the RC is 7¢/lb and the LME price is $4,410/t ($2/lb). On the basis of these assumptions, each metric ton of concentrate contains 639 lb of copper (29% of 2,204.6 lb). The cost of the TC in this case will equate to 70 (the rate of the TC) times 200 (the LME price of copper quoted in U.S. cents) divided by 639, which is 21.9 ¢/lb. The RC has already been given as 7¢/lb so the miner will receive 171.1¢/lb of the payable metal in the concentrate (200 – 21.9 – 7), or 85.5% of the prevailing copper price. Other adjustments will be made to reflect unwanted impurities in the concentrates (e.g., arsenic and mercury) and recoverable by-products such as gold and molybdenum.

Similar arrangements to those for copper concentrates apply also to lead and zinc concentrates, though with different formulas. For aluminum, a common practice is for smelters to purchase their alumina on the basis of contracts specifying a given percentage of the prevailing LME aluminum metal price. The percentage is fixed through negotiation and generally falls into the 10%–20% range. The consequence of this arrangement is that aluminum and alumina prices tend to move broadly in step with each other, helping to reduce smelter costs in adverse market conditions and spread the benefits when prices are high.

Negotiated pricing is the norm for finished metals and alloys, which are not traded on metal exchanges. These include bulk ferroalloys such as ferromanganese and ferrochrome, special steel additives such as molybdenum and tungsten, minor metals such as cadmium and bismuth, and a variety of other specialist mineral-based products such as titanium-containing beach sands and uranium. The pricing of many of these is a function of direct negotiation between producers and consumers of the metals. However, because of the fragmented nature of some of these markets and some of the producers' remoteness from markets, it is typically the case that traders play a bigger part in these markets than with the major nonferrous metals or the bulk mineral commodities. These traders seek to make a profit by intermediating between buyers and sellers and by using their knowledge of these markets. Based usually near major demand centers where they can closely monitor developments in the market, trading companies can provide a useful service to producers who lack such knowledge or else who view marketing as outside their core competence. Historically, traders have accounted for a large part of the supply for these metals coming out of regions such as China, the former Soviet Union, and Africa.

By the nature of the processes involved, pricing in these markets is much less transparent than is the case with the other metals already discussed, and quite often this suits the participants in these markets. Reference prices for many of these commodities, derived from telephone surveys and national customs data, are regularly published by the trade press, and these provide an indication of trends in the various markets, although the reliability of these quotations varies. In some cases and at regular intervals, traders and consultants in the business make the prices at which trades have been conducted publicly available. In the case of uranium, for example, such a service is provided by TradeTech and Ux Consulting Company.

The pricing of industrial minerals is broadly similar to that for these more minor metals; that is, prices are normally established on the basis of negotiation between producers and consumers. The need for this is enhanced in the case of industrial minerals by the wide range of forms in which these products are sold and the specificity of the characteristics that consumers of these products are looking for. Thus, price variations for an industrial mineral may follow, among other things, chemical composition, grade, color, form of packaging, and delivery location (O'Driscoll 2006). To take but one example, prices of barium minerals will vary according to whether the product is deemed paint, drilling, or chemical grade, the amount of Ba_2SO_4 (barite) contained, the mesh size of the micronized product (if being used in paint production), the size of the bags in which it is being delivered (or if it is being sold in bulk), whether it is being sold FOB or CIF, and to which port the FOB or CIF pricing applies.

Prices for a wide range of industrial mineral products are published in trade journals, most notably *Industrial Minerals* and *Mineral PriceWatch*. These products range from clays such as bentonite and kaolin; inputs to chemical production such as borates, sulfur, and salt; refractory products such as chromite, magnesite, and bauxite; glass-making products such as lithium minerals, feldspar, and silica sands; coaters and fillers such as talc, wollastonite, and calcium carbonates; and fertilizer minerals such as potash and phosphate rock. Because of the wide range of different forms, published prices are typically quoted in ranges, and care needs to be taken in using the prices because some are more reliable than others. Because industrial minerals are among the most challenging products to price when evaluating mineral deposits, there is no substitute for talking with potential customers about the salability of the specific mineral under evaluation.

Price Behavior

The cyclical nature of mineral demand, discussed earlier, and the inflexibility of its supply mean that all mineral commodities show some degree of cyclicality in their price behavior. Market structure and the pricing systems employed are also important factors in determining price behavior. Markets that permit the involvement of speculators are more prone to large and rapid price movements than those that do not. Markets for minor metals, which lack transparency and have a large trader presence, are also susceptible to high price volatility, especially when they are produced as a by-product of another more economically important metal and where supply is accordingly inflexible. Conversely, in markets where supply is concentrated and producer pricing is employed, or where prices are fixed on an annual basis, it is likely that the price variability will be less.

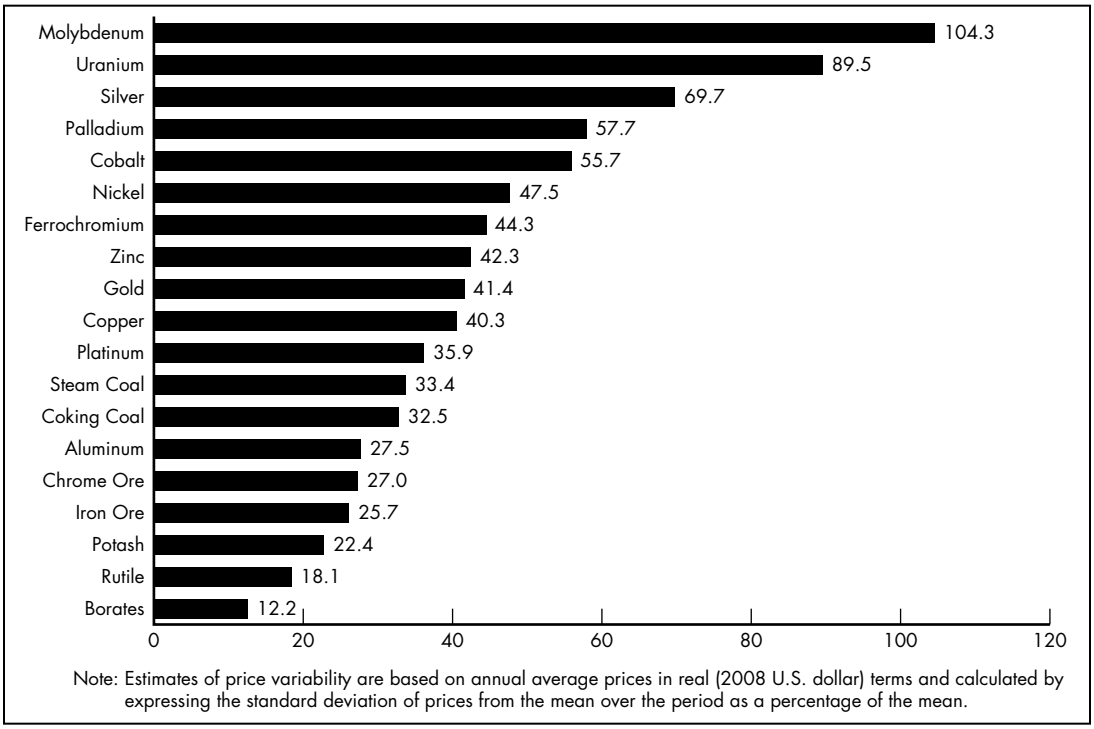
Figure 2.2-8 shows an index of price variability for a variety of metals and minerals between 1970 and 2007. In line with what one might expect, the bottom part of the chart (indicating least-price volatility) is dominated by industrial minerals and bulk commodities while the top of the chart is dominated by minor metals and by-products. The major nonferrous metals fall around the middle of the table, as do gold and platinum. (The uranium price used is the spot price; contract prices would show less volatility.)

This comparison points up some important differences in the adjustment process of different markets. In markets where there is a buyer of last resort to deliver to, such as the LME, producers can pretty much always sell their product—at a price. The consequence of doing so, however, is that stock accumulates and price likely declines. Eventually prices will reach a point where marginal producers are losing money on a scale where they are forced into closure. Lower-cost producers, meanwhile, will almost certainly not be cutting back and indeed could even be seeking to increase their output as a means to reduce their unit operating costs. Under these sorts of conditions, prices have an inevitable tendency to overshoot.

For the many commodities that do not have a market of last resort, the pressure to respond to market imbalances is more immediate. If producers cannot find a buyer then, after they have filled their own storage space, they will generally be forced to cut their output to what the market will bear. In other words, while for base and precious metals the strain of market adjustment is principally taken on price and on a few higher-cost producers, for bulk and industrial minerals the strain is taken more on volume reductions across the industry and through the reduced efficiency of plants operating at less than full design capacity (Humphreys 1991). In the case of a number of internationally traded industrial minerals, this adjustment through volume modulation rather than through sharp price swings is facilitated by the relatively small number of suppliers and by the importance to them of maintaining good long-term relationships with customers. For these reasons, and because of general inertia, prices fixed on an annual basis often respond to market changes with a lag. A good example of this is provided by the iron ore market, where prices typically move in line with changes in steel production in the major ore-consuming areas in the previous year.

In conclusion, and returning to the point made at the beginning of this chapter, it is important for those undertaking the analysis of mineral projects not only to have a good sense of the product's likely average price over the life of a project but also to understand the associated risk of price volatility. For this purpose they will need a clear understanding of the product's price history and an appreciation of the market structure and the specifics of the processes of price formation.

SOURCES OF PRICE INFORMATION



The development of electronic information systems means that price data on metals and minerals are much more readily accessible than in the past. However, it does not necessarily mean that the quality of this data has improved nor that the particular data needed can be obtained free.

Price data for metals traded on metal exchanges are generally available through the exchanges' Web sites. Thus, data on LME prices can be found at www.lme.com, while that for NYMEX can be found at www.nymex.com. Historical price data can be found in a variety of statistical publications, such as those of the World Bureau of Metal Statistics (www.world-bureau.com) and the American Bureau of Metal Statistics (www.abms.com), and are available on line from a number of commercial data suppliers, such as Reuters and Bloomberg. These metals are also well covered by research analysts at the major banks, whose publications are often a good source of information on the nonferrous metals and other metal and mineral products.

Price fixes for the precious metals can be found on the Web sites of the LBMA and LPPM, at www.lbma.org.uk and www.lppm.org.uk, respectively. The World Gold Council Web site, www.gold.org, is a good source for gold prices as well as a range of other gold-related information. Johnson Matthey posts the prices of the platinum group metals it sells on its site at www.platinum.matthey.com.

Commercial publications, such as *Metal Bulletin* in the United Kingdom (www.metalbulletin.com) and *Platts Metals Week* and *American Metal Markets* in the United States (respectively, www.platts.com/metals and www.amm.com) are important sources of information on the prices of major metals as well as on a range of minor metals, ferroalloys, and mineral raw materials. Some of their price series are based on their own regular surveys and are copyrighted. Prices of mineral raw materials such as base metal concentrates or alumina are generally hard to obtain publicly on a consistent long-term basis and generally have to be obtained from proprietary sources such as the publications of CRU (www.crugroup.com), Brook Hunt (www.brookhunt.com), or AME Mineral Economics (www.ame.com.au). Proprietary research on the precious metals is available from GFMS (www.gfms.co.uk).

The trading and pricing of bulk commodities are fairly transparent affairs and well covered in the trade press. An important source of information on the seaborne trade in iron ore and coal is *The Tex Report*, published daily in Japan. The Tex Report Ltd. (www.texreport.co.jp/xenglish) also publishes annually manuals on iron ore, coal, and ferroalloys, which contain a wealth of detailed historical information. The most authoritative source for the North American iron ore industry is the *Skillings Mining Review* (www.skillings.net). Prices for steam coal trades are posted on globalCOAL's Web site at www.globalcoal.com. The Organisation for Economic Co-operation and Development's International Energy Agency (www.iea.org) is a rich source of information on the trade and

Figure 2.2-8 Variability of metal and mineral prices, 1970–2007

pricing of energy products generally and publishes an annual report on coal called *Coal Information*.

As discussed previously, price data on industrial minerals are commonly hard to obtain and difficult to interpret. Many producers like the lack of transparency because knowledge of what is going on in their market is part of their competitive advantage. The publication *Industrial Minerals* (www.mineralnet.co.uk) is one of the few sources of information on these minerals and routinely publishes price data on such minerals in its flagship journal as well as in its specialist publication *Mineral PriceWatch*. However, while these are adequate for getting a general indication of price levels and of price trends, evaluators needing a detailed assessment of the likely prices for a mineral from a particular deposit will generally need the assistance of a consultant specializing in the commodity concerned.

Finally, there are a few government-sponsored sources of information on metal and mineral prices. The best known of these in the U.S. Geological Survey, which, building on the work formerly carried out by the U.S. Bureau of Mines, has a large database of mineral prices going back many years. These are easily accessible at http://minerals.usgs.gov/minerals. Although this covers metals and minerals of all types worldwide, it is particularly useful as a source of information on the smaller and more obscure mineral commodities and on prices within the United States. The Australian Bureau of Agricultural and Resource Economics (ABARE) and its Web site at www.abare.gov.au are also valuable sources of price information on commodities, especially those for which Australia is an important global producer. Similar information is available from Natural Resources Canada at its Web site, www.nrcan-rncan.gc.ca.

CHAPTER 2.3

Market Capitalization

Fiona Perrott-Humphrey

Market capitalization is the value that the equity market places on a company or a group of companies. Over the bulk of 2003 to 2008, the FTSE 350 Mining Index (the market capitalization of the world's most important mining equity market) rose strongly in relative terms against that of the FTSE Med 100 (the top 100 companies listed in London) (see Figure 2.3-1). This relative rise reflected a belief that the structural growth of industrial giant China had created a *supercycle* of demand for commodities to fuel its development that would last decades. This investment thesis saw the risk premium of historically cyclical mining companies reduced as they were treated more like growth stocks with strong underlying cash flows.

Figure 2.3-1 also shows, however, that since mid-2008, these same shares have seen a pullback of more than 50% from their high point, based on fears that the turmoil in financial markets is feeding into the real economy and that even the powerful growth engine of China would not offset demand falls for commodities elsewhere.

These dramatic moves in market capitalization are no mere lottery. The fundamental driver of valuation is the multiple the equity market places on the net present value (NPV) of future cash flows coming from mining projects. To arrive at the NPV, we need to understand factors affecting both

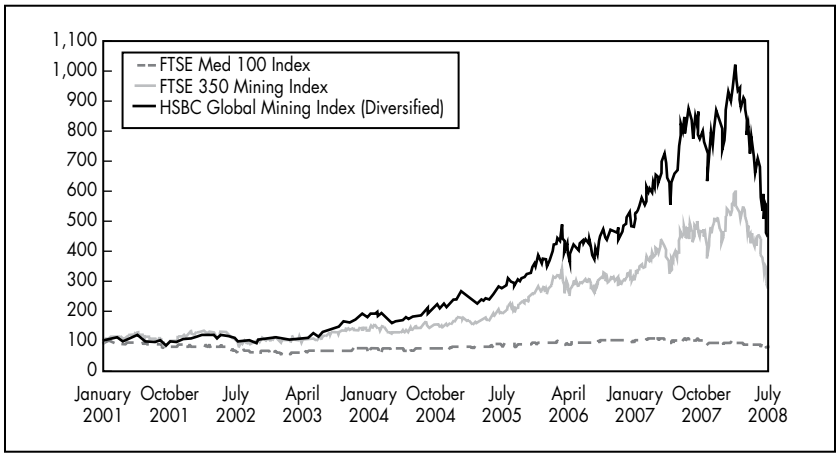
- Projected cash flows and the discount rate applied to them, and
- The multiple that the equity market places on that NPV.

By their very nature, mining companies cannot easily be valued on measures used in industrial and financial sectors—that is, a straightforward price/earning ratio; EV/EBITDA multiples (equity plus debt divided by earnings before interest, tax, depreciation, and amortization); and cash flow multiple or dividend yield of current year's results, because

- In the early stages of development of a mining resource, all potential earnings are in future years;
- Each single resource within a mining group's portfolio has a finite life and is a wasting asset; and
- Variations of grade within each mineral deposit lead to a volatile production profile over the life of the mine and associated differing unit costs.

In addition to these factors, the prices of the commodities produced by mining companies can vary dramatically over an economic cycle, affected as they are by movements in demand, supply, and inventories. At differing points in the economic cycle, therefore, the multiple that the equity market places on future projected earnings also varies. Figure 2.3-2 attempts to encapsulate the influences on the market capitalization of the miners through an economic cycle.

The bulk of this chapter will expand on the factors that affect projected cash flows and the discount rate for mining groups. However, it is worth noting at this point that stock markets contain a wide range of mining companies. The spectrum includes



- Junior exploration companies (ranging from owners of a resource that shows potential, but is still being proven by drilling, to companies where a project is under construction and metal production proposed within a relatively short-term time period);
- Single commodity companies that nevertheless have a range of both producing, developing, and exploration projects, and can spread across more than one geographic region (e.g., Antofagasta plc; Impala Platinum Ltd.); and
- Large multinational diversified mining groups, spread across the whole spectrum of project life cycles, but which also produce a wide range of different commodities and operate around the globe (e.g., Rio Tinto and BHP Billiton).

Figure 2.3-3 shows a graphic representation of theoretical valuation of a *single* mining project. For the investor, his investment risk (the y-axis) reduces as the knowledge of the mineral asset is expanded and as better data on the "modifying factors" that will affect the economic mining of the mineral asset become more reliable (the x-axis).

VALUATION OF JUNIOR MINERS

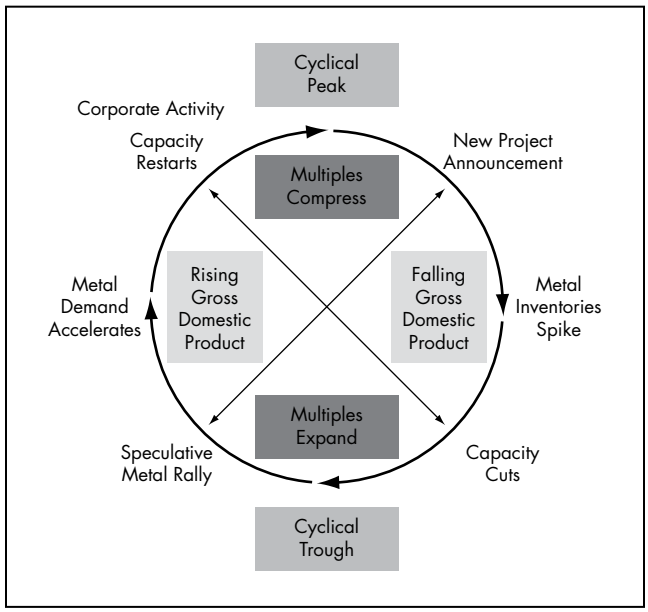
Figure 2.3-3 certainly applies to the valuation of junior mining groups, which are frequently listed on separate stock exchanges (e.g., the Toronto Stock Exchange in Canada and the Alternative Investment Market [AIM] in London). The regulatory requirements of these exchanges reflect the reality that such start-up companies have no history of profit

Fiona Perrott-Humphrey, Consultant to NM Rothschild (mining team), Director of AIM Mining Research & PURE P-H Strategic Consulting, London, UK

Source: Bloomberg 2008.

Figure 2.3-1 Performance of mining indices versus FTSE Med 100, 2001–2008

or cash flows such as those required by the main board exchanges. Because some are not yet producing cash flows or earnings, valuation methods applied to their theoretical future earnings potential are different from those applied to producing miners.



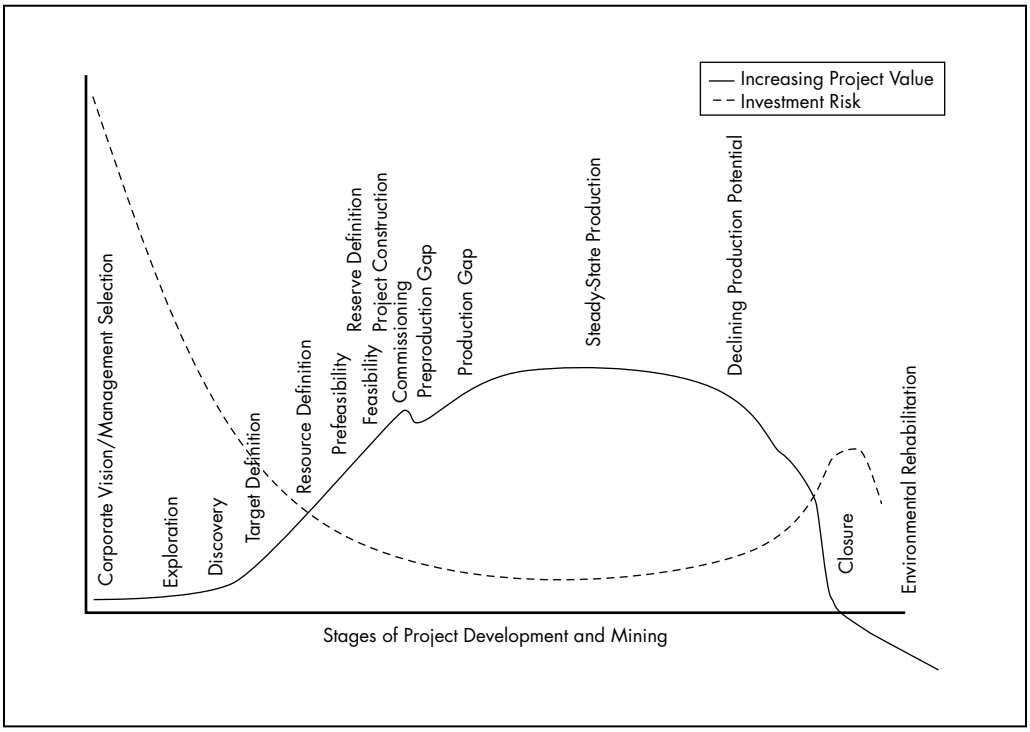
Valuing exploration and development companies in the resource sector is fraught with challenges because of the variability of the information that becomes available through the exploration and development phases, and the fact that each mineral deposit is in some ways unique in its characteristics. For investors with relatively limited access to internal company information and usually no opportunity for a site visit, the process is made even more challenging.

There is an oft quoted, slightly tongue-in-cheek maxim from the mining world that says: "Why spoil a good deposit by mining it?" The implication is that in many ways an exploration junior is like a journey and the stock market believes it is better to travel hopefully than to arrive. When you arrive, after all, and start producing an output that is sold at a fixed price, your company can eventually be valued on the metrics applied across most other sectors of the stock market—that is, price/earning ratio; cash flow multiple, and dividend yield. And the eventual outcome may well be less exciting than the projections built off limited data through the exploration and development phases (e.g., Figure 2.3-3 shows that the theoretical market capitalization of a project is likely to take a dip when the project is commissioned), and probable disappointments occur in the timing/scale of execution of the project versus targets in the feasibility study (termed *preproduction gap*). This fall can then be reversed once revised production targets start to be met.

In that sense, some commentators have compared analysis of early-stage mining juniors to that of biotech companies—that is, not only are the data patchy in the early days of the companies' undertakings, but there also exists a risk that the final outcome could be a complete failure—either no economic mineral body to exploit or no successful biotech product. This is clearly a very different framework from valuation of most other small companies, and the common methods used to value juniors are listed next.

Net Asset Value

In theory, the value of a company equates to the net asset value stated in its report and account. In practice, for junior mining companies in particular, this can be a meaningless figure, for in the early stages of exploration, it reflects no more than the money already spent on the project. This could be overstating its worth (if eventually no economically viable mineralization is found) or severely understating it (if the deposit is proved up according to early projections or even contains further unexpected *blue sky potential*).



Source: N M Rothschild 2008.

Figure 2.3-2 Valuation drivers through the economic cycle

Ore in the Ground

In the gold industry, a very basic guideline that is used for valuations when little real data are available from the property is: "gold in the ground." This valuation will obviously shift along with the ruling commodity price and average industry costs (e.g., in 2007, analysts typically used US$30/oz of reserves for an exploration property but moved up to US$90–US$120 when the company proved that it could actually produce metal).

Companies can frequently trade at premia to the underlying value as calculated on this basis, if investors perceive upside in

Source: Diamond Core Resources 2004.

Figure 2.3-3 Value of mining project versus investment risk

the probability of resources being converted into reserves in the future. There is thus a case for including some kind of weighted value of measured resources as well as reserves, guided by the conversion ratio that the company provides.

There are, of course, significant weaknesses with this valuation tool, primarily the following:

- The wide variances in the *actual cost* of extracting the metal from the wide range of different types of deposit. In addition to the mining costs, there are the logistical and political risk costs associated with operating in a number of far-flung emerging market regions. Finally, processing costs vary dramatically according to the metallurgy required, particularly in the case of platinum group metals, which occur in a combination of five or six elements in differing ratios.
- The *currency-adjusted* cost, which can move significantly as the U.S. dollar moves against the so-called resource currencies, such as the Australian dollar and the South African rand, and possibly even the Chilean peso.
- The variance in regional categorization of resources and reserves. On AIM, for example, a range of standards is used to classify reserves and resources, with the Russian gold producers and a number of companies in the former Soviet Union using the Russian categories of reserves and resources. No formal publication has been released to enable investors to translate the more complex Russian categories into the equivalents provided by the Joint Ore Reserves Committee (Australia), the 43-101 system (Canada), or the South African Mineral Resource Committee.
- The assumed operating margin obviously moves with significant shifts in the commodity prices.

Probability-Weighted NPV

NPV is the most widespread valuation method for resource stocks and in theory is best suited to nonproducing resource companies, given the nature of the development timeline—that is, upfront exploration and development spending before the medium- or long-term benefits flow from producing metal from the mineral asset. The latest guidance note for mining, oil, and gas companies listed on the AIM (London Stock Exchange 2006), issued by the London Stock Exchange, states that the Competent Persons Report should include (among other things): "An estimate of net present value (post-tax) at a discount rate of 10% of reserves (or equivalent depending on Standard used) analysed separately and the principal assumptions (including costs assumptions, effective date, constant or forecast prices, forex [foreign exchange] rates) on which valuation is based together with a sensitivities analysis."

Because of the nature of commodity markets, the scope for variances around many of the items previously listed is significant even when the data available on the mineral asset are becoming relatively well fleshed out. This is clearly so much more the case in the early stages of development, when the geological, and hence all the mining, parameters are prone to major revisions as more data become available.

In the biotech industry, one of the analytical approaches is to develop a discounted cash flow based on the assumption that the products will be successfully developed and sold in a way that is comparable to established industry peers, and then to weight that outcome based on the probabilities of different levels of success in order to come to a final valuation. This approach is also being adopted in different formats in the junior mining sector. The argument for assigning weightings to the four key risk factors in the sector's life cycle based on

probabilities is a compelling one. The risk factors represent four possible downsides:

1. Geological and exploration risk (versus early estimates of the nature of the ore body)
2. Development risks
3. Operational risks (versus feasibility study projections)
4. Financial risks

Offset against these factors would be a weighting for a fifth factor—possible blue sky potential not included in an NPV based only on proven reserves.

VALUATION OF PRODUCING MINING COMPANIES: EXTERNAL FACTORS AFFECTING CASH FLOWS

Typically, investors looking at industrial companies have only one element to consider in interrogating management's projected revenue figures: projected sales volumes at a fixed price. Mining companies provide significantly more of a challenge in this sphere in which, of the three key drivers of the revenue line, two are completely outside of management's control. (Hedging does not allow one to control pricing, only to protect against movements in them.) The three key drivers are

1. Commodity prices;
2. Currency trends, which will determine the actual revenue received in local currency terms translated from U.S. dollar prices; and
3. Production capacity (discussed in the "Valuation of Producing Mining Companies: Internal Factors Affecting Cash Flows" section).

Commodity Prices

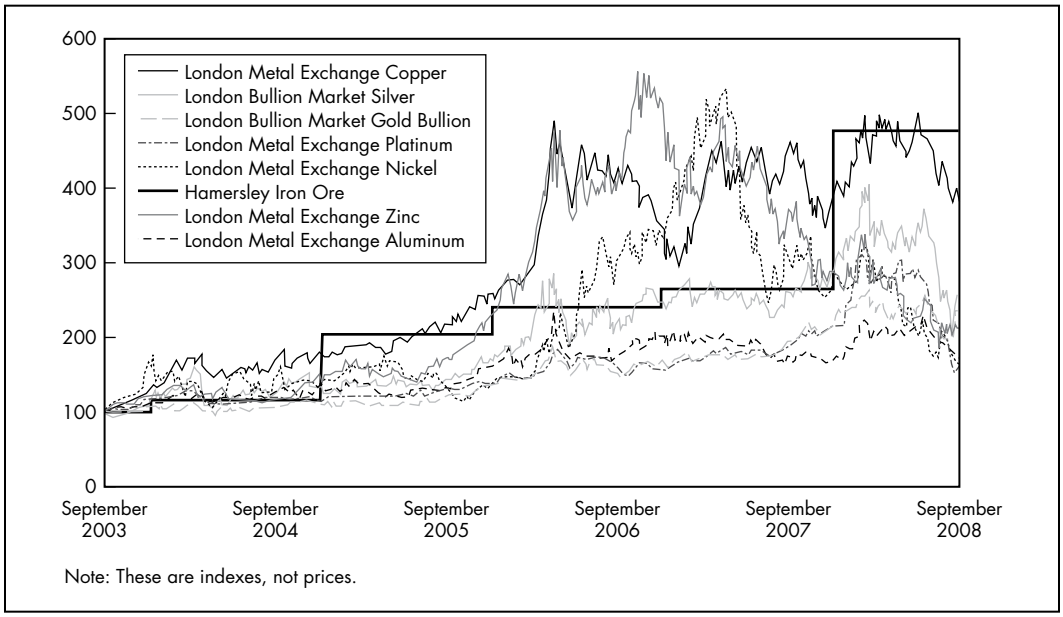
Quoted in U.S. dollars, commodity prices are typically determined on terminal markets, depending on cyclical supply and demand factors. The latter were historically driven by industrial consumers of the metals, but since the 1990s, financial investors' influence at the margin has been growing. Table 2.3-1 shows the categories of metals and minerals and how their prices are set. The terminal markets provide the most visibility on future price trends, whereas those not traded on terminal markets tend to be relatively opaque.

In order to assess how realistic the management assumptions are for future revenue streams, investors are unlikely to become experts in all of the commodity and currency markets, but there are numerous sources of external metal price and currency forecasts, including (but not limited to) most stockbroking research departments plus independent metal consultancies such as CRU, Bloomsbury Minerals Economics, and GFMS. The platinum group metals market is covered by Johnson Matthey in a biannual publication, and diamond prices for different ranges of gems are available from industry sources, the most well known of which are Rapaport and Lenco (www.roughdiamondprices.com).

These external sources are useful not only for the absolute price forecasts that they may provide but also for their information on key aspects of the *structure* of each specific commodity market. That is, prices on terminal markets are influenced not only by overall supply and demand factors but by shorter-term levels of inventory metal held either by end consumers or in market warehouses. In bulk and industrial minerals markets, on the other hand, pricing negotiations are influenced by the level of concentration of industry production (e.g., iron ore) or consumption among that market's players.

Table 2.3-1 Price setting for metals and minerals

Category	How Prices Are Set
Base metals (Cu, Ni, Al, Zn)	Terminal markets such as the London Metal Exchange (LME)
Precious metals (Au, Pt, Pd, Rh, Ag)	Terminal and bullion markets
Diamonds	Influenced by the prices set by largest distributor, De Beers' Diamond Trading Company
Bulk minerals (iron ore, coal, bauxite, chrome, manganese, cobalt, uranium)	Contract prices set by negotiations with large consumers, either annually or more frequently, while spot prices reflect more frequent fluctuations driven by short-term demand and supply factors (and coal markets starting to reflect some of the features of terminal markets)
Industrial minerals (titanium dioxide, borax)	Influenced by individual contracts with major consumers



To assist with the projection of future mining revenues, many of the major mining companies provide some kind of earnings/NPV sensitivities with respect to possible moves in either currencies or commodity prices. Rio Tinto, for example, in its investor presentations will state that, all other things being equal, a 10% move in the Cu price or in the Australian dollar would have a consequent percentage impact on net earnings. These are key in running what-if scenarios on future cash flows at inflection points in the commodity cycles, in view of the scale of the moves in some commodity prices from the bottom of the cycle to the peak (see Figure 2.3-4).

Spot or Long-Term Prices

Given the extent to which commodity prices can move over a cycle, revenue forecasts should be clear as to whether they are based on spot or average long-term prices. At any juncture, spot prices should be treated with some caution, as individual mining companies may have off-take agreements that are tied into contract prices (as well as volume parameters). This is particularly true of smaller, more opaque markets such as uranium, cobalt, and molybdenum, where spot prices can vary significantly from long-term contract prices at some points in the cycle. In most commodity markets, there is also a sliding scale of prices where premia to quoted benchmark prices may be available for better-quality or more highly beneficiated products.

Finally, it is worth checking whether the *theoretical price* will always be available to a mining company operating in a new frontier region. Three particular issues which need to be clarified in this regard are

1. Whether there are restrictions on the potential buyers of the end product, which could influence the price paid (e.g., gold in Zimbabwe);
2. Whether revenue proceeds are able to be remitted freely out of the country where the mining operation is located; and
3. Whether the company is being required by any of its financiers to hedge (sell forward at a fixed price) any element of its future production in order to mitigate political risk considerations.

Figure 2.3-4 Rebased commodity prices, 5-year view

VALUATION OF PRODUCING MINING COMPANIES: INTERNAL FACTORS AFFECTING CASH FLOWS

The graphic representation of the life cycle of a mining project (Figure 2.3-3) points to the factors that affect cash flows in a single-project company. Any larger mining group would simply be a portfolio of such projects, often at very different stages of development. Those mining groups typically rated most highly by the equity investors have the right balance of such projects to ensure that, as a major producing asset starts to tail off in terms of grade and production life, others are waiting to replace it, thus achieving a relatively stable or growing production profile. This is the part of the revenue line that management teams are expected to influence, even as sales and earnings remain vulnerable at another level to the vagaries of the commodity price cycle.

Two key internal components will affect cash flows from any mining project:

1. The *size and quality* of the mineral deposit, which will determine the production potential. In the early stages of exploration, when confidence is low for geological information, the potential is expressed as resources. At later stages, when drilling and geological modeling increases levels of confidence, the potential is expressed as reserves. The size of the economic deposit will determine the life of the mine and the economies of scale to be achieved in mining it, whereas the quality refers to the grade of metal found in the surrounding "waste" material (i.e., the higher the ratio of metal to waste in the deposit, the more economic the project).
2. The *cost of extracting and treating* the ore to turn it into a salable product (either an intermediate concentrate that requires refining by an independent refiner or as a fully refined end product—for example, a gold bullion bar). For a given commodity price, the cost of production can differ substantially between projects (and sometimes countries), thus affecting the profit margin earned.

Table 2.3-2 Production cost standard

Guideline	Features
Cash operating costs	All direct and indirect operating cash costs related directly to the physical activities of producing metals, including mining, processing, and other plant costs; third-party refining and marketing expense; on-site general and administrative costs; and net of by-product revenues earned from all metals other than the primary metal produced at each unit
Total cash costs	Same as cash operating costs plus royalties and mine production taxes
Total production costs	Same as total cash costs plus depreciation, depletion, amortization, and accretion of asset retirement

Equity investors thus rate mining companies according to their relative position on the industry cost curve. Due to the lack of consistency across the industry in reporting cash costs of current production, it is worth clarifying what items are included in various levels of cost categories. Table 2.3-2 contains broad guidelines that are followed by conservative investment analysts.

In addition to the cost items listed in Table 2.3-2, a number of other (sometimes indirect) expenses should be built into any projections that cover the life of the mine:

- **Exploration and mine development expenses, which are typically capitalized.** While not related to the current production, hence the exclusion from the current cost per ounce, this expenditure needs to be incurred to ensure that there are ounces to mine in the future. A key element of this is stripping. The correct measure of the minimum cash expenditure required should thus be "total cash costs plus the essential capital expenditure required for ongoing mining."

- **Financing costs.** Although not included in Table 2.3-2, these costs are a crucial element for junior miners in particular (because they lack cash flow from producing assets), both in ongoing total cash costs and in NPV terms. During the mining boom of 2003–2008, junior miners had relatively easy access to equity financing, usually at rising share prices each time, and this element of costs could thus have been glossed over. Because of the cyclical nature of the industry, however, all aspects of the company's financing issues are also cyclical—access to debt financing alternatives; current cost of debt alternatives and whether this is a fixed or variable element of costs; nature of debt covenants; whether the lenders demand an element of price hedging, which would cap the upside of the project in markets of rising prices; whether the presence of quasi-government lenders on the book imposes any related constraints on the company (e.g., International Finance Corporation); whether the company has fully covered the risks of borrowing heavily from local banks in some of the emerging markets areas; and whether companies have raised sufficient capital to fund their projects to completion.
- **Cost escalation over life of mine.** Because of the variable nature of each geological deposit, today's snapshot of a cost profile day is likely to be subject to significant change over the life of mine. Factors that can cause quantum moves to the cost profile include shifts in grade or stripping ratios, or the need to move from open-pit to underground operations. In addition, the global mining industry is currently experiencing cyclical cost escalation on the back of what has been (up to early 2008) the longest commodity price boom since World War II. It has driven up both the cost and availability of energy, skills, contractors, spares (e.g., tires), and materials. Longer lead times combining with cost escalation in new projects has seen capital expenditure estimates revised upward at almost every mining company reporting period, with implications for both NPV values and financing costs.
- **Smelting and refining costs.** These can also vary significantly over the cycle for a miner that does not have a fully integrated operation (toll smelting agreements are fixed or variable). The efficiency of the metallurgical process in treating more complex metals such as platinum group metals is a key competitive element among producers, as is the cost of energy in highly energy-intensive treatment processes such as aluminum smelting.
- **Royalties and taxes.** Although in theory these should be steady factors over the life of mine, in practice, commodity-related charges tend to be increased by governments as they watch the products' prices rise through the cycle or as new regimes take control in resource-rich nations. This trend of so-called economic nationalism has been evident on almost every continent and resulted in a rise in the risk premium assigned to many companies operating in emerging markets some 6 months before concerns about a global economic downturn emerged.

DISCOUNT RATES APPLIED TO PROJECTED CASH FLOWS

Even though this is a key factor in driving the end result of the NPV, there are no guidelines that hold across the board. The major areas of difference rest on assessments of cost of capital, political risk, and project development risk.

Cost of Capital

Although this should reflect a company's weighted average cost of capital (equity and debt), estimates have historically varied between key resources markets, with the North American analysts tending to use lower figures, ranging from 0% to 5%, in contrast to their counterparts elsewhere who use numbers ranging from 5% to 10% (and interestingly AIM's guideline number of 10% after tax). This whole spectrum of cost of capital is likely to shift as the long period of easy and generally low-cost finance of 2003–2008 ends in a cyclical economic downturn. Within these average statistics, however, the capital structure of individual companies and the cost of the financing available will also vary widely.

Political Risk

These discount factors are even more subjective (usually biased by proximity), primarily because each company is unique in its aggregate exposure to generic (or sovereign) country risk (depending on where its many projects are and to what extent it can benefit from the portfolio effect of one type of risk offsetting another) and to more specific project-related risk (still within the context of political risk assessment). In addition, most investors will be pricing political risk in different contexts, depending on their own portfolio spreads, ability to hedge, and even the requirement for a particular country exposure (where a mining company's discount rate is then priced relative to other sectors in that country, rather than against other geographic regions).

Project Development Risk

The key elements that equity markets consider most important in determining the success or failure of the vital development phase—turning a geological resource into ounces of metal sold—are the following:

- Security of tenure, given the need for most natural resource companies to operate in emerging market regions
- Key characteristics of the ore body, particularly grade
- Operating parameters of open-pit versus underground mine development
- Plant and metallurgical efficiencies
- Logistics, particularly when a mine is located in a remote region
- Management record in developing projects to production stage
- Environmental issues that demand increasing amounts of company time and resources, covering not only the physical environment (where actual legislation will govern company requirements) but also the socio-cultural component (where local communities are capable of stalling potentially viable ventures if their concerns are not addressed)

MARKET CAPITALIZATION: THE FINAL ELEMENT

Much of this chapter has covered the issues surrounding projected cash flows for mining companies and determination of the discount rate used to convert them into an NPV. The final element of a mining company's market capitalization is the multiple which the equity market places on this theoretical NPV. A number of factors affect it:

- **Company profile in terms of the diversity of the asset portfolio by geography and by product.** Typically,

the large diversified groups such as Rio Tinto and BHP Billiton trade at a premium to their peers because of the lower risk to cash flows if one commodity or region is adversely affected. However, it is also true that at certain points in a rising commodity cycle, investors seek to play more highly geared or single-commodity companies that could see higher earnings growth from a lower base. At these junctures, the diversifieds can be de-rated as "dull."

- **Growth potential.** Although large producers may be less risky, investors also worry that it becomes increasingly harder for them to achieve earnings growth from a high base. In a world in which it is a challenge to find new, large, low-cost resources to replace wasting assets, the market will frequently rate small or mid-cap producers more highly than their major peers. This can be particularly true in the gold sector, where the shorter average life of mine means that wasting reserves need to be replaced more frequently than in other sectors.
- **Point in the economic-and-commodity cycle.** Equity markets discount future earnings as far ahead as 18 months to 2 years. Figure 2.3-2 illustrates that (counter-intuitively) multiples compress as the economy heats up, and commodity prices/earnings top out and expand in the depth of a recession as profitability declines.
- **Merger and acquisition activity.** Historically, major upsurges in merger and acquisition activity have occurred at low points in the economic/commodity cycle. Companies with stronger balance sheets have sought to pick up assets at low prices from distressed sellers in order to cut costs and undertake consolidation/capacity closures. In the recent upturn, however, mining companies who believed in the supercycle were worried about a shortage of new high-quality assets to fuel their future growth in supply. A rash of activity thus occurred at a time of historically high metal prices. Either way, a belief that corporate buyers are seeking to add to their asset portfolios can distort valuation multiples away from those based on fundamental analysis.

MARKET CAPITALIZATION: DIFFERENCES WITH JUNIORS

As indicated earlier in this chapter, there can be key differences in valuing early-stage mining companies and major producers. Equally, it is the case that at times during the commodity cycle, indices of junior shares (such as those listed on AIM in London) can tend to show relatively high levels of volatility, not necessarily correlated to the performance of the FTSE Mining Sector Index. Reasons can include the following:

- Internal flow of information is the primary share price driver for early-stage miners, as mispricing frequently occurs on extrapolation of the earliest data. This is either followed by disappointments (e.g., Tran-Siberian Gold, which in 2006 announced that one of its three key deposits would not be economically viable on the technology originally assumed) or upgrades of blue sky potential (e.g., Peter Hambro Mining, which acquired new licenses in auctions during 2006, and, as it met development and production targets on current assets, the market priced in the upside on a similar basis for newly acquired development assets over the following year).
- Liquidity is lower than on the main stock exchange boards, so when new information emerges or when a small circle of original backers looks to take profits, the moves either way can be exacerbated.
- Funds flowing into the sector in an up-cycle can exacerbate price moves, due to the previous point, but when the cycle turns decisively or even has a short-term correction, lack of liquidity can also exacerbate downward price adjustments.
- Political risk shocks have a much more powerful impact, given the exposure of many AIM mining companies to no more than two or three major projects and their current propensity to explore in the new frontier regions without the portfolio insurance effect of the majors.
- Investment by a major in a junior can underpin the share price, but that is not a guarantee that the share price will be immune to either internal news flows or political risk shocks.
- Interest rate moves tend to affect those shares and sectors most reliant on future discounted cash flows for their valuations (rather than more defensive sectors valued on near-term cash multiples). Exploration and development mining companies fall into that category.
- Scarcity value can sustain juniors at what seem to be very high underlying valuations, when there is a perceived shortage of large new discoveries of a particular commodity. This was the case with most diamond juniors during 2006–2007, given the dearth of new supply sources announced in this sector for some years now.
- Primary commodity exposure will also be key over time, as price rises across the spectrum have not been of the same scale. In 2005, for example, iron ore price increases dwarfed those in any other commodities, seeing majors Rio Tinto and BHP Billiton outperform peers for some months. This was clearly a commodity in short supply among the juniors at that time.
- Dividend distribution potential is in most cases a distant prospect for most early-stage juniors, whereas substantial capital returns/special dividends have been a major driver of the main board mining sector during 2006–2008. When the market is focusing on dividends and immediate cash returns (usually in bear market phases), this becomes another potential reason for the two markets to diverge in their performance trends.

CHAPTER 2.4

Investment Analysis

Michael Rawlinson

Investment analysis is the study of the likely return from a proposed investment with the objective of evaluating the amount an investor pays for it, the investment's suitability for that investor, or the feasibility of a proposed development. The result of the analysis would typically be a "buy," "sell," or "hold" action for a listed mining equity or "go" or "don't go" decision on a new investment in, for example, a new mine. Crucially, investment analysis is *not* the exclusive study of whether one company or asset is high quality or not. Good assets can be overpriced and poor ones too cheap; the investment analyst's job is to make money from his or her investments, not find great, well-run companies.

For the purposes of this chapter, the analysis behind making investments in listed equities from the standpoint of a sell-side investment analyst is looked at. (*Sell-side* refers to those in the investment community who make a living selling advice to investors. Their adjunct, the *buy-side*, are their investing clients.) In reality, the process of investment analysis is similar for the buyers of the assets (typically at fund management institutions such as pension funds, insurance firms, or hedge funds).

INTRINSIC VALUE VERSUS "CASTLES IN THE SKY"

Investment analysis is more than a straight analysis of the intrinsic value of an entity. In his book *A Random Walk Down Wall Street*, Burton Malkiel expands on this theme by suggesting at one extreme there is a "firm-foundation theory" behind investing—where intrinsic value should drive investment decisions—and at the other end is the "castles in the sky" theory of investing (Malkiel 1973).

The firm-foundation theory argues that each investment instrument, be it a common stock or a piece of real estate, has a firm anchor of something called intrinsic value, which can be determined by careful analysis of present conditions and future prospects. When market prices fall below (or rise above) this firm foundation, a buying (or selling) opportunity arises, because this fluctuation will eventually be corrected—or so the theory goes. Investing then becomes a dull but straightforward matter of comparing something's actual price with its firm foundation of value. In mining, the net present value, or NPV (see Chapter 2.3), is the primary measure of intrinsic value upon which rational investment decisions ought to be made.

In deriving a company's NPV, the mining equity analyst must estimate key drivers such as production, grade, and costs but also potential future growth and key macroeconomic variables such as commodity prices. Views on such factors—in particular, growth rates and key macroeconomic variables such as commodity prices—are extraordinarily cyclical, so the firm-foundation theory relies on some tricky forecasts that themselves move with market sentiment.

Malkiel's castles-in-the-sky theory of investing concentrates on the psychology of investing. John Maynard Keynes, the famous economist and successful investor, enunciated the theory most lucidly in 1936. It was his opinion that professional investors prefer to devote their energies not to estimating intrinsic values but rather to analyzing how the crowd of investors is likely to behave in the future and how during periods of optimism they tend to build their hopes into castles in the sky. The successful investor tries to "beat the gun" by estimating what investment situations are most susceptible to public castle-building and then buying before the crowd.

WHY INVESTMENT ANALYSIS IS IMPORTANT

Good investment analysis can make or save investors huge amounts of money. Backing Xstrata at its float in 2002 and selling in May 2008 would have made investors a return of 756% versus what many thought was a safer, better investment in the blue chip Anglo American (which was still up an impressive 200% over the period) (Figure 2.4-1). At the smaller end of the scale, picking winners in the juniors can be much more rewarding. Fortescue Metals Group had a similar market capitalization to iron ore miner Mount Gibson Iron in 2002, but an investor backing Fortescue over Mount Gibson could have made 316,986% more (Figure 2.4-2).

By the same token, a good analyst knows when to avoid certain investments—identifying bad companies with problems or perhaps when it is an inappropriate time to buy. The brave call of May 2008 was to sell, and a small handful called that right. Aside from making money for investors,

Michael Rawlinson, Director and Head of Mining and Metals, Liberum Capital, London, UK

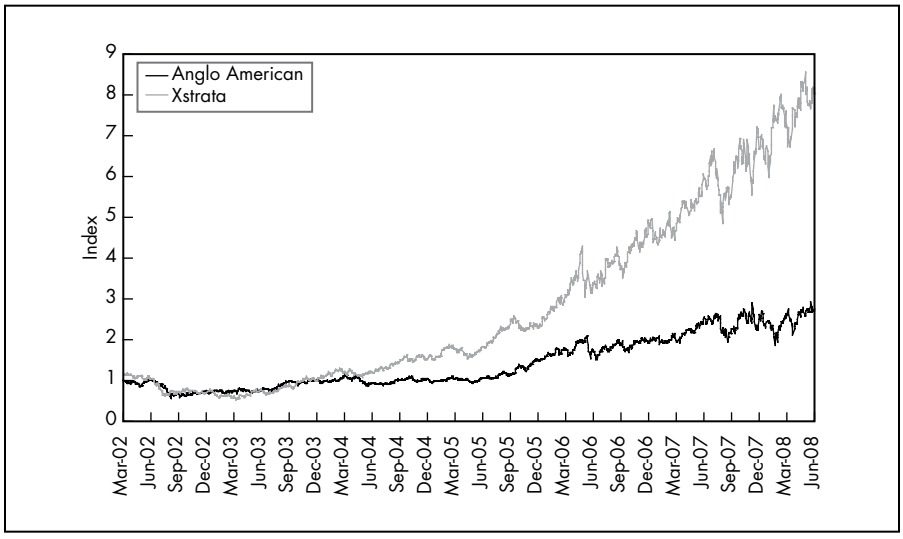

Figure 2.4-1 Relative share performance between Xstrata and Anglo American, March 2002 to May 2008 (indexed March 1, 2002 = 1)

analysts play an important part in the capital markets that allocate debt and equity to companies. Analysts are an integral part of the feedback loops that guide management of publicly listed companies—providing insights and observations about the strategic, operating, and financing practices of each company. Companies that have supportive analysts typically enjoy a heightened profile among financial institutions and also rival corporations. A strong and positive analytical following means companies are often better able to raise equity and debt capital when they need to and attract partners/bidders in mergers and acquisitions work. Although this applies more to smaller and mid-capitalization companies, even large companies need to be sure they are seen (at worst) fairly by the analytical community. Companies that are loathed by analysts often end up with low-rated shares and find it more difficult to raise money cheaply.

JOB OF AN EQUITY INVESTMENT ANALYST

The day-to-day job of a mining investment analyst is split between researching, modeling, and writing about companies; visiting and talking to the companies and industry contacts; and marketing to investors.

Financial Model

Having a financial model on the company is a starting point for an analyst but, importantly, cannot provide the answer as to whether the company is a sound investment proposition. The financial model should have key operational metrics (tonnage, grade, production, and cash costs) with macroeconomic variables such as commodity prices and exchange rates. In larger banks, some of the macroeconomic assumptions are determined by in-house economists, so the analyst's view is necessarily colored by that financial institution's house view. The operational model then creates the traditional outputs of

Table 2.4-1 Valuation as of March 10, 2009

Mining Company	Share Price, £/share	EV	EBITDA		Earnings per Share (US¢/share)		EV/EBITDA		Price/ Earnings per Share	
			2009E*	2010E	2009E	2010E	2009E	2010E	2009E	2010E
Anglo American	9.14	27,460	6,421	5,364	177	118	4.3	5.1	7.3	10.9
BHP Billiton	10.34	89,728	19,896	13,638	192	119	4.5	6.6	7.5	12.1
Rio Tinto	18.23	71,467	16,542	13,655	507	372	3.8	4.5	5.0	6.9
Xstrata	3.36	26,683	5,529	4,795	56	35	4.8	5.6	8.4	13.3

*E = estimated.

the profit-and-loss, cash-flow, and balance sheet statements for the company.

The purpose of a robust but simple model is twofold:

1. It generates the key valuation outputs with which investors compare companies across sectors. The most commonly used metrics in mining remain the traditional ones: price/earnings (P/E) multiples (PERs or price/earnings per share), EV/EBITDA (enterprise value/earnings before interest, taxes, depreciation, and amortization), dividend yields (price/dividend per share), leverage metrics such as net debt/EBITDA and net debt/market capitalization, and the net debt and price/NPV. (See the glossary at end of this chapter for definitions of financial terms.) An example of the valuation metrics for the big four U.K. mining companies is set out in Table 2.4-1.
2. The spreadsheet facilitates the modeling of various scenarios (macroeconomic, production, and costs) that allow investors to understand the company's key characteristics such as operational and financial leverage (earnings and cash-flow sensitivities to operational drivers such as grade, volumes, capital expenditure, unit costs; and macro drivers such as currencies, commodity price, interest rates, and key cost inputs).

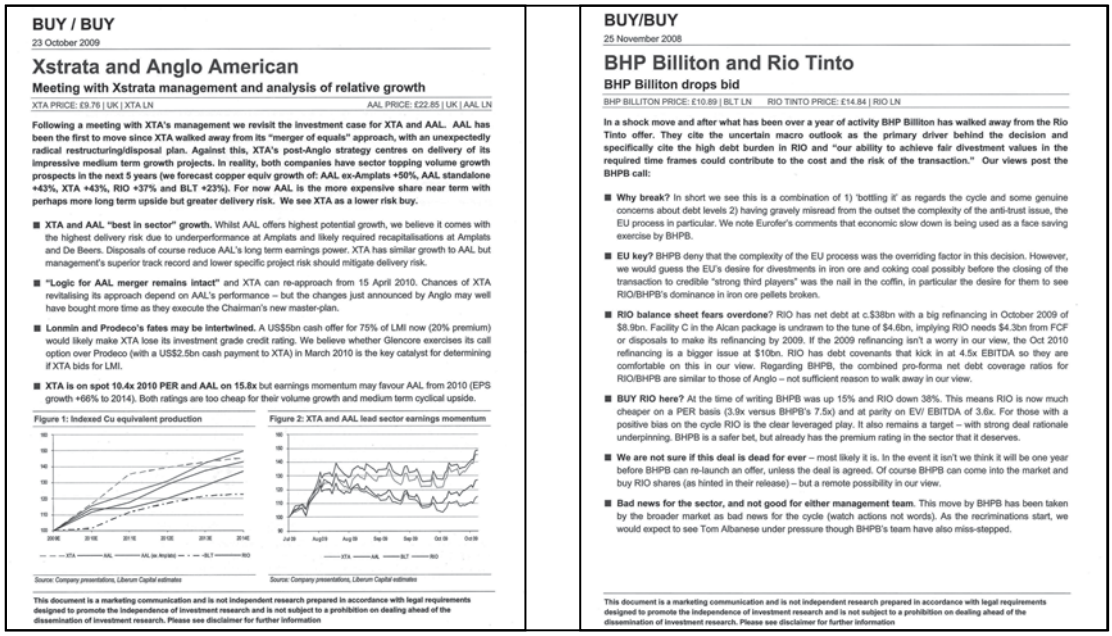
Written Product

To the external world, the product of research is the research note—typically a 10- to 50-page document describing the company, its financials, valuation, and investment thesis, with some pointers to catalysts for share price moves. (See Figure 2.4-3 for examples.) Although the note has a shelf life, in reality, more informal and frequently written communication forms are the main outputs from a research analyst. These tend to be PowerPoint presentations and chart books, e-mails, and/or Bloomberg messages. Indeed, the more influential investment analysts tend to write less and communicate more by way of short update communications (typically e-mails, telephone calls, Bloomberg chat messages).

Client Contact: Analysis as a Contact Sport

Analysts need to be good communicators, because it is their business to gather and trade in information. They build their investment theories via cross-checking information with industry and other market participants and, once done, must market their own research products through direct contact to portfolio managers and buy-side analysts.

INDEPENDENT RESEARCH AND LINK TO INVESTMENT BANKING



When considering the quality and fairness of any investment research, it is worth knowing the context in which it has been written: Is it genuinely independent or was it influenced by some broader investment banking prerogative? Investment banks, the employers of the investment analysts, can make money from mining companies in a number of ways. Their corporate finance/capital markets departments can make lucrative advisory and underwriting fees from equity and debt securities (rule of thumb 2% to 5% of any money raised in a financing), while the securities businesses earn income from providing sales, trading, and research advice to institutions about shares, including mining equities. Traditional payment terms for this kind of secondary agency trading are around a tenth of that for primary (new equity) offerings. In addition, securities firms can make money from trading in the securities themselves (proprietary trading).

In the small-capitalization arena especially, returns from writing primary-oriented research (i.e., favoring corporate clients to win potentially lucrative corporate business for the broader firm) can potentially dwarf the income from secondary commissions. As such, firms without proper, trusted, and transparent policies that address the potential conflicts of interests surrounding research are often not regarded as highly valued providers of investment research. Also, it is more likely at the small-cap end of the market that the existence of truly unbiased, independent research on corporations is scarce, because the economics of secondary commissions do not make coverage worthwhile.

SKILLS FOR THE SUCCESSFUL INVESTOR

The following skills are needed to be a successful investor:

- **Recognize history and investment cycles.** The four most dangerous words in investing are "this time it's different"; therefore, a knowledge of business and investment cycles is especially important for a cyclical sector such as mining. The same can be applied to cycles in market sentiment to a sector or stock: The time of maximum pessimism is the best time to buy, and the time of maximum optimism is the best time to sell.
- **Be contrarian and be patient.** If the goal is to buy low and sell high, it is worth observing the words of Sir John Templeton (an investor of world renown) that "it is impossible to produce superior performance unless you do something different from the majority" (Templeton 1997). Timing of the buying is key, and it is worth being careful to select the right time to buy an industry, stock, or management team. U.S. businessman Warren Buffett draws parallels with baseball in which he observes those batsmen with the best batting averages don't swing at every ball but wait for a "fat pitch" when the right stock can be acquired at an attractive price.
- **Be skeptical and think both top down and bottom up.** Leaving market assumptions and company managements unquestioned will not unearth profitable investment

BUY / BUY
23 October 2009

Xstrata and Anglo American

Meeting with Xstrata management and analysis of relative growth

XTA PRICE: £9.76 | UK | XTA LN AAL PRICE: £22.85 | UK | AAL LN

Following a meeting with XTA's management we revisit the investment case for XTA and AAL. AAL has been the first to move since XTA walked away from its "merger of equals" approach, with an unexpectedly radical restructuring/disposal plan. Against this, XTA's post-Anglo strategy centres on delivery of its impressive medium term growth projects. In reality, both companies have sector topping volume growth prospects in the next 5 years (we forecast copper equiv growth of: AAL ex-Amplats +50%, AAL standalone +43%, XTA +43%, RIO +37% and BLT +23%). For now AAL is the more expensive share near term with perhaps more long term upside but greater delivery risk. We see XTA as a lower risk buy.

- **XTA and AAL "best in sector" growth.** Whilst AAL offers highest potential growth, we believe it comes with the highest delivery risk due to underperformance at Amplats and likely required recapitalisations at Amplats and De Beers. Disposals of course reduce AAL's long term earnings power. XTA has similar growth to AAL but management's superior track record and lower specific project risk should mitigate delivery risk.
- **"Logic for AAL merger remains intact"** and XTA can re-approach from 15 April 2010. Chances of XTA revitalising its approach depend on AAL's performance – but the changes just announced by Anglo may well have bought more time as they execute the Chairman's new master-plan.
- **Lonmin and Prodeco's fates may be intertwined.** A US$5bn cash offer for 75% of LMI now (20% premium) would likely make XTA lose its investment grade credit rating. We believe whether Glencore exercises its call option over Prodeco (with a US$2.5bn cash payment to XTA) in March 2010 is the key catalyst for determining if XTA bids for LMI.
- **XTA is on spot 10.4x 2010 PER and AAL on 15.8x** but earnings momentum may favour AAL from 2010 (EPS growth +66% to 2014). Both ratings are too cheap for their volume growth and medium term cyclical upside.

BUY/BUY
25 November 2008

BHP Billiton and Rio Tinto

BHP Billiton drops bid

BHP BILLITON PRICE: £10.89 | BLT LN RIO TINTO PRICE: £14.84 | RIO LN

In a shock move and after what has been over a year of activity BHP Billiton has walked away from the Rio Tinto offer. They cite the uncertain macro outlook as the primary driver behind the decision and specifically cite the high debt burden in RIO and "our ability to achieve fair divestment values in the required time frames could contribute to the cost and the risk of the transaction." Our views post the BHPB call:

- **Why break?** In short we see this is a combination of 1) 'bottling it' as regards the cycle and some genuine concerns about debt levels 2) having gravely misread from the outset the complexity of the anti-trust issue, the EU process in particular. We note Eurofer's comments that economic slow down is being used as a face saving exercise by BHPB.
- **EU key?** BHPB deny that the complexity of the EU process was the overriding factor in this decision. However, we would guess the EU's desire for divestments in iron ore and coking coal possibly before the closing of the transaction to credible "strong third players" was the nail in the coffin, in particular the desire for them to see RIO/BHPB's dominance in iron ore pellets broken.
- **RIO balance sheet fears overdone?** RIO has net debt at c.$38bn with a big refinancing in October 2009 of $8.9bn. Facility C in the Alcan package is undrawn to the tune of $4.6bn, implying RIO needs $4.3bn from FCF or disposals to make its refinancing by 2009. If the 2009 refinancing isn't a worry in our view, the Oct 2010 refinancing is a bigger issue at $10bn. RIO has debt covenants that kick in at 4.5x EBITDA so they are comfortable on this in our view. Regarding BHPB, the combined pro-forma net debt coverage ratios for RIO/BHPB are similar to those of Anglo – not sufficient reason to walk away in our view.
- **BUY RIO here?** At the time of writing BHPB was up 15% and RIO down 38%. This means RIO is now much cheaper on a PER basis (3.9x versus BHPB's 7.5x) and at parity on EV/ EBITDA of 3.6x. For those with a positive bias on the cycle RIO is the clear leveraged play. It also remains a target – with strong deal rationale underpinning. BHPB is a safer bet, but already has the premium rating in the sector that it deserves.
- **We are not sure if this deal is dead for ever** – most likely it is. In the event it isn't we think it will be one year before BHPB can re-launch an offer, unless the deal is agreed. Of course BHPB can come into the market and buy RIO shares (as hinted in their release) – but a remote possibility in our view.
- **Bad news for the sector, and not good for either management team**. This move by BHPB has been taken by the broader market as bad news for the cycle (watch actions not words). As the recriminations start, we would expect to see Tom Albanese under pressure though BHPB's team have also miss-stepped.

opportunities. In the same way, there is no substitute for long hours of forensic research in understanding the detail behind specific companies and markets. To a degree, a rising tide lifts all boats, but, as the 2008 downturn has shown, large dislocations in markets can trigger some widely differing market outcomes for stocks in a similar sector.

SKILLS FOR THE MINING ANALYST

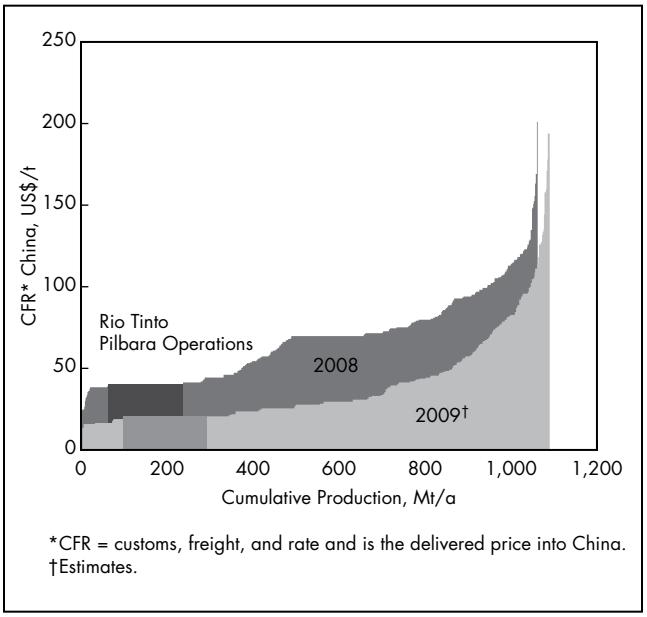
The coverage of small-cap/development mining companies (i.e., less than $200 million to $500 million) requires a different skill set than that required for large-cap companies. In the small-cap world, some technical background (geology, mining engineering) is a likely prerequisite so as to be credible in ascertaining whether a project will be successful. Analysts covering the large diversified mining companies are probably better served if they have a background in business or economics, because understanding the implications of news in the global macro-economy or capital markets is likely to be a far more significant driver to equity performance for a company such as BHP Billiton than knowing the technical viability of a new project.

SKILLS FOR THE SELL-SIDE ANALYST

On a personal level, success can be assisted by several factors:

- Being energetic and committed, following hunches rather than waiting and not acting
- Being first to elucidate an investment idea: identifying then talking about the one thing that matters to a company's share price before it happens
- Taking the time to have better and deeper relationships with company management, industry players, and key institutions

Success is *not* about writing a definitive 200-page report on a single company or producing a multi-megabyte Excel model that no one can understand.



INSIDE THE ANALYST'S TOOLBOX

A mining analyst needs to understand how mining is different from other industries: It is commonly but not always characterized as large-scale, capital-intensive, driven by asset locations, and with low pricing power and high barriers to entry. Long-term returns of a mining company over several investment cycles are driven by the quality of the assets and the management teams that run them. However, for shorter investment horizons, a panoply of other factors can become more important to the performance of a mining share. The full range of drivers is discussed in the following paragraphs.

Assets: Quality, Optionality, and Operational Leverage

The Holy Grail in the world of mining is a large, low-cost, and long-life asset. Superior long-term returns can be enjoyed by companies that own these assets; indeed, Rio Tinto has estimated that the best 30% of the world's mines generated 70% of the investment returns. Companies that have assets at the bottom end of a cash cost curve are likely to generate cash flows throughout the cycle, allowing the owner to survive and prosper in even the worst macroeconomic climate (Figure 2.4-4). Analysts judge assets by their position on the cash cost curve and the capital costs per metric ton (t) of the capacity to build it. Large, long-life assets can be company makers in the longer term, because they have expansion optionality at low capital costs.

Capital intensity and operating costs drive a company's operational leverage—that is, the sensitivity of financial returns (cash flows) to changes in price, cost, and volume throughputs. High-quality assets typically have low operational leverage, which gives the investment relatively stable earnings and cash flows—something rated highly by both debt and equity investors. Of course, there are times in the business cycle when investors seek out operational leverage; recovering commodity prices can transform high-cost producers' earnings, making them massively outperform higher quality peers, in any cyclical recovery.

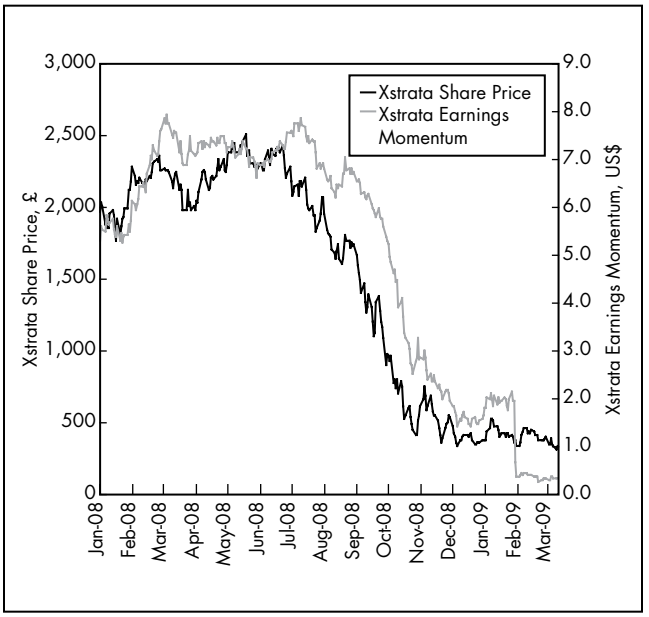

Figure 2.4-5 Xstrata share price versus Xstrata earnings-per-share momentum

Earnings Momentum and the Cycle

Equity markets are often criticized for being short-sighted—with cyclical valuations that fail to look through economic cycles. At the time of writing (early 2009), the mining sector is trading at less than half the level that it was under a year earlier, yet it is not clear that the intrinsic long-term value of the assets has halved (Have asset lives changed? Have long-term pricing and margins for the assets changed?). What has happened in the credit crunch hit of 2009 is that mining company earnings have collapsed and the price of alternative investments has also fallen dramatically. Figures 2.4-5 and 2.4-6 illustrate how the earnings momentum of a stock (here described as the estimated earnings per share of Xstrata on a rolling 1-year forward basis of the spot price of its commodities on that day) is highly correlated with its equity price performance. The resulting PER trades in a tighter range through the cycle, with peak multiples achieved when equity prices (and earnings are troughing) and valuation troughs at the top. Getting the investment calls right then is mostly driven by calling the price cycle for the basket of commodities.

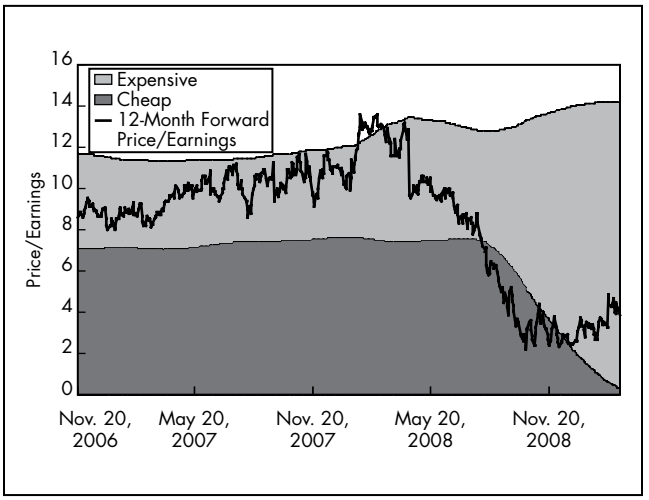

Figure 2.4-6 Xstrata PER range

Calling commodity prices is a dark art in itself—often aided by supply/demand balance models. Analysis of the supply side involves modeling the existing production of a commodity and making educated guesses as to the timing of any capacity additions and/or curtailments and having a view on the all-important stock position. As a general rule, supply additions are usually known well in advance (i.e., there is always a low risk of a surprise price event from new supply), but negative supply shocks (i.e., mine closures) can trigger terrific price movements when markets have no inventory. This occurred in 2008 in ferrochrome and platinum markets when South African electricity supply problems led to supply disruptions and a subsequent spike in pricing.

The demand side of commodity forecasting is heavily influenced by global macroeconomics. The key market for demand has now become China for most major commodities, though the OECD (Organisation for Economic Co-operation and Development) countries account for a greater overall share of demand (Figures 2.4-7 and 2.4-8).

Currencies also have an influence on commodity prices. Typically, a weak dollar (i.e., the dollar is weak relative to the basket of other major currencies) is good for dollar pricing (more purchasing power for a mainly nondollar-denominated consumer). Currencies can be an important driver of unit costs too—the commodity currencies of the rand, Australian dollar, and Canadian dollar tend to be negatively correlated with commodity prices—giving mining companies in those countries somewhat of a natural hedge against the commodity cycle.

Figure 2.4-9 shows the relationship between the Commodity Research Bureau (CRB) Index—an index of key commodity prices including those in energy, agriculture, and metals—and the Australian dollar.

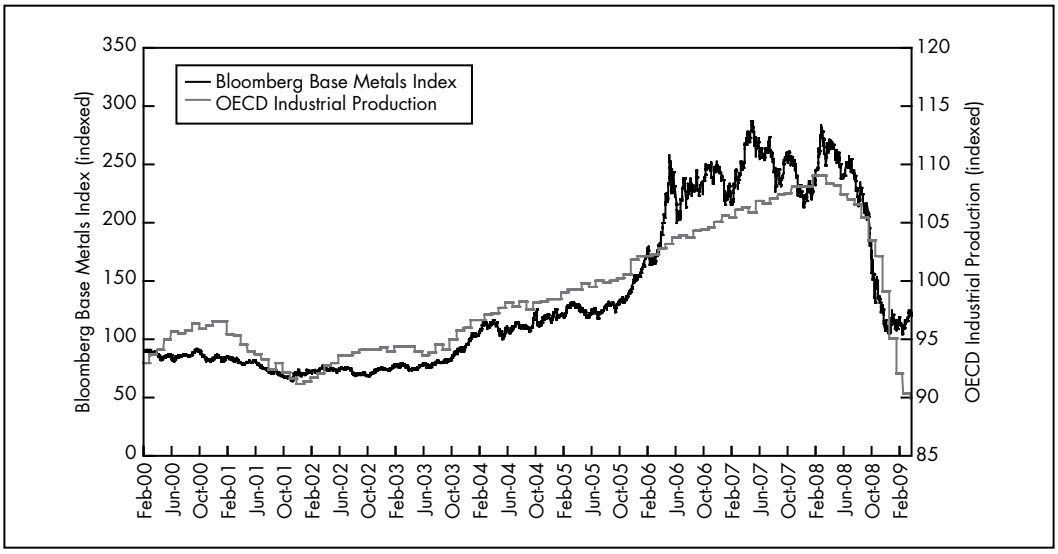

Figure 2.4-7 Base Metals Index versus OECD total industrial production (indexed Feb. 1, 2000 = 100)

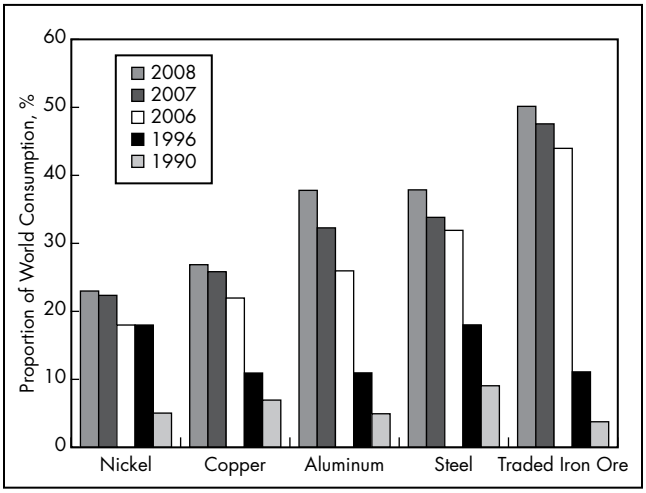

Financial Leverage and Liquidity

Debt and the ability to service debt becomes a major issue in any cyclical downturn. Companies with high levels of debt have more leverage to the cycle, which increases their riskiness to investors and limits their ability to raise capital. Modeling the ability of companies to service debt obligations in a downturn can be crucial in saving investors' money. Things to look for in a balance sheet and cash-flow statement are debt/EBITDA ratios (anything above 2× can be dangerous), interest coverage (interest charge/EBITDA), free cash-flow numbers post-capex (capital expenditure), and other obligations and major debt refinancing dates. Figure 2.4-10 illustrates that highly leveraged companies had poor equity performance in the 2008 downturn relative to their less leveraged peers.

Management Skills: Execution, Mergers and Acquisitions, Governance

It is probably true that a mining company's most important resource is its people and not its ore deposits. A solid management team is one that can run its asset base efficiently through the cycle. Xstrata's management team acquired what at the time was regarded as tier 2 assets, then lowered their unit costs and extended their lives. Similarly, fantastic ore bodies can be ruined by imprudent mine designs and poor operational practices such as high-grading.

Because mining is such a capital-intensive industry, the best returns and most expensive mistakes by a management team are made at the point of approving major capital decisions. These choices define a management team and the shareholder returns of a company, and range from the decision to develop a major project or embark on a major merger and acquisitions (M&A) transaction. Famously sound decisions to develop projects are made in the teeth of bear markets when contracting and construction costs are low and consensus outlooks for commodity prices are so conservative that other producers dare not expand production (thereby setting the scene for a price recovery). Similarly, projects launched at the peak of the boom suffer from high capex costs and poor ability to execute through staffing and other shortages,

Courtesy of Rio Tinto and Liberum Capital.

Figure 2.4-8 China: the world's number one consumer of every major mined commodity

and are typically founded on overoptimistic commodity price decks.

It is perhaps in the world of mergers, disposals, and acquisitions where the most value can be created and destroyed in a cycle. Since about 2000, the sector heroes are those that bought large assets in the early years of the decade: Rio Tinto's acquisition of North Ltd., Anglo American's acquisition of the Disputada copper mine in Chile, and Xstrata's acquisition of MIM Holdings, for example. Interestingly, these same companies, some under different managements, were seen by the market to have made expensive errors of judgement at the tail end of the decade (2007–2009) with the acquisitions of Alcan by Rio Tinto, Falconbridge by Xstrata, and MMX (Mineracao's Minas Rio mine) by Anglo American. A keen sense of the cycle (which can be as much luck as judgment) as well as a robust capital allocation committee can be a key attribute of management.

Aside from strong technical, operating, and capital allocation skills, investors look for management that can deftly

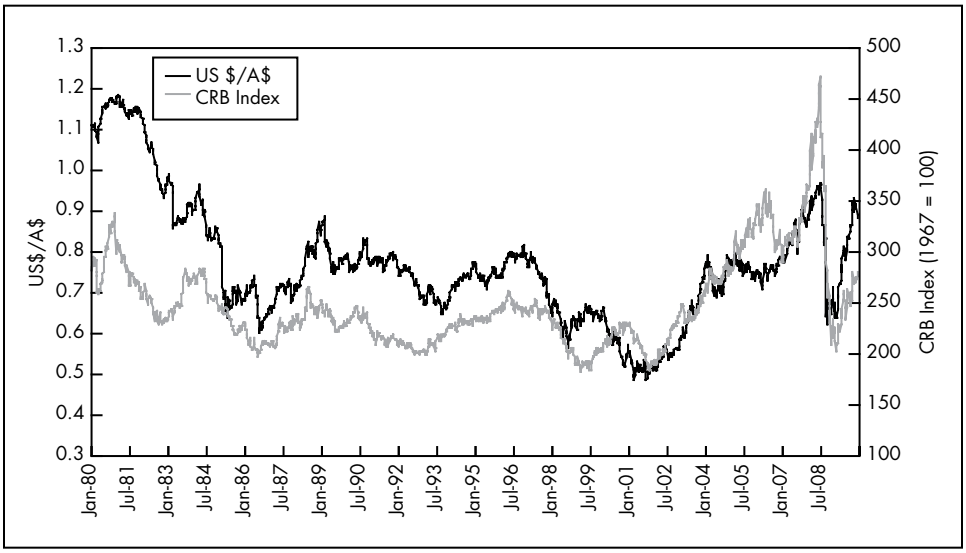

Figure 2.4-9 Relative performance of Australian dollar versus CRB Index

handle political risk; listen to minority shareholders' views; and take social, environmental, and safety risks seriously. In short, investors are prepared to pay a premium for a company whose management they can trust. In the 2008 market meltdown, stretched balance sheets or M&A deals that have gone bad have led to a reassessment of the perceived quality of management teams. In bull markets, most get the benefit of the doubt, but in bear markets, few are trusted fully.

External Environment: Geopolitical, Tax, Financing, Legal

When evaluating a company, the location of its exploration assets or mines is integral in determining its risk profile. Riskier companies often require a higher rate of return from investors and debt holders because of greater uncertainty about the future cash flows of its operations. This is especially true for mining companies, which can be higher-risk companies because of the assets' location.

Generally, companies with operations in countries with established mining industries and laws, such as Australia and Canada, are deemed to be lower risk, owing to low sovereign risk, strong legal systems, stable tax laws and royalty arrangements, and lower probabilities of government intervention.

In high-risk countries, including many parts of Africa and other developing nations, a number of uncertainties may arise, the first of these being sovereign risk. Higher sovereign risk causes debt providers to require a higher rate of return to compensate for the greater uncertainty of developing a project. This may lead to financing becoming unobtainable for some exploration projects, no matter what the grade or resource. Additionally, the legal system in these countries may be weak or ad hoc, providing no protection from government intervention or challenges to mineral and property rights. There is also greater risk that mining laws or royalties may change, resulting in uncertainty of future cash flows or contributions from operations. This has been evident in Zambia, where new windfall taxes were proposed for copper producers.

In developing nations, it is often the case that mines provide a large source of employment and income to the government through royalties and corporate tax. In the absence of other major industries, mining may also provide a country

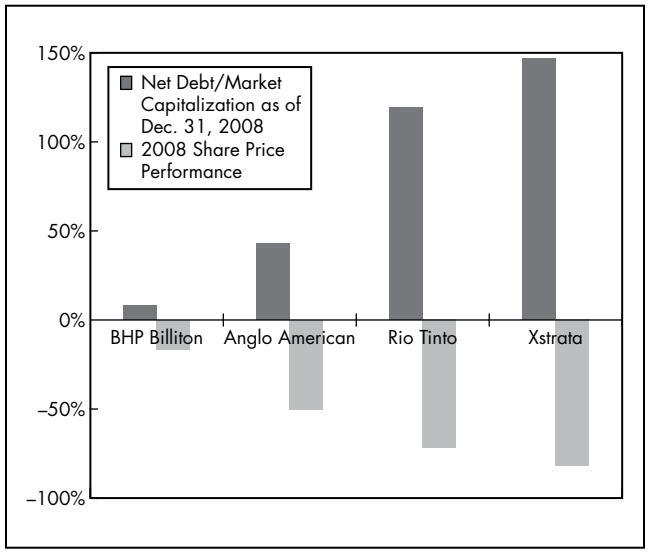

Figure 2.4-10 Net debt/market cap for the "Big 4" mining companies versus 2008 share price performance

with the majority of its exports and therefore foreign currency. For example, in Zambia, mining accounts for 90% of the country's exports. Therefore, governments have a vested interest in keeping mining projects in operation, which may limit the scale of any downsizing or cuts in production that may be needed in a downturn.

Spotting step changes in the external environment can be a key to anticipating large changes in the value of listed mining companies. How will a global credit crunch differentially affect various listed mining companies? How will a banking crisis in Kazakhstan affect a mining company with assets there? (Clue: What will happen to exchange rates and exchange controls?) How does equity issuance across all sectors affect the returns for liquid and nonliquid mining companies?

CONCLUSIONS

This chapter conveys two points. First, the usefulness of the analytical community goes beyond making money for a

potential investor but, in fact, collectively shapes and informs corporate management decision-making processes and, by identifying winners and losers, makes the capital markets more efficient.

Second, investment analysis is both empirical and a black art. Understanding and modeling financial statements are important elements for success, but the ability to see through management and interpret macroecomomic and political trends can be even more important in the art of investing.

Understanding how mining share prices have moved can be fairly obvious after the event, so the trick for any investor is to sift through the myriad of daily data and decide what is significant and important and will have a lasting effect on the company's value. Distinguishing early enough what is important from what is not generates the differentiated investment returns and by association defines the great investment analyst.

ACKNOWLEDGMENTS

Special thanks are due to Liberum Capital for providing most of the figures and tables in this chapter.

GLOSSARY OF FINANCIAL TERMS

- **Balance sheet:** One of the main components of a company's report and accounts, which provides a snapshot of everything the company owes and owns at the end of the financial year in question. On a specific date, the balance sheet lists tangible assets, intangible assets, stock, debtors, cash, bank creditors, trade creditors, share capital, and reserves. The profit-and-loss account reveals how the company has performed in the previous year, while the balance sheet is more revealing about its fundamental health, indicating whether it can pay its debts and how good its cash management is. A strong balance sheet is where liabilities (including borrowings) are considerably outweighed by assets (including cash). If a company is having problems, the balance sheet (together with the cash-flow statement) will reveal whether it can stand the strain.
- **Cash flow:** The amount of money that flows in and out of a business, the difference between the two being the important number. If more money flows into a business than out, it is cash positive. If more money flows out than in, it is cash negative. Cash flow is regarded by many as the ultimate test of financial health. Seasoned analysts do not entirely trust the stated net-profits-after-tax figure, because profits can be massaged, whereas cash is more difficult to manipulate. Profit, as they say, is a matter of opinion. Cash is a matter of fact. The best way to check the cash-flow position of a company is to scrutinize the cash-flow statement in its annual report and accounts. It provides facts on whether a company has generated or consumed cash in the year and how. It can be used in conjunction with the profit-and-loss statement to assess the trading results or with the balance sheet to assess liquidity, solvency, and financial flexibility.
- **Dividend yield:** The annual dividend income per share received from a company divided by its current share price. This is simply how much income a shareholder is getting out of the company for the capital locked up in it. Dividend yields are calculated on the net dividend paid over the course of a year divided by the stock's price. For example, if a company declares a net dividend of 2.1 pence (p) per share and has a share price of 150p, the dividend yield is 2.1/150 = 1.4%. The higher the share price, the lower the dividend yield.
- **EBITDA (earnings before interest, taxes, depreciation, and amortization):** A commonly used way of measuring the profitability of a company and an approximation for pretax operating cash flows.
- **Enterprise value (EV):** A measure of the worth of a company's ongoing operations. This is typically the market capitalization of the company plus any debt and minorities to fund it.
- **EV/EBITDA:** A valuation multiple that is an alternative valuation metric to the price/earnings ratio. This methodology is useful for comparing companies that have very different capital structures (e.g., companies that may have lots of debt versus those that don't).
- **Market capitalization (market cap):** The market value of a quoted company, calculated by multiplying its share price as quoted on an exchange by the number of shares in issue.
- **Price/earnings (P/E) ratio:** P/E is the current share price of a company divided by its earnings per share. A company with a share price of 100p and earnings per share of 5p has a P/E ratio of 100/5 = 20. A company's P/E (also known as its multiple) shows how high its shares are priced in relation to its historical earnings. Although mathematically it relates share price to past performance, the reality is that P/Es are more about forward expectations than past. A high P/E indicates that the investment community expects the company's earnings to grow fast in the future.
- **Profit-and-loss (P&L) statement:** A set of accounts, usually prepared annually, that depict a company's trading performance and are normally read in conjunction with the balance sheet and cash-flow data. The P&L account can broadly be shown as follows:
  - Turnover (sales) less manufacturing costs (or cost of sales if, for example, a retailing company) = gross profit or loss
  - Gross profit plus any nontrading income less operating costs = operating minus profit
  - Operating profit less interest payments on bank loans or loan stock = profit before tax (pretax profit)
  - Pretax profit less tax = net profit after tax

Part of the net profit after tax may be used to pay a dividend, with the balance being retained within the business for future investment.

Exploration

CHAPTER 3.1

Geological Features and Genetic Models of Mineral Deposits

Richard Herrington

INTRODUCTION

Mineral deposits are natural concentrations of one or more mineral commodities that may be termed *ore deposits* if they reach levels where economic extraction is viable. They form as a result of many geological processes, but they form within specified geological settings. Similar genetic processes may operate to form deposits that have similar characteristics and, thus, may define a "class" of deposits. The geological processes that may concentrate minerals include fractional crystallization of magmas, release of volatiles from a crystallizing magma, magmatic interaction with host rocks, metamorphic reactions producing fluids, chemical changes in circulating heated groundwater, organic interactions, and weathering, among others. Eckstrand et al. (1995) neatly summarize that "mineral deposit types" are mineral deposits that share a set of geological attributes and contain a particular commodity (or commodities) that collectively distinguish them from other types.

Ideally, mineral deposit types should reflect how the mineral deposit was actually formed, and in this case, one might be able to use the term *genetic model*. However, in many cases there is considerable debate among geologists as to how a specific deposit was formed, and thus classifications based purely on a given genetic model will encounter problems. An alternative is to classify deposits based on empirical features (minerals, host-rock association, etc.), which will lead to the unique fingerprint of a particular deposit (i.e., a descriptive model). Even though no two mineral deposits are identical, empirical descriptions of deposits tend to show natural groupings into a small number of loosely definable categories or types. In turn, these categories tend to coincide with genetically derived models; so even by using purely physically descriptive classifications, there is often a close coincidence between these and models defined using genetic criteria.

Prior to the 20th century, models for the formation of mineral deposits were subject to the often-polarized views of either plutonist (all deep igneous origins) or neptunist (all sedimentary origins) theories for the origin of rocks, and it was really only in the 20th century that modern views of mineral deposit formation emerged.

From the late 1960s, plate tectonic theory has revolutionized geological thinking, and in the mid-1980s, Guilbert and Park (1986) devised a mineral deposit classification scheme based on plate tectonics.

Figure 3.1-1 is a very broad attempt to show an interpretation of the environment of formation of key mineral hypogene deposit types with respect to plate tectonic settings in their broadest sense.

ORE GENESIS (FORMATION PROCESSES)

Linking deposit types directly to ore-forming processes is certainly the preferred way to classify, as it will provide better criteria for the understanding of the deposit with respect to associated features (such as how its formation relates to associated igneous rock suites, alteration patterns, etc.). In turn, this will lead to better exploration models for their discovery and evaluation. Nevertheless, descriptive models are needed in practical terms to aid engineers in the evaluation of particular deposits (choice of exploration tool, elements to analyze in geochemical exploration, etc.).

Evans (1993) divides ore-forming processes into the four main categories of internal processes, hydrothermal processes, metamorphic processes, and superficial processes. The former three processes relate to subsurface phenomena, while the last of these obviously covers those processes occurring at the earth's surface. In this chapter it is preferred to use the three main divisions of orthomagmatic, hydrothermal, and surficial deposits in line with Einaudi (2000) and broadly encompassing the range of Evans' criteria (Evans 1993). Hydrothermal should be further subdivided into magmatic hydrothermal, metamorphic hydrothermal, diagenetic hydrothermal, and surface hydrothermal to refine the nature of the hydrothermal process.

Further qualifying terms such as syngenetic and epigenetic are useful in discussing the genesis of ore deposits. Syngenetic is used for mineral deposits that are interpreted to have formed at the same time as the enclosing rocks. Syngenetic deposits are bounded by the host rocks themselves as in the case of a deposit formed by crystallization of magma, the result of precipitation within sediments on the seafloor from a hydrothermal vent, or perhaps by the physical sedimentation of heavy mineral sand. Conversely, epigenetic is used for mineral deposits that formed later than the enclosing rocks, and as a result the deposits are found as masses, layers,

Richard Herrington, Researcher, Economic Geology, Natural History Museum, London, UK

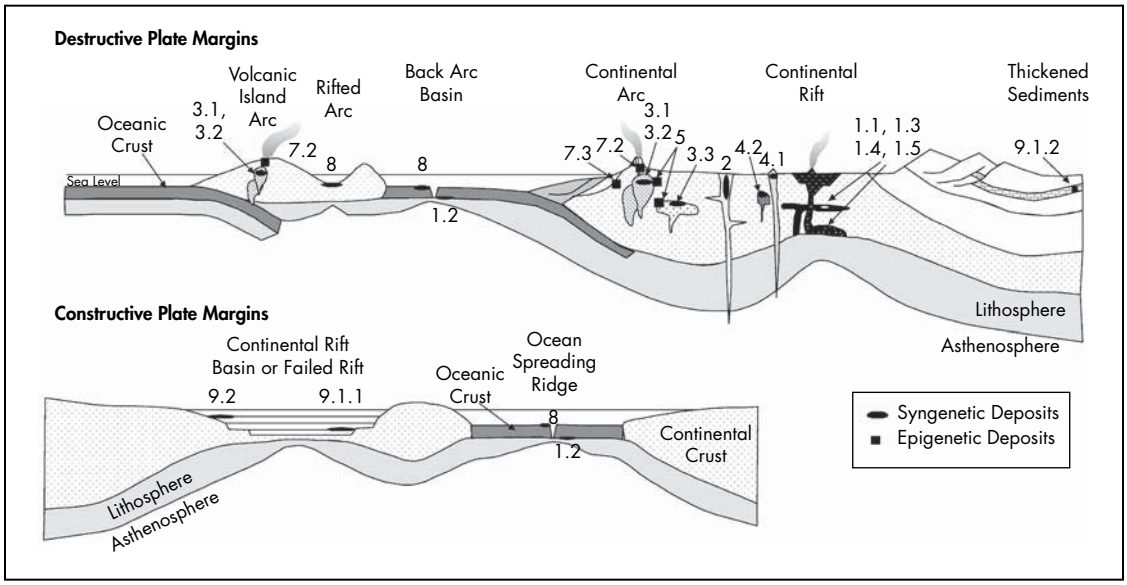

Figure 3.1-1 Plate tectonic settings for key magmatic and hydrothermal deposit types (numbers refer to deposit classes and types shown in Table 3.1-1)

or disseminations that are seen to cut or overprint the original rock. An example of this might be a gold-quartz vein crossing a deformed greenstone.

Hypogene is another useful term used to describe mineralization formed by processes deep in the earth, whereas *supergene* refers to processes superimposed on original mineralization. Often these terms are synonymous in their use with the terms *primary* and *secondary*, respectively. In the context of a sulfide deposit formed, for instance, as a magmatic segregation of chalcopyrite that is then partly oxidized by weathering to, for example, chalcocite, the chalcopyrite is considered to be hypogene (or primary), while the weathering product chalcocite would be termed supergene (or secondary).

KEY DEPOSIT-FORMING PROCESSES

Orthomagmatic Deposits

Orthomagmatic deposits are those that form from primary magmatic processes (i.e., cooling and crystallizing magmas). They are hosted within the rocks from which they formed. Therefore, they are by definition also syngenetic. Deposits may form as a result of

- Solid phases crystallizing as a differentiate as the magma cools;
- Minerals crystallizing from the enriched residual fluids formed as magma cools and crystallizes;
- The formation of a sulfide melt that developed by immiscibility from a coexisting silicate melt; or
- Where a magma transports xenolithic or xenocrystic phases that it has picked up on its passage through the earth's crust.

Hydrothermal Deposits

Hydrothermal deposits are those that literally form from hot water (hydrothermal fluids) circulated through the earth's crust. Direct evidence for the presence of these fluids in the earth's crust are surface manifestations such as hot springs and fumaroles, but indirect evidence is provided by the presence of hydrous minerals in even crystalline rocks. Hydrothermal fluids may have their origin in igneous plutons or from metamorphic reactions deep in the crust, but they can also be the result of deeply circulated and heated meteoric or seawater, or they may be the release of trapped water from sedimentary basins undergoing diagenetic change.

Tracking the original source for this range of fluids is now largely possible using studies of fluid inclusions trapped in minerals and the use of a range of isotopic markers. At one end of the range of hydrothermal deposits there are fluids directly related to or exolving from cooling igneous intrusions, and at the other end there are surface waters heated as they have been circulated into deeper, hotter parts of the earth's crust. Technically speaking, the term *hydrothermal* should only be used for water-dominated fluids, whereas fluids in the gaseous state should be referred to as *pneumatolytic*. Hydrothermal deposits can be either syngenetic or epigenetic, depending on where and when the deposit formed.

Magmatic Hydrothermal

Magmatic-hydrothermal fluids form as a body of magma cools and crystallizes. In some cases the magmatic system may simply be a passive source of heat that drives the circulation of fluids exotic to the magma through adjacent fractured crust into which the magma is intruding. In many other cases the magma, particularly felsic magmas such as those that form granitic rocks, contain very significant amounts of miscible water, which is carried in the magma itself. As this magma cools and crystallizes it becomes more concentrated and eventually forms an immiscible fluid phase, which in the process collects other components that prefer to partition from a silicate melt into a hydrous-fluid phase. Gases are also miscible in silicate melts at higher temperatures and pressures. But again, as the magma cools and is intruded into shallower portions of the crust, the gases become immiscible and may partition into a fluid phase or may escape entirely as a vapor (pneumatolytic fluids). Components concentrating in a fluid phase that may exsolve from magma include chloride ions, which leads

Table 3.1-1 Major classes of economically important mineral deposits

Class	Type/Subtype			Formation
1 Deposits in mafic magmas	1.1 Layered chromite deposits			Syngenetic
	1.2 Podiform chromite deposits			Syngenetic
	1.3 Titanomagnetite deposits			Syngenetic
	1.4 Magmatic platinum group metal deposits			Syngenetic
	1.5 Nickel sulfide deposits	1.5.1 Sudbury		Syngenetic
		1.5.2 Flood basalt association		Syngenetic
		1.5.3 Ultramafic volcanic association		Syngenetic
		1.5.4 Other mafic and ultramafic intrusive associations		Syngenetic
2 Magmatic diamond deposits	Kimberlites and lamproites			Syngenetic (xenocrystic)
3 Deposits associated with felsic magmas	3.1 Porphyry Cu-Mo-Au deposits			Epigenetic (with respect to host rocks), contemporaneous with magmatic activity
	3.2 Porphyry Mo (W) deposits			Epigenetic (with respect to host rocks), contemporaneous with magmatic activity
	3.3 Granite-hosted Sn-W deposits			Epigenetic (with respect to host rocks), contemporaneous with magmatic activity
	3.4 Intrusion-related gold deposits			Epigenetic (with respect to host rocks), contemporaneous with magmatic activity
4 Deposits associated with peralkaline and carbonatite magmas	4.1 Peralkaline Ta-Nb, rare earth element deposits			Syngenetic with late magmatic activity and epigenetic
	4.2 Carbonatite Cu, rare earth element, Nd, Fe, P deposits			Syngenetic and epigenetic
5 Skarn and carbonate replacement deposits				Epigenetic
6 Iron oxide copper-gold deposits				Epigenetic
7 Hydrothermal gold and silver deposits	7.1 Sediment-hosted gold deposits			Epigenetic
	7.2 Epithermal gold and silver deposits	High-sulfidation epithermal		Epigenetic
		Low-sulfidation epithermal		Epigenetic
	7.3 Lode (or orogenic) gold deposits			Epigenetic
8 Volcanic-hosted or volcanogenic massive sulfide deposits	Mafic			Syngenetic
	Bimodal mafic			Syngenetic
	Pelitic mafic			Syngenetic
	Bimodal felsic			Syngenetic
	Siliciclastic felsic			Syngenetic
9 Sediment-hosted deposits	9.1 Sediment-hosted sulfide deposits	9.1.1 Sedimentary exhalative Pb-Zn (Cu) in clastic sediments (*+Broken-Hill type deposits*)		Syngenetic (*Epigentic*)
		9.1.2 Mississippi Valley type (MVT) Pb-Zn		Epigenetic
		9.1.3 "Irish" type Pb-Zn (Cu)		Syngenetic-epigenetic
		9.1.4 Clastic sediment-hosted Cu		Epigenetic
	9.2 Sediment-hosted iron and manganese deposits	9.2.1 Ironstones		Syngenetic
		9.2.2 Banded iron formation (BIF)	9.2.2.1 Algoma BIF	Syngenetic (+epigenetic)
			9.2.2.2 Superior BIF	
			9.2.2.3 Rapitan BIF	
		9.2.3 Manganese ore		Syngenetic
	9.3 Sedimentary uranium deposits	9.3.1 Unconformity vein type uranium		Epigenetic
		9.3.2 Sandstone-hosted uranium		Epigenetic
	9.4 Gold and uranium in conglomerates			Syngenetic (+epigenetic?)
	9.5 Chemical sediments	9.5.1 Evaporites		Epigenetic
		9.5.2 Manganese nodules		Syngenetic
10 Ores related to weathering	10.1 Laterites	10.1.1 Bauxite		Epigenetic

		10.2.2 Secondary zinc		Epigenetic
11 Placer deposits				Syngenetic

to the formation of high-temperature brines that are effective solvents for many metals such as iron, copper, lead, and zinc (Brimhall and Crerar 1987). These metal-rich fluid phases can then migrate away from the magma and can begin to interact with minerals and fluids in previously crystallized magma or outside rocks, which can cause these to become altered by chemical reaction and lead to precipitation of new mineral phases, including the ore minerals. These fluids can also concentrate miscible gases, for example, carbon dioxide (CO_2), sulfur dioxide (SO_2), and hydrogen sulfide (H_2S), which can also aid in the transport of dissolved components with vapor-dominated fluids derived from magmas implicated in the transport of some metal deposits (Williams-Jones et al. 2002).

All mineral deposits that formed by replacement or in fractures around the cooled magma chamber are by definition epigenetic because they overprint the host rocks, although they are contemporaneous with associated magmatic activity. Other rarer metals may remain miscible in the silicate magmas much longer but may become concentrated in the final hydrous fluid phase, trapped at the very final moment within the cooling magma chamber itself. In this case, the deposits are defined as syngenetic, because the deposit fills interstices in the magma as it crystallizes in a similar fashion to orthomagmatic deposits. Depending on the crystallization path for the magma and its interaction with external components, a range of deposits may form from these processes.

Metamorphic Hydrothermal

Metamorphic-hydrothermal fluids form as metamorphism results in mineral-chemical processes that may release volatiles, often dominated by water but which may include gases such as CO_2. Metamorphism is induced in rocks by external heat or pressure or (usually) by a combination of both. Heat may be provided by the deep burial of a rock mass through time or alternatively by the intrusion of a magma body nearby. Pressure to cause metamorphism may be provided again during deep burial or else by tectonic processes. By definition, all of these deposit types are epigenetic because the effects are seen to overprint rocks that have already formed.

Diagenetic Hydrothermal

Diagenetic-hydrothermal fluids are formed as pore waters trapped during sedimentation, then loosely bonded to clays and other minerals, which are released during compaction and lithification. This process may develop on a large scale in a sedimentary basin undergoing burial and lithification and is a related process to hydrocarbon generation. The released water can pick up dissolved salts (becoming a brine), which then has a greater ability to transport many cations and ligands to a point of deposition to form an ore deposit (Brimhall and Crerar 1987). In these sedimentary basins, evaporite beds may be a specific source of salts that can be dissolved by the basinal water.

Basins undergoing diagenesis become heated, and thus the basinal brine may become a highly effective solvent for dissolving large quantities of metals. These basinal brines may then migrate via crustal faults and permeable horizons to depositional environments. Syngenetic deposits can form when these fluids are expelled in a submarine or lacustrine environment, where chemical precipitation can result in layered deposits of minerals. Epigenetic deposits can also be formed where the fluid interacts with already lithified rocks causing alteration and the precipitation of minerals.

Surface or Seafloor Hydrothermal

Surface or seafloor hydrothermal fluids are generated as deeply penetrating meteoric- or seawater-derived waters descend and become heated deeper in the crust. This process is particularly apparent in regions where there is elevated crustal heat flow, often where the earth's crust is being thinned. In the case of the seafloor, this phenomenon is common where a new ocean is formed by the seafloor spreading through the formation of submarine volcanoes. On land, such hydrothermal fluids can be generated in zones of crustal attenuation, often associated with subaerial volcanism. These phenomena may not directly relate to igneous activity, however, as fluids may be simply interacting with residual and convecting heat in the deep crust.

Surface manifestations of this process may be the presence of hot springs on land or seafloor hydrothermal vents. Deposits formed by these processes can by epigenetic, where they replace rocks already formed, or they may be syngenetic, for example, in the case of seafloor hydrothermal vents where exhaled fluids may result in layers and masses of chemically precipitated ore minerals. Syngenetic deposits can also form on land where hot springs vent to the surface and minerals are deposited in layered masses.

SURFACE UPGRADE (LOW TEMPERATURE)

Low-temperature (<50°C) surface processes can also be responsible for the formation of economic ore deposits. Physical processes such as physical erosion, transportation, and deposition lead directly to the redistribution and accumulation of specific minerals. Such deposits are formed as a result of the differing physical and chemical behavior of the minerals forming the original rock. These physical processes can be either hydraulic (water) or aeolian (wind).

Weathering is also a very important ore-forming process resulting in chemical change and redistribution of components in surface rocks by migrating solutions. The differential chemical properties of minerals at the earth's surface and within the surface-crustal interface can lead to residual upgrades or chemical dissolution and reprecipitation mechanisms to concentrate the metal/mineral of interest. In such cases, ore formation is driven by the circulation of largely meteorically derived water at the earth's surface, although similar analogous processes can take place on the seafloor. These subsurface waters can dissolve components, reprecipitating them at favorable mineral sites or surface interfaces. Another process important for ore formation that is a surface phenomenon is the process of evaporation. Dissolved salts precipitate as water is lost in an evaporating basin for example, or by the evaporation of water from the ground's surface due to heat energy from the sun.

SPECIFIC DEPOSIT TYPES

Deposits have been classified in a number of ways by different authors. Table 3.1-1 shows the classification scheme preferred here, which is largely based on empirical features of the deposits but which happily coincides with genetic classification in many cases. A number of less-important deposit types are not covered in this section. Their omission (e.g., vein-style base metal deposits) is largely on the grounds that current economic considerations do not make these deposits attractive targets for mining operations. References for this section are in the "Source References" section at the end of the chapter.

CLASS 1: DEPOSITS IN MAFIC MAGMAS

Type 1.1: Layered Chromite Deposits

- Bushveldt, South Africa
  1,100 Mt (million metric tons) at 42% to 45% Cr_2O_3 (chromium oxide)
- Great Dyke, Zimbabwe
  113 Mt at 26% to 51% Cr_2O_3
- Kemi, Finland
  59 Mt at 26% Cr_2O_3
- Campo Formoso, Brazil
  17 Mt at 17% to 21% Cr_2O_3
- Bird River, Canada
  60 Mt at 4.6% Cr_2O_3

Age and Distribution

Most significant deposits of this type are Achaean or Early Proterozoic in age and are known in cratonic regions of Canada and the United States, South Africa, South America, and Finland.

General Characteristics

These deposits occur in large layered intrusions that show a differentiation into a lower ultramafic zone and an upper mafic zone. They generally occur in two forms: the first are emplaced like tabular sills where igneous layering is parallel to the intrusion floor (or roof), whereas the second are funnel-shaped, with the layering dipping into the center like a saucer shape. Bodies can be enormous (e.g., Bushveldt, which is 480 × 380 km; Great Dyke, which is 530 × 6 km) or they can be quite small (e.g., Kemi, which is 15 × 2 km). The intrusions are developed in different tectonic settings and can relate to cratonic rifts or be synvolcanic intrusions.

The deposits themselves generally take the form of laterally continuous chromite-rich layers that vary from one centimeter to several meters thick. Laterally, they can extend for many hundreds of kilometers. The chromite may be interlayered with other rock types such as dunite, peridotite, pyroxenite, anorthosite, or norite, but those with the best grades are usually associated with primitive peridotites.

Type 1.2: Podiform Chromite Deposits

- Kempirsai, Kazakhstan
  >90 Mt at 50% Cr_2O_3
- Kavak, Turkey
  2 Mt at 20% to 28% Cr_2O_3

Age and Distribution

Podiform chromite deposits are all typically Phanerozoic in age, occurring in the tectonized mantle parts of ophiolite complexes. Significant deposits are recorded in the Philippines (Tertiary), Albania (Jurassic), Turkey (Jurassic-Cretaceous), Kazakhstan (Silurian), and many small occurrences in the Caledonian-Appalachian orogen.

General Characteristics

The chromite is found in the basal part of an ophiolite sequence, namely, the ultramafic tectonite (usually a harzburgite). Ophiolites are the obducted fragments of oceanic crust usually preserved in orogenic belts, where thrusting has exposed the basal mantle sections of the sequence. These ultramafics are likely to be the residual mantle, and the upper contact of this unit with overlying cumulate ultramafic dunites is normally taken to be the petrological Moho.

The deposits take the form of lens-like bodies of massive to heavily disseminated chromite, although often the bodies are highly discordant and rod-like. The variable morphology undoubtedly reflects the tectonized nature of these upper mantle rocks. Ores are dominated by chromite that occurs with interstitial olivine, orthopyroxene, clinopyroxene, and plagioclase. This assemblage is often partially serpentinized or altered to more hydrous minerals such as chlorite, amphibole, talc, and carbonate. Textures may appear to be magmatic or clearly overprinted by deformation.

Type 1.3: Titanomagnetite Deposits

- Lac Tio, Canada
  125 Mt at 32% to 35% TiO_2 (titanium oxide)
- Tellnes, Norway
  >380 Mt at 18% TiO_2
- Kachkanar, Russia
  6,937 Mt at 53% Fe, 5.3% TiO_2, 0.2% V

Age and Distribution

Large anorthosite intrusions of Mesoproterozoic age hosting titanium, vanadium, and iron extend from North America to the Sveconorwegian province of Scandinavia. Similar deposits are found in many tectonic belts around the world, such as in the Ural Mountains in Russia.

General Characteristics

Deposits relate to large differentiated intrusive complexes composed largely of anorthosite, gabbro, norite, and monzonite. Concentrations of metallic oxide minerals occur in the following styles: disseminated oxides in the host rocks, conformable lenses with sharp to indistinct boundaries with earlier crystallized phases of anorthosite and gabbro, late-stage dykes rich in oxide minerals cutting host gabbro and anorthosite, and as replacements linked to alteration zones on the margins of host intrusions. Ore minerals may be disseminated and interstitial to silicate minerals or else form massive aggregates separated from the silicates. The giant Lac Tio deposit in Canada is an irregular, tabular, 1,100-m-long, 1,000-m-wide intrusion, whereas the Tellnes deposit in Norway takes the form of a 14-km-long dyke.

Type 1.4: Magmatic Platinum Group Metal (PGM) Deposits

- Bushveldt Merensky Reef, South Africa
  2,160 Mt at 8.1 g/t PGM + Au
- Bushveldt UG2, South Africa
  3,700 Mt at 8.7 g/t PGM + Au
- Bushveldt Platreef, South Africa
  1,700 Mt at 7.3 g/t PGM + Au
- Stillwater (J-M Reef), United States
  421 Mt at 18.8 g/t PGM + Au
- Great Dyke, Zimbabwe
  1,680 Mt at 4.7 g/t PGM + Au
- Lac des Iles, Canada
  6.7 Mt at 5.4 g/t PGM + Au

Age and Distribution

The bulk of the intrusions hosting these deposits are Archaean to Proterozoic. Stillwater and a group of smaller Canadian

examples are Achaean, whereas the Great Dyke and Bushveldt are early and mid-Proterozoic, respectively. The Skaergaard intrusion in Greenland is Tertiary in age and is the youngest known. The deposits occur in large intra-continental rifts or at the margins of rifted continents, and thus they are usually hosted in older continental crust.

General Characteristics

The mineralization in all cases is largely stratiform, but there are some differences in the degree of conformity to enclosing host rock. Broad common features occur in all deposits. For example, PGMs are almost entirely found within sulfides and specific PGMs. The morphologies and mineral associations are diverse, however.

The Proterozoic-age Bushveldt-layered intrusion is the world's largest PGM repository. The intrusion forms a cloverleaf-shaped outcrop measuring 400 × 240 km, and it comprises mafic and ultramafic cumulate rocks located around a granitic core. The lower cumulate rocks, the Rustenburg Layered Suite, is up to 7 km thick, with the lowermost Critical zone the main host to PGM deposits in the Merensky Reef and UG2 layers. Mineralization is also developed in a unit known as the Platreef, which forms the base of the Critical zone in the northeastern lobe of the Bushveldt.

Type 1.5: Nickel Sulfide Deposits

The four categories of nickel sulfide deposits are Sudbury, flood basalt association, ultramafic volcanic association, and other mafic intrusive associations. These are discussed as follows.

Subtype 1.5.1: Sudbury

- Sudbury, Canada (global)
  1,648 Mt at 1.2% Ni, 1.03% Cu (+ PGMs and Au)

Age and Distribution

The Sudbury Igneous Complex formed during the Proterozoic age as the likely result of a meteorite impact. This impact ruptured the earth's crust and allowed the intrusion of a mantle-derived mafic magma body, which differentiated to form the igneous complex and its nickle-copper sulfide deposits.

General Characteristics

The rather unique Sudbury nickel-copper sulfide deposits are largely confined to the so-called "sublayer" unit of the Sudbury Igneous Complex at its contact with the rocks into which it was intruded. The complex is a 65-km-long, 25-km-wide oval-shaped outcrop. In section across the narrow dimension, it forms a funnel-shaped body widening at the surface. Two types of sublayer are host to the nickel-copper deposits in two settings. The contact sublayer is a discontinuous gabbronorite at the basal contact with nickel-copper sulfides and xenoliths of footwall and exotic ultramafic units. The offset sublayer comprises apophyses of quartz-diorite, which crosscut into the footwall. The sublayer has a distinctive mineralogy of quartz, plagioclase, biotite, hornblende, and copper-nickel sulfides and may contain exotic xenoliths of the wall rocks.

The nickel sulfide ores in both cases are dominated by pyrrhotite-pentlandite-chalcopyrite with pyrite and magnetite. Bornite is common in the copper-rich zones. Arsenic-bearing sulfides are common in places. Copper-rich vein ores are known in the footwall of the complex and are dominated by chalcopyrite and cubanite. PGMs include complex tellurides and arsenides.

Subtype 1.5.2: Flood Basalt Association

- Norilsk, Russia
  900 Mt at average grade of 2.70% nickel
- Jinchuan, China
  515 Mt at average grade of 1.06% nickel

Age and Distribution

Flood basalt provinces are fairly widespread through the geological record, but not all have nickel sulfide deposits associated with them. Special conditions appear necessary to produce the nickel sulfides and then to trap and retain them in ore deposits.

General Characteristics

The deposits can comprise both massive sulfide and disseminated sulfides. The relative proportions of the two styles of mineralization vary widely, with massive mineralization dominant at Norilsk but minor mineralization at Jinchuan. The principal minerals are pyrrhotite (FeS), pentlandite (Fe,NiS), and chalcopyrite ($CuFeS_2$), though there are minor amounts of many other minerals.

The igneous provinces that host these deposits are typically very large, commonly more than 1,000 km in diameter. They are dominantly tholeiitic in composition although alkaline volcanic rocks are often associated, and the occurrence of olivine-rich rocks indicates they formed from high-temperature melts.

Subtype 1.5.3: Ultramafic Volcanic Association

- Kambalda District, Australia
  48 Mt at 3.6% Ni, 0.25% Cu
- Thompson Belt, Canada
  69 Mt at 2.5% Ni, 0.13% Cu
- Raglan, Canada
  18.5 Mt at 3.13% Ni, 0.88% Cu
- Shangani, Zimbabwe
  22 Mt at 0.71% Ni

Age and Distribution

Komatiites are mainly restricted to Archaean sequences, and Kambalda-type deposits are almost exclusively developed in Precambrian sequences. In addition to the type locality in Western Australia, good examples occur in similar rocks in Zimbabwe and Canada, and deposits are recorded in Brazil and Russia. Most deposits occur in mid-Archaean to late-Archaean rocks, with only a few minor deposits developed in the oldest greenstone sequences of southern Africa or the Pilbara in Australia. Younger komatiite-like rocks are barren of significant nickel sulfide deposits.

General Characteristics

The nickel sulfide ore bodies in this class can be stratiform or stratabound. Stratiform deposits typically form tabular or ribbon-shaped bodies situated at the base of the host ultramafic units. Such deposits have dimensions from a few hundred meters to 5 km in length, but mostly the stratigraphic thickness of the sulfide zone is less than 10 m, with distinct lower and upper contacts. In some cases they show marked

elongation parallel to the regional volcanic or tectonic grain, with length-to-width aspect ratios of up to 20 at Kambalda.

Stratabound massive and disseminated mineralization is not confined to the base of ultramafic units but can be distributed through the lower to central portion of the host cumulate unit. The shape and size of stratabound deposits are more difficult to quantify because of their diffuse, gradational character; the margins are defined by arbitrary economic cutoff grades. Broadly, they have oblate to elongate lens shapes, depending on the shape and size of the host unit. Dimensions are generally much larger than equivalent stratiform deposits, particularly stratigraphic thickness, which may be up to several hundred meters.

Ore minerals are pentlandite, present as granular aggregates, and, to a much lesser extent, locked in pyrrhotite. Chalcopyrite, pyrite, and ferrochromite are the other principal minerals present. Nickel tenors within the sulfide component (as opposed to the Ni grade of the whole rock) can vary from less than 5% to more than 20%, but they are usually constant in an ore lens. Copper, cobalt, and the platinum-group elements are minor components of the mineralization. Arsenic is present and can occur in significant concentrations, resulting in adverse environmental impact when nickel concentrates are sent to a smelter.

Subtype 1.5.4: Other Mafic and Ultramafic Intrusive Associations

- Voisey's Bay, Canada
  136 Mt at 1.59% Ni, 0.85% Cu
- Selebi-Phikwe, Botswana
  110 Mt at 0.75% Ni, 1% Cu
- Lynn Lake, Canada
  20 Mt at 1.02% Ni, 0.54% Cu

Age and Distribution

This type is generally found in areas of thickened crust in late Achaean to Proterozoic terranes, usually in highly deformed regions where reconstruction of the tectonic setting is difficult. Key examples are Lynn Lake, Canada; Selebi-Phikwe, Botswana; Monchegorsk, Russia; and Kotalahti, Finland. Voisey's Bay, Canada, is possibly also in this type but shows many features similar to the Norilsk deposit (see "Subtype 1.5.2: Flood Basalt Association" section).

General Characteristics

The host mafic/ultramafic intrusions associated with these Ni-Cu sulfide deposits include a variety of types: multiphase stocks, multiphase chonoliths, multiphase sills, and highly deformed sills. The styles of mineralization are also varied, including massive sulfides, breccia sulfides, stringers and veins, and disseminated sulfides. The sulfide minerals are usually pyrrhotite-pentlandite-chalcopyrite-pyrite assemblages and may form massive, matrix, or disseminated types. Pyrrhotite is often dominant, and as a result of this, nickel tenors are generally lower than other magmatic deposits. Nickel–copper ratios are typically between 3:1 and 1:1.

CLASS 2: MAGMATIC DIAMOND DEPOSITS

- Argyle, Australia
  83 Mt at 2.7 ct/t (carat per metric ton)
- Ekati, Canada
  60 Mt at 0.9 ct/t
- Jwaneng, Botswana
  287 Mt at 1.44 ct/t

Age and Distribution

Economic diamond deposits occur with volcanic centers of unusual, highly alkaline volcanic and subvolcanic intrusive rocks, which are known as kimberlites and lamproites.

Diamond-bearing kimberlites and lamproites only occur around the margins of or within stable cratonic blocks that have not undergone major deformation or metamorphism. Productive kimberlites vary widely in age from Precambrian to Mesozoic. Some of the lamproites that host diamond deposits are as young as 55 Ma (million years). Thus, it is likely that the formation of primary diamond deposits has gone on throughout geological time.

General Characteristics

Both kimberlites and lamproites are formed from very volatile-rich magmas that are generated at great depth (about 200 km deep for lamproites and between 200 and 300 km deep for kimberlites). Kimberlites are more gas-charged (with carbon dioxide) than lamproites, so they are more likely to form large diatreme structures close to the surface. In both cases they occur as dykes, sills, and minor plugs formed at depths of several kilometers. However, these are generally small, and so they cannot provide the tonnage required for an economic deposit.

Kimberlite magmas tend to form a deep conical explosion crater or diatreme (pipe). These so-called pipes typically range from 50 to 500 m in diameter with four contrasting rock facies. The diatreme facies consists of fragmented wall rocks and material brought up from deep below. The maar facies contains bedded material that fell back into the crater after an eruption. The crater facies includes finely bedded ash and crater-lake sediments, possibly containing fossils. The pyroclastic facies forms as a tuff ring around the vent. All facies may be diamondiferous, but because diamonds are not actually formed as a part of the magmatic process but are xenocrysts simply carried by the magma from the mantle where they formed, their grades can be highly variable.

The shape of kimberlite pipes is typically steeply conical, rather like a carrot. Lamproites, by contrast, form shallower conical to irregular bodies that commonly do not extend to depth.

CLASS 3: DEPOSITS ASSOCIATED WITH FELSIC MAGMAS

Felsic ("granitic") magmas are often generated in subduction-zone settings, and within this setting, different types of granitic magmas are linked to different metal associations. Subduction-related ore-forming magmas have been classified into two broad chemistries of granitoids: S-type and I-type granites, reflecting contrasting sources for the magmas deep in the crust. It is apparent that Sn-W deposits are associated with S-type granites, whereas Cu-Mo-Au mineralization is associated with I-type granites. A further A-type of granite has been discriminated, and these are associated with Mo-W mineralization.

Type 3.1: Porphyry Cu-Mo-Au Deposits

- Chuquicamata, Chile
  15,000 Mt at 0.77% Cu, 0.01% Mo, 0.0133 g/t Au
- El Teniente, Chile
  11,850 Mt at 0.92% Cu, 0.02% Mo, 0.0236 g/t Au

- Kalmakyr, Uzbekistan
  5,625 Mt at 0.4% Cu, 0.509 g/t Au
- Morenci, Arizona, United States
  4,693 Mt at 0.52% Cu, 0.00639 g/t Au
- Grasberg, Indonesia
  3,409 Mt at 1.12% Cu, 1.07 g/t Au
- Oyu Tolgoi, Mongolia
  2,700 Mt at 1.15% Cu, 0.4 g/t Au
- Sar Cheshmeh, Iran
  1,200 Mt at 1.02% Cu, 0.03% Mo, 0.27 g/t Au
- Madjanpek, Serbia
  1,000 Mt at 0.6% Cu, 0.3 g/t Au

Age and Distribution

Most porphyry deposits are Mesozoic or younger, but deposits are known from rocks older than 3,000 Ma. Porphyry copper deposits have been directly related to the process of subduction and formation of volcanic arcs, and this accounts for their distribution along active subduction margins of the Cordillera of the Americas and western Pacific. Porphyry copper deposits are also found distributed along ancient volcanic arcs, now preserved in such structures as the Tethyan orogenic belt and the Central Asian orogenic collage.

General Characteristics

Typically porphyry copper deposits take the form of low-grade disseminations and fracture-hosted sulfide mineralization usually developed within or at the margin of high-level felsic intrusive rocks. The deposits may take the form of irregular to ovoid bodies in plan and from solid to cup or hollow cylindrical shapes in section. Individual ore bodies may be discrete, they may overlap or even be stacked, and they may have dimensions up to thousands of meters in each direction, such as in the case of the "supergiant" deposits at El Teniente. Ore bodies are characteristically zoned according to ore minerals and alteration assemblages with several "classic" models proposed to describe the distribution of such zonation. In reality, these zones are often far more complex and overlapping, commonly with the superimposition of alteration zones.

Principal ore minerals are chalcopyrite, bornite, chalcocite, tennantite, enargite, molybdenite, and electrum. Associated minerals include pyrite, magnetite, quartz, biotite, potassium-feldspar, anhydrite, muscovite, epidote, chlorite, and clay minerals. In gold-rich porphyries, tellurides and arsenopyrite may be part of the ore assemblage, while accessories such as scapolite, calcite, albite, fluorite, and even garnet may be present.

Hydrothermal alteration is extensive and zoned, and at a deposit scale, it ideally comprises an inner potassic zone characterized by the presence of biotite and/or K-feldspar often accompanied by one or more of magnetite, amphibole, and anhydrite. Outside this is a propylitic zone comprising quartz, chlorite, epidote, calcite, and sometimes albite, with local development of pyrite. A further alteration type, phyllic, may be developed between the potassic and propylitic zones, but it may be more irregular or tabular and show evidence for being often "changed" later than the initial alteration stages. The economic sulfides are usually closely associated with the potassic alteration, although in some cases the presence of strong sodic alteration is important.

Type 3.2: Porphyry Mo (W) Deposits

- Climax, Colorado, United States
  907 Mt at 0.24% Mo, 0.02% W
- Henderson, Colorado, United States
  727 Mt at 0.171% Mo
- Quartz Hill, Alaska, United States
  1,700 Mt at 0.136% Mo
- Malmbjerg, Greenland
  136 Mt at 0.138% Mo, 0.016% W

Age and Distribution

Most porphyry molybdenum deposits are Mesozoic or younger. Located in continental arc terranes, the deposits are hosted in A-type (or anorogenic) granites normally related to a rift or extensional setting related to a mature subduction-zone setting. Most economic deposits are located in the Cordillera of the Americas, with a few in the Pacific region, and there is an important prospect in Greenland.

General Characteristics

The key examples of the type, Climax and Henderson, are genetically related to a small cupola of a regional intrusive batholith emplaced during regional extension. The batholith is an anorogenic or A-type pluton. Host intrusions vary from quartz monzodiorite through to granite. Mineralization is more likely to form as a stockwork than as disseminations. The intrusive bodies at Climax are highly evolved granite magmas rich in tin, tungsten, fluorite, and rubidium, while other bodies are adamellite in their composition.

Ore bodies can be associated with simple, composite, or multiple intrusions associated with dykes and breccia pipes. Multiple intrusions are common, which has given rise to multiple, often stacked, ore bodies (known as "shells") in some of the deposits. The shapes of the ore bodies often form inverted cups, shallow bowls, or hollow cylinders mantling an intrusive stock.

The principal ore minerals are molybdenite, scheelite, wolframite, and sometimes associated cassiterite and bismuthinite. Fluorite and topaz are common accessories not seen in typical porphyry copper deposits. Molybdenite occurs in quartz veinlets that carry other sulfides and gangue, in small fissure veins, in fracture coatings, in breccia matrix, and very rarely as disseminations.

Alteration patterns are very similar to porphyry copper deposits (mentioned earlier), with potassic alteration and silicification particularly important in the cores of the deposits.

Type 3.3: Granite-Hosted Sn-W Deposits

- East Kemptville, Nova Scotia
  56 Mt at 0.165% Sn (+ Cu, Zn)
- Ardlethan, Australia
  9 Mt at 0.5% Sn
- Wheal Jane, Cornwall, United Kingdom
  5 Mt at 1.2% Sn
- Hemerdon, Cornwall, United Kingdom
  42 Mt at 0.18% WO_3 (tungsten trioxide), 0.025% Sn
- Panasqueira, Portugal
  31 Mt at 0.3% WO_3, 0.02% Sn
- Cerro Rico, Bolivia
  828 Mt at 0.35% Sn, 200 g/t Ag

Age and Distribution

The age of these deposits ranges from Archaean to Tertiary, with the bulk of the deposits of Mesozoic age. The Hercynian orogenic belt of Europe (Cornwall to Central Europe) is host to a significant proportion of these deposits, and important deposits are associated with granites in the Appalachian-Caledonide belt of North America. The common feature to all these belts is the association with late-stage magmatism in collisional orogens, where the deposits group in distinct metallogenic provinces.

Well-known locations of Sn-W deposits occur in Cornwall (England), Portugal, Erzgebirge of Central Europe, Malaysia, Bolivia, Tasmania (Australia), and Brazil. The deposits are all related to granitoids but show a range of styles from porphyry Sn (Bolivia), tin greisen deposits, to lode-type Sn-Cu (Cornwall and Tasmania). Tin skarns are often developed in the same terranes (see next section).

General Characteristics

Primary tin deposits can occur within granites or within pegmatites or aplites (dyke-like rocks) associated with the granite. They also occur in rocks surrounding the margins of the intrusive rocks as veins, disseminations, skarns (discussed later), or more distal carbonate replacements (generated by magmatic fluids). Pegmatites, fault-controlled veins, stockworks, and breccias are common, as well as the development of distinctive altered granite contact zones known as greisens. Greisen is a metasomatic-hydrothermal rock that results from high T-alteration of granite by fluorine-rich fluids that exsolved from enriched magma during the last stages of solidification. Greisens are associated with silicification and areas where alkali feldspar is replaced by quartz and muscovite. Wolframite- and cassiterite-bearing quartz veins often form swarms within the alteration, and tourmaline is a common accessory silicate. The outer margins of greisen tend to be marked by zones of intense kaolinization. Mineralization tends to form near the top of granite intrusions (often within the margin of a cupola), but also occurs in large quartz-cassiterite-sulfide veins that may pass from the granite into the metamorphosed margin to the granite.

Type 3.4: Intrusion-Related Gold Deposits

- Fort Knox, Alaska, United States
  220 Mt at 0.9 g/t Au
- Salave, Spain
  15 Mt at 2.99 g/t Au
- Mokrsko, Czech Republic
  57 Mt at 1.9 g/t Au
- Vasilkovskoe, Kazakhstan
  100 Mt at 2.4 g/t Au
- Kidston, Australia
  94 Mt at 1.48 g/t Au

Age and Distribution

Most intrusion-related gold (IRG) deposits so far identified are Phanerozoic, particularly the Cretaceous and mid-Paleozoic. Key belts are the mid-Cretaceous Tintina Gold Province in western Canada and Alaska, the New England-Lachlan Fold Belt of eastern Australia, parts of the Paleo-Tethys belts of Europe, and regions of the Tien Shan in Central Eurasia. Further Paleozoic deposits are recorded in New Brunswick, Canada.

General Characteristics

The deposits are highly variable in precise features, but they generally can comprise a range of mineralization styles reflecting their location with respect to distance from a felsic, ilmenite-series (reduced) pluton. A general zonation of the mineralization is seen with distance away from any associated intrusion, with characteristically a more proximal W-Mo-bearing assemblage passing laterally to a more distal Au-As-Bi assemblage.

Intrusion-proximal deposits may comprise sheeted veins associated with thin aplite and pegmatite dykes developed in the brittle carapace of the reduced pluton itself. In the best example of this type, Fort Knox, gold relates to both higher-temperature magmatic features and more distal hydrothermal veins. The ore assemblage contains gold typically intergrown with bismuth- and tellurium-bearing phases and commonly molybdenum or tungsten minerals. There is generally a low sulfide content, but where present, the more common associated sulfide phases are consistent with a reduced magmatic source often comprising pyrrhotite, pyrite loellingite, and arsenopyrite. Some of the deposits are like skarns, where mineralization replaces adjacent host rocks. The more distal examples of this deposit type share many features found in deposits classed as lode or orogenic gold deposits in metamorphic rocks, where causal intrusions have not been unequivocally identified (see "Type 7.3: Lode Gold Deposits" section). Because of this, discrimination between gold deposits in metamorphic rocks (lode gold deposits) and IRG remains controversial.

CLASS 4: DEPOSITS ASSOCIATED WITH PERALKALINE/CARBONATITE MAGMAS

Type 4.1: Peralkaline Ta-Nb Rare Earth Element Deposits

- Lovozero, Russia
  >1,000 Mt at 0.3% Nb_2O_5, >1% REE

General Characteristics

Peralkaline rocks are important repositories of rare metals such as zirconium, niobium, beryllium, uranium, thorium, tantalum, rare earth elements (REE), yttrium, and gallium. Currently, only deposits in Russia are being mined for niobium. Peralkaline rocks form plutons in stable cratonic, anorogenic regions. Their occurrences are controlled by regional fault systems, and they may form ring complexes. The concentrations of rare metals occur as a closed magmatic system and slowly crystallize with rare metals concentrated in the latest cooling phases. High fluorine in the magma lowers the freezing point and the viscosity, allowing the complexes to fractionate to extreme compositions, concentrating rare metals in the residuum.

Type 4.2: Carbonatite Cu, Rare Earth Element, Nd, Fe, P Deposits

- Mountain Pass, California, United States
  36.3 Mt at 7.67% REE
- Palabora, South Africa
  286 Mt at 0.69% Cu
- Aley, Canada
  20 Mt at 0.7% Nb_2O_5 (niobium pentoxide)

Age and Distribution

Four recognized frequency highs of carbonatite magmatism related to tectonic activity are as follows:

- Mid-Proterozoic: 1,800 to 1,550 million years ago (coincident with the Hudson-Svecokarelian orogeny)
- Mid- to late-Proterozoic: 1,100 million years ago (Grenville orogeny)
- Late-Proterozoic to Paleozoic: 750 to 500 million years ago (Caledonide orogeny)
- Breakup of Pangea: 200 million years ago

The major hard rock niobium deposits are in Brazil, Canada, Palabora, and the major Kovdor apatite deposit in northern Russia.

General Characteristics

Carbonatites are igneous rocks that contain at least 50% (modal) carbonate minerals. These comprise calcite, dolomite, and ankerite, as well as sodium- or potassium-bearing carbonates along with diopside, sodic pyroxenes, or amphibole; phlogopite; apatite; and olivine. They are generally found in stable intraplate areas but are located along major tectonic features, usually associated with topographic doming constrained by crustal-scale faults.

Carbonatites form modest-sized intrusive bodies, flows, or tuffs, and they are closely associated with a range of alkali silicate rocks such as syenites. Carbonatites are usually surrounded by an aureole of metasomatic rock called fenite. Mineralization associated with carbonatites can be either magmatic or metasomatic, where mineralization occurs in the altered assemblage.

Mineralization relates to magmatic layering and flow structures, with the mineralization in the case of the niobium deposits taking the form of irregular lenses. Ore minerals include pyrochlore (niobium), rare earth fluorocarbonates or phosphates, perovskite-magnetite, and apatite. Host rocks also contain many unusual accessory minerals. Barite is common in almost all carbonatites. Phosphorus-rich deposits contain apatite with olivine and magnetite.

CLASS 5: SKARN AND CARBONATE REPLACEMENT DEPOSITS

Examples of Skarns

- Hedley District, Canada
  7.0 Mt at 1.7 g/t Au, 17.1 g/t Ag
- Fortitude, Nevada, United States
  5.1 Mt at 10.45g/t Au, 27.8 g/t Ag, 0.2% Cu
- Mactung, Canada
  33 Mt at 0.88% WO_3
- Antamina, Peru
  745 Mt at 1.24% Cu, 1.03% Zn
- Moina, Tasmania
  30 Mt at > 0.15% Sn
- Las Bambas, Peru
  339 Mt at 1.3% Cu, 0.15g/t Au

Examples of Carbonate Replacements

- Cerro de Pasco, Peru
  175 Mt at 7% Zn, 2% Pb, 103 g/t Ag and
  50 Mt at 2% Cu (+ Au, Ag)
- Colquijirca, Peru
  25 Mt at 7% Zn

General Characteristics

A skarn is defined as an assemblage of zoned, coarse-grained, generally iron-rich mixture of calcium or magnesium silicates resulting from the alteration of an original rock-type. Main types of skarn are those resulting from the following:

- Metamorphic recrystallization of silica-carbonate rocks
- Local exchange of components between lithologies during high-grade metamorphism
- Local exchange of components between magmas and carbonate rocks at high temperatures
- Large-scale transfer of components over a broad range of conditions between magmas and predominantly carbonate rocks

Replacement skarns can form a carapace of altered intrusive rock (endoskarn) surrounded by a zone of alteration in the wall rock (exoskarn). Skarns may be associated with both I-type and S-type magmas (as discussed previously), and the type of magma associated may in part dictate the metal budget of the skarn. Carbonate replacement deposits may lack the typical skarn alteration assemblages.

Because of the complications of describing skarns based on the alteration minerals (which are a combined function of wall-rock chemistry and the superimposed system), mineralized skarns are best classified in terms of component of interest. Seven major types are recognized: iron, gold, tungsten, copper, zinc, molybdenum, and tin.

Carbonate replacement deposits, often termed *mantos* in the literature, tend to be hosted in carbonates or calcareous sediments and are largely polymetallic zinc-lead rich, often with copper and silver. Alteration of the host rocks in this deposit type can be quite cryptic and may be represented by minor calcite and dolomite and quartz, developed close to the ore body itself.

CLASS 6: IRON OXIDE COPPER-GOLD (WITH OR WITHOUT URANIUM) DEPOSITS

- Olympic Dam, Australia
  8,300 Mt at 0.8% Cu, 280g/t U_3O_8 (uranium oxide concentrate), 0.76g/t Au, 3.95g/t Ag
- Candelaria, Chile
  600 Mt at 0.95% Cu, 0.2g/t Au, 3.1g/t Ag
- Ernest Henry, Australia
  122 Mt at 1.18% Cu, 0.55g/t Au
- Salobo, Brazil
  986 Mt at 0.82% Cu, 0.49g/t Au

Age and Distribution

Within Australia and parts of South America, where the largest of these deposits is found, the deposits tend to be hosted in Mesoproterozoic to Neoproterozoic rocks (1,800 to 850 Ma). However, many deposits are found in the Phanerozoic, with the important Chilean iron oxide copper-gold (IOCG) belt hosting the Mesozoic Candelaria deposit. Worldwide, recorded ages of IOCG deposits range from 1,800 to 15 Ma for the deposit group.

General Characteristics

The deposits included in this class range from around 10 Mt to more than 8,000 Mt of contained ore at grades around 1% Cu plus gold, which brings them into the size of porphyry copper deposits. In the case of the giant Olympic Dam deposit, the

setting is interpreted as a diatreme breccia within a caldera, and many authors regard the presence of breccias as a key diagnostic for this deposit type. Other deposits clearly relate to major crustal structures or else have a strong association with the aureole of a distinctive intrusive suite. Kiruna-type iron ore deposits have been proposed by some to represent the copper-poor end members to this deposit class.

The deposits are characterized by the development of large volumes of low-titanium magnetite and/or hematite with a simple assemblage of copper, usually as chalcopyrite and associated gold and sometimes uranium. In the copper-rich deposits, paragenetically late chalcopyrite and bornite occurs within or near the iron oxide phases. The oxides are often zoned from an earlier magnetite to a later or more distal hematite. Other associated minerals are phosphates, dominated by apatite and usually highly enriched REE and sometimes a cobalt and silver enrichment. Silicate gangue minerals include actinolite, pyroxene, epidote, chlorite, and tourmaline. Apatite and other phosphate minerals are common, as well as the rare earth-rich epidote mineral allanite.

Wall-rock alteration is a characteristic of the deposit type. This is often developed on a regional scale (>100 km^2) and may comprise regionally extensive sodic and calcic alteration (up to tens of kilometers away from mineralized districts) and more focused, proximal potassic alteration more closely associated with mineralization. In some cases, the alteration resembles skarn seen associated with magmatic intrusive suites.

CLASS 7: HYDROTHERMAL GOLD AND SILVER DEPOSITS

All the deposits in this class are epigenetic and are subdivided into three broad groups based on host-rock association and depth of formation within the earth's crust.

Type 7.1: Sediment-Hosted Gold Deposits

- North Carlin trend, Nevada, United States
  491 Mt at 5.86 g/t Au
- Twin Creeks, Nevada, United States
  90 Mt at 2.5 g/t Au
- Jerritt Canyon, Nevada, United States
  33 Mt at 6.9 g/t Au
- Bau, Malaysia
  ca. 40 Mt at ~2 g/t Au
- Barneys Canyon, Utah, United States
  2.8 Mt at 2.4 g/t Au
- Zarshuran, Iran
  2.5 Mt at 10 g/t Au

Age and Distribution

Deposits with common features in this class are generally Mesozoic or younger. The type locality is the Carlin District of the United States, which has produced more than 50 million ounces (1,600 t) of gold up to 2002. Here, the deposits are hosted in Paleozoic rocks (largely Devonian) although the mineralization is dated at 42 to 36 Ma. The most comparable deposits are found in the West Qinling and Dian-Qian-Gui areas of southern China, while other analogs are found in Utah, Chile, Malaysia, Indonesia, and Iran. Nevada is by far the most productive district for this deposit type to date.

General Characteristics

Carlin-type deposits are characterized by auriferous pyrite associated with a range of anomalous trace elements occurring as replacements in carbonate-rich host rocks. The deposits may take a variety of forms (e.g., tabular, branched, carrot-like, and irregular), and they may be stratabound or clearly crosscutting. The mineralization appears to be hosted in locally porous lithologies, particularly developed where such lithologies intersect high- and low-angle faults related to regional thrust faults.

Deposits are up to 3 km long, with mineralization occurring in a depth range of up to 1,000 m, although this may comprise several stacked ore bodies. Barren zones between ore bodies are generally formed of less-permeable horizons. Impermeable units generally cap ore zones, and the best mineralization is developed in structural-lithological settings similar to favorable traps for oil reservoirs.

At Carlin, gold is associated with As, Sb, Tl, and Hg and was deposited in main-stage arsenian pyrite and marcasite. Quartz, kaolinite, dickite, and illite are minor gangue phases.

Type 7.2: Epithermal Gold and Silver Deposits

Examples of High Sulfidation

- El Indio, Chile
  23.2 Mt at 4.6 g/t Au, 10 g/t Ag
- La Coipa, Chile
  52.1 Mt at 1.58 g/t Au, 50 g/t Ag
- Lepanto, Philippines
  38 Mt at 3.53 g/t Au
- Pueblo Viejo, Dominican Republic
  150 Mt at 7 g/t Au

Examples of Low Sulfidation

- Martha Hill, New Zealand
  83.3 Mt at 3.2 g/t Au, 33 g/t Ag
- McLaughlin, Nevada, United States
  17.5 Mt at 5.2 g/t Au
- Hishikari, Japan
  3.2 Mt at 63 g/t Au
- Gunung Pongkor, Indonesia
  6 Mt at 17 g/t Au, 162 g/t Ag

Age and Distribution

Epithermal and related deposits occur in modern volcanic arcs such as the circum-Pacific "Rim of Fire" of active volcanism. Other deposits are found in similar volcanic arc settings in other parts of the world, where processes similar to those active around the Pacific Ocean occurred in the past. Ancient volcanic arcs such as parts of the Tethys and the arcs of Central Asia also yield such deposits.

Many of the epithermal deposits occur in regions where copper-gold porphyries and skarns form (see previous sections), and there is sometimes a direct genetic relationship.

General Characteristics

Epithermal deposits formed at shallow crustal levels (typically from the water table to about 1,000 m below at the time of formation). The temperatures that correspond to this depth range (controlled by the boiling point of water with depth) are from less than 100°C to about 350°C.

A major difference is recognized between two contrasting classes of epithermal deposit usually referred to as low sulfidation and high sulfidation, which reflect the nature of the hydrothermal fluid. Low sulfidation means an association of the minerals quartz ± calcite ± adularia ± illite, while in high-sulfidation systems, alteration is dominated by the minerals quartz ± alunite ± pyrophyllite ± dickite ± kaolinite.

Both deposit types can occur in subaerial volcanic settings of calc-alkaline to alkalic and intermediate to acid composition. High-sulfidation deposits tend to occur in proximal volcanic settings, whereas low-sulfidation deposits can occur in any setting and may be hosted in basement rocks. Both deposit types are localized by structures, but any suitable structure may be used including favorable volcanic features such as calderas.

For low-sulfidation deposits, the most important features are their typically open-space vein-fill character, their diverse range of distinctive textures, and the characteristic alteration pattern. Silica (quartz) veins and the presence of surface sinters (hot-spring deposits) are typical in low-sulfidation systems. For high-sulfidation deposits, the most important features are their typically massive, disseminated character; their mineralogy (especially the ore mineral enargite and gangue mineral alunite); and the characteristic alteration pattern. Quartz is uncommon as a vein mineral in high-sulfidation systems but may be present as distinctive vuggy or sometimes massive-quartz alteration.

Hydrothermal alteration around low-sulfidation deposits is characteristic of that produced by neutral-pH fluids. The characteristic ore minerals in low-sulfidation deposits are pyrite, gold (often electrum), other base-metal sulfides (chalcopyrite, high-Fe sphalerite and galena), and often selenides along with gangue minerals quartz, chalcedony, calcite (and other carbonates), adularia, and illite. Hydrothermal alteration in high-sulfidation deposits results from very acid fluids, and the zonation results from their progressive neutralization. The characteristic ore mineral phases of this deposit type are pyrite, enargite (copper arsenic sulfide), pyrite, chalcopyrite, tennantite, covellite, and gold. Tellurides are uncommon but present in some deposits.

Type 7.3: Lode (or Orogenic) Gold Deposits

- Muruntau, Uzbekistan
  1,320 Mt at 4.0 g/t Au
- Ashanti, Ghana
  430 Mt at 4.73 g/t Au
- Golden Mile, Australia
  1,000 Mt at 1.98 g/t Au
- Homestake, South Dakota, United States
  148 Mt at 8.34 g/t Au
- Sukhoi Log, Russia
  388 Mt at 2.7 g/t Au
- McIntyre-Hollinger, Canada
  104 Mt at 9.47 g/t Au

Age and Distribution

These deposits are widespread in metamorphic, orogenic terranes around the world, and settings include Precambrian shields, more specifically Archaean greenstone belts, Paleoproterozoic fold belts, late Proterozoic, and younger orogens. These younger orogens are located along the former margins of the supercontinents of Gondwana and Laurentia, and there are more recent belts related to orogens at the margins of the Pacific. Deposit frequency highs occur in the periods 2,800 to 2,550 million years ago, 2,100 to 1,800 million years ago, and 600 to 50 million years ago.

General Characteristics

Lode gold deposits are normally located adjacent to regionally extensive, often broad first-order deep crustal structures that have a complex geological history. The gold deposits themselves are usually located along second- or third-order structures linked to the regional first-order features, often in sites where the structures bend, change direction, or branch.

Mineralization styles vary from quartz-sulfide stockworks and breccias to quartz dominated vein deposits, showing simple to complex banded textures to disseminations without discrete vein development in sheared rocks. Mineralization is most commonly developed in rocks of greenschist metamorphic grade, although important deposits are found in both lower- and higher-grade rocks.

The wall rocks around the mineralization are often altered, with the commonest type of alteration dominated by sericite, carbonate minerals, and sulfides. Silicification is also common as are tourmaline, K-feldspar, biotite, and albite in some cases. Alteration intensity and width vary with the style of deposit and the nature of the host rocks. In deposits developed in higher metamorphic grades, the alteration can resemble skarn-like assemblages.

The largest of the deposits are typically 2 to 10 km in their longest dimension and up to 1 km wide. The deposits are characterized by generally low amounts of contained sulfide (typically 2% to 5%), with gold–silver ratios generally between 1:5 and 1:10. Pyrite and arsenopyrite are dominant sulfides, although pyrrhotite is common in deposits in higher-grade metamorphic rocks. Tungsten, bismuth, and tellurium are often geochemically anomalous in the deposits, with discrete minerals containing these elements often present.

CLASS 8: VOLCANIC-HOSTED OR VOLCANOGENIC MASSIVE SULFIDE DEPOSITS

- Rio Tinto, Spain
  500 Mt at 2.5% Zn, 0.8% Pb, 0.7% Cu, 0.8 g/t Au, 30 g/t Ag
- Gai, Russia
  380 Mt at 1.57% Cu, 0.74% Zn, 0.06% Pb
- Kidd Creek, Canada
  300 Mt at 9.50% Zn, 1.5% Cu, 0.4% Pb, 130 g/t Ag
- Bathurst, Canada
  110 Mt at 7.3% Zn, 2.4 % Pb, 1% Cu, 65 g/t Ag
- Rosebery, Australia
  9.4 Mt at 16.2% Zn, 5% Pb, 0.74% Cu, 2.9 g/t Au, 155 g/t Ag

Age and Distribution

Volcanogenic massive sulfide (VMS) deposits are one of the few mineral deposit styles that occur throughout the geological record up to the present day. The oldest known sulfide deposits of this type are located in the pre-3,700 million year old Isua group in Greenland, and the youngest are actively forming today in the deep oceans and are the subject of active mineral exploration. Much is understood about the deposits, as there have been many detailed studies of modern seafloor hydrothermal systems where these deposits are seen to form in generally deep ocean areas of active volcanism, either

at mid-ocean ridges or in volcanic back-arc basins. Rare examples are known from the relatively shallow water of the Mediterranean. In the geological record, 80% of VMS deposits are hosted in former volcanic-arc sequences.

General Characteristics

In broad terms, the deposits ideally comprise a broadly stratiform, stratabound mass or lens of sulfide that most likely is hosted in volcanic rocks or sediments. The sulfide lens may vary from less than a meter to several tens of meters thick and have highly variable length and widths. The deposit may thicken in the center, and below this a stockwork zone of altered and mineralized rock may be developed. Above the massive sulfide lens, the deposit may be covered by volcanic rocks or sediments with commonly a very distinct change in the nature of the footwall and hanging wall rocks. Individual deposits vary widely in size and shape. Multiple sulfide lenses are common. Most mines consist of several closely spaced ore bodies.

Plots of the dominant metals in VMS deposits define three major groups of deposits, namely, a copper-zinc, a zinc-lead-copper, and a lead-zinc group. The metal contents of the deposits relate to the nature of the host-rock package, and thus a fivefold classification of mafic, bimodal-mafic, mafic-siliciclastic, bimodal-felsic, and felsic-siliciclastic deposits is proposed. In the broadest sense, the first three groups are dominated by deposits where iron and copper sulfides dominate, while in the last two groups, more polymetallic sulfide assemblages dominate.

In the copper-zinc deposits, the massive sulfide lenses are usually dominated by pyrite, with pyrrhotite, chalcopyrite, and sphalerite normally forming the other major sulfide minerals. Magnetite is a common accessory mineral. Quartz, chlorite, barite, gypsum, and carbonates are the main gangue minerals. The ore bodies are commonly strongly zoned with copper enriched at the base of the deposit with zinc (and lead) at the top. This is usually marked by a mineralogical zonation, particularly in the sulfides. The regional ore-equivalent stratigraphy is sometimes marked by a metalliferous sediment. In the more polymetallic deposits, galena, sulfosalts, and barite are common.

Gold and silver are common credits in VMS deposits, particularly the more polymetallic types. The stockwork feeder zone to the deposits and the peripheral margin to the massive sulfide lenses are likewise commonly gold enriched.

CLASS 9: SEDIMENT-HOSTED DEPOSITS

Examples of this deposit type can be broadly subdivided into sulfide deposits, iron and manganese oxide deposits, sedimentary uranium deposits, chemical sediments, and gold- and uranium-bearing conglomerates.

Type 9.1: Sediment-Hosted Sulfide Deposits

This group of deposits ranges from clastic-hosted copper deposits, such as the Kupferschiefer and the African copper belt, to the clastic-hosted sedimentary exhalative (SEDEX) Zn-Pb (Cu) deposits, where a syngenetic, seafloor origin is proposed, and the clearly epigenetic carbonate, or rarely sandstone replacement Mississippi Valley type (MVT) Pb-Zn deposits. The "Irish type" carbonate-hosted deposits are a subgroup with much in common with SEDEX Zn-Pb deposits, but they also have a few aspects of MVT deposits making them a distinctive group.

Subtype 9.1.1: Sedimentary Exhalative Pb-Zn (Cu) in Clastic Sediments

- Red Dog, Alaska, United States
  150 Mt at 5% Pb, 17.1% Zn, 82.3 g/t Ag
- Gamsburg, South Africa
  150 Mt at 0.5% Pb, 7.1% Zn, 6 g/t Ag
- McArthur River, Australia
  227 Mt at 4.1% Pb, 9.5% Zn, 40 g/t Ag
- Rammelsburg, Germany
  27.2 Mt at 1.0% Cu, 7.8% Pb, 16.4% Zn, 103 g/t Ag

Age and Distribution

These deposits are found in large sedimentary basinal sequences from the mid-Proterozoic to the present. Although SEDEX deposits are probably found in rocks from the Archaean to the present, there are two frequency peaks in the mid-Proterozoic and Palaeozoic. The Proterozoic is host to a series of deposits in Australia (e.g., Mt. Isa), Canada (Sullivan), and South Africa (Gamsburg). The Paleozoic of western Canada and Alaska is host to a number of deposits, including Cirque, Howards Pass, and Red Dog. The Paleozoic of Western Europe hosts the Meggen and Rammelsburg deposits.

The common theme of association is the formation of deposits during periods of major continental rifting. In the case of the Proterozoic, there is a link to the breakup of a large supercontinent to separate Australia, Antarctica, North America, and South Africa. The deposits in the Rhenish of Western Europe and Selwyn Basin of Canada and Alaska are linked to major continental rifting in the Devonian to Carboniferous.

General Characteristics

The deposits form largely conformable to semiconformable stratiform lenses of sulfides and associated hydrothermal products. Deposits typically have a length-to-thickness ratio in the order of 1:20, and many are underlain by some form of vein system that can be interpreted as a feeder. The deposits are usually compositionally layered to some degree on a millimeter-to-meter scale. Breccias, irregular veining, and disseminated textures are common.

Mineralogically, the deposits comprise sulfides together with carbonates and very commonly barite. Pyrite often dominates as the major sulfide, although in many of the Proterozoic deposits, pyrrhotite is the main phase. Sphalerite and galena are usually the main economic sulfides. Siderite and ankerite are common gangue minerals.

Zonation in the deposits is often both lateral and vertical, with transitions from sulfides to oxides common from the core to periphery, both laterally and vertically. Carbonate alteration haloes are common in these deposits, and very commonly the Zn–Ba and Zn–Mn ratios decrease in carbonate with distance from the "feeder" system or core of the deposit. Silicate alteration and silicification may occur in some deposits.

Subtype 9.1.2: Mississippi Valley Type Pb-Zn

- Polaris, Canada
  22 Mt at 4% Pb and 14% Zn
- Pine Point, Canada
  76.1 Mt at 2.9% Pb and 6.5% Zn
- Tri-State District, United States
  500 Mt at 0.6% Pb and 2.4% Zn

- Viburnum Trend, Missouri, United States
  111 Mt at 0.8% Zn and 5.8% Pb
- Jinding, China
  90 Mt at 7.8% Zn, 1.6% Pb
- Angouran, Iran
  14.5 Mt at 26.6% Zn, 4.6% Pb
- Silesia, Poland
  200 Mt at 4% to 5% Zn, 1% to 2% Pb

Age and Distribution

Mississippi Valley type (MVT) deposits are generally restricted to post-Proterozoic rocks, with the exception of the Pering deposit in South Africa. They are known in Paleozoic to recent carbonate-rich sedimentary packages with important deposits in Canada at Polaris, Pine Point, Gays River, and Newfoundland Zinc. The platform carbonate sequences of the United States host these deposits, including the district that gives the deposit its name (Mississippi Valley), Tennessee, Missouri, and the Tri-State District. Major deposits of this type are also found in the Lennard Shelf of Australia, Silesia in Poland, and the Cevennes of France.

General Characteristics

The deposits are generally carbonate-hosted, usually in a dolostone or limestone, although, rarely, they can be sandstone-hosted. The deposits occur mostly in relatively undeformed platform carbonate sequences at the flanks of large sedimentary basin sequences. Districts are often large (up to thousands of square kilometers), but they may comprise clustered small (<10 Mt) individual deposits.

The deposits are normally stratabound, but they are sometimes stratiform where they can resemble SEDEX deposits. Mineralization generally cuts across the stratigraphy but often forms bodies within specific horizons or beds. Ore minerals are dominated by sphalerite and galena with an iron sulfide (pyrite or marcasite). Ore grades in deposits rarely exceed 15% combined Pb-Zn, and mineralization is often accompanied by abundant gangue minerals, dominated by carbonates (calcite, dolomite, siderite, etc.). Fluorite and barite are common; the former mineral seems to be absent from SEDEX deposits, which may be a key discriminating feature.

The deposits range from bedded types to discordant bodies commonly taking the form of mineralized breccias. There are often strong physical controls to the development of mineralization, including the location of basement highs, faults, fractures, and the fault-controlled development of solution collapse breccias.

Subtype 9.1.3: Irish-Type Pb-Zn (Cu)

- Navan, Ireland
  70 Mt at 10.1 % Zn, 2.6% Pb (+14 Mt at 9.85% Zn)
- Lisheen, Ireland
  23 Mt at 13.1% Zn, 2.2% Pb
- Reocin, Spain
  80 Mt at 10% Zn, 1% Pb

General Characteristics

The type locality for this deposit subtype is Ireland, although other deposits are known at Reocin and the Kootenay arc in Canada. Deposits are generally stratabound but sometimes occur stratiform, typically wedge-shaped lenses abutting a fault. The mineralized lenses may be up to 30 m thick and extend 200 m from bounding fault. Larger deposits may comprise individual or stacked lenses that are roughly concordant to bedding.

The mineralization often comprises massive sulfides, but in some deposits layered textures are present. Mineralization comprises sphalerite and galena, the principal ore minerals with iron sulfides (generally pyrite and marcasite) variable from being the dominant sulfide to being a minor constituent. Barite is common in most of the deposits forming massive lenses in some cases.

Subtype 9.1.4: Clastic Sediment-Hosted Copper

- Lubin, Poland
  >3,400 Mt at 2.0% Cu, 40 g/t Ag, 0.2% Pb, 0.1% Zn
- Kolwezi, Democratic Republic of Congo
  880 Mt at 4.5% Cu, 0.4% Co
- Konkola, Zambia
  1,000 Mt at 2.5% Cu
- Nchanga, Zambia
  710 Mt at 2.5% Cu
- Udokan, Russia
  1,310 Mt at 1.51% Cu, 9.6 g/t Ag, 0.5 g/t Au
- Dzhezkazgan, Kazakhstan
  2,000 Mt at 1.02% Cu, 0.82% Zn, 0.8% Pb, 13 g/t Ag
- Aynak, Afghanistan
  705 Mt at 1.56% Cu
- White Pine, Michigan, United States
  >150 Mt at 1.2% Cu

Age and Distribution

These deposits are found in rocks ranging in age from early Proterozoic to Tertiary but are most frequent in late Mesoproterozoic to late Neoproterozoic rocks and in late Paleozoic sequences. These were all periods of major continental breakup, glaciation events, and times when there is evidence for the dissolution of thick evaporite sequences. The following six giant districts are known around the world:

- Neoproterozoic Katangan Basin of Central Africa (Central African copper belt)
- Permian basin of Europe (Kupferschiefer)
- Paleoproterozoic Kodara-Udokan Basin of Siberia (Udokan)
- Paleozoic Chu-Sarysu basin of Kazakhstan (Dzhezkazgan)
- Middle Proterozoic mid-continent rift of the United States (White Pine)
- Neoproterozoic-Cambrian Basin in Afghanistan (Aynak)

Other smaller districts are known in Australia and North Africa, among others.

General Characteristics

Two associations are generally involved for this deposit type. One type (Kupfershiefer) is hosted in reduced, organic-rich sedimentary rocks formed in shallow marine or lacustrine environments comprised of silts, shales, sandstones, and dolomites. These units are typically overlain by oxidized coarser units of oxidized red-bed type sequences. The second type of deposit ("red-bed copper") is hosted within continental red-bed sequences where mineralization occurs at the interface between gray (relatively reduced, often pyrite-bearing) and red (oxidized, hematite-bearing) sandstones, arkose, or

conglomerates. Some deposits in the Central African copper belt are found in highly metamorphosed rocks that appear to be the basement sequences to the basinal deposits seen elsewhere hosting copper mineralization. In some cases, such as the Kupfershiefer, thick sequences of oxidized volcanic-rich sediments are present.

In most cases, deposits are generally thin (usually less than 3 m and never greater than 30 m thick), stratiform, sediment-hosted mineralization comprising Cu (±Co, Ag, Pb, Zn, Pt, Pd). The grade of the mineralization is typically 1.5% to 3% Cu, but mineralization is laterally very continuous with huge tonnages developed (the Central African copper belt contained more than 3 Gt of proven ore grading close to 3% Cu). The deposits are dominated by fine-grained disseminated sulfides, comprising largely chalcocite (Cu_2S), digenite (Cu_9S_5), bornite, chalcopyrite, carrolite ($CuCo_2S_4$), galena, sphalerite, and pyrite.

Type 9.2: Sediment-Hosted Iron and Manganese Deposits

Subtype 9.2.1 Ironstones

These deposits include the Minette-type iron ores of Lorraine and Luxembourg; the Northamptonshire ironstone in England; and the Clinton-type ironstones of Newfoundland, Alabama, and the Appalachians. The giant Lisakov deposit in the southern Urals is an oolitic ironstone. The Minette-type oolitic deposits have been major sources of iron in the past, but their low grades (typically 25% to 35% Fe) have made them increasingly uneconomic as a source of iron.

Age and Distribution

Both Clinton-type and Minette-type iron ores are restricted to the Phanerozoic. Clinton-types are developed in Cambro-Ordovician sequences of North America. Minette-type ironstones are common throughout the Mesozoic of Europe, in western Kazakhstan, and in parts of northern Africa. Major Oligocene ironstones are present at Kerch in Ukraine and at Lisakovsk in Kazakhstan, among others.

General Characteristics

Minette ores are characterized by regionally extensive horizons of siderite and chamosite within dominantly limestone sequences. In Europe they are found in the Jurassic, extending from the United Kingdom through to central Germany. The chamosite is often distinctive, as it usually takes the form of oolites in a mixed silicate and carbonate matrix. The ores are thus lime-rich (up to 20%), which leads to these ores being generally self-fluxing. Clinton ores extend for at least 1,000 km along strike across the Appalachians. They are frequently associated with black shales and have been deposited in continental shelf and estuarine basins. Beds in the ores are generally less than 1 m thick, separated by ferruginous shales. The ores are typified by oolitic hematite-rich beds, with features suggesting a shallow depositional environment although minor sulfide-rich (pyrite) facies are developed.

Subtype 9.2.2: Banded Iron Formation

Three types of banded iron formation (BIF) are recognized that broadly equate to three major time periods in the earth's history, from the Archaean to Proterozoic, and three distinctive tectonic settings. Algoma-type deposits formed in rocks 3,500 and 3,000 million years old, Lake Superior (Superior)-type deposits occur in rocks 2,500 to 2,000 million years old, and the smaller group of Rapitan-type deposits are found in rocks 1,000 to 500 million years old.

Sub-subtype 9.2.2.1: Algoma BIF

- Cerro Bolivar, Venezuela
  500 Mt at >60% Fe
- Koolyanobbing, Australia
  116 Mt at 62% Fe

Age and Distribution

Algoma-type deposits are typically found in Archaean greenstone belts with the type locality in the Abitibi greenstone belt of Canada. Other deposits include Kudremuk, India; Cerro Bolivar, Venezuela; and Koolyanobbing, Australia. Similar deposits are known in the Paleozoic of the Bathurst District, Canada, and modern analogs may be present on the current seafloor.

General Characteristics

Algoma-type iron deposits are formed as part of sedimentary sequences, but they show a close relationship to volcanic rocks of mafic to felsic composition. The deposits are geographically related to proximal and distal volcanic centers. Mineralization comprises micro- to macro-interlayered iron mineral (oxides, sulfides, or silicates) and silica bands. These silica-iron bands are typically interbedded with clastic sediments and volcanics. The host horizons are regionally extensive features that are often laterally zoned into silicate, oxide, carbonate, and sulfide-dominated facies. Deposits become mineable usually where metamorphosed to a coarser grade or where thickened by tectonic events, or else where they are residually enriched by secondary processes such as weathering.

Sub-subtype 9.2.2.2: Superior BIF

- Hammersley Province, Australia
  25,000 Mt at >55% Fe
- Quadrilatero Ferrifero, Brazil
  6,000 Mt at >50% Fe
- Serra Norte, Brazil
  17,300 Mt at 66% Fe

Age and Distribution

Superior-type deposits are generally Proterozoic in age, largely in the time period 2,500 to 2,000 million years old, and examples are found distributed around the world. Examples include the following: Transvaal Basin, South Africa; Labrador, Canada; Minnesota, United States; Damara, South Africa; and Krivoy Rog in the Kursk region of Ukraine and Russia.

General Characteristics

Mineable deposits of Superior-type BIF comprise discrete stratigraphic units of oxide lithofacies. Stratigraphic thicknesses may be 30 to 300 m, with strike lengths in the order of kilometers. Folding and faulting may result in favorably thickened packages.

BIFs are characterized by alternating bands of silica and iron minerals that when unmetamorphosed are very fine grained. The primary minerals are largely magnetite, hematite, quartz and minor iron silicates, carbonates, and occasionally

sulfides. In manganiferous facies, pyrolusite, manganite, and hollandite may be present. Primary sedimentary features may be present, such as oolites in a cherty or carbonate matrix, rare cross-bedding features, intraformational breccias, slumping, compaction structures, and stromatolite textures. Nonmetamorphosed BIFs are referred to as taconite, whereas metamorphosed BIFs generally become coarser grained and are known as metataconite or itabirite.

Taconite rarely makes mineable ore unless upgraded by secondary processes. Itabirite is much coarser grained and can be upgraded by physical sorting, although in most cases both types need to be upgraded by secondary processes to produce mineable ore. Secondary upgrading serves to remove silica and to cause iron enrichment by oxidation.

Sub-subtype 9.2.2.3: Rapitan BIF

- Crest, Yukon, Canada
  18,600 Mt at 43.8% Fe

Age and Distribution

Rapitan deposits are known from the Mackenzie Mountains in Canada; Jacadigo, Brazil; and the Adelaide Geosyncline, Australia. They are late Proterozoic to early Paleozoic in age.

General Characteristics

The Rapitan BIFs are generally formed of bedded chert-hematite, much like other Superior-type iron formations. However, their associations are significantly different as they are generally associated with diamictites (tillites), dropstones, sandstones, conglomerates, and argillites. The tectonic setting is one of graben and fault scarps located on the margins of continents or ancient cratons.

Subtype 9.2.3: Manganese Ore

- Mamatwan, South Africa
  13,600 Mt at >20% Mn

Age and Distribution

The largest single manganese resource is the Kalahari manganese field of South Africa, which is Proterozoic and related to an iron-rich BIF. Manganese facies of iron-formation ores are also developed in the Lake Superior region and in the Devonian sequences of Kazakhstan and Russia. Manganese is produced from BIF in Gabon. Other important deposits occur in the Oligocene Nikopol Basin in Ukraine and in the Chiatura Basin in Georgia. Important Cretaceous deposits are found in northern Australia (Groote Eylandt) and in the Molango District of Mexico.

General Characteristics

In BIF-type associations, the manganese-rich bodies lie stratigraphically above the iron-rich facies with manganese minerals such as pyrolusite and hollandite present instead of the iron oxides. Textures in the ores are similar to the BIFs described in the previous sections.

In the case of the important Oligocene deposits of the Ukraine and Georgia, the ores consist of irregular concretions, nodules, and masses of manganese oxides with or without carbonates in a silt to clay matrix. The manganiferous bed averages 2 to 3.5 m thick, runs 15% to 30% Mn, and is traceable for at least 250 km along the strike, although postdeposition erosion frequently disrupts the bed. The main minerals in the ore zone are pyrolusite and psilomelane, together with manganocalcite and rhodochrosite. The deposits are laterally zoned from oxides to carbonate facies.

Type 9.3: Sedimentary Uranium Deposits

Sedimentary uranium deposits can be classified in two catagories: unconformity vein-type deposits and sandstone-hosted uranium deposits.

Subtype 9.3.1: Unconformity Vein-Type Uranium

- Cigar Lake, Canada
  160,000 t at 19% U_3O_8
- McArthur River, Canada
  150,000 t at 21% U_3O_8
- Jabiluka No. 2, Australia
  163,000 t at 0.55% U_3O_8
- Crouzille, France
  13,400 t at 0.25% U_3O_8

Age and Distribution

These deposits are generally Proterozoic in age (2,500 to 600 Ma) and are found in a number of countries around the world, The most famous are the deposits in the Proterozoic Athabasca and Thelon basins of Canada, but other important fields are found in Australia (East Alligator, Jabiluka) and formerly the Crouzille region of France.

General Characteristics

Deposits are generally small but can range up to 50 Mt in size. The deposits can also be very high grade. Cigar Lake and McArthur River in Canada have the highest grades of any uranium deposits, averaging 19% and 24% U_3O_8, respectively. Deposits often produce important by-products, and in the case of Jabiluka in Australia, the deposit carries 15 g/t Au. Key Lake in Canada has a nickel resource but is too radioactive to exploit.

Deposits are largely hosted in sandstone units overlying older, metamorphosed, generally Proterozoic basements (Paleozoic in the case of the French deposits). Mineralization is developed at and below the unconformity, especially where the sequence is intersected by faults passing down into the basement. The ore bodies are generally tubular to flattened cigar-shaped high-grade zones passing into a more disseminated style mineralization. Mineralization is strongly controlled by subvertical faults, shear and fracture zones, as well as the subhorizontal plane of unconformity.

Mineralization appears as either polymetallic mineralization containing uranium, nickel, cobalt, and arsenic, or it is monomineralic containing uranium only. Monomineralic-type mineralization is usually formed of euhedral grains of uraninite and pitchblende within the host rock, which may be arkose, semipelite, graphitic schist, pelite, or in some cases mylonite. Polymetallic mineralization is typical for sub-unconformity mineralization in the Athabasca Basin. At the high-grade Cigar Lake deposit, this consists of pods and lenses of pitchblende and coffinite with arsenides and sulfoarsenides of nickel and cobalt, together with nickel, cobalt, lead, molybdenum, iron, and zinc sulfides. Gold and platinum group metals (PGMs) can also be present. Monomineralic mineralization is commonly hosted in lenses around structures, or as thin stockwork veinlet zones.

Alteration is common and may take the form of chloritization, argillization, carbonation (dolomite), silicification, pyritization, and tourmaline alteration.

Subtype 9.3.2: Sandstone-Hosted Uranium

- Chu-Sarysu and Syrdarya, Kazakhstan
  1.3 Mt contained U_3O_8
- Callabonna, Australia
  41.2 kt contained U_3O_8
- Wyoming Basin, United States
  320 kt contained U_3O_8
- Southern Texas, United States
  ~80 kt contained U_3O_8
- Franceville Basin, Gabon
  ~38 kt contained U_3O_8

Age and Distribution

Sandstone-hosted deposits span a range of host rock ages and are distributed globally with principal deposits found in the Wyoming Basin, Kazakhstan, New Mexico, and Australia.

General Characteristics

These deposits are generally hosted within sandstones as the name suggests, and they are generally medium- to coarse-grained, continental fluvial to marginal marine sediments and are ideal for in-situ leach mining. Foreland basin settings are the most prospective for this deposit type as tectonic activity is a key component to promote fluid flow through the sediments to precipitate uranium. A key feature is also the presence of impermeable units, either a shale or mudstone, interbedded in the host stratigraphy, which helped to focus and contain fluid flow into favorable trap sites.

The deposits are subdivided into the following three main types based on morphology: tabular, roll-front, or basal channel. The tabular-type deposits form elongate lenses of mineralization within sediments that show selective reduction. This reduction may be caused by the presence of organic matter in the host sediments. The mineralization develops parallel to the postulated groundwater flow through the host rocks. Roll-front deposits form disseminations in permeable and porous sandstone beds. The mineralization is developed within the sandstone at an interpreted redox front. Roll-front deposits usually form the largest deposits, and the fact they are hosted in porous sandstone makes them ideal for in-situ leaching. Basal channel deposits are similar to roll-front deposits, but they are specifically hosted in the coarse channel gravels of ancient fluviatile sediments.

The primary mineralization is pitchblende and coffinite, but secondary minerals (e.g., autunite, uranophane, carnotite, and tobernite) are often present due to later weathering events. Grades in the deposits are usually quite low (commonly $<0.4\%$ U_3O_8), but they can usually be mined by low-cost leach technology, making them economic targets for extraction and processing.

Type 9.4: Gold and Uranium in Conglomerates

- Witwatersrand Basin, South Africa
  4,000 Mt at 9.2g/t Au > 200 g/t U
- Elliot Lake, Canada
  140 Mt at 0.09% U

Age and Distribution

These deposits are found in rocks as old as 3.0 billion years in southern Africa and India. Gold-bearing conglomerates in South Africa are 3,070 million years old, whereas the bulk of the Witwatersrand deposits, which have accounted for more than 35% of all gold mine production, are hosted in rocks between 2,950 and 2,710 million years old. The Elliot Lake conglomerates in Canada are 2,450 million years old and the Tarkwian gold-bearing conglomerates in West Africa are 2,130 million years old. Tertiary-aged gold-bearing pebble conglomerates are known in New Zealand with many features similar to the more ancient examples. The bulk of the economic deposits are Archaean to Proterozoic, although if they represent paleoplacer deposits (which is the traditional model for their formation), then modern analogs could be the gold-bearing alluvial gravels found in many goldfields still actively forming today.

General Characteristics

The most significant deposits of this group are the gold-uranium deposits of the Witwatersrand Basin in South Africa and the uranium-bearing conglomerates of Elliot Lake in Canada. The following observations are based on these deposits.

In the Witwatersrand, gold is hosted within a sequence of quartz arenite-dominated rocks that are chemically, mineralogically, and texturally submature to supermature. Quartz pebble rocks dominate, but feldspathic quartzites are also relatively common, suggesting a granitic source for much of the detritus. At Elliot Lake, the mineralization is hosted in similar quartz-rich pebble conglomerates where the detritus appears to have been derived from the reworking of pegmatitic granites.

In the Witwatersrand, a number of host rock types are associated with the gold-bearing conglomerates. At the base of the section, submature arenites are developed in a stream system on granitic basement rocks. Further up, the West Rand Group contains shale, sandstone, and iron formation. The main host part of the package, the Central Rand Group, formed as part of major braided stream systems, clearly developed in broad valleys as parts of alluvial fans. Unidirectional and herringbone cross bedding is recorded, indicative of both single flow directions and a degree of reworking in shallow intertidal conditions. Argillites, siltstones, and minor limestones are testament to standing water during parts of the sedimentation, and in places, glaciogenic deposits and iron formations are developed. Finally, the uppermost part of the sequence comprises a unit called the Black Reef, which contains gold where it has reworked the Central Rand Group rocks.

The ores in the Witwatersrand are typically free-milling, with gold largely present as native grains containing 7% to 14% Ag. The ore material is made up of the following three types of ores: coarse pebble conglomerates ("blanket reef"), carbon seams, and pyritic quartzites. Gold may take one of five different forms: free gold particles with minor sulfides (e.g., sphalerite, linneite, gersdorffite, cobaltite, and chalcopyrite), gold associated with carbonaceous matter, redistributed gold along fractures or on the surface of other grains, gold in pyrite or arsenopyrite, or gold in later secondary quartz veins.

At Elliot Lake, a somewhat similar package of fluviatile sediments hosts mineralization where uraninite occurs as poorly rounded to euhedral grains up to 0.2 mm across within the matrix of a quartz-pebble conglomerate.

Type 9.5: Chemical Sediments

Chemical sediment deposits are divided into evaporites and manganese nodules. These are discussed as follows.

Subtype 9.5.1: Evaporites

Evaporites are the main source of rock salt, potash, borates, nitrates, agricultural fertilizers, and lithium.

Age and Distribution

Evaporites are only known to have formed from the Proterozoic onwards, although in the bulk of cases in the Proterozoic, the evaporite horizons are now no longer present. Basins hosting major exploited evaporite deposits include the Permian Zechstein Formation, present through most of northern Europe and the eastern United States. Other basins are the modern intracontinental lacustrine basins of Chile, Bolivia, Argentina, California, and Utah, where borates, nitrates, and lithium deposits are mined. One of the world's largest borate-producing regions is located in western Turkey.

Subtype 9.5.2: Manganese Nodules

This deposit type is unique, as it occurs largely in international waters of the ocean. The deposits have never been mined owing to the combination of the water depths and the lack of a comprehensive legal framework for the exploitation of the nodules.

Age and Distribution

The nodules occur in the deep pelagic parts of all major modern oceans, but they especially occur in the Pacific Ocean, where exploration indicates there may be up to 100 nodules per square meter. They represent an enormous future resource of nickel, copper, cobalt, and manganese.

General Characteristics

The nodules occur in the deep oceans where normal clastic sedimentation is low to absent. In the Pacific, where the nodules are best developed, they contain up to 2% combined Ni and Cu with substantial Co and Zn. Deposits are very extensive; the most attractive resource is in the so-called Clarion-Clipperton region of the Eastern Pacific, in a belt bounded by longitude 60°W to 180°W and latitude 15°S and 15°N.

CLASS 10: ORES RELATED TO WEATHERING

Type 10.1: Laterites

Lateritization is a weathering process occurring under humid tropical conditions leading to the dissolution of most soluble elements, such as K, Na, Mg, Ca, and some Si, and accumulating less soluble elements, such as Al and Fe. Principal deposits formed by this process are nickel-cobalt, bauxite (Al), and lateritic gold. Lateritization of existing lower-grade iron ores can result in significant upgrades to the deposits, largely as a result of silica removal. Important phosphate and niobium deposits have been upgraded in this way at Mabounie in Brazil, in Gabon, and at Lueshe in the Democratic Republic of Congo.

Subtype 10.1.1: Bauxite

Two main types of bauxite are karstic and lateritic. Karstic bauxites form by the dissolution of carbonate sequences with concomitant weathering of associated aluminosilicates. Lateritic bauxites are developed over a variety of aluminum-bearing rocks and form a characteristic zoned profile. Karstic bauxites are commonly developed in carbonate sequences in the Mediterranean region, for example, at Les Baux in France, from where the deposit type gets its name. Lateritic bauxites are developed in five major regions of the world: Guiana and the Brazilian shield in South America, a province in West Africa, India, Southeast Asia, and Australia. These lateritic bauxites account for around 90% of world's bauxite resources.

General Characteristics

In a typical lateritic bauxite, the fresh parent rock is overlain by a saprolite composed largely of kaolinite with some iron hydroxides and residual parent minerals (e.g., quartz, zircon, and magnetite). Saprolite is where the texture of the original rock is still discernable and where the volume is preserved despite removal of soluble components. This saprolite varies in thickness up to 100 m in deeply weathered terrains. Above the kaolinitic saprolite, gibbsite replaces kaolinite, and this is the bauxite horizon. This horizon, which constitutes the ore zone, is typically a few meters thick and usually has very high aluminum grades and low iron values. Above this, the profile is capped by either a duricrust (which may be bauxitic or ferruginous) or a clay-rich zone. Any duricrust is likely to be composed of oxyhydroxide minerals and kaolinite.

Three types of lateritic bauxite are recognized: orthobauxite, metabauxite, and cryptobauxite. Orthobauxites are those interpreted to have formed in situ by a single-stage weathering process. Metabauxites are more aluminum-rich, having developed on quartz-poor rocks as an upgrade reworking under drier conditions of an already formed orthobauxite. Cryptobauxites are used to describe bauxites buried under clay cover, again resulting from the reworking of an orthobauxite under probably more humid conditions.

Subtype 10.1.2: Nickel (Cobalt) Laterite

- Koniambo, New Caledonia (silicate)
  150 Mt at 2.57% Ni
- Cerro Matoso, Colombia (silicate)
  40 Mt at 2.5% Ni
- Murrin Murrin, Australia (clay-silicate)
  125 Mt at 1.02% Ni
- San Felipe, Cuba (clay-silicate)
  230 Mt at 1.33% Ni
- Euboea, Greece (oxide)
  185 Mt at 1.3% Ni
- Goro, New Caledonia (oxide)
  200 Mt at 1.57% Ni
- Buruktal, Russia (oxide, clay-silicate)
  110 Mt at 1.2% Ni
- Vermelho, Brazil (oxide, silicate)
  410 Mt at 1.23% Ni

Age and Distribution

A number of known nickel laterites occur in the currently tropical zones of the earth, and it is clear that many are actively forming today. Major deposits occur throughout Central America, Africa, Southeast Asia, and the Pacific, and they can be attributed to recent weathering periods. Southern Europe (Balkans and Greece) through to Turkey and many parts of Russia and adjacent states host nickel laterites, which are the result of late

Mesozoic and Tertiary weathering periods. In addition, many deposits are located on ancient crust (e.g., Australia and Brazil), where the weathering history is likely to have been very protracted and difficult to ascribe to one particular time period.

General Characteristics

In broad terms, in-situ nickel laterites form simple zoned profiles over unweathered parent rock. In a number of cases the laterite may be transported to some degree where the nickeliferous unit is no longer authochthonous on its parent. In all cases, the initial parent rock was an ultramafic, and in a rare case, mafic igneous parent rock was largely composed of Mg- and Fe-bearing silicates where nickel substituted for Mg to some degree. Typically, nickel values in unweathered parent rock are 0.2% (by weight) Ni. Apparently there is no necessity for the parent rock to be unusually enriched in nickel. Ultramafic rocks suitable for forming nickel laterites include dunites, peridotites, and serpentinized equivalents, where nickel resides in olivine, pyroxene, and serpentine-group minerals.

A typical laterite profile comprises an unweathered ultramafic parent rock passing up into a saprolite zone (weathered but still retaining a fair degree of competence, original texture, and volume). Above the saprolite zone is an oxide zone that may have a variable component of clay (usually mixed-layer and iron-rich). This oxide zone is often zoned into a lower limonitic (goethite-rich) and upper hematitic facies, which is likely to have silica present as aggregates or distinct ledges. The whole profile is capped by a ferruginous or siliceous duricrust where present.

Nickel is usually enriched in the saprolite zone where Ni substitutes for Mg in a range of hydrous layer silicate minerals (such as serpentine, talc, sepiolite, and chlorite). Nickel is also enriched in the oxide zone, where nickel may be hosted in mixed-layer clays, more commonly in goethite, and also in a range of manganese oxides, including asbolane. Cobalt is an important associated metal in these deposits, and this is strongly fixed by the manganese oxide phases. Hematitic parts of the profile are generally nickel-poor and silicification decreases grade.

Subtype 10.1.3: Lateritic Gold

Artisanal miners in West Africa and Brazil have mined this deposit type for centuries. In these deposits weathering has both liberated gold and also resulted in the physical concentration of gold particles. Major gold resources of this type have been identified at Ity in Cote d'Ivoire, Ashanti in Ghana, and Igarape Bahia in Brazil.

In parts of Australia, nugget-bearing weathering zones have produced spectacular numbers of gold nuggets, and bauxitic deposits in Queensland carry gold where no mineralization is detected in the basement rocks. A major gold resource of 45 Mt at 1.8 g/t Au was identified at the Boddington bauxite mine, Western Australia, in 1988 after material was finally sent for assay.

Type 10.2: Supergene Weathering

Supergene weathering deposits are divided into secondary copper deposits and secondary zinc deposits.

Subtype 10.2.1: Secondary Copper

- Bingham Canyon, Utah, United States (porphyry Cu)
  338 Mt at 1.5% Cu
- Morenci, Arizona, United States (porphyry Cu)
  379.4 Mt at 1.02% Cu
- Potrerillos, Chile (porphyry Cu)
  137.4 Mt at 1.51% Cu
- Chuquicamata, Chile (porphyry Cu)
  684.3 Mt at 2.12% Cu
- El Teniente, Chile (porphyry Cu)
  234.8 Mt at 2.18% Cu
- Phoenix, Cyprus (VMS)
  9.2 MT at 0.78% Cu + 6 Mt at 0.31% Cu

Age and Distribution

Many major porphyry copper camps around the world have a developed supergene zone that makes them attractive targets for exploitation. Many large VMS deposits also have supergene blankets (e.g., Paleozoic of the Urals), although these have not been exploited to date. The Phoenix ore body in Cyprus is an example of a supergene-enriched VMS that has been exploited for the oxidized ores.

General Characteristics

At the base of a typical supergene profile is the primary hypogene ore, which in the case of a porphyry copper deposit is typically comprised of chalcopyrite and pyrite with various silicate phases (e.g., K-feldspar, muscovite, epidote, biotite, and quartz). Above this lies the more-reduced part of the supergene blanket, which may contain secondary sulfide copper minerals such as the more common chalcocite, covellite, and bornite. Above this is the more oxidized supergene assemblage, including copper carbonates and oxides. Above the supergene zone are the leached zones, where sulfide minerals are generally destroyed, and finally, a full profile would be capped by a zone rich in hydrated iron oxides (gossan or iron hat).

The main zone of economic interest is the secondary sulfide zone containing bornite, covellite, and chalcocite. These sulfides are copper-enriched compared to the primary ore, and thus the grades are often significantly higher than the primary ore. In addition, the mineralogy of the ore is more favorable for low-cost solvent-extraction methods of treatment. Gold is generally conserved during the supergene enrichment process, but its fineness and grain size may increase. In lateritic weathering terranes, however, gold grades may be significantly upgraded.

Subtype 10.2.2: Secondary Zinc

- La Calamine, Belgium
  1.9 Mt at 40% Zn
- Jabali, Yemen
  9.4 Mt at 10.8% Zn, 2.3% Pb, 77 g/t Ag
- Angouran, Iran
  3.3 Mt at 38% Zn, 2% Pb
- Jinding, China
  50 Mt at 8% Zn, 1% Pb
- Silesia, Poland
  17.3 Mt at 17% Zn
- Skorpion, Namibia
  24.6 Mt at 10.6% Zn

General Characteristics

Three types of secondary zinc deposits are defined: direct replacement, wall-rock replacement, and residual and karst

fill deposits. Direct replacement deposits are effectively zinc-rich gossans where the sulfide body is weathered. In this case, sphalerite is replaced by smithsonite and hemimorphite. Usually, deposits are complex mixtures of sulfides (galena, pyrite, chalcopyrite, etc.), so the secondary assemblage is usually a more complex mixture of oxides, carbonates, and silicates. Deposits formed from a weathered MVT tend to be the most mineralogically simple, dominated by smithsonite, hemimorphite, and hydrozincite. In more arid weathering profiles, willemite (silicate) is formed.

CLASS 11: PLACER DEPOSITS

Placers have been a source of metals from early times, as they are easily worked by manual methods, processing by washing or winnowing techniques. Most major gold rushes were based on the discoveries of alluvial gold, which may have later led to hard rock discovery. Very significant placer diamond deposits are worked on the west coast of southern Africa. Beach sands are mined in various regions of Australia, eastern Africa, and the Americas.

Deposit types range from various beach sands containing heavy minerals, such as rutile, ilmenite, zircon, and monazite, to deposits of gold, platinum, tin (cassiterite), and diamonds. In all these cases, the mineral of interest becomes concentrated in either river drainages or in active marine environments by the action of moving water. The minerals of interest are generally both obdurate and of higher density than other minerals, so they tend to become concentrated in higher-energy environments in marine or river systems.

CHAPTER 3.2

Minerals Prospecting and Exploration

José L. Lee-Moreno

INTRODUCTION

Minerals prospecting and exploration cover a wide range of earth science disciplines including geology, geochemistry, geophysics, and remote sensing (which incorporates satellite imagery and multispectral data interpretation). New laboratory techniques and computer aids are used for modeling and understanding the genesis of ore deposits. These issues will be discussed in detail in this chapter.

Prospecting

Although *prospecting* and *minerals exploration* are widely considered synonymous, there are still some regions in the world where prospecting is considered the initial, more-primitive phase of exploration, reminiscent of the old gold-panning prospectors, but with the addition of some modern technology. Exploration refers to semidetailed or more-advanced detailed studies. Prospecting can help locate sites that, after a formal exploration program, may result in an ore deposit discovery. These terms will be used indistinctively here.

Ancient prospecting began with panning in creeks and riverbeds and continued with the physical exploration of surrounding hills. These areas were quickly mined out and abandoned but more recently have provided excellent guides for the discovery of source deposits.

In modern prospecting, metal detectors and artisanal heavy mineral concentrators are still used. In more-advanced placer mining operations, draglines and high-capacity gravity, magnetic, and centrifugal classification and concentration equipment are used successfully. A new generation of optical and laser mineral separators have also been introduced.

Minerals Exploration

The main objective of minerals exploration is to locate ore deposits, which are anomalous accumulations of one or more minerals that can be mined at a profit. Drilling is the most reliable, more-expensive technique used to confirm or deny the existence of an ore deposit, but new methods and technologies are still being developed.

Most outcropping ore deposits have already been discovered, so the modern mineral prospector must use more-subtle markers to recognize the presence of an anomalous mineral occurrence. New mining and metallurgical techniques allow today's mining industry to evolve beyond limited high-grade production to take advantage of lower-grade, large-volume extraction and processing. The days of the small mine are practically over.

An additional objective of mineral exploration today is to find significant extensions of preexisting deposits associated with operating or abandoned mines. Some well-known mining districts, under changing economic conditions and the application of modern exploration techniques, may present new opportunities to extract remaining minerals from them.

Increased understanding of ore-deposit modeling using statistical analyses, computer technology, and new laboratory methods provides the explorationist with powerful tools for discovering new deposits in the subsurface including deposits extending from previously known or partially mined ore bodies. Broadly classified, new deposits may be considered either as outcropping (surface) or concealed (subsurface).

There is little new ground to be explored in more-developed countries, except in less-accessible, remote areas. The search for outcropping deposits is carried out primarily in developing countries. In some cases, outcropping deposits may have been buried by tropical soils or by some other post-mineralization event, thereby eluding discovery.

Discovery of concealed deposits at shallow depths requires the integration of various advanced technological methods for preliminary assessment. Sound exploration methods are the most valued tools for the exploration geologist, whose primary objective is to identify the geological characteristics of a mineralized system that can lead to the discovery of an ore body. These characteristics must include geological, lithogeochemical, isotopic, and petrochemical features; physical properties of both altered and unaltered host rocks; structural and tectonic framework; and any other relevant relationships of the mineralizing events in terms of time and space.

José L. Lee-Moreno, Adjunct Professor, Department of Mining and Geological Engineering, University of Arizona, Tucson, Arizona, USA

Compiling and analyzing preexisting data is indispensable. The exploration geologist must identify specific factors that controlled the mineralization in an area, district, or province and, using multidisciplinary methods, "see through" any post-mineralization cover to determine the possibility of a concealed deposit.

Geological surveys, varying in detail and scale, are fundamental to all exploration programs. It is important to accurately identify any geological features of nearby deposits and the general characteristics of their position or emplacement. The features of previously outlined metallogenic provinces are very useful at this stage. Among the most important features considered during this entire exploration process are geochemical, geophysical, and remote sensing signatures; depositional models; mineral alteration; zoning; and other mineralogical guides. The details may be modified and redefined more accurately as the program advances and new indicators are discovered.

Geological interpretation must rely on additional techniques and disciplines such as field mapping, structural geology and tectonics, geomorphology, petrology and petrography, sedimentology and stratigraphy, mineralogy, geostatistics, geotechnical engineering, hydrogeology, metallurgy, geothermometry, topography, and geochemistry. The three major methods that integrate all geological observations in formal exploration programs will be reviewed briefly here: exploration geochemistry, geophysical exploration, and ore deposits. Resource and reserve estimations and definitions constitute one of the final stages before entering into production. These methodologies are discussed in detail in other chapters.

In regional exploration, geochemistry begins with stream sediment surveys followed by detailed sampling of soil and rock. Hydrogeochemistry, biogeochemistry, and geobotany also should be considered and applied when relevant.

Regional aerial geophysics such as magnetic, radioactive, and electromagnetic methods have proven very useful in helping to delineate major structures and in identifying lithology, overburden, and concealed mineralization. In some specific cases, aerial gravimetric technology has been applied, but not with great success. Together with electrical methods, these offer follow-up support to ground geophysical exploration. Some geologists include remote sensing in the area of geophysical exploration, but it is more correctly categorized as a separate method.

Aerial photography continues to be extremely useful, and the Internet allows the downloading of mono- and polychromatic images of nearly every part of the earth's surface, often free of charge. Older methods of low- and high-flight aerial photography have practically disappeared and now are applied only in very specific cases. High-resolution satellite imagery has become the preferred method of aerial photographic imaging.

Multispectral data is also available to the public from some government agencies that possess special satellites. Rock alteration and zoning features can be detected easily by manipulating multispectral data. The technology is still under investigation by universities, federal and state geological surveys, and earth science research organizations; a few private firms offer commercial services.

In the second phase of an exploration program, analysis of survey data and methodologies are selected and applied. The depth of subsurface exploration depends on the mineral commodity. Only a very few minerals such as diamonds and high-grade gold- and platinum-group metals have sufficient unit value to support deep exploration.

In a subsequent stage, local geological studies collect structural, stratigraphic, lithologic, and petrochemical data. All spatial and temporal relations between different rock types must be defined. Of great significance is the relative time of emplacement of volcanic and/or intrusive rocks in the entire local rock package. Each type of mineral deposit will require specific exploration methods. Porphyry coppers, precious metal epithermal veins, skarns, sediment-hosted deposits, and polymetallics should be studied using different combinations of methodologies.

Post-Mineralization Cover

Normal weathering and erosion, as well as tectonic processes, often make direct observation of mineral deposits difficult; however, weathered materials can be excellent indicators of mineralization. Argillization, oxidation, propylitization, and silicification are major alteration varieties that produce significant color and textural changes in outcroppings. Rock alteration therefore is very important at this stage. Detailed geochemistry and geophysics are widely applied in these cases to investigate post-mineralization cover. Remote sensing helps to detect these surface manifestations of altered rock.

Computer databases, geographic information systems (GISs), and statistical analytical methods are used to organize and study the geological data. Commercial software packages are available and useful for these purposes.

The next step typically is to sample and test the potential target directly by diamond core and reverse circulation drilling. Core samples allow the direct observation of the rock for more-detailed geological, geotechnical, and structural data. Reverse circulation provides a more general idea of lithological variation and permits faster sampling for grade determinations.

The primary problem for the exploration geologist is finding anomalous mineral accumulations in accessible locations with grades that will make their extraction, processing, and marketing profitable. Exploration concessions are registered regularly by the thousands, primarily in developing countries. Most are simple "land play" by junior companies or the hope of an old-time prospector to own a mine. Prospect submittals must be selected carefully and technically reviewed before investing any time and capital in further examining such concessions.

Modern exploration involves an initial reconnaissance visit, followed by a more-intensive exploration program if warranted. Very few ore bodies are discovered today as a result of only one geological visit. The high cost of exploration can be reduced by applying additional methods of scientific evaluation rationally. World metal prices are the primary factor controlling mineral production; however, complex global economic factors such as politics and armed conflict may cause unexpected and unpredictable price fluctuations.

The search for concealed ore deposits is ongoing and conducted in areas hitherto considered prohibitive. These include deeper subsurface ore bodies and those under the oceans. Industrialized countries will continue to be the major consumers of mineral raw materials, while developing countries will continue to be the main providers. Talented exploration geologists will be more in demand, along with the use of

technologies, some of which still need defining, refining, and even discovery.

EXPLORATION GEOCHEMISTRY

Exploration geochemistry (EGCH) is an exploration method based on systematic measurements of the amounts and distribution of chemical elements along with their migration in the earth's crust. The exploration of minerals is based on the premise that elements or traces of geochemical "pathfinders" migrate out from the original ore body by various means to form anomalous areas or dispersion aureoles that can be detected by highly sensitive methods of analysis (see Table 3.2-1 for some of these elements). Further details are discussed in Chapter 3.4.

In general, the larger the anomaly, the larger the source. Also, the intensity of the anomaly is usually proportional to the grade of mineralization; however, the interpretation of a potential ore body depends on the different mobilization capacities of pathfinder elements that occur in various environments.

EGCH has important applications in all stages of mineral exploration. In large areas such as metallogenic provinces, regional low-density stream sediment surveys are initially conducted (one sample every 100 km^2) followed by more-detailed stream sediment sampling intervals (1–3 km/sample as determined by local topography). Soil and rock geochemical sampling are planned and conducted after an approximate perimeter of the anomaly is delineated.

Geochemical data is stored using orthogonal coordinates of sample locations as well as the values of the elements analyzed. Statistical methods are then applied to assist in interpreting the results. Normal (background) and anomalous (above threshold) values within a given geochemical population must be estimated in the initial phase of an investigation. Contrast, which consists of the ratio between a sample and background values, is also commonly used. Profiles of distance versus element value are very useful. Frequency and cumulative frequency distribution plots thus are produced in combination with other basic statistical analyses. Isograd or isopach maps are drafted by contouring selected elements mostly from stream sediment surveys; circles of various sizes represent relative element ranges. Element ratios have proven highly successful in geochemical interpretation. Noneconomic accumulations of metals and human contamination often produce insignificant or spurious geochemical anomalies. The exploration geologist must be alert to these potentialities and filter them out.

Although a relatively young technique, EGCH's economic utility in the discovery of mineralization has a proven track record. EGCH is now universally accepted as the most important and effective exploration method for the discovery of precious metal deposits.

Dispersion Models

A dispersion model illustrates the abundance and distribution as well as the stability of a chemical in the local environment. Element dispersion is the foundation of EGCH. Dispersion halos are of a primary or secondary nature. Primary dispersion halos are directly related to the place of mineralization, and many sometimes occur as a reflection of the deposit's alteration halos, but they can be of a much larger extension. Secondary dispersion halos are formed by later migration of traceable guide elements. In large mineral districts, dispersion halos form "geochemical provinces" with higher than normal background values. The specific applicable methods of EGCH and the associated sampling materials depend on these dispersion halos. These are briefly discussed in the following sections; however, one should always run orientation surveys to determine which group of elements is best to analyze for, along with the types of sampling and sample spacing.

Table 3.2-1 Elements acting as pathfinders of ore deposits

	Ore Deposits												
Pathfinders	Ag	Au	Be	Co	Cu	Li	Mo	Ni	Pb	Sn	U	W	Zn
Ag		x		x	x				x				x
As	x	x		x								x	
Ba	x								x				x
Cd													x
Co	x							x					
Cu		x		x			x	x	x				x
H_2S					x			x	x				x
Mn					x								
Mo					x							x	
Ni						x	x						
Pb				x	x								x
Re							x	x					
Sb	x	x											
Se							x		x		x		x
Sn										x		x	
SO_4					x		x	x	x		x		x
Te	x	x					x						
W							x						
Z n	x	x	x		x	x		x	x				

Primary Dispersion Halos

There are three main types of primary dispersion halos:

1. *Geochemical provinces* are specific zones in which the chemical composition is suspiciously different in one or various elements from adjacent zones or from average crustal values.
2. *Aqueous fluid dispersions* are produced along paths of hydrothermal mineralizing solutions. This results in disseminations on wall rocks and seepage halos along broken ground around the deposit.
3. *Gaseous dispersions* are produced by high-temperature gaseous fluids that invade adjacent ground. These can be detected later in their gaseous forms or as elemental condensates. Mercury, some radioactive gases, and carbon dioxide or sulfur dioxideare used in the study of gaseous halos.

Secondary Dispersion Halos

The physical and chemical properties of the rock-forming minerals and the types of erosion agents control distribution of the disintegrated products of the parent rock. These processes are responsible for forming secondary dispersion halos. The patterns that result are very useful in geochemical exploration and are discussed in the following paragraphs.

Weathering is the process whereby rocks are broken down by the action of chemical, physical, and/or mechanical agents.

The following main products of weathering are important in EGCH:

- Primary residual products are more stable, only partially disintegrated, and help in defining the parent rock.
- Secondary residual products occur close to the source; hydrolysates such as clays and iron oxides may carry tracks of nearby mineralization.
- Soluble products are unstable products that travel considerable distances from their source(s) as dissolved solids (e.g., calcium and magnesium carbonates, sodium and potassium salts, manganese and iron oxides, and other basic metal salts).

Surface waters carry visible to microscopic particles of organic and inorganic compounds with traces of chemical elements incorporated along the way. Element mobility is the main factor controlling this type of dispersion. It is the basis for hydrogeochemical prospecting.

Groundwater involves the same principles as in surface waters. Shallow and deeper water wells and spring waters are used for sampling.

Stream sediments are clastic materials derived from ore deposits and are often transported large distances by fluvial water, then deposited by mechanical or chemical effects, particularly near confluences. Stream sediment geochemistry has been a very effective method in exploration. Anomalous values are followed upstream to discover the source.

Soils retain chemical and mineralogical characteristics of their parent material and often capture elements that travel through them. Most soils have a great capacity for absorption and so they become useful in EGCH. One should recognize whether soils are transported or residual in nature to correctly interpret anomalous patterns and possible sources. In soil sampling, always sample from the same soil horizon; however, a new methodology analyzes soil samples at the same depth regardless of horizon. This topic is examined further in the following section.

Vegetation may indicate soil chemistry because some plants grow only where certain nutrients occur. Others are natural absorbers and accumulators of specific elements. These travel through soils and fractured rocks and are taken up by vegetation. In some cases, plants grow long, deep roots that may reach subsurface dispersion halos and take up some of their chemical components. In other cases, deleterious elements and compounds may result in detectable atrophies or hypertrophies in plants that can lead to discovering mineralization.

Organic accumulations resulting from some organic materials that possess a high ionic exchange capacity can cause them to act as traps for certain cations. This is usually observed in swampy areas near water feeder channels.

Animal actions are less important in EGCH, and only in a few isolated cases have they been helpful. Burrowing animals such as foxes and ants, for instance, or mound builders such as termites may bring subsurface metal-bearing minerals or precious-gem indicators to the surface where they can be sampled and observed easily.

Glacier sediments may be explored similarly to stream sediments. Terminal and lateral moraines may contain mineral fragments from upstream. Also useful are fine clays, which should be collected and analyzed. If an anomaly is detected, any additional geochemical sampling would be difficult because of the glaciated terrain; therefore, indirect geophysical methods can be used to investigate further.

Meltwater actions may carry traces of certain anomalous elements trapped in the pore spaces in rocks. Freezing produces upward flows of some groundwater that could be helpful in locating concealed deposits. This method is only of limited advantage.

Geochemical Analytical Methods

Although geochemical methods are routinely updated and redefined, the exploration geologist must keep three main factors in mind:

1. Sensitivity
2. Precision
3. Cost

All samples from a particular area must be analyzed by the same technique and preferably by the same laboratory for consistency. In some cases, incorrect results have caused additional unnecessary expenses, or worse, unjustified project abandonment. Duplicate sets of samples should be prepared and delivered to the lab, with one blank and one known standard provided for each set of twenty samples. Double-checking the analyses at different laboratories is highly recommended.

EGCH is based on the detection of very small amounts of certain elements, making use of many modern methods of analysis. The most common are the following:

- Regular fire assay remains a preferred method for gold analysis.
- Spectrometric methods are mostly applied for multi-elemental analyses:
  - Atomic absorption, developed in the 1950s, is still widely used in EGCH when a single or small number of elements need to be determined. In atomic absorption the electrons of an element are promoted to higher orbitals for a short time by absorbing a quantity of energy specific to that particular element. This gives the technique its elemental selectivity. The amount of energy is measured and is directly related to the concentration of the element in the prepared sample.
  - Inductively coupled plasma–mass spectrometry (ICP-MS) is the preferred method in modern geochemistry that allows for quick and precise multi-elemental analysis. ICP-MS determines the elemental composition of samples by counting the number of ions at a certain mass of the element.
  - Inductively coupled plasma–optical emission spectrometry (ICP-OES), a complement to the mass spectrometer, is also used in detecting lighter elements of the periodic table.
- Mobile Metal Ion is the low-level chemical analysis of soils by use of special extractant solutions and later concentration determination by ICP-MS. Soil samples are taken from equal depths regardless of soil horizon. Initially applied by the Geochemistry Research Centre of Australia, this method is now widely used.
- X-ray fluorescence handheld analyzers allow for fairly accurate detection of low elemental concentrations of most types of solid geochemical samples in the field.
- The colorimetric method was one of the pioneering methods of analysis several years ago. It was replaced

Table 3.2-2 Main applications of geophysical methods of exploration

Method	Application Media	Main Exploration Applications
Gravimetric	Ground, marine	Heavy minerals deposits, iron ores, pyrite, chalcopyrite, chromite, salt domes, intrusive vs. volcanic or sedimentary rocks, structural mapping
Magnetic	Ground, marine, airborne, drill-hole logging	Iron ores, magnetite, pyrrhotite, black sands, kimberlites, chromite ores, mafic intrusives, basement irregularities, geological and structural mapping
Electrical: Resistivity	Ground, marine, drill-hole logging	Sulfide deposits, conductive vs. resistive rocks, massive sulfides, base metals, graphite, quartz and calcite veins, salt domes, coal beds, underground conductive fluids, tectonics
Electrical: Induced polarization	Ground, drill-hole logging	Nonconductive polarizable mineralization; disseminated and massive sulfides; porphyry copper and gold, and silver deposits; tin; zinc; stockworks
Electrical: Self-potential	Ground, drill-hole logging	Sulfide ores; tin, cobalt, nickel, gold and silver deposits; massive sulfides
Electromagnetic: Coil sensors	Ground, airborne, drill-hole logging	Sulfides and oxides, magnetite, graphite, base metals, kimberlites, shear zones, geological and hydrological mapping
Electromagnetic: Superconductive quantum interference device (SQUID) sensors	Ground, airborne, drill-hole logging	Deep conductive deposits, massive sulfides
Radioactive	Ground, airborne, drill-hole logging	Radioactive minerals: uranium, thorium, potassium; coal; phosphates; monazite; structural mapping; differentiation of intrusives
Seismic	Ground, marine	Coal, uranium, heavy minerals, buried placer deposits, sand and gravel deposits, fractured rocks, lithological changes
Remote sensing	Airborne, satellite	Geological and structural mapping, tectonics, alteration

by more-accurate methods; however, it is still applied in remote areas where on-site results are required quickly.

Data Interpretation

Statistical analysis is the best method to assist the exploration geologist in interpreting large amounts of geochemical data. Numerous commercial software packages exist, ranging from simple statistical calculations (e.g., the mean and standard deviation, and normal and log-normal frequency distributions) to more-advanced geostatistical analysis including Kriging, cluster analysis, discriminant analysis, factor analysis, correlation, and multiple regression analysis.

All data are entered in digital databases and later integrated into GISs and spatially related through the Global Positioning System. This allows for compiling various layers of information to facilitate interpretation. Many software programs, either canned or proprietary, are used for plotting different kind of maps, profiles, and block models.

GEOPHYSICAL METHODS OF EXPLORATION

Geophysical exploration is based on measuring the contrast between natural and induced physical properties of materials. Geophysical surveys begin with airborne reconnaissance methods to outline broad geologic features. Radiometric, magnetic, electromagnetic, and, more recently, gravimetric methods have been applied successfully in airborne surveys. The exploration geologist continues to use more-detailed geophysical methods that provide more-detailed information, including downhole measurements, searching directly for indications of concealed mineralization.

Geophysical exploration methods have gained considerable popularity in the last few years. More precise and easy-to-use instruments have been developed. Modern surveying techniques and software aid in interpreting results faster and with more reliability than previously.

Table 3.2-2 shows the main geophysical methods used in the exploration of various minerals. Survey design and the nature of the data are dependent on the characteristics of the detecting instruments. The geophysical detection of mineral deposits requires that they possess physical properties different than those of their host rocks.

Geophysical Methods

Highly sensitive gravimeters can detect anomalies caused by differences between the local measured gravitational acceleration and the regional expected value for a given point on the earth's surface. Multiple corrections (for geographical and topographical effects) to the field data, however, must be calculated before a final interpretation can be made. Gravity data is analyzed using digital techniques to obtain regional anomalies, first and second derivatives, residual anomalies, and horizontal gradients.

Magnetic Surveys

Magnetic surveys are based on the earth's magnetic field. Similar to gravimetric surveys, magnetic surveys show anomalies caused by differences between values obtained locally from survey readings and that calculated for the normal intensity of the earth's magnetic field at any given point. Aeromagnetic surveys have proven very useful in regional reconnaissance exploration. The application of remote magnetometry has also been used on research ships in oceanographic studies, and, even more remotely, from artificial satellites.

Modern magnetometers are highly sensitive, can produce results in a short amount of time, and are relatively inexpensive to operate. In addition to the detection of ferromagnetic mineral deposits (mainly magnetite and pyrrhotite), remote magnetometry helps in regional mapping of lithological, structural, and tectonic features.

Downhole magnetic logging has been widely used when magnetic minerals are present in detectable amounts in the survey area. Magnetometric methods can also help define concealed formation contacts, unconformities, major faults, and thicknesses of sedimentary cover.

Electrical Methods

Electrical methods operate by measuring natural or induced electrical fields. Although there are many varieties of electrical methods, resistivity, induced polarization, and self-potential are most commonly applied in mineral exploration. Electrical methods may be used to define structural and tectonic features, but they are more useful in the search for metallic conductors associated with ore bodies. Downhole logging is used widely and successfully to define ore bodies. In the proper geological setting, surface data should be employed in conjunction with downhole survey data.

Resistivity is controlled by porosity and fluid content of the rock and the presence of conductive minerals; therefore, different rock types will have different natural resistivities. The depth of penetration and investigation is dependent on the energy injected into the ground by the power source, and by the spacing and array of electrodes. Resistivity has been used broadly in detecting all kinds of mineral conductors and in groundwater investigations.

Induced polarization is often applied in parallel with regular resistivity surveys, making use of the same electrode array or with minor modification. It is based on the detection of electrochemical activity and/or the polarization at a mineral interface brought about by the application of an electric or magnetic field.

Induced polarization is very effective in detecting disseminated mineralization such as the sulfide zone in porphyry coppers or disseminated ore minerals in precious metal deposits.

Self-potential is used when the effect of a "natural battery" is produced, such as occurs by the flow of groundwater and, in the case of minerals exploration, by the interface of a sulfide ore body and its oxide zone. These occurrences are related to outcropping ore bodies or those that have been oxidized corresponding to phreatic zone fluctuations.

Electromagnetic Methods

Several coil arrays are used in electromagnetic methods to measure a combination of induced long-wave electrical fields and the earth's natural electromagnetic fields. An electromagnetic field is generated by a transmitter creating a secondary magnetic field, which is registered together with the primary magnetic field. Subsequent reductions and corrections are calculated so that a final interpretation is done in conjunction with geological and geochemical data.

A superconducting quantum interference device (SQUID) uses an extremely sensitive magnetometer that registers very low magnetic fields. Sometimes it is used in mineral exploration together with coil sensors to detect deeper conductors and to isolate the signal from that coming from overlying conductive cover. Many successful applications have occurred in exploring for deep massive sulfide deposits.

Radioactive Methods

Radioactive methods measure natural or artificial radioactivity. Uranium and thorium are the main sources of radioactive emissions. Regular radioactivity detectors can only reach shallow depths of no more than a few meters; however, emanometry, which detects radon emissions, can "see" deeper into the subsurface and is sometimes used together with regular radioactivity detectors.

Airborne gamma-ray surveys have wide applications exploring over large areas and are useful in geological mapping, taking advantage of minor radioactive emissions from naturally occurring rock-forming minerals.

Decaying radioactive elements produce gamma rays, which are easily detected by modern gamma-ray spectrometers. Potassium, uranium, and thorium are common radioactive trace elements that occur in many rock-forming minerals. As they decay, they provide natural sources of gamma rays that are detected in these surveys.

Seismic Surveys

With limited applications in mineral exploration, seismic methods measure changes in the velocity of shock waves produced by explosive charges or mechanical vibrators (even those from sledgehammer impacts). Reflection and refraction waves are recorded and used to define formational and structural contacts in the subsurface. Seismic surveys are relatively expensive but can be applied directly on the earth's surface or from sea vessels. They are more widely used in petroleum exploration.

Remote Sensing

Infrared sensors register changes of temperature, which have been used successfully in environmental studies and in delineating groundwater zones and exothermic zones of mineral alteration. High-resolution satellite imagery and imaging spectroscopy are gradually displacing traditional aerial photographic methods.

Imaging spectrometry uses multispectral detecting devices. The National Aeronautics and Space Administration's Airborne Visible/Infrared Imaging Spectrometer (AVIRIS) is among the most advanced in use with 224 channels. Other sensors are listed as follows:

- HyperCam infrared hyperspectral imaging camera (ground based or taken by aircraft)
- Moderate Resolution Imaging Spectroradiometer (MODIS; aboard the Terra EOS AM-1 satellite)
- Medium Resolution Imaging Spectrometer (MERIS; aboard the European Space Agency's Envisat satellite)
- Hyperspectral Digital Imagery Collection Experiment (HyDICE) spectrometer
- Hyperion sensor (aboard Earth Observing-1 satellite)

The large multichannel feature gives the sensors the capability to observe atmospheric and planetary phenomena in environmental studies and mineral exploration. Absorption of spectral energy caused by chemical bonds allows the detection of different types of vegetation and many synthetic materials, minerals, and mineral assemblages. Interpretation is not simple and requires advanced training and experience along with the use of sophisticated software.

Costs are relatively high and depend on the size and characteristics of the area to be covered. The popularity of imaging spectrometry is certain to increase in the future.

ORE DEPOSITS

The exploration geologist must have an idea of the type of ore deposit being sought prior to starting a mineral exploration program. In regional studies, the general geologic setting provides the first clues. The proximity to any mineral district or predefined metallogenic province also helps to anticipate the type of mineralization.

Ore Deposit Models and Classification

Most modern authors refer to the initial, and still popular, classification of ore deposits proposed by Lindgren in 1933, or that proposed by Schneiderhohn (and later modified by Niggli in 1929). Many other classifications have been proposed but these still prevail.

Modern studies have established geological and geophysical ore-deposit models whose parameters provide important guides for mineral exploration. Each deposit, however, should be studied or explored on its own merit.

The most widely accepted classification schemes are based on genetic characteristics. Five groups are defined: magmatic, hydrothermal, sedimentary, metamorphic, and surface accumulations. Morphological classifications, such as vein type, disseminated, massive, or strata-bound are normally subdivisions of these. Each group is subdivided into classes, families, or types, and very often there is some overlapping between two or more groups. Some ore-body classifications are based on mineralogical associations. Although there may be some economic or genetic implications, the result has limited relevance in exploration. Greater significance is placed on classifications based directly on geological setting and ore-formation processes.

In all cases, it is very useful to model the deposit under exploration after a similar well-known or previously studied deposit. The geologist should be prepared to confirm or change the model as more data become available.

When evaluating an exploration prospect (or any mining property), the explorationist must adhere to terms and definitions for resources and reserves, which are now required and regulated internationally. The most widely accepted standards are those in National Instrument NI-43-101 (2005), proposed by the Canadian Institute of Mining, which is similar to the Joint Ore Reserves Committee (JORC) Code from Australia (AusIMM 2004). Both are accepted in international mining stock exchanges. The two documents also define a "qualified person" who is required to sign-off on any technical reports.

Zoning

Mineralogical and geochemical zoning constitute valuable guides in mineral exploration. They reveal subtle clues of certain indicator chemical elements or accumulations of ore minerals. Zoning occurs in regional, district, or ore-body scales. Regional zoning is related to metallogenic provinces; district zoning is observed in areas with several mines; ore-body zoning is particular to an identified deposit type and is more relevant in mineral exploration.

Ore-body zonal arrangements are manifest in three dimensions. Their proper identification is especially helpful in lateral or vertical mine planning, in the selection of new exploration targets, and in decisions to terminate drilling and mine-development programs, or both.

Generalized zoning patterns have been recognized for most types of ore deposits; however, each case is different. Most ore-body zonation is characterized by several pulses of mineralization, which often cause patterns of overlapping zones. These must be identified, registered, and properly mapped as soon as the information becomes available. It is not uncommon to follow two or more zoning patterns in mine production. Figure 3.2-1 shows an idealized zoning pattern for a hydrothermal gold–quartz vein deposit.

Zoning is often related to paragenetic sequences and therefore is greatly influenced by changes in temperature and pressure, and by the composition and stability of the mineralizing fluids. The concepts are well known and cited abundantly in the technical literature. Among the subtle zoning guides mentioned previously are geochemical indicators. Geochemical zoning reflects the elements present in mineralizing solutions, and these depend on their relative mobility in and through the rock environment.

Wall-Rock Alteration

Wall-rock alteration is related to the action of hydrothermal fluids in epigenetic and high-temperature remobilization processes, which are observed most often in felsic rocks. It may also be caused by some metamorphic or diagenetic processes. Weathering of outcropping deposits may cause "strong rocks alteration" as well, due to the oxidation of iron-rich minerals and some argillization. All alteration processes are the result of chemical exchange and mineralogical modification.

Alteration halos are typically present in zonal arrays emanating from mineralized circulation channels outward to fresh country rock. They often extend outward several times the perimeter of the ore deposit, making them easier to detect. However, they may also be of very limited dimensions, depending on the reactivity and permeability of the rock, and the amount of circulating fluid.

The most common alteration assemblages are as follows:

- Potassic involves the introduction of K-spar and other potassium minerals.
- Sericitic, also referred to as phyllic, consists of the presence of micaceous potassic silicates derived from primary felsic minerals.
- Argillic is represented by kaolinite and montmorillonite after plagioclases and amphiboles. Advanced argillic is a variation that results from strong acid-leaching.
- Silicic involves the abnormal injection of siliceous solutions (and the almost universal presence of free quartz).
- Propylitic is produced by low temperature–pressure formation of epidote, chlorite, and calcite.
- Fe oxidation, although not properly a result of hydrothermal alteration, gives rise to the common decay or alteration of Fe-containing minerals. These are highly visible and widely used in minerals exploration. This phenomenon has developed into the study of leached and oxidation caps (or gossans), which, in their diverse assemblages, provide excellent clues to the presence of ore deposits and their sources.

All these alteration processes produce color changes in the original rocks. White to bright reddish and yellow are common, passing through shades of green and pink. They all constitute primary guides for the explorationist.

Fluid Inclusion Studies

In idealized deposition models for many ore deposits, temperature and chemical zoning becomes useful in understanding mineralization and its origin. Identifying these features can be accomplished through the study of fluid inclusions, particularly during the drilling of a prospect, or when the upper portions of an ore body have been eroded away, or when structural or tectonic movements have modified the original ore-body's position.

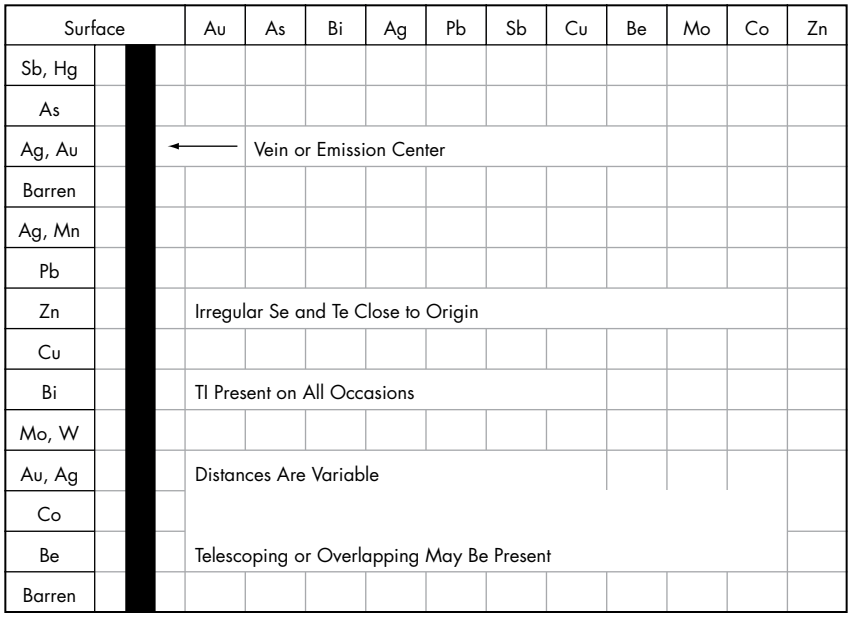

Figure 3.2-1 Idealized vertical and lateral zoning in gold–quartz veins

Fluid inclusion studies are based on the collection of transparent mineral crystals that have trapped gases and/or liquids in vacuoles at the time of deposition. The vacuoles are observed under the microscope and then subjected to temperature manipulation by special heating–cooling stages to determine the temperature of homogenization. Their chemical compositions can be defined by one of many analytical techniques, such as laser spectrometry or electron microprobe.

Isotopic Studies

Some isotopes have been used to study the sources and compositions of mineralizing fluids in many ore deposits and to determine their geochronology. Isotopes of hydrogen, carbon, oxygen, sulfur, strontium, and lead are most commonly studied. Distinctions between barren and productive intrusive and volcanic packages have been made successfully by this method.

Isotopic studies are performed mostly as academic research because of a lack of knowledge and experience of the technique in the mining industry; however, its importance in mineral exploration is becoming more relevant as more experimental data (and its interpretation) are published.

Geometallurgy

Geometallurgy is a relatively recent technique in mineral exploration. It is based on precise quantitative mineralogical and chemical measurements using electron microprobes or similar instruments, followed by statistical analyses to determine variabilities in physical, mineralogical, and geochemical characteristics of a mineral prospect. The information obtained is used in all stages of exploration, as well as in the development of an ore deposit, reserve and resource evaluation, and metallurgical processing.

Geometallurgy may be applied to stream sediment samples, mineralized outcrops, drill cores, or even in productive mine stopes. Ore-deposit models can be proposed, and strategies for further exploration may then be designed. It is also very useful in ore-body modeling, predicting possible extensions and determining the quality of mineral accumulations.

ACKNOWLEDGMENTS

The author is particularly grateful to Stan Krukowski of the Oklahoma Geological Survey for his help in reviewing this chapter. Monica and Steve Rich, and Gil Colgate also assisted.

CHAPTER 3.3

Geophysics Prospecting

J.A.J. (Barry) de Wet

INTRODUCTION

Geophysics prospecting is defined as "making and interpreting measurements of physical properties to determine subsurface conditions, usually with an economic objective, for example, discovery of fuel or mineral deposits." Measurements include seismic travel times and wave shape changes, electrical potential differences, magnetic and gravitational field strengths, and radiometrics (Sheriff 2002).

Geophysicists have developed methods for estimating physical properties from surface measurements. It is a difficult problem to solve because there is often much ambiguity in the solution. This problem is overcome to some extent by constraining the problem with factual information from surface geological mapping, measured physical properties, or drill-hole information. Therefore, it is critical to understand the ranges, or errors, in data acquisition—those introduced through processing and those introduced through the assumptions made while interpreting the data. The "answer" is never exact; nevertheless, some geophysical tools have major technical and financial impacts on mine planning, often with significant influence on the costs of development.

OUTLINE OF METHODS AND TECHNIQUES

Applied geophysical methods are classified according to the transmitting energy source (Table 3.3-1). Detection of the resulting signals is achieved by contact with the ground or remote-sensing platforms. In near-mine or on-mine exploration, this is usually done through physical contact with the ground. Greenfield exploration projects mostly tend to use airborne methods.

Natural sources include the following:

- Potential fields such as magnetic and gravity fields
- Electromagnetic energy due to sun flares and sunspots
- Radiometric methods based on the radioactive emissions from thorium, potassium, and uranium
- Seismic energy from earthquakes and tremors, as well as rockfalls (passive seismic)

Active (human-made) sources include the following:

- Grounded current electrodes and inductive loops powered by batteries and/or generators
- Seismic energy from surface excitation (hammers, vehicles, dynamite, vibrators, core drilling, etc.)

The application of a geophysical technique in the mining environment is usually constrained by the mining infrastructure. Geophysics is usually most effective in mining at the prefeasibility stage. For instance, conducting a three-dimensional (3-D) seismic survey at the prefeasibility stage establishes a base case for future mine planning. To undertake such a survey after the mine has been developed is disruptive to mining and production schedules, and it increases the cost while producing inferior signal quality due to infrastructure "noise."

NATURAL SOURCES

The earth's magnetic, gravitational, and natural electromagnetic fields are included in the potential-fields category. Magnetic and gravitational fields are important contributors to geophysical prospecting. Accuracy is a function of position (vertical and horizontal) and the sensitivity of the instrument. The application of potential fields in prospecting is summarized in Table 3.3-2 by exploration objective.

Table 3.3-2 can assist the engineer in selecting the most appropriate geophysical tools for an exploration objective. The "output and products required" column is intended as a guideline for discussion with the contracting geophysicist when writing the scope of the work. (All costs in this chapter are in U.S. dollars.)

POTENTIAL FIELDS—MAGNETICS

Magnetic surveys should be designed for the target objective (see Table 3.3-2). For example, for targets >100 m deep, airborne systems are the most cost-effective way to collect the data. Shallow target objectives require high spatial resolution surveys (<100 m target objective) on the ground with relatively high sample density per unit area.

Two sets of internationally accepted units can be used to denote the magnetic field (H). The International System of Units is the tesla (T), and the centimeter-gram-second (CGS) unit is the oersted (Oe). One nanotesla (nT) equals 10^{-5} Oe. The earth's magnetic field is about 0.1 Oe.

J.A.J. (Barry) de Wet, Director and Consulting Geophysicist, BDW Geophysics Consulting, Brisbane, Queensland, Australia

Table 3.3-1 Geophysical methods by energy source

Source	Method	Detection	Configuration	Applications		
Natural Sources						
Earth tremors and rockfalls	Seismic	Seismic earthquake detection	Mantle seismic tomography	Earthquake locations and predictions	Diamond and nickel exploration	Crustal studies
	Piezoelectric	Seismoelectric	—	—	—	—
	Passive seismic	Micro-seismic tomography	Surface and underground arrays	Rock mechanics	Rockfall predictions	—
Atmosphere (lightning), 1 to 10 kHz	Audio frequency magnetotelluric (AFMAG) ground and helicopter	Electromagnetic spectrum	Induction coils	Minerals exploration	—	—
Hydromagnetic (magnetosphere), <1 kHz	Plane-wave electromagnetic	Electromagnetic and electrical field	Induction coils and grounded potential electrodes	Deep crustal studies	Diamond and nickel exploration	—
Potential fields	Magnetic	Total field magnetic field, vector, and gradient tensor measurements	Ground, airborne, satellite, and downhole logging	Downhole three-component magnetics	Downhole susceptibility	—
	Gravity	Vertical field and gravity gradiometry	Ground, airborne, and downhole gravity logging	Engineering, foundations, sinkholes, and excess mass	Exploration, groundwater, and sulfide minerals	—
Nuclear radiation	Radiometric	Counts per second from radiation in sodium iodide crystals	Ground, airborne, and downhole logging	Detection of nuclear waste products in mining	Minerals exploration	—
Active Sources						
Electromagnetic induction	Horizontal, vertical, and in-loop	Time domain B and dB/dT; multifrequency amplitude and phase measurements	Ground, fixed wing, and helicopter	Groundwater and agriculture salinity mapping	Exploration for conductive sulfides	—
Electromagnetic grounded wire	Controlled-source audio magneto-tellurics (CSAMT)	Multifrequency magnetic and electrical field	Far-field grounded wire	Minerals exploration for resistive and/or conductive ore	—	—
Direct current grounded wire	Resistivity sounding; induced polarization	Current and electrical potential	Expanding or profiling arrays	Groundwater and agriculture salinity mapping	Sulfide mineral exploration	Conductivity mapping for geological structure
Radio waves	Radio imaging method (RIM), ~520 MHz and ground-penetrating radar, ~16 to 1,600 MHz	Various antenna arrays	Ground surveys and in-mine surveys	Shallow structure (0–30 m); civil engineering problems	Exploration for laterite ores	—
Seismic	Dynamite, vibrator trucks, hammer, and weight drops	P and S waves, either three-component or single vertical component geophones	2- or 3-D surveys; reflection, refraction, and vertical seismic profiles	Oil exploration and production	Coal exploration and mine planning	Witwatersrand gold and Bushveld platinum exploration

The earth's magnetic field originates within the earth and acts like a giant bar magnet located near the center of the earth's core. Buffeting of the earth's magnetosphere by solar wind is the primary cause for the diurnal field. Field reversals (i.e., the North Pole and the South Pole swap positions) have been common throughout geologic history. A magnetic pole is located where the inclination of the magnetic field is vertical. At the North Pole the field enters the earth and at the South Pole the field leaves the earth (by convention). At the magnetic equator the inclination of the field is horizontal.

Susceptibility, k, is the ratio of the magnetic moment per unit volume, M, to the magnetic field strength, H, or $k = M/H$ (the quantity has no units). Values are positive for paramagnetic materials and negative for diamagnetic materials. This is the fundamental property exploited by the magnetic method. This can be rewritten as $M = k \times H$. Normally the earth's magnetic field magnetizes earth materials proportional to the magnetic susceptibility of the material.

Types of Magnetism

All matter reacts to a magnetic field, but only two classes of matter actually exhibit strong interactions: ferromagnetic and ferrimagnetic (Clark et al. 2003).

1. Ferromagnetic refers to materials that one normally thinks of as magnetic, such as Fe, Ni, Co (such as primary ore for iron), nickel sulfides, and volcanogenic sulfides. They exhibit parallel alignment of moments resulting in large net magnetization even in the absence of a magnetic field.

Table 3.3-2 Interpretation of potential fields by objective

Objective	Methods	Output and Products Required	Cost (U.S. dollars)	Improvement If Multiproperty Survey (e.g., magnetics + gravity)
Dykes, intrusives, extrusives (basalt), and faults	Magnetic survey, with gravity optional	• Total field, reduction to the pole, analytical signal, and first and second derivative contour/gridded maps. • Profile modeling across dykes and faults to determine depth, width, and strike	• Airborne: $20/km • Ground: $120/km	• Adding gravity helps to detect nonmagnetic dykes and improves fault detection when faults are not filled with magnetic material.
Sedimentary basin/ thickness mapping	Magnetic survey, with gravity and/or electromagnetic (EM) optional	**Magnetics:** • Total field grid and contour • Depth to magnetic basement grid and contour • Vector magnetic amplitude 3-D inversion, depth to magnetic basement (no remanence)	• Airborne: $20/km • Ground: $120/km	• Remanent magnetic effects affect positional accuracy and body geometry. Depths are usually acceptable as long as the basement is more magnetic than sediments.
		Gravity: • Joint inversion using vector magnetic and gravity 3-D inversion • Euler deconvolution produces depth to basement on both physical properties • Profile interpretations to check depths, width, and strike of basement features	• Airborne gravity and magnetic on single platform: $160/km	• Two physical properties better resolve basement depths. Both suffer from lack of horizontal layer resolution.
		Electromagnetics: • Magnetics products as above. EM products include conductivity depth profiles, conductivity and conductance bullet. • Layer thickness maps • Structural maps (lineaments) • Depth to resistive or conductive layers	• Helicopter magnetic and EM on one platform: $120/km	• Mapping capability improves substantially by resolving layers with high conductivity contrast to depths of <100 m. • Reflection seismic is best for resolving layers but expensive (see later).
Bauxite thickness profile	Ground-penetrating radar (GPR) and ground magnetics	• Profile images of conductivity that look like seismic sections • Depth to unweathered rock • Often saprolite thickness contours if lines are dense enough • Analytical signal of magnetics to map intrusives and dykes	• Ground magnetics as above • GPR: $3,000/d	• Adding seismic refraction helps to verify depth to unweathered rock. • Cost benefit is questionable.
Nickel laterite	GPR and ground magnetics	• Profile images of conductivity that look like seismic sections • Depth to unweathered rock • Often saprolite thickness contours if lines are dense enough • Analytical signal of magnetics to map intrusives and dykes	• Ground magnetics as above • GPR: $3,000/d	• Adding seismic refraction helps to verify depth to unweathered rock. • Cost benefit is questionable.
Nickel sulfide	Combination of magnetic and EM methods is most effective. Gravity must be used when ultramafic is altered by carbonate fluids (no magnetite development).	• Detailed magnetic surveys required • Maps of total field, analytical signal, and first and second derivative maps • Reduction to the pole useful • Profile interpretations to estimate depth to sulfides; but if uncorrected for remanent magnetization, large errors are possible • EM using in-loop and large-loop methods • B-field sensors preferable	• Airborne magnetics: $20/km • Ground magnetics: $150/km • Ground EM: $2,000/d	• Downhole EM is mandatory for all holes drilled. • It is essential for detecting off-hole anomalies.
Iron oxide copper-gold (IOCG)	Magnetic and gravity and/ or induced polarization optional	• IOCG source in hematite alteration produce high-density anomalies without magnetic anomalies. • Magnetic anomalies are often associated with sulfides (e.g., Cannington deposit, Australia). • Joint 3-D inversions are essential for spatial distribution of anomalies.	• Airborne gravity and magnetic on single platform: $800/km^2	• Induced polarization helps to map sulfides but is often misleading.
Broken Hill type silver, lead, and zinc	Magnetic and gravity and/ or induced polarization optional	• BHT source in hematite alteration produce high-density anomalies and magnetic anomalies. • Magnetic anomalies are sometimes associated with sulfides (e.g., Cannington deposit, Australia). • Joint 3-D inversions are essential for spatial distribution of anomalies.	• Airborne gravity and magnetic on single platform: $160/km	• Induced polarization helps to map sulfides but is often misleading.

(continues)

Table 3.3-2 Interpretation of potential fields by objective (continued)

Objective	Methods	Output and Products Required	Cost (U.S. dollars)	Improvement If Multiproperty Survey (e.g., magnetics + gravity)
Iron ore	Magnetic and gravity surveys	• Hematite alterations produce high-density anomalies and magnetic anomalies. • Magnetic anomalies are associated with banded ironstone. • Joint 3-D inversions are essential for spatial distribution of hematite iron bodies.	• Airborne gravity and magnetic on single platform: $160/km	—
Porphyry copper	Magnetic surveys followed by regional induced polarization (IP). IP anomalies are followed up with IP profiles to discriminate between shallow clay anomalies and sulfide alteration in porphyry copper alteration.	• Porphyry copper deposits have characteristic magnetic halos and are often associated with major lineaments. • Maps of analytical signal, total field, and derivatives are required to map structure.	• Airborne: $120/km	• IP costs are $3,000/d.
Kimberlite	Combination of magnetic and EM methods are most effective. Gravity must be used when Group 2 kimberlites are dominant in an area.	• Maps need to show coincident magnetic high and conductive anomalies. • Gravity lows are characteristic of weathered kimberlite.	• Helicopter magnetic and EM on one platform: $120/km	• The addition of gravity, either on an airborne platform or on the ground, confirms kimberlite geometry and reduces risk of failure substantially.

2. Ferrimagnetic materials exhibit a more complex alignment of atomic moments, but they exhibit the same general magnetic character as ferromagnetic material (magnetite, maghemite, pyrrhotite mostly in ore bodies derived from alteration processes such as iron oxide copper-gold [IOCG] deposits and Ni laterites).

The most common magnetic material within the earth's crust is magnetite (Fe_3O_4), which is mostly found in iron ores, banded iron formations, metamorphic and igneous rocks, and in small concentrations in some sedimentary rocks. Magnetite is often associated with metallic sulfide ores such as pyrrhotite ($Fe_{1-x}S$). Ilmenite ($FeTiO_3$) is the next most common magnetic mineral (but to a much lesser extent than magnetite).

The following list describes the types of magnetization:

- **Remanent magnetization:** Remanent magnetization is the magnetization remaining in the absence of an induced magnetic field, such as in a common iron bar magnet. It is important because interpretations of magnetic data are highly complicated by remanent magnetization, and this can result in serious and costly errors if disregarded.
- **Normal remanent magnetization (NRM):** NRM is the residual magnetization retained by rock and other material in situ; unless otherwise qualified, this is the implied meaning.
- **Thermo-remanent magnetization (TRM):** TRM remains after a sample has been cooled to a temperature below the Curie point in a magnetic field.
- **Chemical remanent magnetization (CRM):** CRM is acquired when a magnetic substance is chemically formed or crystallized in a magnetic field at a temperature below the Curie point.
- **Depositional or detritus remanent magnetization (DRM):** DRM is acquired in sediments when magnetic mineral particles are preferentially aligned by the ambient magnetic field during deposition, usually by settling through water.
- **Isothermal remanent magnetization (IRM):** IRM is remanent magnetization in the ordinary sense; that is, it is the magnetization after application and subsequent removal of a magnetic field. IRM is not involved in palaeomagnetism, except for the effect of lightning currents in exposed surface rocks.
- **Pressure or piezo-remanent magnetization (PRM):** PRM is remanent magnetization acquired under the application of stress; the effects generally become more pronounced as the strain proceeds from elastic to plastic deformation.

The magnetic properties in rocks are affected by many geological and physical processes that all contribute to the complexity of the final magnetic vector direction, and this is the reason why the magnetic surveys are so useful. Magnetic surveys are useful for mapping geological structure, lineaments, and intrusive volcanic rocks. From the earlier explanation of remanence in rocks, the practice of assuming a uniform induced magnetic direction (inclination and declination of the induced field) is simplistic and an unreliable approach. Recent developments in 3-D inversion will produce block models of the vector magnetic components that are useful in discriminating different lithologies. Recent work shows that it may discriminate alteration zones in mineralized sequences.

Magnetometers

A magnetometer is an instrument that measures magnetic field strength. The most common magnetometer used today is the proton precession magnetometer, also known as a proton magnetometer. It measures the resonance frequency of protons (hydrogen nuclei) in the magnetic field due to nuclear magnetic resonance. Because the precession frequency depends only on atomic constants and the strength of the ambient magnetic field, the accuracy of this type of magnetometer is very good.

A direct current flowing in an inductor creates a strong magnetic field around a hydrogen-rich fluid, causing some of the protons to align themselves with that field. The current is then interrupted, and as protons realign themselves with ambient magnetic field, they precess at a frequency that is directly

Table 3.3-3 Survey types and intended uses

Survey Type	Intended Use	Flight Line Spacing
Total field magnetics	For regional surveys	Line spacing about 2× flight height
Total field magnetics	For structural interpretation using gradients	Flight height equal or less than line spacing
Gradient and full tensor	For detailed structure and unexploded ordinance	Flight height about half the line spacing

proportional to the magnetic field. This produces a weak alternating magnetic field that is picked up by an inductor, amplified electronically, and fed to a digital frequency counter whose output is typically scaled and displayed directly as field strength or output as digital data.

The relationship between the frequency of the induced current and the strength of the magnetic field is called the proton gyromagnetic ratio and is equal to 0.042576 Hz/nT (hertz per nanotesla).

Cesium vapor magnetometers are commonly used in airborne systems. Optically pumped cesium vapor magnetometers are highly sensitive (0.004 nT/√Hz) and are well suited to higher-resolution surveys.

Superconducting quantum interference devices (SQUIDs) measure extremely small magnetic fields; they are very sensitive vector magnetometers, with noise levels as low as 3 $fT \cdot Hz^{-0.5}$ in commercial instruments and 0.4 $fT \cdot Hz^{-0.5}$ in experimental devices (fT stands for femtotesla, 1 $fT = 10^{-15}$ tesla).

Magnetic Surveys and Survey Design

Magnetic data are obtained using a magnetometer transported over land, water, or in the air—referred to as ground, marine, and airborne surveys, respectively. Normally, a stationary reference magnetometer (base magnetometer) measures the diurnal magnetic field during data acquisition. A Global Positioning System (GPS) is used on most airborne and marine surveys and is standard practice in ground surveys. Data are normally obtained along parallel lines perpendicular to geological strike. Tie-line data are collected at right angles to survey lines but at a much wider spacing (usually 10×). Tie lines help correct for magnetic instrument drift and diurnal variation in the earth's magnetic field. Data collected along a line is referred to as a magnetic profile.

The resolution of a survey is dependent on the sensor height, and line and station spacing. Table 3.3-3 can help prevent oversampling of the field (and therefore unnecessary acquisition costs), depending on the depth of the target.

Table 3.3-3 summarizes the maximum line spacing used in various types of surveys to avoid misleading results. If the target is 100 m below the magnetic sensor (h), it makes little sense to collect data at a line spacing (Δx) of less than 200 m to produce a useful contour map. However, if one needs to resolve lineaments and dykes, then one should fly 100-m flight line spacings so that gradient maps can be calculated. The maximum height of the sensor should be 50 m if single anomalies need to be modeled at a 100-m line spacing.

Line bearings should parallel magnetic north-south when the geological strike varies considerably; otherwise one should choose lines at right angles to geological strike. Common practice is to fly tie lines at right angles with intervals approximately 10× the flight line spacing. With a modern GPS or flight-line photographic tracking is no longer required for positioning and drift leveling of the magnetic map compilation. Survey costs for airborne surveys vary from $10 to $120/km, depending on the access and remoteness; the wide variance is due to a number of factors, which will be discussed later.

Guidelines for Scope of Work for Magnetic Surveys

General specifications for a scope of work should include the following.

- **Project scope:** The area outline and number of line kilometers to be surveyed needs to be clear.
- **Time:** The time period of the contract needs to be specified.
- **Authorities:** In some countries, there is a no-flyover policy over areas licensed to another explorer's properties. Permission is required to traverse across such tenements. One may be required to access private property to map geological structures effectively, so permission must be sought.
- **Deliveries:** It is important to ensure that the contractor has performance criteria for the project, including health and safety, environment, and cultural standards, and criteria for work schedules and the delivery of data and reports.
- **Legalities:** Property access and aboriginal rights are the primary legal concerns.
- **Payment:** The basis of payment needs to be specified.
- **Excluded costs:** The contractor should indicate if accommodation, transport, and fuel access are excluded and should indicate whether goods and services taxes are included or excluded.
- **Missing or substandard data:** Noise specifications should be realistic. The issue of "drop-outs" (i.e., when the magnetometer is not properly orientated and data are lost) needs to be addressed, and an agreement on possible reflights is required.
- **Contract price:** A price quote needs to be submitted.

Survey equipment specifications should include the following:

- Instrument or survey type
- Minimum data accuracy and frequency of measurement; data acquisition system
- Minimum navigational accuracy and navigation systems
- Ground monitoring requirements
- Digital recording medium for delivery

Survey flying specifications need to include the following:

- Traverse line spacing and, when necessary, control line spacing
- Base station for diurnal variations in the magnetic field recorded in close proximity to the survey area and the variation envelope defined, and magnetic storms from sun flares monitored
- Flight altitude tolerances (rugged terrain becomes a major consideration for airborne surveys because the data sensitivity is compromised)
- Instrument calibration requirements
- Navigation and flight path tolerances
- Base-map source and coordinate systems to be selected

Data compilation and interpretation include the following:

- Flight path recovery (method and accuracy)

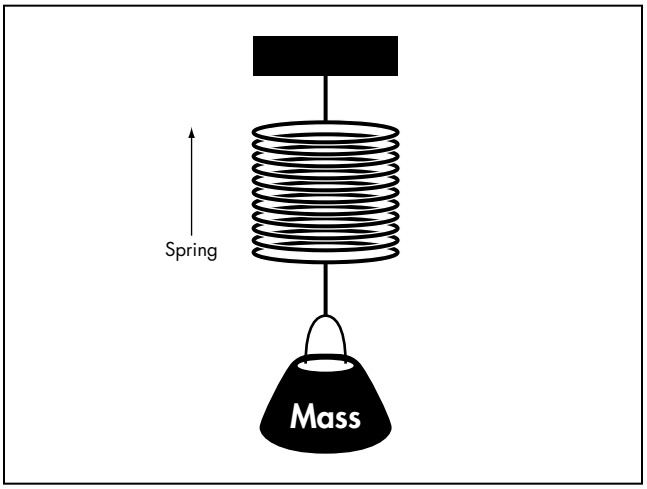

Figure 3.3-1 Simple gravity meter

- Data corrections required (leveling procedure for magnetic data)
- Final compilation products required, including map and chart scales, titles, and legends
- Interpretation (if required) and presentation products and procedures

Survey costs depend on the following:

- Survey type
- Number of parameters measured
- Number of required products delivered
- Type of platform required (ground, helicopter, or fixed wing)
- Acceptable measurement and navigation tolerances
- Time constraints of the survey
- Location of the survey
- Current fuel costs and/or fuel adjustments
- Mobilization time required for contractor to arrive at the survey area (usually quoted at cost)
- Other required products (e.g., interpretation products)
- Survey size

POTENTIAL FIELDS—GRAVITY

Gravity instruments measure the acceleration due to gravity (g). The average value of g at the earth's surface is 9.80 ms^{-2}. Gravitational attraction depends on the density of the underlying rocks, so the value of g varies across the surface of the earth.

A simple gravity meter (Figure 3.3-1) can be thought of as a mass on a spring. The spring exerts an upward and opposite force to exactly oppose the downward component, g_D, of gravity acceleration. The extension of the spring is proportional to the force exerted. The meter requires a stable and level platform for operation.

Airborne gravity and gradiometer systems have been developed for petroleum and minerals exploration. The airborne gravity systems are commonly used for petroleum exploration basin analysis, whereas the gravity gradiometer systems are used in minerals exploration where the detectability requirements are for small, compact ore bodies (Figure 3.3-2).

Costs range from $150/km for gravity gradiometer surveys (~0.1 mGal at 200 m half-wavelength) and range from $75/km to more than $1,000/km for petroleum gravity surveys accuracy (2.0 mGal at 3 km half-wavelength). (Note: Gal is the CGS unit of acceleration. One Gal is an acceleration of 1 cm/s^2. In minerals exploration, the gravity anomalies over structures are very small, so they are measured in thousandths of a Gal, or mGal.)

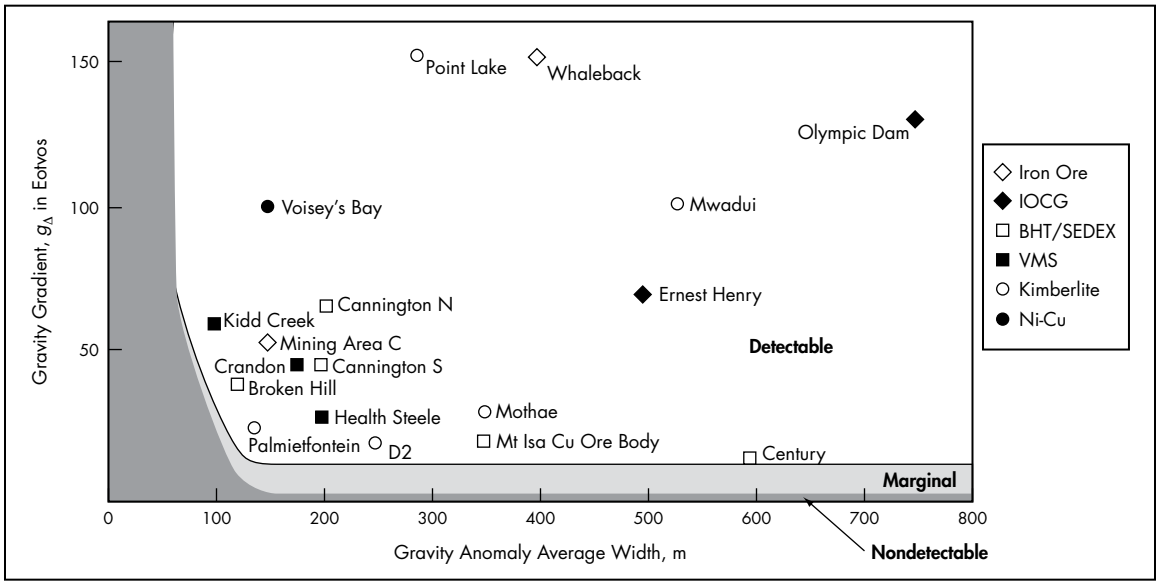
The detection of ore bodies is highly variable, but in general, iron-rich ore bodies are most readily detected, as seen in Figure 3.3-2. The size of the anomaly is proportional to the total mass or density × volume.

Variations of g due to density differences in rocks near the surface of the earth are very small compared to the g due to earth's overall mass. Many corrections to the data are needed so that density variations can be observed and recorded. There are two types of gravity measurements: absolute gravity and relative gravity.

1. **Absolute gravity:** To determine absolute gravity, an object is dropped inside a vacuum chamber and gravity is measured at reference points.
2. **Relative gravity:** Relative gravity is a change in gravity from one place to another.

In exploration it is necessary to measure small changes in gravity accurately. Gravity surveying is carried out with a portable gravimeter that determines the variation of gravity relative to one or more reference locations. Several corrections are required to transform gravity accelerations into useful exploration information, as follows (Rose and de Wet 2005):

$$g_{obs} = g_{1,967} + g_{free\text{-}air} + g_{Bouguer} + g_{terrain} + g_{tidal} + g_{isostatic} + g_{geo}$$



where

g_{obs} = observed gravity (980.000 mGal)
$g_{1,967}$ = reference ellipsoid gravity, rotation, earth bulge (970.000 mGal)
$g_{free\text{-}air}$ = gravity effect of elevation above sea level (0 to 1,000 mGal)
$g_{Bouguer}$ = approximate gravity effect of mass between observation and sea level (0 to 500 mGal)
$g_{terrain}$ = gravity effect of terrain variations (0 to 50 mGal)
g_{tidal} = gravity effect of earth-tides (0 to 0.3 mGal)
$g_{isostatic}$ = only required when doing large-scale regional surveys, calculated as for terrain effects to compensate for root zones in the crust
g_{geo} = gravity effect of geology (residual) (0.1 to 100 mGal)

Gravity Instruments

Ground gravity meters have accuracies between 5 and 15 mGal. The primary application of ground gravity is in engineering geophysics. In minerals prospecting, gravity often is used to verify airborne gravity survey anomalies prior to drilling. The cost of ground gravity surveys range from $20 to $50 per point, depending on terrain and size of surveys.

Gravity survey design is similar to magnetic survey design for both airborne and ground surveys. Gravity meters are usually calibrated at a national gravity-grid base-station point. Information on the locality of national gravity grid points is available at all government geological departments;

Courtesy of Fugro Airborne Surveys, Perth, Australia.

Figure 3.3-2 Gravity gradiometer response of some ore bodies

for example, for Australia one can obtain information from Geosciences Australia (Wellman et al. 1985).

Gravity measurements are the vertical component of the gravity field. The potential field due to the density of rocks does not have the vector complications that the magnetic field has, such as the remanent magnetic field superimposed on the earth's magnetic field. Interpretation of the gravity potential field is similar to magnetic interpretation, and 3-D inversions are common practice in interpretation.

ELECTROMAGNETIC FIELDS FROM NATURAL/ PASSIVE SOURCES

Natural electromagnetic (EM) sources come from a variety of processes—from within the earth's core and from distant galaxies. Frequencies for minerals and mining exploration are in the range 0.001 to 10,000 Hz. The only two sources that qualify are from the atmosphere and the magnetosphere. Electric storms in the lower atmosphere generate EM frequencies ranging from 1 Hz to 10 kHz. Frequencies lower than 1 Hz originate mainly from hydromagnetic waves in the magnetosphere. The concept of "skin depth" (δ) estimates the depth of exploration as given by Zonge and Hughes (1991) as approximately $\delta \cong 503\sqrt{(\rho/f)}$ meters, where ρ is resistivity of a half-space uniform earth and f is the frequency in hertz. Figure 3.3-3 illustrates the skin depth graphically, showing the increase in depth with increased resistivity.

Passive EM methods include magnetotellurics and natural source audio-frequency magnetotellurics (NSAMT). As seen in Figure 3.3-3, a broadband frequency system can explore from near surface to great depths using natural EM energy making the use of artificial sources superfluous when using the appropriate measuring equipment and software. The EM fields generated by lightning activity are seasonal, and one needs to make sure the surveys are conducted during the times of maximum EM activity (Goodman 1995).

The trend in brownfields exploration is toward deeper depths of exploration, which makes high-powered artificial current sources unacceptable in busy mine-site environments.

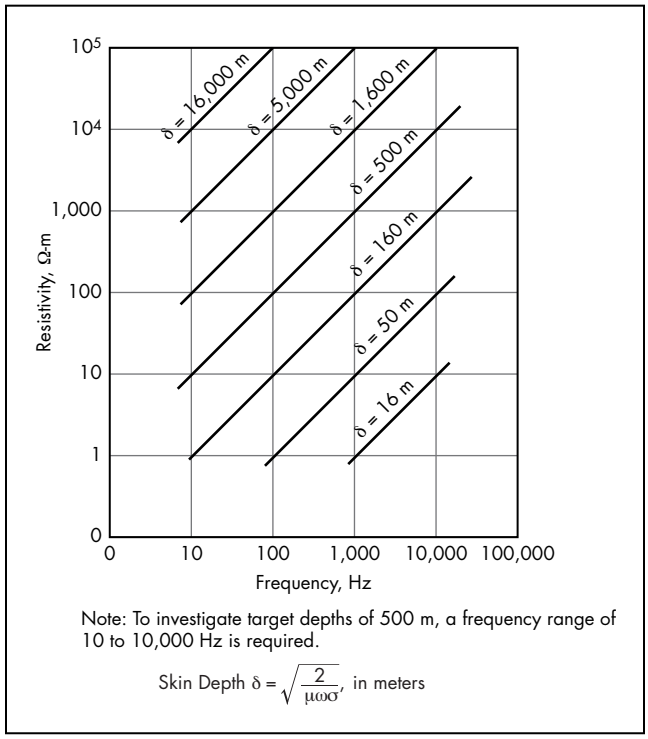


Figure 3.3-3 Example of skin depth

NSAMT is a viable alternative that minimizes the risk of electrical accidents.

Active Sources in Electromagnetic Methods—Principle of Induction

Faraday's law states that "if the magnetic flux perpendicular to the plane of the loop changes with time, then an electromotive force (emf) of the same magnitude as the rate of change of flux ($\delta B/t$) will be induced in the loop." The induced emf causes

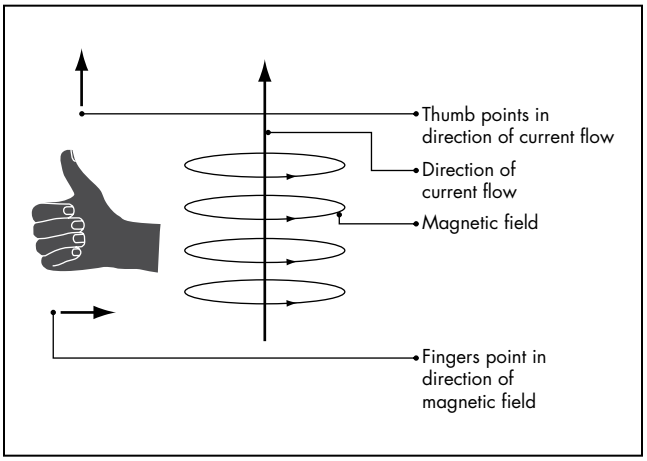

Figure 3.3-4 Right-hand rule in electromagnetic induction

current to flow in the loop so that the magnetic field of the current opposes the change of flux (Lenz's law)—so if the applied B-field is increasing, then current will flow in the loop in a direction so as to reduce the rate of increase (Figure 3.3-4).

Active-Source Methods

Active-source methods employ an artificially generated inducing field. Configurations used in minerals exploration using inductive loop sources include the following:

- Fixed-transmitter methods
- Moving-transmitter methods
- Downhole electromagnetics (DHEM)
- Airborne electromagnetics (AEM)
- Controlled-source audio-frequency magnetotellurics (CSAMT)
- Very low frequency (VLF) methods

Quantities and Units

The EM field may be described by the following vector functions:

B = magnetic induction, Wb/m^2 (tesla)
E = electric field intensity, V/m
H = magnetic field intensity, A/m
D = dielectric displacement, C/m^2

When measuring EM fields, the following units are used:

σ = conductivity, S/m (Seimens per meter)
ρ = resistivity, Ω-m (ohm-meters)
μ = magnetic permeability, H/m
μ_0 = magnetic permeability of vacuum, $4\pi 10^{-7}$ H/m
f = frequency, Hz
t = time, s

Usually one assumes that $B = \mu_0 H$ (linear, isotropic media).

Because the current in the transmitter varies with time, the primary magnetic field also varies with time and will induce secondary currents in nearby conductors according to Faraday's law. The secondary currents have their own secondary magnetic field, which can be detected at a receiver (Rx) coil.

EM fields can be generated by diverse human-made sources. Electrical currents are generated by specialized lightweight generators (traditionally sourced from aviation generators) and batteries.

Time domain electromanetic (TDEM) systems (Figure 3.3-5) are popular because the data are recorded during the off time, which eliminates the need for the high precision geometry required by the frequency domain system. Frequency domain systems are very sensitive to geometry of the receiver and transmitter orientation. However, TDEM systems are sensitive to telluric noise, which seriously affects the late time information. Frequency domain noise can readily be filtered using Fourier analysis.

Galvanic resistivity and induced polarization (IP) can be thought of as special cases of EM. The lower the frequency of the signal, the greater will be the depth of EM penetration within a conductive earth.

Airborne Electromagnetic Methods

The use of AEM methods has become mandatory in many exploration strategies because of their ability to map conductivity contrasts to relatively large depths. The broadband nature allows for depth sounding that, when stitched together, can be converted to conductivity depth images (CDIs). These data, integrated with magnetic and gravity inversion images, effectively reduce ambiguity in the interpretation.

AEM methods produce good-quality CDIs because of the excellent electronic technologies available. One can expect improvements in both functionality and miniaturization in the future. AEM technologies are fast approaching the resolution achieved by ground EM methods, so that the cost benefit of ground EM surveys is rapidly diminishing. AEM surveys are orders of magnitude more cost-effective than groundwork, except when small areas and/or mine infrastructure surveys are required. Mine infrastructure is always an issue when working with EM methods because of the electrical interference (i.e., noise) generated by mining activity; the high electrical currents deployed are seen as a safety risk.

Figure 3.3-6 shows a typical helicopter TDEM system in flight. The transmitter loop is at an altitude of about 30 m, the receiver is at the center of the loop, and a magnetometer is halfway between the helicopter and the transmitter loop.

Many publications describe the theory of EM prospecting; Figure 3.3-7 reviews and recommends EM methods by commodity, and although not exhaustive, it is a convenient and quick guide to most common exploration situations.

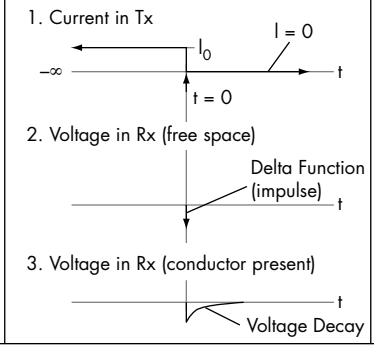
Galvanic Methods

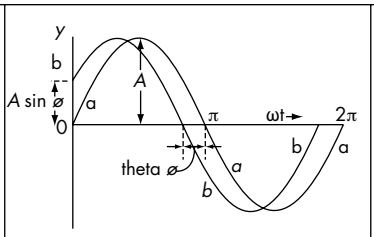
Galvanic EM methods involve grounded electrode current sources, which cycle below a frequency of 1 Hz. The convention is to refer to conductivity in relation to EM methods and to resistivity in galvanic resistivity/induced polarization methods. The units of resistivity are ohm-meters, and the units of conductivity (the inverse of the resistivity) are Siemens per meter.

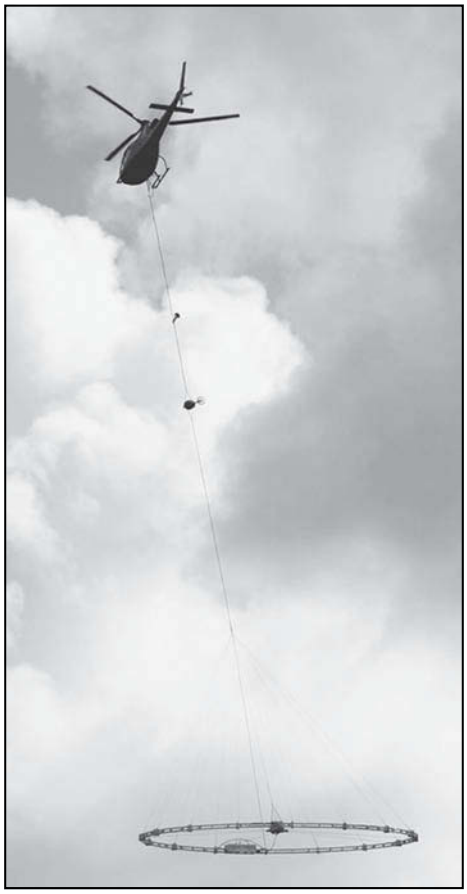
Electrical conduction in rocks occurs in the following ways:

- Electronic (motion of electrons)
- Electrolytic (movement of ions)
- Dielectric (displacement of electrons and positively charged atomic nuclei)

Most rocks are electronic conductors (semiconductors). The conductivity of rock matrices is generally poor because there are usually only a few unbound electrons. The bulk conductivity of rocks in the upper few kilometers of the crust is due mainly to electrolytic conduction (i.e., through the movement of ions contained in pore fluids).







Time Domain Method				
Concept	A pulse of current energizes the earth and then is turned off. The decay of the electric and magnetic field tells us about the conductivity of the earth.		When transmitter (Tx) is on, a static magnetic field exists in the earth. When Tx current is stopped, currents start to flow in the earth that resist the collapse of the magnetic field. These currents can be approximated by a filament of current that grows in diameter with time and increases in depth in the earth. The magnetic field generated by these currents is called the primary field.	Because the current in the transmitter is time-varying, the primary magnetic field is also time-varying and will induce secondary currents in nearby conductors according to Faraday's law. The secondary currents have their own associated secondary magnetic field, which can be detected at a receiver (Rx) coil.
Frequency Domain Method				
Concept	A continuously varying current energizes earth and is altered in phase and amplitude as it passes through rocks of different conductivity. This variation in phase and amplitude tells us about the conductivity of the earth.		The cosine of the phase angle is called the in-phase component and the sine of the phase angle is called the out-of-phase component (or imaginary or quadrature component).	In frequency electromagnetic methods, the Tx current is typically sinusoidal with a given frequency. The Tx current is always on, and measurements are therefore always made in the presence of the B-field due to the current in the Tx wire (primary field).

Figure 3.3-5 Active electromagnetic sources

Courtesy of Fugro Airborne Surveys, Perth, Australia.

Figure 3.3-6 Typical helicopter time domain EM system. Note the magnetometer halfway down the tow cable. The receiver is at the center of the transmitter loop.

Major factors affecting electrolytic conductivity of rocks include the following:

- **Porosity:** Conductivity increases as porosity increases. This includes macro- and microscale porosity (e.g., fracturing, jointing, intergranular porosity, and vugs/vesicles).
- **Water saturation:** Conductivity increases with increased saturation.
- **Water salinity:** Conductivity increases with increased salinity.
- **Connectivity of pore spaces (permeability/pore tortuosity):** Conductivity is higher in permeable rocks.
- **Clay content:** Conductivity increases with increasing amounts of clay.

Other factors affecting electrolytic conductivity of rocks include the following:

- Fresh crystalline rocks typically have low conductivity because of their low porosity; however, they can be relatively conductive if extensively fractured/jointed.
- Unconsolidated materials (weathered layers) are generally conductive due to high porosity and clay content (and the presence of saline groundwater).
- Alteration of rocks into clay increases the conductivity of unmineralized rocks.
- Geological processes that decrease porosity (e.g., silicification) will decrease conductivity. Processes that increase porosity (e.g., fracturing, weathering) also increase conductivity.

Electrode Arrays Used for Galvanic Resistivity Surveys

The exploration objective usually defines which electrode array is most suitable and cost-effective to image the target; the selection also depends on whether the survey is required to map a large two-dimensional (2-D) area (e.g., for detecting

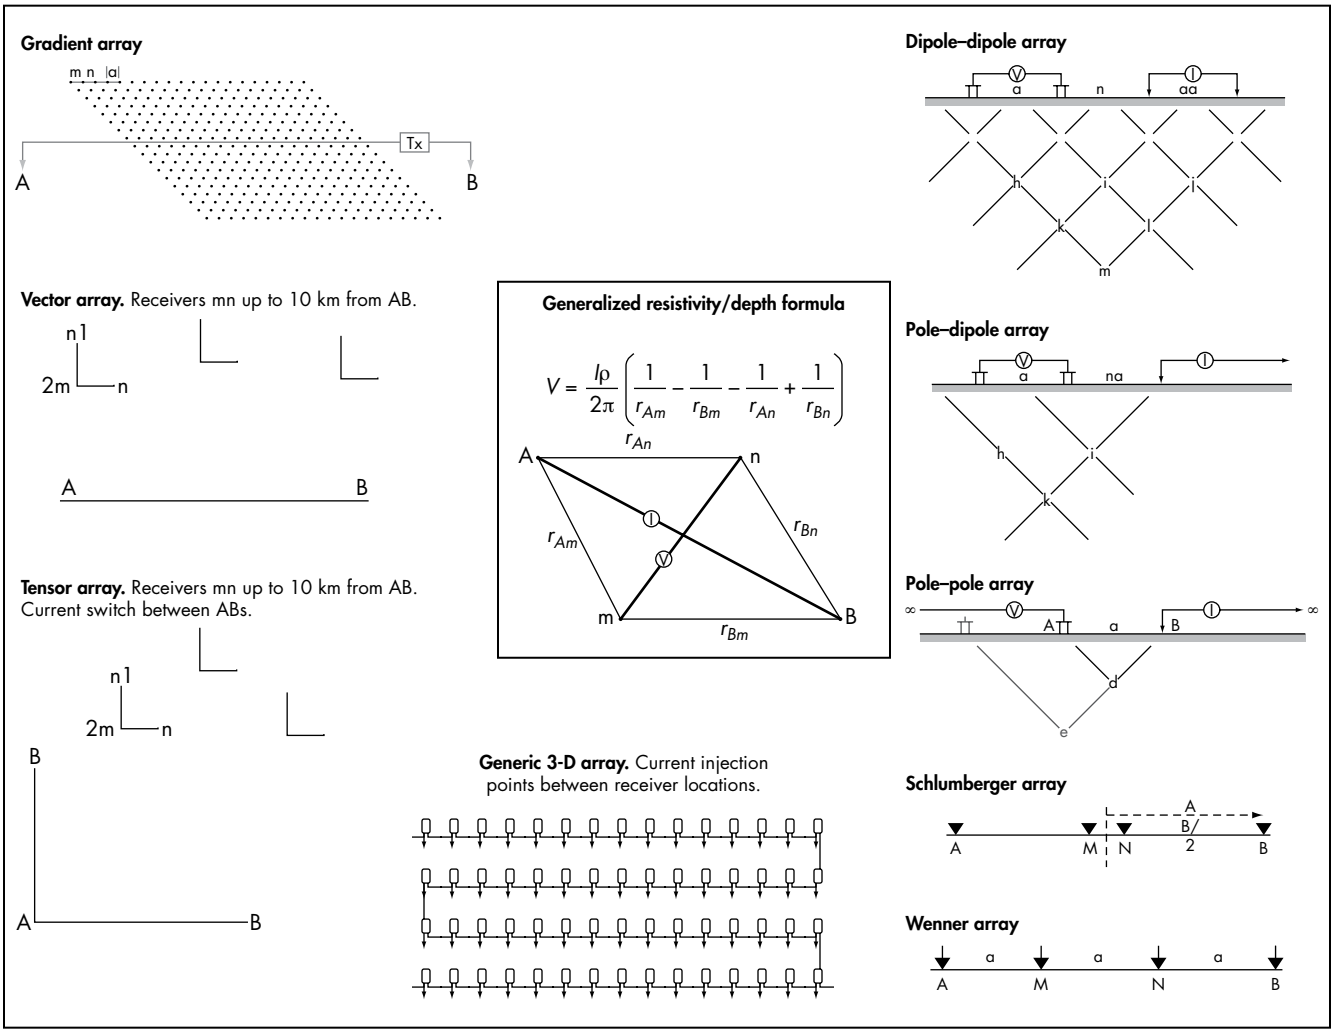


Figure 3.3-7 Galvanic resistivity arrays commonly used in exploration

gravel channels, for groundwater, or for porphyry copper targets) or whether the survey is for preparing a drilling campaign where finer resolution is required using a 2- or 3-D approach. Several arrays, illustrated in Figure 3.3-7, were developed and include the following.

- **Regional mapping arrays**
  - *Gradient:* Grounded current electrodes are fixed throughout the survey. Data are collected on a grid within an area approximately one-third of the current electrode separation. This method produces a resistivity map of the area.
  - *Vector:* This array is designed for rapid mapping of resistivity and induced polarization of large 2-D areas. Current electrodes separations are 2 to 5 km, and potential fields are measured parallel and at right angles to the azimuth of the current electrodes.
  - *Tensor:* This array has the same setup as for vector array except current electrodes are deployed at right angles, requiring measurements from each of the current orientations for calculating tensor fields. This array is useful when there is no reliable geological map for an area where geological strike directions (which could control current channeling) are uncertain.
- **Targeting for drill-hole positioning arrays**
  - *Dipole–dipole:* The electrode array is symmetrical, which simplifies the interpretation. The array is sensitive to steeply dipping structures.
  - *Pole–dipole:* This array is more labor efficient than the dipole–dipole array because only one current electrode needs to be moved. The asymmetrical array is difficult to interpret unless 2-D inversion software is used to create a CDI.
  - *Pole–pole:* This array has only two moving electrodes, making it even more labor efficient. Interpretation is effective when using 2-D inversion software.
  - *Schlumberger expansion and profiling:* This is the most popular method for groundwater and sedimentary basin mapping. It is sensitive to flat-lying sedimentary layers for coal and oil exploration. A symmetrical array makes interpretation relatively easy.
  - *Wenner expansion and profiling:* This is much the same as Schlumberger soundings, but it is more sensitive to lateral effects such as dykes and faults.

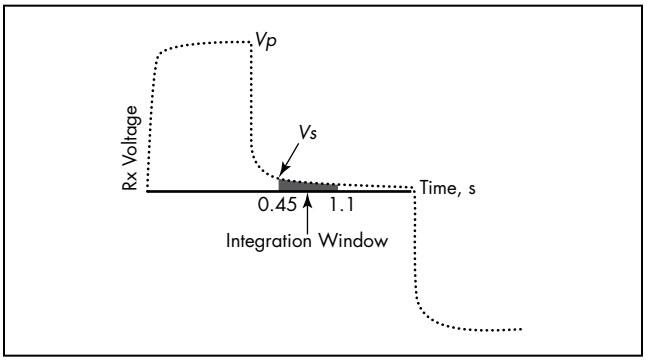

Figure 3.3-8 Time domain wave shape

  - *Three-dimensional:* Similar to seismic 3-D surveys, the current field is active in three dimensions so that all 3-D geological effects are mapped. This is becoming an important prefeasibility mapping tool for resource estimation.
  - *Marine:* Recently developed for oil exploration, hydrocarbons are imaged as resistive layers in the sedimentary sequence. Interpretation is relatively simple using inversion software.
- **Drill-hole resistivity arrays**
  - *In-hole:* Current and potential field electrodes are built into a flexible tube allowing similar survey methods as for surface mapping. This method is essential for reviewing IP targets.
  - *Mise-a-la-masse:* This method maps the surface image of an ore body at depth. Current electrodes are positioned in two drill holes at the sulfide intersection, and potential fields are measured on a grid at the surface. The method is based on the premise that current is channeled along the conductor.
  - *Downhole radial:* This is similar to the mise-a-la-masse method but with only one current electrode in the drill hole. Potentials are measured along radial lines starting from the drill collar. Used for detecting extensions when only one drill hole has intersected ore.

Induced Polarization

The arrays described previously are all used to measure IP on an exploration play. The method is used for detecting the presence of sulfide at depth. Unfortunately, IP effects are also produced by other minerals such graphite, clay, and some shales.

IP is a measure of the earth's storage capacity for electrical energy. When current ceases to flow in the presence of an IP (but no EM coupling), the voltage will drop instantaneously (Figure 3.3-8) to a secondary voltage value and then decay toward zero. The ratio of the secondary voltage (Vs) to the steady-state or primary voltage (Vp) is the (true) chargeability (M), which is a dimensionless parameter where $M = Vs/Vp$. By transmitting current into the ground through two grounded electrodes and measuring the electrical potential between two other electrodes, IP and resistivity are measured.

Transmitted currents will range from 0.1 to ≥15 A; larger currents improve the signal-to-noise ratio. An IP transmitter will put out up to 1,000 V. If the transmitting circuit has a resistance of 100 Ω, the transmitted current will be 10 A (Ohm's law: $I = V/R$). Except for the contact resistance between the electrodes and the ground, all parts of the circuit, including the earth itself, have negligible resistance. So contact resistance is the only important parameter. Therefore, special attention is given to the position of electrodes to lower the contact resistance during a survey.

Table 3.3-4 Relative cost of IP surveys based on a dipole–dipole coverage equal to 1.0 (typically $2,000 per day)

Survey Method	Relative Cost
Vector IP	0.1
Tensor IP	0.2
Gradient IP	0.5
Conventional pole–dipole/dipole–dipole	1.0
3-D array	3.0

IP costs are represented in Table 3.3-4, which shows the relative costs (based on a dipole–dipole coverage equal to one) of arrays previously discussed. Vector IP would be about one-tenth the cost of dipole–dipole surveys. Similarly, a 3-D array would cost about three times that of a dipole–dipole survey.

Electromagnetic Methods

EM methods are an important geophysical technique in the exploration for most ore bodies. Table 3.3-5 is a guide for selecting the appropriate EM method by exploration objective.

SEISMIC METHODS

Seismic methods are discussed to assist the engineer in understanding the scope and benefits to mining.

Table 3.3-6 shows the seismic methods deployed using natural/passive sources as well as those more generally used in exploration geophysics. Natural sources are primarily used for crustal and mantle studies. Earthquake prediction and mine seismicity monitoring are used for safety management and are mandatory applications in all underground mining ventures. These are outside the scope of this chapter but nevertheless are very important applications of geophysics.

Active source seismic methods are employed as either refraction or reflection surveys. The seismic method ranks as a high-resolution technique because of its ability to map relatively thin beds and local discontinuities. It is the only effective method to map geological unconformities.

Snell's law (Figure 3.3-9) is the guiding principle of seismic exploration. The law of reflection states that the angle of incidence of a ray is equal to the angle of reflection. The law of refraction states that a ray will refract at an interface where its velocity changes.

A wave is refracted when the velocity or refractive index of a medium changes. As shown in Figure 3.3-9, a reflection occurs when an amount of energy is reflected from a subsurface back into the same medium; the interface is known as an "acoustic impedance contrast," and the reflection coefficient, Rc, is the ratio of the amplitude of the reflected ray to that of the incident ray. The acoustic impedance, ρV, is density times velocity. The amount of energy reflected and transmitted depends on the ρV on either side of the interface, where the amount of energy reflected is the reflection coefficient, which is calculated as follows (Waters 1981):

$$Rc = (\rho_2 V_2 - \rho_1 V_1)/(\rho_2 V_2 + \rho_1 V_1)$$

The most direct way of determining seismic resolution is to measure it in a drill-hole geophysical log. The minimum

Table 3.3-5 Interpretation of geoelectric data by objective

Objective	Methods	Output and Products Required	Improvement If Multiproperty Survey (e.g., magnetics + gravity)
Deep crustal soundings	• Magnetotellurics (natural field source)	• Conductivity depth sections to depths of up to 50 km • Reveals deep structures acting as conduits for magma to the surface (e.g., Olympic Dam mine, nickel source rocks, and kimberlite)	• Adding gravity and magnetics helps to discriminate rock types. • Seismic tomography combined with magnetotellurics is ideal for such studies.
Petroleum exploration	• Controlled-source electromagnetics (CSEM) • Multichannel transient electromagnetics (MTEM)	• Conductivity depth sections to depths of up to 5 km	
Bauxite thickness profile	• Ground-penetrating radar • High-resolution time domain electromagnetics (TDEM)	• Profile images of conductivity depth images (CDIs) • Look like seismic sections • Depth to unweathered rock • TDEM output in CDIs • TDEM required to discriminate layers	• Adding seismic refraction helps to verify depth to unweathered rock. • Cost benefit is questionable.
Nickel laterite	• Ground penetrating radar • High resolution TDEM soundings	• Profile images of CDIs • Look like seismic sections • Depth to unweathered rock • TDEM output in CDIs • TDEM required to discriminate layers	• Adding seismic refraction helps to verify depth to unweathered rock. • Cost benefit is questionable.
Nickel sulfide	• Airborne EM methods to locate targets • Ground B-field TDEM methods most effective	• TDEM using in-loop and large-loop methods • B-field sensors preferable • dB/dT coils do not discriminate sulfide from sedimentary sulfides in banded ironstone	• Downhole EM is mandatory for all holes drilled. • This is essential for detecting off-hole anomalies. • See Table 3.3-3 for potential field contribution.
Iron oxide copper-gold	• Induced polarization (IP) • TDEM optional	• Copper sulfides usually associated with high-density hematite anomalies and low magnetic susceptibility anomalies • IP detects sulfides, but some hematite species also produce IP anomalies • Supergene copper usually conductive (e.g., Ernest Henry mine, Australia)	• IP helps to map sulfides but is often misleading. • Adding potential fields (see Table 3.3-3) improves the ability to discriminate.
Broken Hill type (BHT) silver, lead, and zinc	• IP • TDEM optional	• BHT mineralization usually associated with sulfides, thus very conductive (e.g., Cannington mine, Australia) • Airborne EM and ground TDEM useful for targeting drill sites	• Adding potential fields improves the ability to discriminate. • IP and TDEM helps to map sulfides but is often misleading.
Iron ore	• Resistivity section mapping (electrical resistivity imaging) • Output as resistivity depth image	• Hematite alteration produces resistivity anomalies in channel iron deposits • Clay degrades quality and can be mapped with resistivity	• Integrates with potential field data, especially density. • Discriminates iron ore from host rock (see Table 3.3-3).
Porphyry copper	• IP • TDEM optional	• Porphyry copper deposits have characteristic pyrite halos (donuts) and are often associated with major lineaments. • Because of the large size of alteration halo, they can be mapped using vector IP and/or gradient IP.	• See Table 3.3-3 for integration with potential fields.
Kimberlite	• Combination of helicopter magnetic and TDEM methods most effective	• Maps need to show coincident magnetic high and conductive anomalies. • Gravity lows are characteristic of weathered kimberlite.	• Addition of gravity, either on an airborne platform or on the ground, confirms kimberlite geometry and substantially reduces risk of failure.
Gold	• Airborne magnetic and EM with IP follow-up	• Gold deposits are found in diverse geological settings. • Basic mapping for structure, magnetite veins, quartz veins, etc. • Best accomplished through airborne EM and potential field methods • Ground IP detects sulfides in host rocks such as banded ironstone, magnetite veins, and quartz veins.	• TDEM methods not often applied but are only used when geologically justified.

Table 3.3-6 Seismic surveys by target objective

Objective	Output and Products	Improvement Adding Other Geophysics
Coal	• 2- and 3-D seismic high resolution surveys • Outputs are fault, thrust, intrusive, and coal seam geometry • Refraction for weathering profile	• Potential fields help to focus on dykes and sills that are not well mapped by seismic methods • Ground-penetrating radar helps on open-pit benches for roof of coal depth mapping • Wire-line logging is used for accurate measurement of coal thickness, quality, and borehole-to-borehole lithology correlation.
Nickel/platinum	• In layered intrusive, platinum reef and hazards such as dunite "pothole" • Faults and post-mineralization intrusives • Depth to reef and reef geometry	• Magnetic surveys help to discriminate intrusives such as dykes and porphyries.
Kimberlite	• Geometry of the walls of a kimberlite pipe with host rock	• Potential fields help to define geometry
Potash	• Primary purpose is mapping hazards in the roof of the deposit (water seal) • Faults and stratigraphy • Lateral changes in potash depositional environment	• Wire-line logging is used for determining the roof strength by means of sonic logs and for lithology correlation.

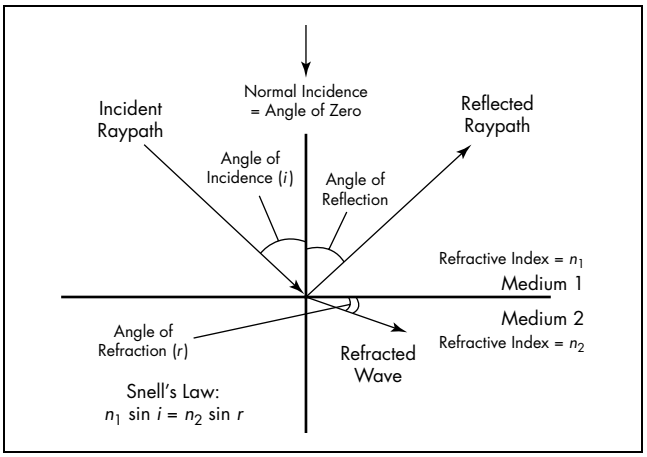

Figure 3.3-9 Snell's law showing reflection and refraction

quantities would be the P-wave velocity and the density logs. Unfortunately, a drill hole only gives the information for a short distance from the actual hole, so that a number of holes need to be logged to estimate the average for an area. These controls are essential when converting from time to depth during the interpretation.

Planning for reflection surveys is an involved process, and its complexity is often underestimated. Reflection seismic crews can number as many as 150 people with a variety of equipment and machinery—more so when drilling of shot holes are required. Typical seismic reflection costs are about \$15,000/d for two dimensions and about \$300,000/km^2 for a high-resolution, 3-D seismic reflection survey. Table 3.3-7 is a checklist that provides an outline of the planning and organizing required. The objective is to have the right people in the right jobs communicating effectively.

Table 3.3-7 Checklist for planning a seismic reflection survey

Planning Step	Checklist
Presurvey	☐ Familiarization introduction: Presurvey project team scoping ☐ Scheduling regular meetings ☐ Production of meeting action minutes and addressing of each item at meetings until closed out ☐ Determination of the survey schedule project/license time requirements ☐ Survey design: Project team to provide technical information required ☐ Survey data ☐ Regulatory approvals ☐ Budget
Seismic acquisition contract*	☐ Pre-tender contractor meetings ☐ Contract preparation
Other contracts	☐ Review of seismic acquisition contract ☐ Determining list of other contractors
Health and safety	☐ Contractor prequalification
Environment and community	☐ Environment management plan
Pre-mobilization	☐ Project execution plan
Mobilization	☐ Crew audits, which include follow-up and close-out of prior audit items
Field operations	☐ Survey progress reporting—includes joint venture partners and government ☐ Data harvesting
Postsurvey	☐ Accountable contractors ☐ Financial reconciliation ☐ Delegation of responsibility for invoice settlement

*This contract often causes the most objections from the contractor's legal representatives, and it can be onerous to negotiate a final agreement.

WIRE-LINE AND DOWNHOLE GEOPHYSICAL LOGGING

The ability to constrain surface geophysical interpretations with additional information such as downhole logging increases the value of the surface data. The most common methods include the following:

- Petrophysical logging in coal exploration is used to calibrate surface seismic processing and interpretation. In coal exploration, the information is critical for coal quality, thickness, ash content, and stratigraphic mapping. Tools are usually density, resistivity, gamma, acoustic impedance, susceptibility, and self-potential.
- Downhole electromagnetic (DHEM) sensors are high-resolution, three-component sensors used primarily for nickel and other sulfide exploration. DHEM can detect

conductors up to 150 m from the drill hole, defining a target vector for drill orientation. The receivers measure mostly in the time domain and use the popular University of Toronto electomagnetic (UTEM) on-time transmitted signal for better sensitivity (e.g., as is used in nickel exploration in Sudbury, Canada).

- Downhole gravity has been common in petroleum exploration for decades. The advantage over the conversional neutron logging sensors is that it can measure the relative gravity field that can be used to detect off-hole density targets. The gradient information can also be transformed into real density measurements. A limiting factor with neutron tools is the maximum density that can be reliably measured is about 2.8 kg/t, whereas the gravity-logging tool will measure higher gravity values, making it ideal for resource estimation for commodities such as iron ore.
- Three-component, downhole magnetic surveys are uncommon and are sometimes employed for mapping the off-hole presence of magnetic minerals, such as magnetite and pyrrhotite, and for mapping magnetic intrusive plugs. The difficulty with magnetic logging is in accurately tracking the orientation of the three-component sensor while traveling downhole.
- Downhole IP is useful for calibrating surface IP interpretations for drilling. Good practice dictates that all drill holes targeted on IP anomalies should be logged.

CHAPTER 3.4

Geochemical Prospecting

Jeffrey A. Jaacks, L. Graham Closs, and J. Alan Coope

Exploration geochemistry, or geochemical prospecting, includes any method of mineral exploration based on the systematic measurement of one or more chemical or chemically influenced properties of a naturally occurring material. The property measured is most commonly the trace concentration of some chemical element or group of elements. The naturally occurring material may be rock, soil, stream sediment, glacial sediment, surface water, groundwater, vegetation, microorganisms, animal tissues, particulates, or gases.

HISTORY OF GEOCHEMICAL PROSPECTING

It is clear from historical records that the principles of geochemical exploration have been applied in prospecting over several thousand years. The prospector who panned for gold and traced the colors upstream to a bedrock source used mineralogical observations in a similar way to the modern geochemist who utilizes sensitive chemical analyses to outline patterns of dispersion in the surficial environment. Geobotanical indicators were recognized as early as the eighth and ninth centuries. The mid-16th century work by Agricola (1556) describes the analysis of natural waters, springs, and their residues.

Modern methods of exploration geochemistry were first used in the early 1930s in the Soviet Union. Shortly thereafter, the methods were applied in the Scandinavian countries, particularly Sweden. In North America, the earliest geochemical surveys were carried out between 1938 and 1940 by H. Lundberg in Newfoundland and in 1944 by H. Warren in British Columbia. The first comprehensive geochemical exploration studies commenced at the U.S. Geological Survey under the leadership of H.E. Hawkes in 1947 and at the Geological Survey of Canada with R.W. Boyle in the early 1950s. The Applied Geochemical Research Group was established at the Imperial College of Science and Technology in London in 1954 under the direction of J.S. Webb, and in France, research related to exploration geochemistry began in 1955.

The successful application and adaptation of geochemical exploration techniques in all parts of the world, the rapid development of analytical and computer technology, and improvements in field transportation have made geochemistry one of the more effective and widely applied exploration disciplines. Analytical capability is such that relatively rapid, sensitive analysis can be achieved for virtually all metals of economic interest. New technological advances are expanding our established capability to cost-effectively detect and interpret dispersion patterns related to mineral deposits in a wide variety of environments. Recent geochemical research has focused on detecting ore bodies hidden beneath transported overburden and development of geochemical dispersion models to aid in the interpretation of anomalies developed in these environments (Cameron et al. 2004).

Through multielement analysis, geochemical data can reveal signatures related to distinct geological units and geochemical processes. This capability, when applied to rock samples, permits geological correlation as well as the more precise delineation of otherwise invisible alteration features related to mineralization. When applied to soil and other types of samples, multielement data can help outline major geological units and the extent of alteration systems, and identify the presence of mineralization buried under extensive cover.

GEOCHEMICAL PROSPECTING METHODS

The various components of a geochemical exploration program include sampling design, choice of sample media, sample collection, sample analysis, quality control of analyses, data visualization and evaluation, and interpretation. These components of a geochemical survey are interdependent and should be focused on the geologic objective to be achieved. Good design and planning (including orientation) and well-conducted sampling programs constitute the foundation of all sound geochemical exploration work (Closs and Nichol 1989). Inappropriate sample preparation prior to analysis can destroy the integrity of the well-chosen sample. It follows that no matter how accurate and precise the techniques used for analysis or how advanced the statistical treatments

and computer programs used for data handling and interpretation, they cannot resurrect the lost quality and representativity and restore the decreased probability of exploration success caused by poor planning, improper field sampling, faulty sample preparation, or mismatch between sample media and digestion method.

GEOCHEMICAL PROGRAM PLANNING

Experience has confirmed that the success of a geochemical survey depends largely on the correct assessment of all the natural factors that influence the mobility and dispersion of the metallic elements of interest. These natural factors, which are described more fully in textbooks by Rose et al. (1979) and Levinson (1974, 1980), are

- Physical and chemical properties of the elements or parameters of interest,
- Nature of the geology and mineralization,
- Geomorphological history of the field area,
- Vegetation, and
- Topographic and climatic conditions.

These factors are completely interrelated, and any change in one condition—such as a geologic change from an acidic to a basic environment, a local climatic change caused by elevation, or a topographic change from rolling to mountainous terrain—can significantly influence element mobilities and the lateral extent of the dispersion from any mineralization type. Consequently, procedures for sampling, sample preparation, and analysis that prove to be satisfactory in one field area may be inadequate and unreliable in an adjacent region.

The processes of oxidation, weathering, erosion, transportation, sedimentation, and diagenesis that characterize the surficial environment are too complex to describe in detail in this summary. The physiochemical conditions determine whether the weathering products of mineralization disperse either in solution in a hydromorphic form or in a solid or clastic form. The low pH, high Eh conditions of the acid-weathering environment (e.g., oxidizing massive sulfides) promotes the solubilization of many base metal and other elements and their more widespread hydromorphic dispersion in surface and groundwaters. Alkaline conditions developed over a weathering limestone or in a semiarid climatic condition prohibit or arrest this hydromorphic dispersion. Under these conditions, the insoluble metal particles disperse mechanically to form clastic patterns.

A series of publications sponsored by the Association of Exploration Geochemists develops conceptual models based on conditions in Canada (Bradshaw 1975), Scandinavia (Kauranne 1976), the Basin and Range province of the western United States (Lovering and McCarthy 1978), Australia (Butt and Smith 1980), tropical and subtropical terrains (Butt and Zeegers 1992), and arctic and temperate terrains (Kauranne et al. 1992). These conceptual models describe the principles and mechanisms of formation and configuration of anomalies and dispersion patterns revealed through geochemical exploration surveys in these regions. This format has been expanded in the *Handbook of Exploration and Environmental Geochemistry* published by Elsevier, currently with 11 volumes covering many aspects of geochemical exploration.

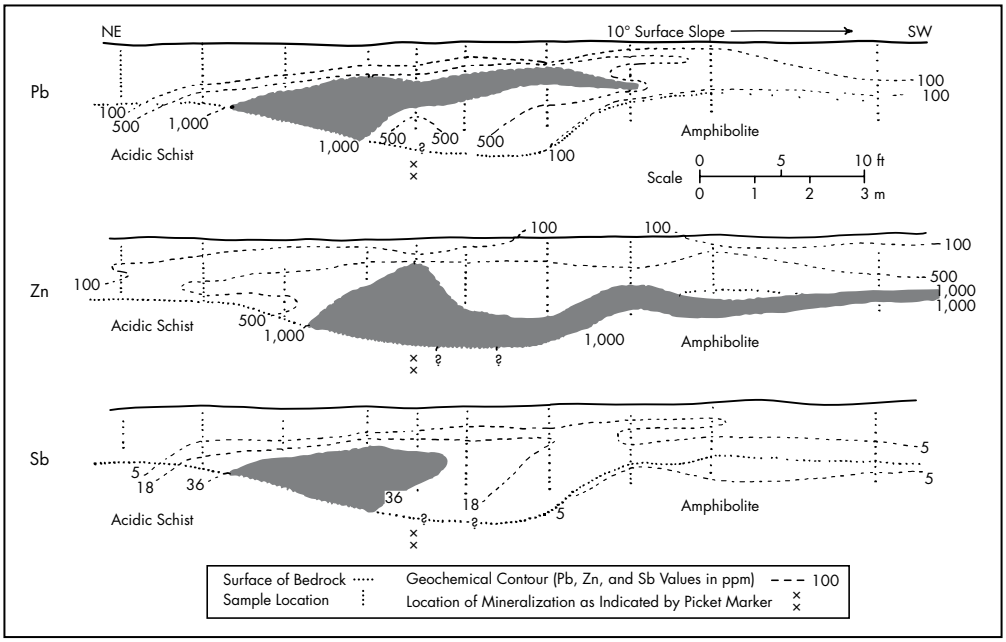
GEOCHEMICAL ORIENTATION SURVEYS

When contemplating a geochemical survey in a new region, the most reliable method of determining the extent and nature of dispersion patterns is to conduct an orientation survey. The objective of orientation sampling is to determine and outline the existence and characteristics of dispersion patterns or anomalies associated with mineralization and also background levels in similar environmental conditions. The specific sample media used are dependent on a knowledge of the field area, the prospecting problem, and, if available, previous experience, but may include any of the following: rocks, soils, stream sediments, surface waters, groundwater, glacial sediment, lake sediment, vegetation, soil gases, and microorganisms.

The orientation survey commonly involves the collection of a number of relatively closely spaced samples over and in the vicinity of known but preferably undisturbed mineralization with the express purpose of outlining the dispersion patterns in the available sampling media. This information can then be used to select the most reliable sampling method, sample preparation, and analytical techniques capable of detecting similar anomalies under similar environmental conditions. The detailed examination of the nature and shape of the dispersion patterns invariably yields information on the principal natural factors responsible for the observed distribution of anomalies. This is a significant aid in the development of interpretation procedures.

Table 3.4-1 is a synthesis of the important parameters that can be derived from a properly planned and executed orientation survey. Based on this information, the optimum physical parameters (sample depth, sample interval, analytical technique, etc.) for routine surveying can be chosen that necessarily take into account the defined dispersion characteristics as well as the physical, logistical, and economic conditions pertaining to the project. Large samples should be taken to provide sufficient material for the full evaluation of the parameters listed in Table 3.4-1, and representative samples should be collected from nonmineralized areas to adequately define background conditions and contrast of anomalies, where contrast is defined as the ratio between background and threshold value of anomalous samples.

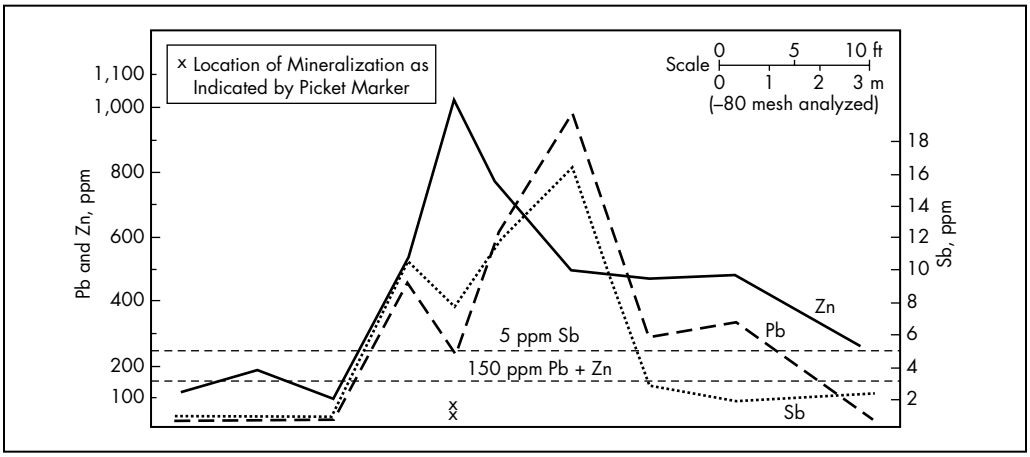
A survey conducted over gold-silver vein mineralization at Mount Nansen in the Yukon Territory of Canada (Coope 1966) illustrates the application of the orientation approach. Detailed profile sampling of soil and overburden exposed in a trench across virgin mineralization produced patterns of lead, antimony, and zinc, as illustrated in Figure 3.4-1. It is apparent from these patterns that the dispersion behavior of lead and antimony is similar but quite contrasting with the patterns for zinc. All metals have been influenced by downslope movement in the overburden, but the zinc pattern is compatible with dispersion in solution along the bedrock surface. Examination of the patterns also indicates that near-surface sampling (0 to 300 mm, or 0 to 12 in.) would not reliably indicate the mineralized vein. It was concluded that a sample depth of 460 to 610 mm (18 to 24 in.) and a sample interval of one-third the anomaly width at this depth (5 m, or 15 ft) were the optimum parameters necessary for routine surveying (Figure 3.4-2). Observation of these sampling criteria led to the discovery of several previously unknown veins.



The soil profile interval in an orientation survey over more extensive types of mineralization will be proportionately larger than the intervals chosen for narrow-vein-type mineralization.

The sample intervals employed in orientation surveys will vary according to the anticipated size of the target

Table 3.4-1 Parameters to be derived from a properly planned orientation survey



Rock	Soil	Sediment	Water	Biogeochemical	Gas
Shape, extent, reproducibility, homogeneity, and controls of geochemical patterns					
Most suitable indicator elements and best analytical methods

mineralization and the dispersion characteristics of the metals of interest. In areas where no previous experience exists, a short interval is recommended so that three or more samples are collected within the distance spanning the zone of mineralization. This interval should then be progressively expanded with distance from the metal source to the limits of the known or anticipated dispersion pattern. Samples must also be collected from nonmineralized areas to establish the background range, and sufficient material should be collected at each site to allow for the determination of optimum size fractions, analytical techniques, and other factors listed in Table 3.4-1.

SAMPLE COLLECTION AND HANDLING

Effective sampling of all surficial media requires well-trained personnel capable of recognizing and describing the correct sample material and the sample site characteristics. Samplers should be able to recognize and, if possible, avoid situations where contamination from human activity or changes in the natural physiochemical conditions can produce spurious or unusual results. In most situations, these sampling duties can be undertaken by trained technical personnel with geochemical exploration experience. For some specialized types of surveys, where identification of the correct sample material is critical (as in biogeochemical or glacial till sampling programs), it is prudent to employ qualified specialists (e.g., botanists and quaternary geologists) to conduct orientation surveys and instruct and supervise the sampling teams.

Sampling tools vary according to the medium and the field situation. Non-contaminating equipment is essential, and care should be exercised in not only choosing noncontaminating steels for shovels, trowels, augers, and so forth, but in ensuring that lubricants and adhesives, weldings, and solders are metal free too. This awareness of geochemical cleanliness extends to the dress of the sampler, who should avoid wearing metal buckles, gold rings, and so forth, and avoid handling coins, which might lead to contamination by chipping or transfer of metal on fingers.

The same caution is necessary in the choice of sample containers. Kraft paper (with noncontaminating waterproof glue and closures), olefin, and plastic bag containers of appropriate size are frequently used. Kraft and olefin allow samples to be dried without transfer, while plastic bags are commonly used for larger samples. More rigid polypropylene bottles can be utilized in water sampling, and a variety of sampling devices are available for the sampling of gases and particulates.

Collecting Different Sample Media

Soil

Soils vary considerably in composition and appearance according to their genetic, climatic, and geographic environment. Classified into residual and transported types according to their relationship to their substrate, soils are mixtures of mineral and biologic matter and may be distinctively differentiated into a series of soil horizons. Residual soils characteristically contain detectable dispersion patterns developed during the weathering of mineralization in the underlying bedrock, and these patterns are revealed by careful sampling of appropriate soil horizons. Transported soils present more difficult sampling problems, but meaningful sampling is possible in many areas after the genetic origins of the transported cover are understood.

With all but a few exceptions, soils are sampled along traverses or grids in the follow-up or detailed prospecting stage of a geochemical program. Orientation programs define criteria such as sample depth or soil horizon to be sampled, sample interval, and the size fraction for analysis. It is essential that these criteria be applied consistently through the survey (Hoffman and Thomson 1987).

Stream Sediments and Surface Water

Stream sediment is one of the more commonly used media for geochemical reconnaissance surveys. The sediment at any point in a stream is a natural composite sample of erosional materials from upstream in the drainage basin and will include clastically, hydromorphically, and biogenically derived products from weathering mineralization. The length of anomalous dispersion trains will vary with the nature of the mineralization, source, and physiochemical environment of the field area or drainage basin. In humid, actively oxidizing environments, dispersion trains from sulfide-rich base metal deposits may extend downstream for several kilometers.

Active stream sediment—material constantly or most frequently washed by stream waters—is collected from the

center of a drainage, avoiding sites that may be contaminated or influenced by bank collapse. In most survey programs, approximately 500 to 1,000 g (1.1 to 2.2 lb) of fine-grained material are collected from the upper few tens of millimeters of the sediment. If heavy minerals are to be examined, larger samples from deeper in the streambed are collected from carefully selected sites. In all surveys in new areas, the critical parameters of sample interval, sediment size fraction, appropriate analytical procedures, significant anomaly contrasts, and background levels are determined through orientation surveys (Hale and Plant 1994).

In the regional reconnaissance prospecting mode, stream sediment surveys can be designed to systematically cover areas up to several hundred square kilometers. To pinpoint source areas in more detail, anomalous indications of mineralization can be followed up with more detailed sediment sampling. Follow-up sampling of seepage areas is particularly effective in delimiting anomalous groundwater sources containing metal derived from oxidizing mineralization. If appropriate, soil sampling can be used to define suboutcropping mineralization in the anomalous source areas defined by the sediment survey.

Regional reconnaissance can also be achieved by sampling the waters of actively flowing streams where metal is dispersing in solution. A prospecting approach similar to the sampling of stream sediments is necessary, collecting waters in clean 250-mL (0.07-gal) polypropylene or glass bottles. Sampling of groundwater seepage sites is an integral part of stream water surveys. To keep the dissolved metals from adhering to the bottle walls, a few milliliters of acid is routinely added to the water samples after collection. Temperature, pH, total dissolved solids, conductivity, and certain other measurements are commonly made at the sample site.

Lake Sediments and Lake Water

Lake sediments and lake water sampling have been developed into effective geochemical reconnaissance techniques in areas of Canada and Scandinavia where lakes are common, conditions are swampy, and/or where stream drainages are inaccessible or poorly developed. In low-relief regions, the lake sediment medium is dependent on the hydromorphic dispersion of metals into the lake environment through groundwaters and the adsorption of this metal onto hydrous oxides and the organic-rich muds deposited on the lake bottoms. The sampling focuses on the collection of these organic muds using specially designed sampling devices. In more mountainous areas, fine-grained clastic dispersion into the lake sediment becomes a more important factor. In all areas, satisfactory sample locations are found well away from lake shores and are reached using boats, float planes, or helicopters. Lake waters are commonly collected at the same sites as the lake sediments (Coker et al. 1979).

Glacial Deposits

Extensive quaternary glacial deposits occurring over most of Canada and the northern United States, northern Europe, and northern Asia have presented major challenges to exploration. As a better understanding of the origin and formation of these glacial sediments has grown, their blanketing presence has become progressively less formidable, and effective exploration techniques have been developed.

Mineralized boulder tracing in glaciated regions is an established technique of the traditional prospector in Scandinavia and parts of Canada. Methods were developed for sampling tills in the 1950s, and this technique is now the preferred sampling method in modern geochemical exploration programs. Approximately 70% of lodgment till is locally derived, and most of the early success with till sampling was in areas of shallow till cover (<10 m [30 ft]) where the sample medium is reasonably accessible. In the 1960s, lightweight percussion drills, such as the Pionjar and Cobra models, were adapted to collect small samples of till from immediately above the suboutcropping bedrock to geochemically categorize anomalous geophysical features at depths of up to 21–24 m (70–80 ft).

Overburden drilling technology, particularly reverse circulation and sonic drilling, advanced rapidly with the utilization of larger drills in programs for uranium and gold deposits in glaciated areas. Because most types of gold deposits are not detectable by conventional geophysical methods, lodgment till sampling using overburden drills to depths of 100 m (330 ft) has been used routinely in prospecting for gold in the Canadian Shield through the 1980s. Large samples of till (~10 kg [20 lb]) are recovered in these programs from which the heavy mineral fraction is separated and examined both visually and chemically for gold and other metals (Averill 2001).

The correct interpretation of these data is dependent on an understanding of the till stratigraphy and provenance of the transported material. The technique is expensive, with combined drilling, sample treatment, and analytical costs ranging from $20 to $50/m ($60 to $100/ft), but it is cost-effective in this deep overburden-covered environment where other methods in gold exploration have not been as successful. In contrast with the heavy mineral sampling of tills practiced in Canadian exploration, Scandinavian explorers place a greater reliance on the 63 μm (–240 mesh) fraction of till. This fraction has successfully indicated the presence of several types of mineralization, including gold.

Rocks

Rock sampling, or lithogeochemical surveys, comprise systematic sampling of outcrops, trenches, drill cores, or drill cuttings. As with other types of geochemical surveys, the sampling procedures and the sample material collected in lithogeochemical work should be standardized as much as possible.

Lithogeochemical sampling necessarily must take into account the geological environment and the type of mineral deposit of interest to the explorer. Very briefly, syngenetic lithogeochemical patterns (which developed at the same time as the rocks that enclose them) can develop, for example, in (1) intrusives genetically associated with specific mineral deposit types, (2) volcanic stratigraphy where exhalative activity has dispersed detectable quantities of metals during the formation of volcanogenic massive sulfide deposits, or (3) the vicinity of sedimentary deposits. The scale of sampling necessary for detection of these and other types of patterns will be determined by orientation surveys but may include the regional sampling of individual plutons or more detailed sampling of specific parts of an exposed stratigraphic section.

Epigenetic lithogeochemical patterns (those developed long after the rocks that enclose them) can develop as diffusion aureoles in the rocks hosting epigenetic mineral deposits or as leakage aureoles along fractures and other structures that mark the pathways followed by hydrothermal or groundwater fluids prior to and subsequent to the deposition of the significant mineral deposits. Both these processes introduce the concept of mineral zoning of geochemical aureoles. The

ratios of the different elements introduced during the mineralization period varies with distance from the principal deposit according to the properties of these elements and the host rocks and the physiochemical conditions at the time of deposition. Leakage anomalies can extend for hundreds of meters or feet from a deposit, whereas diffusion anomalies rarely exceed 30 m (100 ft). The scale of dispersion, the presence of zoning patterns, and the sampling parameters for epigenetic geochemical patterns are determined by appropriate lithogeochemical orientation surveys.

It is clear that surveys designed to detect leakage anomalies will focus on a standardized collection of fault or fracture zones and, possibly, bedding structures. In contrast, the preferred lithogeochemical sample material for the detection of syngenetic haloes is likely to be unfractured and the scale of sampling much more detailed. In all instances, geochemical analysis of lithogeochemical material has the potential of delimiting dispersion patterns associated with mineralization beyond visible alteration.

Vegetation and Humus

Early scientific observers dating from the eighth and ninth centuries recorded that the morphology and distribution of certain plants were affected by the presence of metals in the soils. Such visible variations in a plant species are referred to as geobotanical indicators. Many other plants, while not showing any visible variations, are capable of concentrating metals in their tissues, and the presence of anomalous metals in the soils or groundwater is often reflected in the metal content of leaves, twigs, or other plant organs. These invisible metal concentrations are known as biogeochemical indicators (Brooks 1983).

The seasonal fall of leaves and needles transfers some of the accumulated metals to the surface soil where they are incorporated in the humus layer. Sampling of this humus (alternatively known as mull, A_o, or A_h material) by Scandinavians in the 1930s revealed its potential for geochemical prospecting. This is especially true in areas of transported material where the root penetration of the plant exceeds the thickness of this cover and obtains nutrients from the underlying mineralized bedrock and groundwater.

In addition to the direct recognition of geobotanical indicators, the most attractive feature of vegetation sampling is the ability of biogeochemical and mull prospecting to see through thicknesses of barren transported overburden.

Plants are complex organisms and so is their metabolism. Different species respond differently to the same conditions, and, consequently, some species are more effective biogeochemical indicators than others. Deep-rooted plants (e.g., the mesquite) are much more effective prospectors of the deeper groundwater than the shallow-rooted flora of the southwestern U.S. deserts and are, therefore, preferred species in biogeochemical work. Evapotranspiration has been suggested as a mechanism for movement of metals into the nutrient depth of these plants.

Some species preferentially concentrate metals in specific tissues such as leaves, twigs, bark, or wood. It is therefore important to establish the most favorable tissues for sampling after a useful species has been identified (Dunn 2007). This complexity is accentuated by the fact that metal uptake may vary with aspect, and degree of uptake commonly varies with the seasons. In temperate forest regions, accelerated uptake and higher concentration commonly occur during the spring growth following a dormant winter season. In hot desert regions, following the exhaustion of available near-surface water during the dry season, deep-rooted plants will tap the deeper, more metal-rich groundwater.

These variables make biogeochemical sampling a specialized exercise. The expertise of an experienced geochemist or botanist is essential during orientation studies and the supervision of vegetation surveys. Because of the seasonal variations, biogeochemical surveys must be completed quickly, and sampling in the spring and fall is generally avoided.

The same complexities do not affect the humus or mull medium. Dead tissues are not subject to seasonal variations, and annual accumulation has an integrating effect. Weathering, leaching, and bacterial decomposition will work to diminish the metal contents, but signatures in mull are generally preserved.

Soil Gas

Under certain conditions, weathering mineral deposits produce gaseous emanations that can be detected by specialized measurements. Radon, for example, is produced during the radioactive decay of uranium and radium. Survey techniques measuring the alpha particle emissions during radon decay have been used extensively in the search for uranium. Helium is another gas produced during radiogenic decay and is considered by many to be also of deep-seated origin. Mercury-bearing minerals, which can include sphalerite and other sulfides, often release mercury vapor during oxidation.

The oxidation of sulfides leads to the generation of sulfur dioxide, dihydrogen sulfide (H_2S), and carbon dioxide (CO_2). Because of the consumption of oxygen in the oxidation process, the atmospheric proportions of carbon dioxide and oxygen change in the vicinity of oxidizing sulfides, and these imbalances can be measured in the soil gas to detect buried mineralization. More recently, organic gases have been used to define mineralized and alteration zones located beneath transported cover. Organic gas species are zoned relative to mineralization, with heavier reduced compounds occurring over ore and lighter, more oxidized gas species occurring at the boundaries of mineralization (Klusman 1994).

SAMPLE PREPARATION

Inappropriate sample preparation can completely nullify the careful work of the sampler who has invested time and expertise in the selection and collection of representative material. Furthermore, it is impossible to restore the integrity of the poorly prepared sample by enterprising analytical treatments and interpretational procedures.

Drying

Prior to mechanical treatment, surficial and rock geochemical samples have to be dried. In some climates, this can be achieved by exposure to the sun, but most samples are dried in drying ovens. Heating these ovens to temperatures in excess of 70°C (160°F) can lead to the loss of volatile elements (Hg, As, Sb) that may be of value to the exploration program. Organic samples, including humus, may be dried in a conventional drying oven or in a microwave oven at temperatures not to exceed 70°C (160°F).

Sieving and Crushing

After drying, surficial samples should be agitated and disaggregated to achieve complete separation of component

particles without crushing. This can be done with a pestle and mortar or other suitable non-contaminating mechanical device that can be thoroughly cleaned between samples. In earlier geochemical prospecting work, orientation studies on soils, stream sediments, and other surficial materials revealed that the separation of –80 mesh material for analysis was appropriate in many surveys. With some elements, such as those commonly concentrated in residual minerals (W, Sn) and other elements dispersed in weathering products in arid/semi-arid environments, fractions coarser than 80 mesh give superior geochemical patterns with better contrasts. Surveys in glacial till environments benefit from the analysis of the –240 mesh (63 μm) or even finer fractions. Careful size fraction analysis during orientation will not only indicate the most appropriate fraction for routine work, but the metal distribution throughout the sample reveals invaluable information on metal behavior for interpretation purposes. Sieves must have a non-contaminating composition. Those most frequently used are made from stainless steel.

Heavy Mineral Separations

Heavy mineral separations from stream sediment, glacial till, and rock samples commonly utilize the liquids tetrabromoethane (specific gravity [sp gr] 2.9) and methylene iodide (sp gr 3.3). More recently, solutions of sodium polytungstate, with specific gravity ranging from 1.0 to 3.1 according to dilution, can also be used to avoid the disposal issues associated with tetrabromoethane and methlyene iodide. Usually these liquid separations are carried out on coarser sample size fractions (e.g., –30 + 80 mesh), but separations can be made on material down to 200 mesh if the metal of interest is present in the finer size fractions. If necessary, heavy mineral concentrates can be further subdivided by electromagnetic separation into magnetic, paramagnetic, and nonmagnetic fractions and analyzed separately.

Vegetation Samples

Ideally, vegetation and humus samples should contain no clastic material. Dust on leaves and twigs can be removed by rinsing with demineralized water, but humus material is rarely 100% organic. The presence of excessive clastic material may dilute or contaminate the metal content of the organic material and adversely interfere with lower detection limits possible on organic material using the neutron activation analytical technique.

After drying at temperatures of less than 70°C (160°F) in a standard drying or microwave oven, vegetation samples are macerated in a Wiley mill to a –2 mm mesh size. This material is compressed into either 8.0- or 30.0-g pellets for direct analysis by neutron activation or can be ashed in a muffle furnace at 450° to 470°C (842° to 878°F) for approximately 15 hours. The plant ash is then analyzed in a similar manner to clastic sample material.

Rock Samples

Some surveys call for the analysis of specific minerals in rock samples. Such minerals may include magnetite, biotites, feldspars, and sulfides that may be concentrated by magnetic separation or with heavy liquids from the most suitable size fraction, after appropriate sample treatment (Govett 1983).

Most rock samples collected in geochemical programs are analyzed for their whole rock or trace element contents. This requires crushing and pulverizing and, if the contained metals of interest are heterogeneously distributed (e.g., as with coarse gold), the principles of sampling theory must be observed (Pitard 1993). The pulverized whole rock product that is commonly analyzed has a grain size of less than 150 to 200 mesh. The sample is rarely reduced to this fine grain size in its entirety, but, as a general rule, the finer the sample can be crushed or ground prior to sample splitting, the more representative the split is likely to be.

The emphasis on gold exploration in recent years has focused attention on sample heterogeneity. This has stimulated some significant developments in the design and adaptation of crushing and grinding equipment for improved sample preparation. In addition to sample representativity, the geochemist must be concerned with sources of contamination in the sample preparation equipment. Grinding plates and blades of different composition are available so that the obvious contamination from chrome steel, tungsten carbide, and other materials can be avoided. Similarly, loss of sample representivity through *smearing* of native copper, native gold, molybdenite, or other soft material on pulverizer plates can be avoided in many instances by the selection of alternative equipment with a different comminuting action.

Because sample weights analyzed in geochemical work are small (0.1 to 50 g [0.0002 to 0.1 lb]) compared with the original sample size, sample homogeneity is important. Improved mixing can be achieved, when necessary, by careful blending and the pulverization of coarser fractions to the –200 mesh size.

ANALYTICAL TECHNIQUES

Analytical Methods

A prime requirement for cost-effective geochemical exploration surveys is the availability of analytical procedures capable of high productivity, low detection limits, high precision, and acceptable accuracy. These criteria were met in the 1950s by a series of colorimetric analytical techniques with productivities ranging from 20 to 100 samples per day. Technological developments have subsequently led to the introduction of atomic absorption spectrophotometry (AAS), inductively coupled plasma (ICP) spectrometry , X-ray fluorescence (XRF), and instrumental neutron activation analysis (INAA) with far greater analytical sensitivity and vastly increased productivity.

These analytical techniques provide accurate, precise determinations with detection limits of less than 5 ppb to 1 ppm for many of the elements commonly measured in exploration geochemical surveys. The ICP-mass spectrometer instrument is capable of even greater sensitivity. Comparison of some of these analytical methods is shown in Table 3.4-2.

In the minds of the inexperienced, the spectacular analytical capabilities of these instruments often overshadow the critical importance of the sample preparation and sample decomposition stages of sample treatment.

It was emphasized in the preceding section on sample preparation that the most informative fraction of a geochemical sample may be the heavy mineral fraction, a relatively coarse fraction (–30 + 80 mesh), a fine fraction (–80 mesh), or a very fine fraction (–250 mesh), depending on the material being analyzed or the particular property of interest in a sample. If an improperly chosen solid sample material is correctly analyzed, the results can be no better than mediocre in the context of the exploration program and may even be misleading.

Table 3.4-2 Comparison of characteristics of analytic methods

Method	Capital, $	Multielement	Determinations per Day	Comments
Colorimetry	1×10^3	No	20–100	Very simple; adaptable to field
AAS	2×10^4	No	500	Easy to set up; several elements can be determined on same solution but not simultaneously
ICP	$1–3 \times 10^5$	Yes	>2,000	Requires skilled analyst to supervise plus computer; sample in solution
XRF	$1–5 \times 10^5$	Yes	>1,000	Requires skilled analyst to supervise plus computer; solid sample analyzed
INAA	$0.8–20 \times 10^6$	Yes	<3,500	Requires skilled analyst to supervise plus computer; solid or liquid sample analyzed

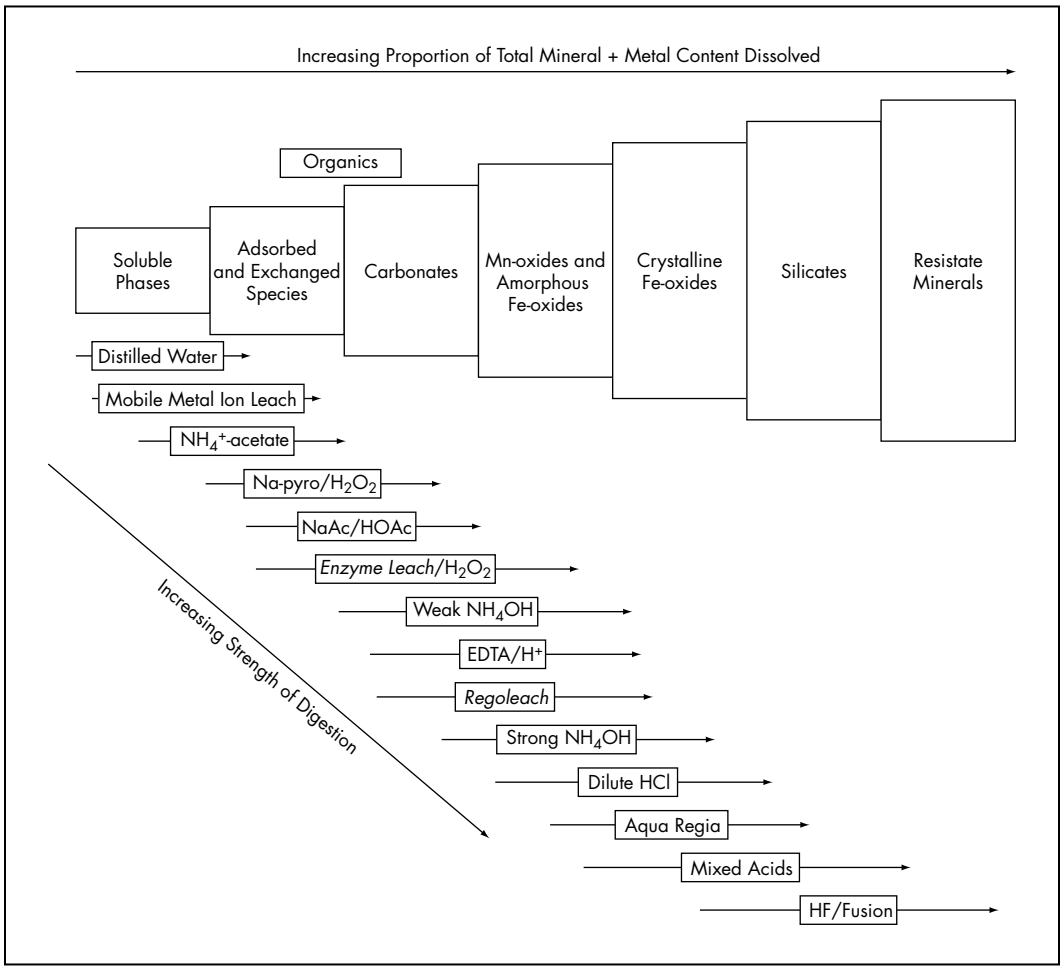

Figure 3.4-3 Relationship between various selective geochemical extractions and the extent of regolith mineral components attacked

Digestion Methods

Sample decomposition presents even greater complexities. The newer analytical methods require that elements of interest be introduced to the instruments in solution. The choice of method to take elements into solution requires careful consideration of the mineralogy of the material (Figure 3.4-3). Strong decompositions of a geochemical sample can be achieved through treatment with hot concentrated acids or by fusion. Some resistant minerals (e.g., chromite) may not be soluble in hot concentrated acids but are broken down by fusion.

The amount of metal extracted by the strong decompositions achieved with nitric, hydrochloric, or perchloric acids or their mixtures is not total and will vary with the mineralogy of the sample. Hydrofluoric acid is the only acid decomposition medium that will dissolve silicate minerals in the typical clastic or lithogeochemical sample. Even with acid mixtures, extraction efficiency will vary with the acid, sample-to-acid ratio, and the duration and temperature of extraction (Fletcher 1981). Of the fusion techniques, lithium metaborate can be effective in attacking resistant minerals and extracting specific elements.

Comparison of the quantities of metals extracted by techniques capable of different degrees of decomposition can be informative. Metals in silicate lattices of rock-forming

minerals commonly constitute the background or threshold level of the geochemical sample material. The mineralization component of an anomalous sample is generally contained in sulfides, iron or manganese oxides, or in adsorbed positions on clay minerals. The metal on the clays, and that contained in the sulfides and hydroxides, is more easily extractable than the background/threshold component contained in the rock-forming minerals. Stronger decompositions, which break down the rock-forming minerals, will effectively dilute the anomalous metal components by releasing the lower concentrations of metal in the background/threshold component. Partial decomposition techniques utilizing cold or weaker acids and other reagents that do not break down the rock-forming silicates enhance the more readily extractable mineralization component, resulting in a much greater contrast between the anomalous and background values in the survey. In numerous geochemical surveys, therefore, the data from partial decompositions, when ratioed against total decompositions, can be much more definitive in target delineation than data from strong or total decompositions. Examples of different decomposition techniques and the corresponding mineral phases digested into solution are shown in Figure 3.4-3.

Sequential extractions are series of digestions of progressively increasing strength, which can be used to selectively remove mineral phases in succession within a sample. This protocol has been used to successfully delineate copper mineral phases in copper deposits and delineate ore types for mineral processing (Parkison and Bhappu 1995).

Gold Analyses

Gold can be analyzed using geochemical or assay methods. For reconnaissance and follow-up programs, gold can be analyzed using *geochemical methods* including aqua regia digestion with an inductively coupled plasma–optical emission spectrometry (ICP-OES) finish. For resource evaluations, gold should be analyzed using traditional *assay methods,* including 30-g fire assay digestion followed by an ICP-OES or AAS finish if the grades are below 2 ppm and by gravimetric finish if grades exceed 2 ppm. This would be true for any element of ore grade concentrations. If the samples are to be analyzed and incorporated into a resource evaluation, the assay methods are the preferred method to determine concentrations for the element(s) of choice in the resource determination. If a nugget effect exists, *metallics* assays should be used to establish grades.

QUALITY CONTROL

In addition to observing the basic principles of orientation, sampling, sample preparation and analysis, adequate assurance of analytical quality, representativity, accuracy, and precision are essential when all data are evaluated. The term *QA/QC* is used in discussing quality control programs. QA indicates quality assurance, which is the plan for implementing a quality control program. Quality control is the analysis and evaluation of the results of the analytical control program.

Quality controls should be introduced at all stages in the geochemical program. Specially prepared certified reference samples (standards) with known metal contents provide essential material for checking the accuracy of an analytical laboratory on a batch basis and also for monitoring analytical drift with time when numerous batches are forwarded to the same laboratory over the life of a project. It is important to know that analytical data from all stages of a project are comparable without any significant bias between analytical batches. The reference materials should be prepared from a similar matrix as the project samples using a vendor accustomed to preparing certified reference materials. Failing that, personnel responsible for monitoring QC programs should acquire certified reference materials (standards) from a reputable source.

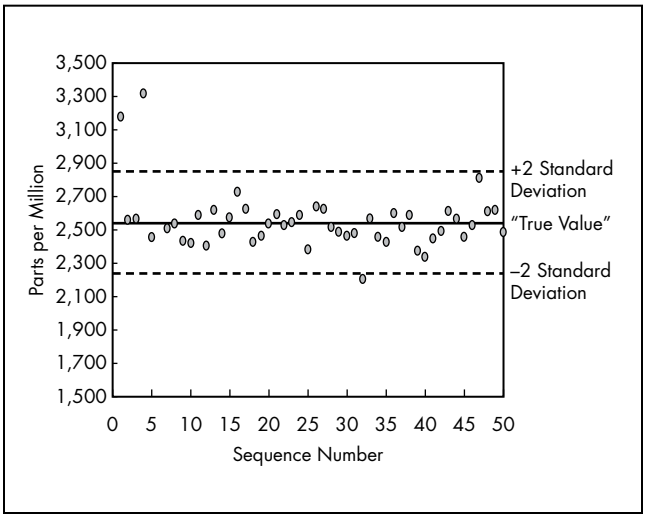

Figure 3.4-4 Standard quality control chart

Duplicate sampling can be used at every level where the sample volume is reduced and then subsampled to measure sample, sample preparation, and analytical reproducibility. Duplicate sampling of the designated material at the same sample site produces two samples (sample duplicates) that will give a measure of the sample reproducibility. Splitting of a subsample after the appropriate sample preparation (preparation or crush duplicates and pulp or analytical duplicates) will provide information on sample preparation reproducibility and analytical variance.

The accepted practice is to include a suite of standard reference samples, as well as sample, preparation, and analytical duplicates, to provide a 10% QC volume within every analytical batch. For each batch, the client should include a higher-grade standard, a lower-grade standard, a coarse blank that needs to undergo sample preparation, a sample duplicate, and an analytical duplicate as a minimum. Where samples are being submitted to determine ore reserves, the frequency of standard insertion should be greater.

Routine scanning of results from these standards and duplicates will give an immediate indication of unsatisfactory accuracy and precision and sample inhomogeneity. A set of pass/fail criteria should be established for the project. Acceptable industry practice recommends that standards should report within ±2 standard deviations of the mean using the mean and standard deviations determined from the reference material (standard) certification process. Figure 3.4-4 illustrates a QC chart for presenting standard analyses. Samples can be arranged by analytical sequence number or date—in this illustration by sequence number—to display accuracy. Lines indicating the certificate value (solid line) and ±2 standard deviations (dashed lines) are also plotted. Those analyses that exceed the +2 standard deviation pass/fail criteria are considered failures, which need to be investigated.

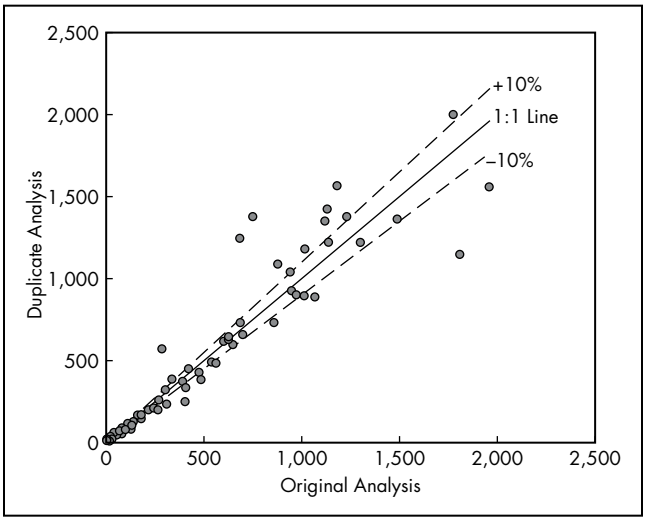

Figure 3.4-5 Duplicates quality control chart

Generally, sample duplicates should be reproducible to within ±20%, preparation duplicates to within ±15%, and analytical duplicates to within ±10%. Figure 3.4-5 illustrates a QC chart used for presenting results of duplicate analyses—in this case, for analytical duplicates with a precision envelope of ±10%. Any control samples exceeding the pass/fail criteria should be reanalyzed and reevaluated.

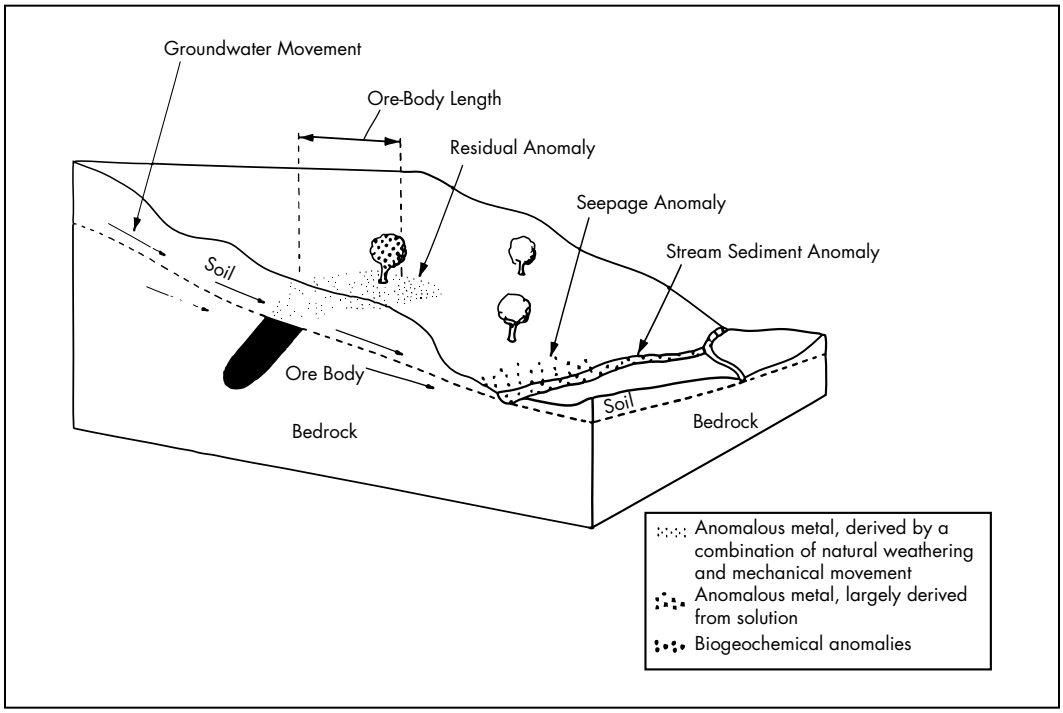
Because it is the objective of the geochemical laboratory to produce good and reliable data and maintain an ongoing, profitable customer relationship, quality control is of concern to both the laboratory and the exploration client. If irregularities are noted, the laboratory should be contacted immediately and the discrepancies discussed. Every reputable laboratory will have its own standard reference samples and other controls and should rerun samples if the quality of its output is questioned. If erratic analytical results are experienced with the duplicate and batch samples but not with the standard reference materials, sample inhomogeneity (*nugget* effect) is indicated. Experienced commercial laboratory personnel can assist with these problems by utilizing special preparation techniques designed to overcome sample inhomogeneity.

INTERPRETATION PRINCIPLES

Geochemical interpretation does not begin only after all samples have been collected, prepared, and analyzed. Interpretive methodologies develop progressively throughout a geochemical project. The patterns observed during the orientation program are directly related to the dispersion characteristics of the metallic elements, the nature of the overburden, and the overall general geochemical environment. Such recognition contributes to the formulation of interpretation procedures, and this understanding directly affects the sampling, sample preparation, and analytical procedures that are selected for the geochemical program.

The cumulative experience of geochemical behavior gained from orientation surveys and case histories in a broad spectrum of environments has enabled geochemists to compile models that represent dispersion behavior in a wide variety of landscape configurations. The simplified example in Figure 3.4-6 illustrates the formation of geochemical anomaly as patterns related to natural factors within the landscape. All dispersion models have certain common features (Hoffman and Thomson 1987):

- A body of mineralization or another source that may mimic mineralization
- The relative distribution of bedrock, overburden, soil, groundwater, surface water, vegetation, and other factors
- Highlighted dispersion pathways related to mineralization and anomaly formation
- Preferential sites or geochemical barriers, where metals concentrate to form anomalies
- Portrayal by each model of dispersion as a series of patterns related to and controlled by a variety of identifiable natural factors



Fundamentally, geochemical interpretation involves the recognition of these patterns, the identification of the factors causing them, and the extrapolation of the patterns back to a mineralized or other source.

The importance of the preferred emphasis on patterns of dispersion rather than the magnitude of the geochemical values in units of parts per million or parts per billion can be illustrated by reference to Figure 3.4-7. Precipitation and accumulation of hydromorphically transported metal in the seepage anomaly area adjacent to the stream channel can invariably result in concentrations markedly higher than in the surface horizons of a residual soil anomaly on a well-drained slope. In such a situation, reference only to the magnitude of values would result in first priority for follow-up being assigned to the seepage anomaly, whereas recognition of the location and shape of the seepage anomaly would immediately indicate its origin and direct the interpretation to the source areas upslope.

In parallel with pattern recognition, geochemical interpretation requires a knowledge of the anomalous, threshold, and background values of the elements of interest in the survey. The fundamental observations leading to the identification of these values come from the orientation survey. In the simplest orientation scenario, background values are not influenced by the presence of mineralization and in Figure 3.4-7 are represented by the relatively homogeneous areas of low values at the extremities of the hypothetical soil traverse. Anomalous values are, in this example, the higher values peaking a short distance downslope of the suboutcropping vein zone. Weaker mineralization, disseminated in the rocks on either side of the vein zone, also gives rise to anomalous but less spectacular values, which are also influenced by the topographic slope.

The upper limit of the background population is referred to as the *threshold*, and it is clear that contouring this data at the threshold level will outline an anomalous pattern related to the mineralization in the bedrock. It is common for background levels to shift with changes in lithology or alteration systems, which also need to be determined during interpretation of the data, such as the lower and the elevated background of the volcanic rocks illustrated in Figure 3.4-7. Introduction of geological and geomorphological complexities such as those shown in Figure 3.4-7 can also produce spurious anomalies, which need to be considered during interpretation.

Conversely, during mineralization processes, some elements may be leached from the host rocks by the mineralizing fluids. In such a situation, a depletion in values below the regional background for the element will cause an *anomalous low* that is geochemically and economically significant.

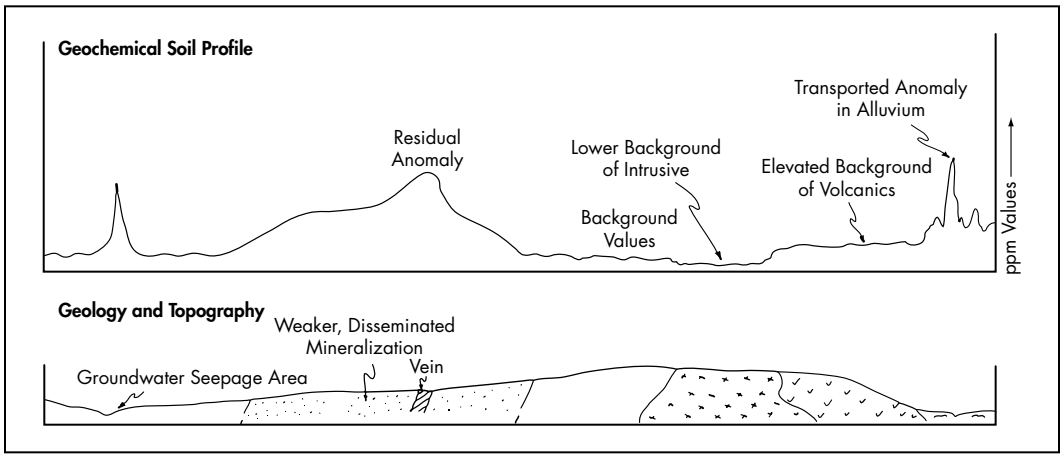
Figure 3.4-6 Simplified model showing formation of geochemical anomalies



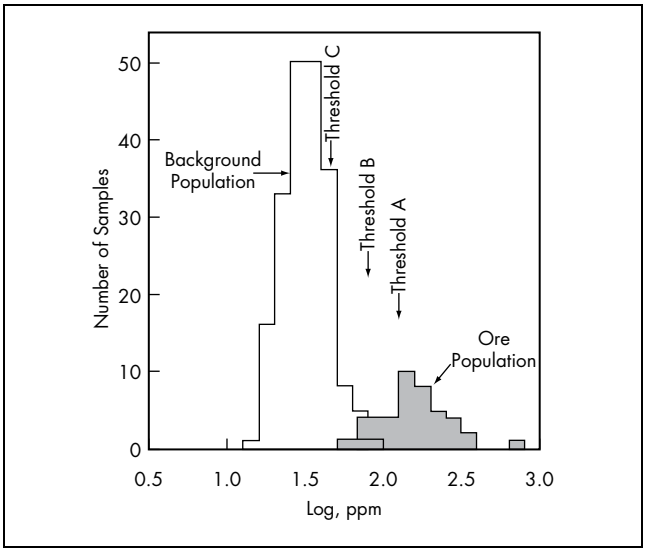


Figure 3.4-7 Hypothetical soil profile illustrating anomalies related to geological and geomorphological complexities

The interpretation of geochemical data and the correct identification of significant anomalies therefore require a fundamental awareness of the geochemical environment as presented in the geochemical model (Figure 3.4-6); a knowledge of the geology, structure, and other characteristics of the type of deposit sought; and an underlying understanding of the geochemical behavior of the elements of interest. This procedure is clearly described and illustrated with numerous actual examples in a workbook format by Levinson et al. (1987).

During the past several decades, geochemists have adapted statistical methods of evaluation to assist in geochemical interpretation. Effective application of statistical methods, whether *univariate* or *multivariate*, requires not only the same full appreciation of the geochemical environment, the geology, and the chemistry of the elements as described in the preceding paragraphs but also an understanding of the statistical technique employed. In addition, this effectiveness is also dependent on correct design, representativity, and quality of the sampling and analytical phases of the program. Given these essential understandings, statistical techniques provide useful and often powerful tools for geochemical data analysis. They can assist in explaining previously unrecognized characteristics in a data set and making significant anomalous patterns more easily recognizable.

A basic assumption applied in the statistical treatment of geochemical data is that the data are unbiased and continuous. Most geochemical data are discrete, but fortunately, in practice these discrete values commonly are sufficiently abundant

Source: Rose et al. 1979.

Figure 3.4-8 Histogram with overlap of values in background and ore populations

and close that they can be assumed to be continuous. A review of basic statistics is beyond the scope of this presentation, but a comprehensive treatment is covered by Howarth (1983).

Univariate statistics allow the geochemist to quickly become familiar with voluminous sets of data. Histograms are used to provide visual information on the total range of values, the existence of one or more populations, and possible thresholds separating background and anomalous values, as illustrated in Figure 3.4-8. Probability plots are used to determine partitioning of populations and the estimation of threshold values, as well as to detect outliers that can bias the initial statistical analyses (Sinclair 1976).

The significance of identifying populations is that individual populations represent geologic or geochemical processes. One can often separate lithology, alteration, and ore signatures by isolating individual populations and plotting these samples spatially on maps with an appropriate scale to identify a given geologic or geochemical process within the survey area.

Multielement chemical analysis of samples is extremely cost-effective, and the resulting data sets provide the opportunity to more specifically characterize features in the data based on their multielement geochemical signature. Correlation analysis is used to determine intraelement relationships, which are examined visually using scatter diagrams showing the relationships between individual element pairs.

Multivariate data analysis is used to investigate relationships between elements and can include other types of exploration parameters based on geological, geophysical, or other data. Based on this information, it is possible to investigate intraelement relationships using a variety of techniques (principal component, factor analysis, cluster analysis, multiple regression, discriminate and characterization analysis) (Howarth 1983). Elements that are highly correlated with one another represent geochemical associations, which indicate geologic or geochemical processes. Plotting coincident anomalies of these highly correlated elements spatially on maps shows where the process is operative in the survey area.

Figure 3.4-9 illustrates the principles discussed previously for a property prospective for sediment-hosted gold mineralization. Figure 3.4-9A displays the anomalous population of gold from a soil grid. Several gold anomalies occur throughout the survey area. Figure 3.4-9B displays an imaged gold geochemical signature (of Au+As+Sb+Hg) as determined by principal component analysis of multielement analyses on soil samples. The geochemical anomaly presented in the images is controlled by fault intersections, which acted as conduits for mineralizing fluids and favorable stratigraphy where mineralization was deposited. The gold geochemical signature (Figure 3.4-9B) indicates the extent and controls of the mineralizing system. The anomalous gold image (Figure 3.4-9A) indicates that the highest population represents gold deposited at structural intersections of northwest- and northeast-trending faults.

OTHER GEOCHEMICAL PROSPECTING TECHNIQUES

The remarkable advances in new technology have provided numerous avenues of research and the development of new methods that can be applied in mineral prospecting. Usually, each new method experiences a breaking-in period during which the technology is applied in a variety of situations, leading to a better understanding of the properties being investigated and refinements in interpretation procedures.

Before these methods are described briefly, it is appropriate to note that certain well-established techniques of prospecting are still as effective today as they were in the earlier days of mining. Such techniques include the skillful use of heavy mineral panning, particularly in the search for gold, platinum, cassiterite, tungsten, barite, and other resistant metals and minerals of high specific gravity. Although undocumented, panning may be responsible for the discovery of more ore and mineral occurrences than any other technique.

The ultraviolet light, or blacklight, method is another established technique with specific application in the search for naturally fluorescent minerals such as scheelite, willemite, and fluorite.

Portable XRF analyzers, initially developed in the 1960s, today use both radioisotope sources and excitation tubes to irradiate the sample material with gamma rays (Glanzman and Closs 2007). The resultant X-ray spectrum is selectively filtered, and specific elements can be measured directly at the outcrop, the drill site, or the underground face in concentrations as little as in the low parts-per-million range for selected elements.

The penetration of the sample surface by X-rays emitted by the radioactive source is limited and generally less than 3 mm (0.1 in.). The accuracy of any determination is dependent, therefore, on the sample surface exposed to the detector. Measurements on unprepared rock surfaces, whether the sample is a rock face, a hand specimen, or piece of drill core, display greater variation and represent, at best, a semiquantitative measurement. To obtain quantitative results, it is necessary to homogenize and mix the sample through grinding and pulverization. The sensitivity of the portable XRF analyzers is generally less than more conventional geochemical or assay techniques, but nevertheless, the positive identification of metals of interest in the field contributes to an increased prospecting effectiveness. The metals that can be identified and quantitatively measured by the portable analyzers include barium, copper, iron, lead, molybdenum, nickel, silver, titanium, tungsten, tin, zinc, and zirconium.

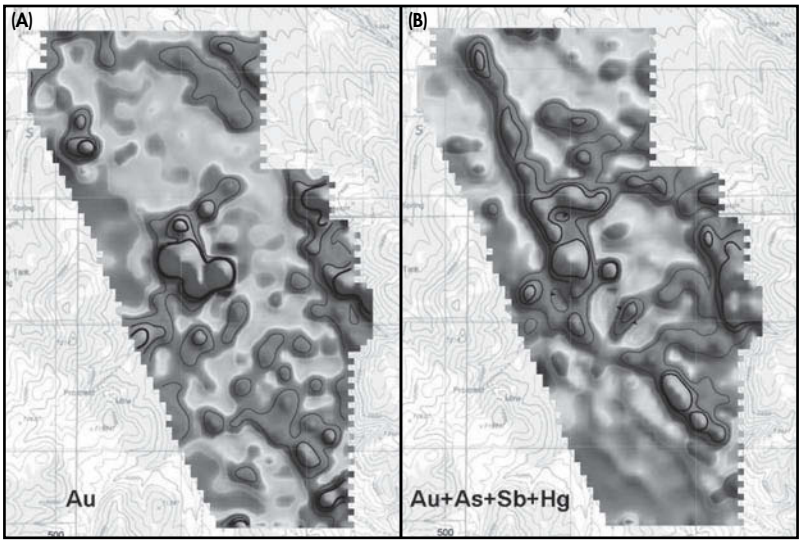

Figure 3.4-9 Contoured images of (A) anomalous gold population and (B) multielement Au+As+Sb+Hg geochemistry association, as determined by principal component analysis

Portable infrared mineral analyzers are field spectrometers that measure infrared reflectance spectra of core and crushed rock samples, which allows the identification of minerals. These instruments have been used extensively by those exploring alteration systems associated with porphyry copper deposits and epithermal gold deposits.

MINE SITE APPLICATIONS OF GEOCHEMISTRY

This section provides an overview of applied geochemistry and highlights specific aspects of geochemistry that impact resource development and mine site responsibilities of geologists and mining engineers.

Sampling

Representative sampling of mine materials is one of the most important and difficult tasks. When done poorly, it generally leads to erratic and noisy data, and poor decisions. The purpose of sampling is to provide a representative estimate from which valid decisions follow. Appropriate sampling starts with geology and encompasses both what and how. It also includes mining considerations—for example, the bench height and block size used to estimate the deposit characteristics for mine planning purposes.

Once the initial sample is obtained, subsampling aspects need to be considered to maintain the representativity of the sample prior to the measurements of properties under consideration (Springett 1984; Pitard 1993). Alternatively, sample separation of the original material collected can be undertaken for specific informational purposes. For example, when a new section of the mine is opened, samples from the new section should be tested to determine if any changes in ore mineralogy or metal content might affect recovery. This process must also follow protocols that ensure the representative aspect of the subsample.

Chemical Analysis

Chemical analysis of samples can provide information about the anticipated commodities to be recovered, elements that may potentially provide by-products (thereby enhancing value), elements that may be penalty metals during processing or be environmental liabilities, and input to overall mine planning and scheduling. Initial investigations of mineralization types should be assessed via high-quality multielement data to identify those elements that may be either value enhancers (depending on deposit type—e.g., silver or cadmium) or potentially penalty constituents (e.g., arsenic, mercury, or cadmium). Analytical methods can be selected to aid in assessment of mine design—for example, fire assay data to obtain estimates of total metal versus cyanide extraction of gold—to address the options of either milling or heap leaching plant design.

Mineralogy, particularly clay mineralogy, is also important to assess. It can affect rock competency and stability, milling and heap leach plant design, and degree of weathering and oxidation in mine and tailings facilities.

Quality Assurance and Quality Control

As noted earlier, QA deals with selecting the appropriate analytical method for the issue at hand. An example is the choice of selecting total analysis of gold via fire assay versus cyanide extractable gold as input to plant type selection. QC of analytical assessment of data is essential in making initial production and development decisions, in construction of the database on which project economics and financing are based, and in reconciliation and ongoing project management. Typically, production analyses are carried out on-site. QC responsibilities often fall on mine staff geologists and mining engineers who use these data on a daily basis. External independent checks should be a routine part of this process. Properly designed QA and QC protocols quantify, monitor, and document how well important variables are known and where corrective action is required.

Deposit Zoning and Mine Sequencing

The distribution of mineralization types in an ore deposit is significant in mine planning. This knowledge allows for consideration of ore blending during mine extraction sequencing to potentially mitigate the negative impact of included penalty metals.

Baseline Studies

Initial exploration and development studies, ongoing assessment during production and reclamation, and monitoring during postproduction to satisfy environmental regulatory requirements are all based on correct assessment of the site before, during, and after mining. A departure point for these studies is the geological and geochemical nature of the material being mined. Geoenvironmental models developed initially by the U.S. Geological Survey (du Bray 1995; Filipek and Plumlee 1999) provide a starting point for identifying potential problems and developing a plan to address these issues at the beginning of a project rather than later when a more expensive retrofit is often required.

Communication

Applied geochemistry has a great deal to offer to the efficient, effective, and profitable execution and ongoing operation of a mine. Many different professional skills are required. Each professional has a responsibility to appreciate the contribution of fellow professionals. The overall management and responsibilities commonly fall to mining engineers. Integrating knowledge and effective communications with fellow professionals will allow each to more efficiently and successfully carry out individual responsibilities.

ACKNOWLEDGMENTS

This chapter in the previous edition of the handbook was originally written by J. Alan Coope, who is now deceased. The current chapter has been restructured and updated by J.A. Jaacks and L.G. Closs. During the preparation of this summary, the authors benefitted considerably from wise and pertinent comments from a great number of people. Their contributions are gratefully acknowledged.

PART 4

Deposit Assessment

CHAPTER 4.1

Geological Data Collection

A.J. (Joe) Erickson Jr. and Jeffrey T. Padgett

PROJECT AND MINING GEOLOGY

Exploration geology focuses on activities that lead to the discovery of a potentially valuable mineral deposit, recognizing that the deposit may develop into a mine. *Project geology* following discovery focuses on the more detailed evaluation of the mineral deposit, up to and including feasibility studies, and evolves into *mining geology*, which is directed toward the planning and operation of the mine. Methods employed for project and mining geology require an engineering discipline to ensure that the data and information provided are appropriate for use in project evaluation and mine production. The most important aspect of the geologist's work is to discover and delineate the mineral deposit and to prepare a detailed definition that describes the deposit's location, size, shape, variability, and grade continuity. This detailed definition ensures accurate and reliable mineral resource and reserve estimates.

Every mineral project or mine is based on a geologic entity—an ore (mineral) deposit. A well-defined mineral deposit and its geologic characteristics are the only aspects of a project that cannot be altered. Mine plans can be modified to exploit the deposit using alternative approaches that often yield similar results. Varied processing methods also are typically available for producing comparable results. Major modifications can be made to other aspects of a project without substantially changing project economics. Regardless of the approach taken, however, all engineering and metallurgical aspects of a mine must be accommodated to the specific location and unique geologic characteristics of the deposit being evaluated.

Geologic data and interpretations form the foundation for both mine evaluation and mine production, providing essential information for estimating resources and reserves and for mine planning and process design or control. Proper geologic work requires a keen awareness of and an ability to anticipate the technical requirements of mining engineers, metallurgists, geotechnical engineers, hydrologists, and other technical specialists who all rely on the geologic data. Geologists are integral members of the project evaluation or production team. Presentation of pertinent data in a usable format and frequent communication of new geologic knowledge to the other technical specialists are integral components of the geological program. Thus, excellence in written and oral communications of geologic information is essential to guide the evaluation process and to achieve production goals.

The ultimate objective of the exploration geologist is to find ore; that of the project geologist is to define the ore; that of the mine geologist is to keep the mine in ore. Project geology sequentially follows exploration, after a discovery of potentially economic mineralization has taken place and evaluation and development proceed. Mining geology begins on commencement of production, though sometimes it has been defined to include project geology. By comparison, project geology combines many elements of both exploration and mining geology through the delineation of mineralization and the estimation of resources and reserves. With the large number of mineral deposits that have been developed in recent decades, project geology has become recognized as a separate discipline requiring special knowledge distinct from either exploration or mining geology. Feasibility studies and development decisions involving large capital outlays require great accuracy in mineral deposit definition and resource and reserve estimation. The greatest single cause of mine failure worldwide is unreliable reserve estimates. In addition to involvement with these aspects of the work, the project or mine geologist is expected to identify various metallurgical ore types as well as potential ground stability and hydrological problems.

Ore reserves are the basic wealth of mining and minerals companies and the principal source of future earnings. A mining company's existence, growth, and survival depend on its ore reserves. It is necessary to periodically review and update resource and reserve estimates to account for changes related to additional ore discovery, mine ore depletion, upgrading or downgrading of resource categories, or fluctuations in economic conditions. During the 1990s, the international mining industry established standardized definitions for the terms *resources* and *reserves* that are generally accepted throughout the world. In 2005, the Society for Mining, Metallurgy, and Exploration

A.J. (Joe) Erickson Jr., Mining Geology Consultant (retired), Anaconda, UPCM Co., AMAX, EXXON Coal & Minerals Co., Houston, Texas, USA
Jeffrey T. Padgett, Consulting Geologist, Monterey Coal Company, Carlinville, Illinois, USA

(SME) established guidelines in *The SME Guide for Reporting Exploration Results, Mineral Resources, and Mineral Reserves*, which it revised to accommodate requirements of the U.S. Securities and Exchange Commission (SME 2007). The Canadian Institute of Mining, Metallurgy and Petroleum (CIM) also adopted its rules in the *Estimation of Mineral Resources and Mineral Reserves Best Practice Guidelines*, which uses the standard international definitions (CIM 2003). The CIM guidelines were subsequently codified and are generally accepted throughout North America, and in many countries elsewhere in the world where North American mining companies are established, to ensure best-practices project management and to comply with National Instrument NI-43-101, *Standards of Disclosure for Mineral Projects* (2005).

Additional support provided by geologists to other specialists in mine evaluation and production includes

- Gathering and assessing geologic data and samples for geotechnical analysis;
- Collecting groundwater data for hydrological investigations;
- Defining the ore body and distinguishing ore grades and types for mine planning and production;
- Exploring for additional ore bodies and other materials in the district;
- Collecting samples for metallurgical testing;
- Evaluating geology and ore potential of sites designated for waste dumps, a mill, leach pads, shops, offices, and associated facilities; and
- Assisting with land, legal, environmental, and permitting studies.

GEOLOGIC DATA COLLECTION AND RECORDING

Mining is a physical endeavor that extracts some valuable resource from the earth. For a mining company to do this effectively, it is essential that company management has as accurate as possible a characterization of resource-zone geometry. A good understanding and clear representation of the shape, size, quality, variability, and limits—the geologic characteristics of the resource zone—are needed at the evaluation, development, and productive stages of a project. This characterization requires a high-quality geologic database so the geologist can provide management with the information needed for critical project decisions.

The financial success of the mining venture is directly related to the accuracy and completeness of the geologic database and the quality and understanding of the characterization that describes a resource zone. The geologist who fails to provide the best geologic characterization based on data available at the time "is delinquent in his or her responsibility for providing management with the best possible information for intelligent decision making" (Barnes 1980).

This chapter deals with basic geologic data collection principles and the need to improve the accuracy of this deposit characterization and modeling by collecting more and better-quality geologic data. General comments are provided first, followed by a review of the type of data needed. Also presented are common symbols and abbreviations typically used in geologic data collection, mapping, and core or cutting logging.

General Comments

Geologic data vary greatly within a deposit and from deposit to deposit. This applies if we are concerned with metallic, coal, or nonmetallic commodities. Specific geologic features differ considerably, and likewise the importance of any specific feature varies from deposit to deposit. Geologists are faced with the task of collecting many types of geologic data and seldom know in advance which features are critical; therefore, they must collect detailed data on all features of potential importance. Data may be collected via surface or underground mapping; drilling; geophysical or geochemical surveys; or specific studies examining such features as structure, rock mechanics properties, specific gravity, alteration effect and distribution, or mineralogy.

The data may be collected using the long-established pencil-and-paper-based method of mapping, posting, and compiling. Data collected via this conventional method can be converted to digital electronic form through the use of computer-aided design (CAD) systems, computer spreadsheets, a geographic information system, and other software in computer-facilitated systems. Alternatively, the development and evolution of computer-based systems and software has enabled collection of data by direct digital means through the use of portable or pen-and-tablet computers hosting the appropriate software. In the latter method, data are recorded electronically on computer screens that host digital base maps (probably topographic maps) or, alternatively, property-specific simple grid sheets that are stored in the computer and commonly linked to Global Positioning System (GPS) methodologies. This allows the user to create electronic geologic maps or drill logs for direct use on computer screens or to provide hard-copy printouts as desired.

Collecting adequate geologic data requires a great deal of time, effort, and expense; and with either data collection methodology, similar geologic skills are required. It is essential that data collection systems be planned in advance so that all data and descriptions are systematically gathered to ensure high quality and completeness. Data collection should employ some standardized system or format to ensure consistency, accuracy, neatness, legibility, objectivity, quantification, and timely completeness. Fact must be discernible from inference. Personnel should be trained in the requirements imposed by either the conventional or computed-assisted or computer-based recording system. It does little good to have two people, biased by personal experience, making data recordings on the same outcrop or sample, the ultimate records suggesting two entirely different geologic units. Quantification of the geologic variable should be done wherever possible. This requires estimation, which—although imprecise—is far superior to vague generalizations such as "much" or "strong amounts" of some particular mineral species.

Accuracy is a recurring theme in the foregoing discussions of any of the numerous types of geologic data normally collected. This accuracy requirement implies that an appropriate QA/QC (quality assurance/quality control) system or algorithms of some type are in place to ensure that the data collected are checked for accuracy and correctly entered into databases, and that automatic backup is available. Not uncommonly, these algorithms are present in data entry programs that check to ensure that drill-hole data are entered sequentially from top to bottom and that transposition errors are minimized. Some data entry programs contain algorithms that identify and flag for review or reduction assay values that appear high or out of normal for the type of deposit under study. Numerous other checks and balances of this nature exist.

Adequate security and restrictions against database access should be in place to prevent corruption of data by inappropriate access or improper data handling or updating. Geologic data—the facts—must remain available and in an unaltered and periodically updated and secure form to ensure that as interpretations are developed, they do not inadvertently become part of "the facts."

Geologic data are extremely important and costly to obtain, and they are essential for proper interpretation, evaluation, and ultimately mining and processing ores from a deposit. The data collection may be a one-chance occurrence due to constraints imposed by mining or distance. A second observation of a critical area may be impossible as the drift or bench may be mined out or the core crushed for assay. If data are collected in the manner just described, they will provide a useful record that is timeless in character.

Ultimately, it is essential that geologic data be converted to some digital format. This conversion will enable their incorporation into the database to support interpretations, control resource and reserve estimation, characterize mineralogical and metallurgical conditions, or clarify other mining-related issues.

Further observations on these topics are made by McKinstry (1948) and Malone (1995). Malone discusses the roles of the geologist and the mine geologist; the importance of comprehensive, standardized mapping and core logging; areas where geologic input is essential in operational support; and positive and less desirable aspects of computer-based logging and mapping systems. He points out that while "computer systems do not reduce the geologic effort and skill required for accurate mapping and logging," they do, however, "provide much greater flexibility and speed in manipulating and using the data." Malone also suggests that

> it is never good for management to try to save money by reducing the quality of geologic mapping. Attempts to constrain mapping to fit an artificially simplified geologic model are always counterproductive in the long run. Accurate geologic mapping, faithfully recording the exposed geology (the geology that is revealed not what is expected), is the best insurance a mine can have against unexpected disasters.

The practice of geology is not easy and requires a great deal of patience, diligence, discipline, and simply hard work. Adequate training and a high level of professionalism are required.

Required Data

Every effort must be made to observe, objectively record, and describe all geologic features that may be of importance in characterizing the size, shape, and variability of the resource and its associated environment under study. Broad categories of data to be collected routinely are location information and data on lithology, mineralogy, assay samples, alteration, and structural and rock competency. As experience is gained in specific areas, deposits, or suites of rocks, the capability to subdivide various units into key subunits typically will be developed. This will enable the geologist to improve description, correlation, projection, and understanding of the genesis of the deposit. More importantly, it will allow for superior resource estimation and will improve recommendations needed for management decision making.

Geologic Data Collection: Key Features

For the following categories of data collection, the keys are careful observation and clear description.

Location Data

Sample, map, mine, or drill location should be recorded on each sheet. This may include geographic data such as state, county, section, township, range, latitude, longitude, coordinates, elevation, mining district, mine, pit, bench, level, working, claim, claim corner, or any and all information that will clearly identify the unique location of the geologic data points. Data cannot be used if the geologist does not know where they came from.

Lithologic Data

Typical data to describe rock, sample, or unit should include color, texture, mineralogical characteristics, lithology, and rock type. Appropriate descriptive modifiers, stratigraphic information if known, top and bottom data, age relationships, and general gross features such as hardness, competency, and bedding characteristics should be included. Subjective generic terms should be avoided unless well established or qualified to distinguish inference from observable facts. Primary sedimentary structure and sedimentologic features (e.g., bedding, laminations, casts, soft-sediment deformation, graded bedding, burrows, bioturbation, and fossil content, as well as banding, foliation, and lineation with appropriate attitudes) should be noted where possible.

Structural Data

Secondary structural features that postdate rock formation should be described. Data should include a clear description and attitudes of joints, fractures, and faults; breccias with quantitative description of selvages, gouge zones, and fragment size; and healed or re-cemented character of breccias. Information related to rock competency such as rock quality designation (RQD) and natural fracture frequency is important. These data are best if collected at the drill site prior to boxing of core, although useful data are frequently accumulated after the core has been boxed. Folds, drag folds, crenulations, lineations, and foliation should be noted. Age relationships, mineralization association, and overall effect on rock mass are important. Weathering and oxidation intensity data are usually critical and commonly structure related but may be included with lithologic data. Quantification of structural data where possible is extremely important as it may play a key role in determining mineability of a deposit.

Alteration Data

Alteration data include nature, mineralogy, intensity, and distribution of features. This should include color, texture, mineralogy, intensity, fracture or vein/veinlet relationship, control, stages, mineralization association, and pervasiveness with respect to the overall effect on rock mass. Weathering and oxidation intensity are important but may be included with lithologic data. Quantification where possible is extremely useful, as is description of age relationships of various alteration features.

Mineralization Data

This category includes nature, intensity, mineralogy, and distribution of the desired resource. It should include primary and secondary classification; estimates of specific and total

quantity of various minerals; intensity; character of veinlets, vein, or disseminations; supergene features; weathering and oxidation intensity; and associated gangue mineralogy. As an example, estimates of total sulfide content, mineral and metal ratios, and gangue mineralogy are of use in deposit description, in support of metallurgical studies and testing, and in waste characterization. Vein age relationships tied to mineralogy, alteration, or lithology provide important data in understanding both zoning and grade estimates and overall deposit genesis. Assay work should include desired ore elements, deleterious elements (arsenic, etc.), and iron or sulfur or both to calculate total sulfide content for the previously mentioned waste characterization. Geologists must clearly understand the methods and the significance of sampling, sample preparation, sampling procedure, and sampling protocol. Individual ore deposits typically host multiple metallurgical ore types based on mineralogy, alteration, or oxidation, most of which are based in geology and therefore require careful geologic description and metallurgical testing to determine distributions, possible process modification, or varying mining sequences to ensure optimum recoveries.

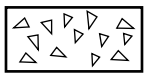
Coal Data

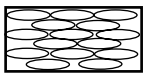
In addition to standard lithologic and structural data, it is important to map or log any and all features that aid in correlation, understanding the distribution of sedimentary facies, and constructing a depositional model of the coal bed(s) and coal-bearing sequence. Detailed descriptions of horizons immediately above and below the roof and floor are critical, as are accurate measurements of depths and thickness of all units associated with the coal. Some key features include abundance and type of marine or freshwater fossils, slickenside in roof or floor rocks, the presence of roots representing old soil horizons, pyrite bands, nodules or streaks, siderite or ironstone nodules, and plant debris. Description of individual coal beds, either the banded or nonbanded groups, requires careful measurement or estimates of the banded lithotypes, vitrain, clarain, durain, and fusain content (Ward 1984). A more practical system (Schopf 1960) describes the thickness and amount or concentration of vitrain and fusain bands in a matrix of atrital coal. The latter is described by five luster levels that range from bright to dull. Description of nonbanded sapropelic coals and boghead and cannel end members relies on identification of these massive, faintly banded, fine-grained accumulations of algae or spores and usually requires a microscope for adequate description. The nature of cleats, partings, bone, and shale layers needs description and careful thickness measurements to separate net from gross coal-bed thicknesses. Coal-bed description, while straightforward, requires some supervised training to ensure adequate data recording.

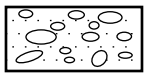
Other Features

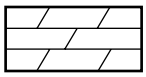
Other features that may supply extremely important information with direct bearings on mining and/or metallurgy should be recorded. This may be reasonably objective (fracture frequency, rock quality determination measurements, longest and shortest unbroken core recovered in a run) or more subjective (an overall estimate of rock strength, friability, or competency). Total sulfide content or assay is extremely important for waste characterization as well as metallurgical process development. Metallurgically significant features such as hardness, which affects grindability; grain size, which controls grinding for particle liberation; or oxidation intensity should be noted—as well as mineral species and alteration mineralogy, which affects flotation recoveries. As an example, supergene copper mineralization coatings on sphalerite provides a challenging metallurgical problem, as does activated pyrite due to similar chalcocite coatings on pyrite beneath more thorough supergene copper enrichment zones. Metallurgical personnel need to be made aware of the presence of these features. Numerous other examples could be cited. Added testing is almost always needed here; however, geologic data collections should indicate these and other potential problem areas requiring specialized study.

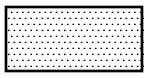
SYMBOLS

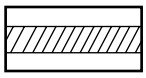


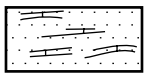


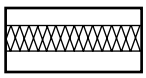


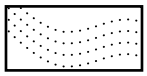


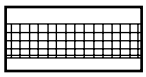


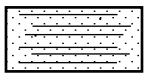


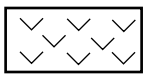


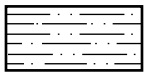


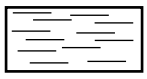


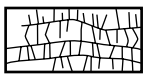


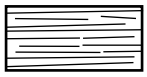


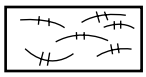


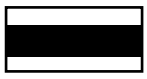


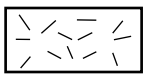


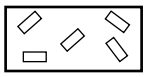


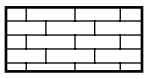


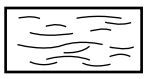


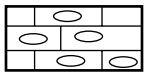


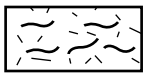


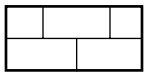


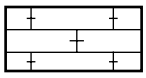


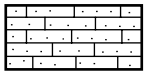


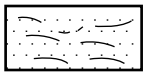


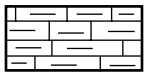


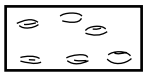








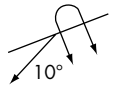


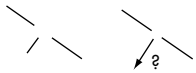


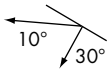
Geologic representation, geologic mapping, core logging, data compilation, and interpretation are heavily dependent on visual presentation as "geologists think and communicate best in pictures. The basis of almost all geologic work is the making of maps, plans, sections and the like. The graphical form is the most efficient way of displaying and explaining geological observations and ideas" (Dixon 1979). Standardization in the way geologic data are collected, recorded, or displayed is desirable as the concepts being portrayed are frequently difficult, and varied symbolism may cause confusion. A simple line or symbol on a map is a powerful decision-influencing tool and may have innumerable connotations, and it therefore should be presented in a clear, self-explanatory way. Symbol standardization, a very difficult objective, helps in obtaining the desired clarity.

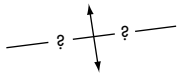
There is no single standardized set of geologic and mine-related symbols or abbreviations in use, but the symbols compiled in Table 4.1-1 are commonly used in the United States and elsewhere. They were compiled from works by Peters (1987), Compton (1985), Dietrich et al. (1982), Berkman and Ryall (1982), Reedman (1979), Lahee (1952), and McKinstry (1948). Additionally, the first of the excellent five-volume Geological Society of London Handbook Series by Barnes (1981) is very useful and practical. Blackadar et al. (1968) illustrate symbols used in Canada, and several chapters in Finkl (1988) cover symbology and other topics on field methods.

Table 4.1-1 is not all-inclusive, but it includes many commonly used symbols. Simplicity, clarity during reproduction, and practicality should be the guides.









Some mapping systems, such as the Anaconda system developed in the early 1900s in Butte, Montana, United States (Brimhall et al. 2006), use black for culture, lithology, and rock data; blue for structure; and red for mineralization. This practice is convenient, useful, and readily understood. These authors also discuss the expansion of this three-color system to 10 colors to record vein types, ore, and alterations minerals to better record geologic data during the evolving study and mapping of additional ore deposits. Still other systems collect all data in black, which is quite useful for modern copying technology, although color copying equipment is readily available in most areas. Modern computers, printers, plotters, and software typically offer an endless array of colors. Any system should be well planned in advance, simple to learn and use, consistent, well documented, and should aid, not hinder, data collection and understanding.

Table 4.1-1 Common mapping symbols

Lithological Symbols			
Breccias		Chert	
Conglomerate		Dolomite	
Sandstone, bedded		Gypsum	
Sandstone, calcareous		Ahydrite	
Sandstone, crossbedded		Salt	
Sandstone, shaly		Volcanics	
Siltstone		Tuffs, breccias	
Mudstone-claystone		Flows, basic	
Shale		Flows, other	
Coal		Granite	
Calcareous shale		Porphyritic	
Limestone, bedded		Schists	
Limestone, cherty		Gneiss	
Limestone, massive		Marble	
Limestone, sandy		Quartzite	
Limestone, shaly		Serpentine

Table 4.1-1 Common mapping symbols (continued)

Culture Symbols, Surface or Underground (continued)			
Mine (abandon inverted)		Lagging, cribbing	
Sand, gravel (abandon inverted)		Stope	
Drill hole, no., (inclination)	MH31 –90°	Drill hole, no., inclination	MH31 –17°
Drill hole, no., elevation, depth	2116′ MH31 TD397′	Survey point, no., elevation at back, distance to sill	1571 –9.3

*Bedding dips show options with and without double arrowheads. The arrowhead prevents map confusion if the blocky limestone symbol is used. It is advisable to use half arrow on veins and faults as it allows clear symbol identification and shows relationships where considerable detail is involved.

ABBREVIATIONS

The extensive observations and descriptions essential in geologic work are commonly facilitated by the use of abbreviations. Standardization of these abbreviations is desirable because logs and maps may be used by numerous individuals, and they therefore require some basic commonality. Additionally, a long lag time may be involved between data recording and actual use. Abbreviations as shown in Table 4.1-2, largely abridged from Chace (1956), are fairly standard and commonly used in the United States and other English-speaking nations. Other lists of abbreviations appear in Finkl (1988), Compton (1985), Berkman and Ryall (1982), and Blackadar et al. (1968). Quantification of these abbreviations is achieved by the addition of superscripts or subscripts, as py^2 or py 2-10, which indicate estimates of 2% or 2% to 10% pyrite content in a rock. The abbreviations cp_1 and py_2 indicate 1% and 2% chalcopyrite and pyrite, respectively, whereas cp:py = 1:2 or cp1:py2 indicates a ratio of chalcopyrite to pyrite of 1 to 2. Combinations are endless. The only requirements are that the estimate be reasonable and that an explanation or legend describing the notation accompany each log, map, or project.

GEOLOGIC MAPPING

Surface or underground mapping requires uniformity and standardization as well as systematic, unbiased, and objective data collection and recording. Note-taking, abbreviation, and symbology are best if they employ a company-wide established methodology that reflects common initial training of personnel involved. In addition to being consistent with logging, to be discussed in the following section, mapping data must be accurately located and tied to known locations that preferably have been surveyed conventionally or using survey-quality GPS.

In general, regardless of the resource type, geologic mapping is for the purpose of providing data on lithology, alteration, mineralization, structure, and ground conditions, as well as analytical data (i.e., assays or coal quality) for resource evaluation. The following eight-item list summarizes the typical requirements, considerations, and steps in the mapping process. The list illustrates how one might proceed in what is essentially an exercise in detailed mineral and rock identification, characterization, and record keeping, which will be discussed in more detail later in this chapter. These steps assume a basic knowledge and understanding of the symbols and abbreviations generally used in geologic data collection.

1. Conduct a pre-mapping review based on general geologic knowledge of the area and deposit type under investigation. This is to determine the purpose of the mapping, to identify geologic parameters of probable importance identified according to guidance in the "Geologic Data Collection: Key Features" section in this chapter to consider the scale(s) to be used, and to determine the local physical geography of the area under investigation.
2. Secure base maps, air photos, grid sheets, survey information, claim locations and ownership, survey points, and geographic information system (GIS) data. Secure approval for property access as appropriate.
3. Secure typical items useful during the mapping process, such as mapping vest, compass, tapes, hand lens, and so on (the "Core/Cutting Logging Process" section lists other items), for conventional work or in support of observation entry into portable laptop computers.
4. Select recording bases as available, such as air photos or topographic maps; data may be recorded directly on the base map or on acetate overlays attached to the base. If no base maps are available, notes on observations of geologic data can be taken on simple grid sheets and locations can be determined through the use of compass and tape or GIS data. Cut selected recording base maps, air photos, or grid sheets to the size that is appropriate for the aluminum sheet holder to be used.
5. Make one or more visit(s) to the field location (i.e., deposit, exploration/evaluation area, or mine site) to make observations and collect and record geologic data with appropriate symbols and abbreviations on selected base maps/air photos or grid sheet. Alternatively, use laptop computers to record geologic data directly and construct maps using mapping software.

6. As mapping proceeds, it is important to carefully note and record the location of important cultural features such as roads, buildings, key topographic features, or survey points for later data compilation and development of the geologic map. If surface or underground mine workings are involved, secure ground outlines as available, annotated with known survey point locations if possible.
7. *Unless the geologist is extremely experienced, it is inadvisable to enter old mine workings alone.*
8. Compile note sheet data on larger sheets to build the geologic map of the project.

Historically, compass and tape(s) commonly have been used to construct ground outlines for data recording, to locate outcrops, and to tie in culture or survey control; and if used

carefully, they will provide sufficient accuracy. This is a fairly straightforward procedure and consists of stretching a cloth measuring tape or tapes from or between known points and determining the bearing of the tape with a compass. This tape line is then plotted to scale in its proper orientation on the field note sheet, and tick marks are posted and identified each 3 m (10 ft) along the bearing of the tape line. Following this, offset measurements are taken at right angles to the cloth tape from the tape to the edge of the drift or pit bench. A small pocket tape is used to take these offset measurements at 3-m (10-ft) intervals along the cloth tape. Points corresponding to these offsets are then plotted on the field note sheet and connected, and an outline of the drift or edge of the pit bench is thus created for geologic note-taking. Figure 4.1-1 illustrates the methodology of developing a ground outline and shows some simple geologic notes. Location, scale, date, geologist, and orientation are clearly indicated on each example.

In typical mine-related work, geologic field note-taking is commonly done on a relatively large scale, such as 1:240 or 1:600 (1 in. = 20 ft or 1 in. = 50 ft). Smaller scales—1:1,200 and 1:2,400 (1 in. = 100 ft and 1 in. = 200 ft)—are also used, generally to collect data on overall resource setting or to simplify more detailed work in the mine itself. For regional work, scales of 1:12,000 or 1:24,000 (1 in. = 1,000 ft or 1 in. = 2,000 ft) may be appropriate. Some variability is necessary, and the actual mapping scale used depends on needs of specific projects. Advance planning here is useful. Although detailed 1:240 (1 in. = 20 ft) mapping in a vein or massive sulfide deposit is desirable, attempting to get the same detail in a 13.5-Mt/a (15-million-tons/yr) open-cut coal mine or a 1.8-Mt/a (2-million-tons/yr) underground coal operation would be inappropriate.

Mapping techniques are described in a number of good references, which vary somewhat in perspective. Proper supervised training is desirable. Peters (1987) provides considerable detail in a good description of general surface, surface open-pit, and underground work. He describes an outcrop mapping system in which three acetate overlays (shown in modified form in Figure 4.1-2A) are superimposed over a base map or air photo and used to take notes describing geology, mineralization, and alteration for each outcrop. The field manual by Compton (1985) provides good coverage of geologic mapping techniques, as do earlier textbooks by McKinstry (1948) or Forrester (1946), both of which remain excellent sources on techniques in mine mapping.

The geologic data may be collected conventionally using the long-established pencil-and-paper-based mapping and compilation system or methodology. This system can be augmented with the use of digitizers or other computer-facilitated electronic databases to prepare maps, sections, or other displays for use.

Alternatively, because of the rapid development of computers, enlarged electronic storage capacity, and software, the data may be collected by direct digital means using portable or pen-and-tablet computers. With these devices, it is possible to record data directly on computer screens in the form of spreadsheets, commercially available digital base maps visible on the screen, or perhaps property- or company-specific custom grid sheets. The geologic data, contacts, attitudes, mineralogy, structure, and so on, are posted directly on the screen and captured digitally (XYZ coordinates) through the software and saved in the storage medium of the computer. The stored data are available for later use as desired in plan map or cross-section construction, three-dimensional (3-D) manipulation and study, geologic or resource model development, resource estimation, or other needs.

Walker and Black (2000) review the development of a computer-based field mapping program at a midwestern university. They note that computer use is increasing in most aspects of geologic work, that the location-dependent nature of geologic data corresponds to both the importance and the limitations of digital information, that direct digital recording may save time, and that digital topographic data are generally readily available. Additionally they supply some key references, identify hardware and software issues and some products, and conclude that in addition to teaching conventional field skills they will continue to use computers in field courses at the university.

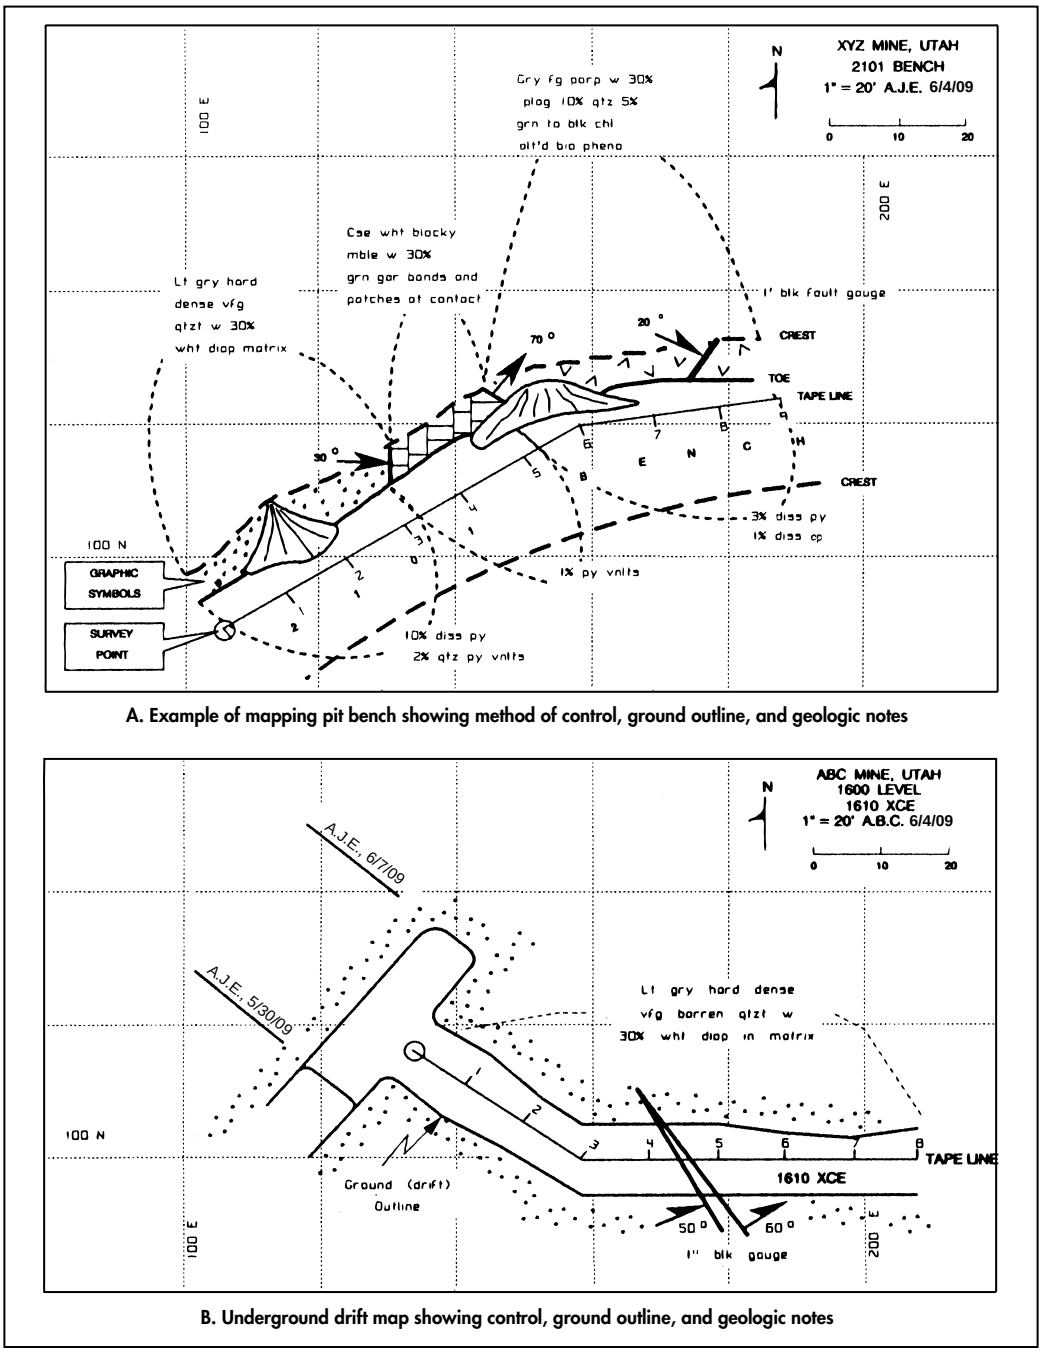
Another technological development is the portable X-ray analyzer, which can provide useful analytical data to incorporate into geologic mapping.

Brimhall et al. (2006) provide a thoughtful review of the fundamental importance of geologic mapping and some history of the development and modification of the Anaconda system of geologic mapping. The system was initially developed in the early 1900s at Butte, Montana, and underwent subsequent modifications and expansion (to 10 colors and the use of specific symbols and plotting positions on the field sheets) in Chile in South America, Nevada in the United States, and elsewhere. Einaudi (1997) discusses this mapping technique in an excellent, well-illustrated, unpublished Stanford University paper. Geologists interested in ore deposit mapping may wish to secure a copy of this paper. Additionally, an excellent paper by Proffett (2003) demonstrates and documents the results that can be expected through the use of careful detailed field mapping and core logging or relogging (discussed and referenced in Chapter 4.2 of this handbook) techniques that serve as the basis for the geologic evaluation of the Bajo de la Alumbrera copper–gold deposit in Argentina.

In addition to fully describing and illustrating the use of this paper-based mapping system, Brimhall et al. (2006) also discuss digital mapping based on pen-and-tablet portable computers as well as the GIS revolution in mapping and data manipulation with CAD systems. Importantly, both conventional and computer-based digital methodologies require the same basic geologic skills, and both have their advantages and disadvantages (Malone 1995). Adequate training is needed for either methodology.

Geologic mapping in underground coal mines can greatly increase the geologic understanding, productivity, and ultimately the profitability of a mine. Krausse et al. (1979a, 1979b) provide excellent examples of underground mine mapping methodology and the effect of lithology and structural features on mining. Their work and that of Ledvina (1986) further describe the increasing use of geologic mapping in underground coal mines and stress the importance of roof rock characterization. Moebs and Stateham (1984) summarize contract studies investigating the relationship between geologic factors and roof stability in coal mines. The work is well referenced and clearly identifies mine and core mappable geologic features that control roof stability.

The Coal Mine Roof Rating (CMRR) system developed by the National Institute for Occupational Safety and Health (NIOSH; Anon. 2008) incorporates rock composition, structural defects, and thickness into a rating index that ranges from 1 to 100. The system is increasingly being used as a basis



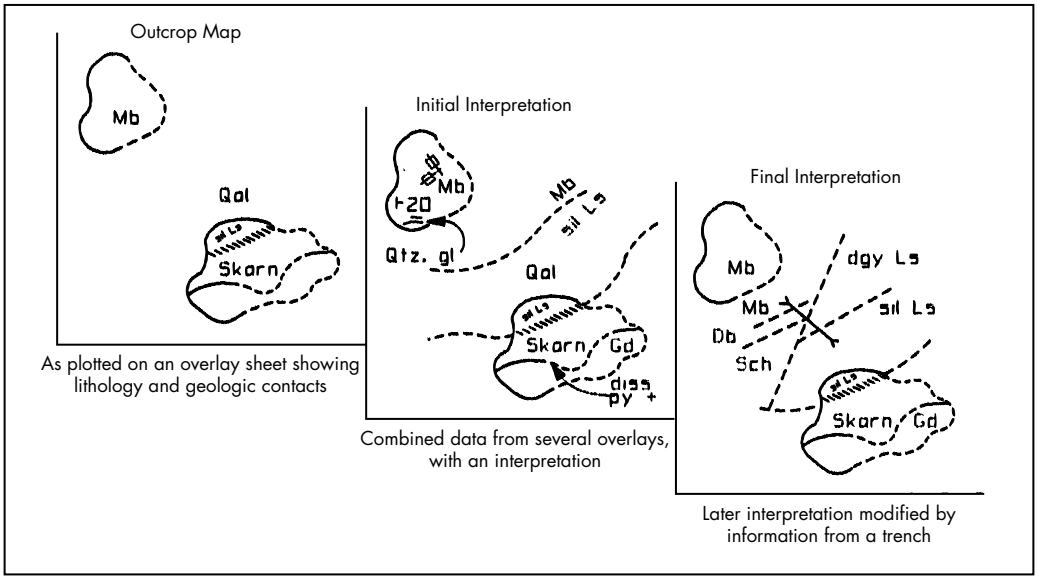


Figure 4.1-1 Simple geologic field note sheet

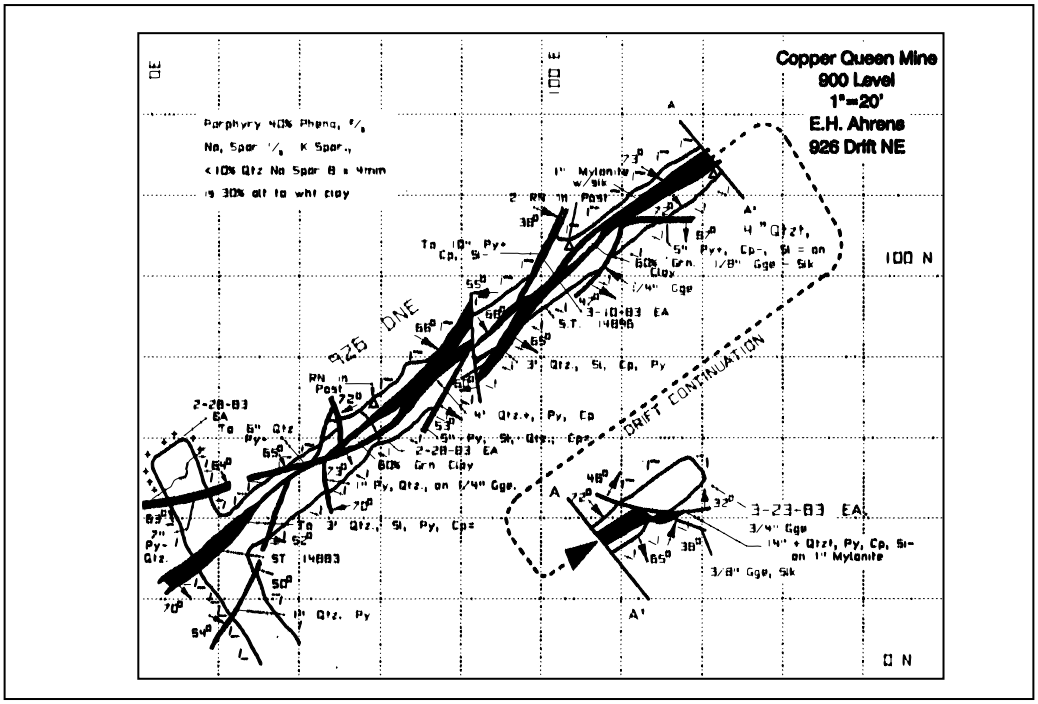
for mine design applications. The current version is available as a download file from the NIOSH Web site.



Coal geologic work tends to depend heavily on computerized geologic data handling with its extensive reliance on structure contour, isopachs, numerous coal quality maps, and other geology-based elements that influence operations.

Early papers by Linforth (1914, 1933), McLaughlin (1933), McLaughlin and Sales (1933), and Sales (1941) clearly show techniques and discuss the importance of careful geologic mapping.

Information and comments on specific software packages useful for geologic work have been outlined by several authors in the *AAPG Computer Applications in Geology, No. 4* (Gibbs 2000) and in *Mining Magazine* (Anon. 2006). The packages vary from simple one-purpose programs to fully integrated production programs, commonly with powerful 3-D capability, for geologic data gathering, analysis, resource estimation, feasibility studies, and mine planning. Software programs for computer assistance in data gathering and analysis are readily available in geochemistry, geologic modeling, geology, geophysics, geotechnical areas, hydrology, resource modeling, and resource estimation. Properly used, they can provide important, timely support and allow geologists to consider alternate options or respond to the effects of changes

in mine operational parameters. Examples are changes in cut-off grade, reserve estimation, production planning, and others. Additionally, the Internet site www.miningsoftware.com (Gibbs Associates 2008) provides excellent coverage and descriptions of various geologic software programs.

The following sections on surface mapping, pit mapping, and underground mapping review additional important points to consider.

Surface Mapping: General Points

The following comments and recommendations are offered for surface mapping:

- Use aluminum sheet holders for 216 × 279 mm (8½ × 11 in.) gridded sheets, topographic bases, or air photo base maps, which are superior to bound notebooks, as they allow sheet removal and filing, and reduce the chance of data loss.

CHAPTER 4.2

Geologic Interpretation, Modeling, and Representation

A.J. (Joe) Erickson Jr.

INTRODUCTION

In Chapter 4.1, discussion centered on the importance of clear, complete, accurate, detailed, and systematic collection of varied and descriptive geologic data, and methodologies to accomplish this goal were suggested. Narrative guidelines and narrative-graphical formats were provided to ensure the desired standardization in the acquisition of geologic information. The area of activity in that chapter is referred to as the data collection step in the three-step geologic information processing effort required in resource evaluation.

This chapter builds on Chapter 4.1 in discussing the purpose and recommending methodology for carrying out the remaining two steps: data analysis and interpretation. All three of these steps are required to discharge the critical responsibility of resource characterization for quantification, evaluation, mine planning, and extraction. *Resource characterization* is defined as the determination of the shape, size, quality, quantity, and variability of the geologic entity. Equally importantly, resource characterization determines the limits of various parameters or features of the geologic entity. Correct characterization has both operational and exploration implications, as it provides the information for synthesis of often subtle features into an accurate, predictive description of the resource environment. This description—the geologic model—can then be used either in support of mining operations or in the ongoing search for additional reserves.

GEOLOGIC INTERPRETATION

Thompson (1992) has stressed the importance of the development of computers on geologic data integration and modeling, noting the great increase in and accessibility to computer power and software for modeling varied data and the speed with which two-dimensional and three-dimensional (3-D) data analysis may now take place. He notes that "complex data sets can be integrated directly with ore deposit models based on empirical features…and supported by genetic or process concepts." There is improved ability to visualize multiple data sets graphically and statistically. He also notes a trend toward computer use in all areas of economic geology and warns of possible abuse if computers are seen as magic black boxes requiring no understanding of fundamentals on the part of the researcher. Inappropriate analysis, prediction, and estimation may be the result. To be successful, computer use and analysis must be based on careful geologic data gathering, mapping, and logging—all of which are discussed in Chapter 4.1 of this handbook.

Mason (1993) points out that technical failures in mine development have been frequent and attributes this to the "pronounced decline of economic geology as a field-mine based discipline" and to the "significant advance in computing technology" that has made reserve calculation "painless [and] frequently inaccurate." After recognizing the style and type of mineralization, and after drilling and sampling to allow the mineralized zone to be evaluated and defined, the most important parameters for a geologic database to address include "boundaries to mineralization and ore, continuity of mineralization and ore, classification of mineralization and ore types, and ore quality (grade)" (Mason 1993). To this can be added mineral variability with respect to metallurgical processes and mining conditions.

Continuity relates directly to the type of deposit (Mason 1993) and hence to the understanding of the appropriate geologic model. Knowledge of structural complications is critical. Classification of mineralization as to deposit type and ore type is important for resource/reserve estimation, and both conventional and geostatistical estimates require careful geologic evaluation and awareness of ore types.

Like Journel (1988), Mason (1993) stresses that the need has never been greater for more and improved "geologic control" to eliminate "computer cover-up [caused by] inadequate data bases and interpretation of such data bases." In both estimation and production of ore reserves, says Mason, 3-D modeling has put "greater demands on the appropriateness and accuracy of geological data bases."

GEOLOGIC MODELING

Current terminology refers to resource characterization as the geologic model, or perhaps the 3-D geologic model, whereas previously the model concept was conveyed using the approximately synonymous term *zoning patterns*. The model consists

A.J. (Joe) Erickson Jr., Mining Geology Consultant (retired), Anaconda, UPCM Co., AMAX, EXXON Coal & Minerals Co., Houston, Texas, USA

of a compilation of all geologic data, observations, and studies available at the time, assembled to display and explain the observations and limits from an empirical and/or genetic point of view. The model may be extremely simple or highly complex depending on the nature of the resource, the data available, or the degree of sophistication in studies of the resource.

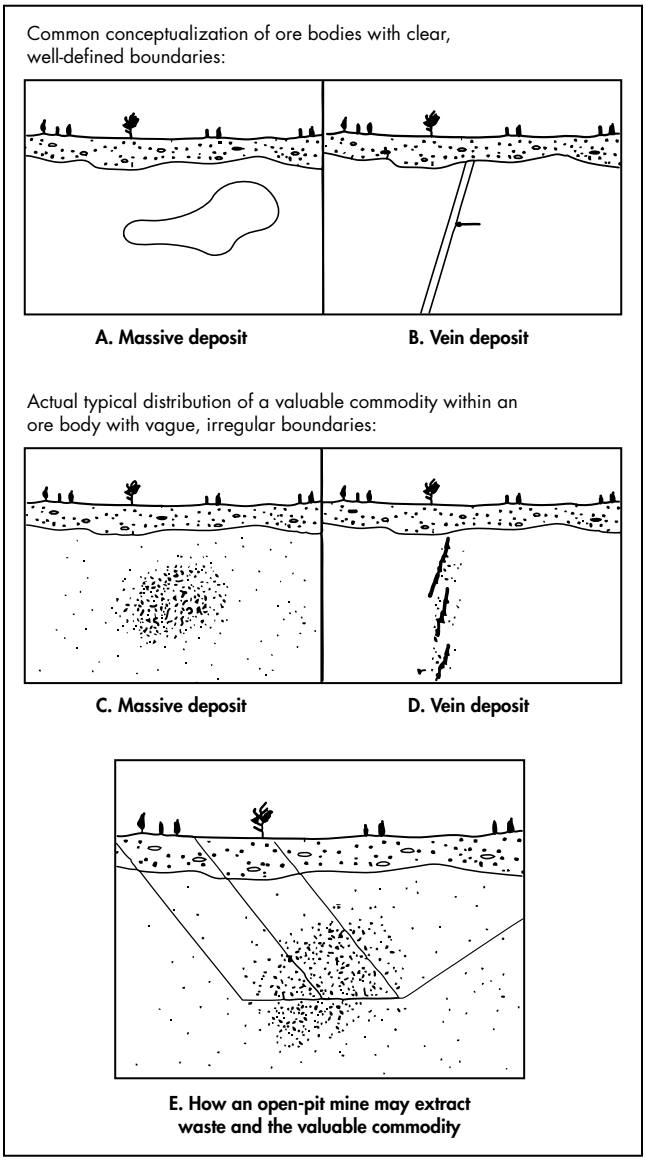
One may compare a volcanogenic massive sulfide (VMS) deposit model in simpler form (Franklin et al. 1981) with a more complex genetic model (Franklin et al. 2005). Both are useful and essentially correct as they are based on information, data, and understanding available at the time. The empirical model represents the compilation and integration of numerous types of chemical, mineralogical, structural, and—not uncommonly—numerically quantifiable zoning studies. The conceptual or genetic model attempts to explain the distribution and origin of these features in a useful and meaningful way. Development of a geologic model forces the geologist to think about and explain the rock, mineral, alteration, and other relationships described in the mapping and logging process; to develop an understanding of their relationships; and to provide a predictive tool in support of ongoing exploration and production. The geologic model is frequently incomplete and, as discussed by Peters (1984), probably will change or be revised as additional geologic data are acquired.

Eckstrand (1984), Cox and Singer (1986), Roberts and Sheahan (1988), and references in Erickson (1992) synthesize geologic data from a broad spectrum of mineral deposits into a number of both empirical and genetic models. Stoeser and Heran (2000) provide a CD version of more recent extensive work by the U.S. Geological Survey on mineral deposit models.

Hutchinson and Grauch (1991) provide historical perspective on the development of genetic concepts for VMS and other deposits in their publication on varied deposit types, whereas Keays et al. (1989) review gold in VMS and other deposit types. Large (1992) provides perspective on approximately 30 Australian VMS deposits, including illustrations that show styles of VMS deposits and, importantly, the effect of deformation on interpreted seafloor morphology on several deposits. LaBerge (1996) provides data about several Wisconsin (United States) VMS deposits—Ladysmith, Lynn, Crandon, and others. Two additional important references are Barrie and Hannington (1999) on modern and ancient settings and Hannington and Barrie (1999), the definitive volume on the Kidd Creek VMS deposit in Canada.

Key references on porphyry-related deposits and models include Lowell and Guilbert (1970), one of the best-known works; Gustafson and Hunt (1975), describing detailed mapping, vein relationships, geology, and a genetic model for El Salvador, Chile; Titley (1982) on southwestern United States porphyry deposit studies and descriptions; Nielsen (1984), discussing the evolution of porphyry models, identifying variation, and discussing some associated problems; Pierce and Bolm (1995) on the American cordillera deposits; and Camus et al. (1996) on new Andean discoveries and studies. Proffett (2003) provides an excellent study regarding the mapping, description, analysis, and emplacement genesis of the Argentinean Bajo de la Alumbrera deposit, including the first in the large-format *Economic Geology* Map Series. Hedenquist et al. (2005) reviews porphyry and other deposit types and includes papers on environments, processes, and metallogeny. Sillitoe (2010), in an invited general overview–summary paper on giant porphyry copper systems, provides an excellent field-oriented review paper on these deposits. Key geologic features are discussed from a regional, district, and deposit-scale perspective. Sillitoe discusses regional and district characteristics; stresses the multiple-occurring nature of these deposits, which are commonly found in "clusters" or in "alignments"; the variability in deposit "footprint"; deposit-scale features; and zoning. He presents excellent illustrations of empirical and genetic models of these intrusion-centered systems.

Useful resources on gold deposit models include Macdonald (1986) and Hausen et al. (1990). The latter provides a review of deposit geology and contains several papers that discuss metallurgical process problems associated with these deposits. Skinner (1981) contains good papers on gold deposits, and Corbett and Leach (1998) describe the different styles of gold–copper deposits in the southwest Pacific Rim countries.



Two textbooks, *Geology of Ore Deposits* (Guilbert and Park 1986) and *Exploration and Mining Geology* (Peters 1987) remain extremely useful references.

Work by Dapples and Hopkins (1969), Kaiser et al. (1980), Ayers (1986), and Thomas (2002), as well as references cited in Erickson (1992), provide excellent descriptions of coal deposits and the associated geologic environments and processes. Models described in all of these references provide a state-of-the-art picture of the products and of geologic processes and events. They are extremely useful for broadscale exploration activity or more tightly controlled resource evaluation and operational support work. These useful volumes are compilations from and syntheses of numerous varied studies of long-established mining districts or regions. Typically these are areas where extensive exploration, development, and operational geologic programs have provided large factual geologic databases and extensive material for laboratory studies. Although each district or region may exhibit specific variations, the volumes summarize observations and studies from many deposits of a similar nature. Hence they provide a guide to the commonly observed typical features to be expected in a particular deposit type—the geologic model. They are extremely important and useful guides for interpreting geologic observations while work is being conducted on projects, when new district-specific models are being constructed, and as aids during ongoing exploration or development programs.

Models should attempt to explain all observable facts. Geologic data should not be ignored or discarded if they do not fit the perceived model. The lack of agreement between facts and theory may indicate incorrect data, incorrect models, or insufficient data, or all three, and this lack identifies the need for further investigation.

The fundamental problem associated with resource characterization for evaluation and estimation is in taking a very limited amount of geologic data, correctly analyzing and interpreting the data, extending these interpretations into unknown areas, and then making summary quality, quantity, and limit statements about the area. In simplest terms, resource characterization answers these questions: Where is the resource (ore)? What are its limits (shape)? What is the quality (grade)? What is the nature of the associated environment?

It would be easier to answer these questions if the boundaries were sharp, but that is the case in only a few specific types of deposits. More often one is dealing with an irregular, poorly constrained distribution of values of a commodity (Gentry and O'Neil 1984). Figure 4.2-1 is a lucid and simple

Source: Adapted from Gentry and O'Neil 1984.

Figure 4.2-1 Ore-body representation

explanation of problems related to resource estimation, external and internal dilution, and limit or edge problems that plague many operations.

Sound, careful geologic data analysis, review, and verification during model construction go a long way toward solving the previously described fundamental geologic problems in resource characterization. The geologic data and interpretation (the model) comprise the foundation of the evaluation process and are essential for resource estimation and extraction (Ranta et al. 1984). As Call (1979) indicates in his discussion of statistical data handling in development drilling programs, "the validity of any analytical model must ultimately be determined by geologic interpretation." Sound geologic judgment, discipline, and hard work are needed to deduce the detailed geologic setting from drill holes, mapping, and sampling programs and lead to the construction and understanding of the geologic model and its variations. The model is based on numerous varied geologic studies; assuming that all other factors (sampling, hole or data locations, analysis, assays, or others) are correct, the model ensures the best possible reliable resource estimate and an understanding of ground conditions. Data about drill holes (or any other data) can be misleading if interpretation is incorrect (Ranta et al. 1984), and manual, computer-assisted, or the more sophisticated geostatistical estimates may also be incorrect. The simple line on a map or cross section depicting the limit of a geologic feature (e.g., alteration type, lithology, ore) is an extremely powerful decision-influencing item, and only proper geologic interpretation ensures its correctness. Sound interpretation is the only way a geologist can fulfill the challenge issued by Barnes (1980) to "accept the responsibility of recognizing and recording boundaries" that characterize the deposit or distributions within the deposit. It is imperative that the geologist draws the line establishing these boundaries.

In summary, "good geology based on well-understood data is still the only recipe for good reservoir/site/deposit characterization" (Journel 1988). The geologist must thoroughly understand the total geologic environment and distributions to reliably estimate resources, delineate areas for mine planning, and support day-to-day operations.

Methodology

Previous discussion in this chapter has introduced the concept of geologic characterization—the interpretative model—and has emphasized the importance of developing a good model for accurate resource evaluation. The discussion now turns to guidelines on how best to construct a geologic model of a resource. Emphasis is on an empirical model, one that accurately records the factual geologic observations. The same principles apply whether developing a conventional or computer-based geologic model.

The typical steps in constructing and interpreting a geologic model are summarized in the following list. These steps are generally time-consuming because of the dependence on data collection through mapping and logging. They vary somewhat depending on the resource being evaluated.

1. Begin with fundamental knowledge and understanding of various deposit types and their models.
2. Accurately and precisely locate surface and drill-hole data points; accurately collect the appropriate geologic data. Accuracy is essential.
3. Carefully plot drill-hole locations and the data on drill-hole traces on a set of cross sections.
4. Identify correlatable contacts, geologic units, mineralization, or other features on the drill-hole traces.
5. Correlate the interpreted limits of geologic features on a drill-hole-to-drill-hole basis on individual cross sections.
6. Carefully plot data, transfer information, and correlate interpreted limits of the geologic features on a drill-hole-to-drill-hole basis on a second set of cross sections at right angles to the first.
7. Construct a set of plan maps at desired elevations using drill-hole intersections on the plan maps and interpreted limits of units as developed on sets of cross sections.
8. Construct simple illustrations (the geologic model) for discussion and comparison.

The geologist usually starts with surface outcrop data and drill-hole logs that, as reviewed in Chapter 4.1, are of high quality and have been collected using rigorous standardized methodology and appropriate quality assurance/quality

control (QA/QC) measures. This will provide unbiased factual data for compilation and analysis. The geologist builds a geologic outcrop map from surface work that contains all geologic observations. This map (hard copy or on a computer screen) must clearly differentiate factual outcrop data from geologic interpretation and inference between outcrops. A common graphic methodology uses bold solid lines and patterns or dark colors for outcrops and dashed or dotted lines of similar colors, but applied in a paler or lighter fashion, for interpretations. Herness (1977) emphasizes that "there must be no screening of data to eliminate 'unimportant' facts" because frequently "the importance of insignificant data is realized 20 or 50 years later" when mine workings or core may not be available for remapping.

With respect to core availability, the deliberate disposal of core from known ore deposits or established mining districts is unconscionable. Stored core is simply one of many items in the geologist's files that will be constantly examined and reviewed as new ideas or data become available. E. Klohn, manager of the Geology Department of Compañía Minera Disputada, comments, "Core is our record; we must always go back to it" (personal communication). Numerous ore discoveries have been made because core was available for reexamination, re-sampling, and reinterpretation. Braun (1991 and personal communication) emphasizes the importance of the availability of old drill core for relogging and re-sampling that may lead to the discovery of a new gold ore body.

More recent presentations by Leonardson et al. document a significant reserve expansion in a mature mining district in the northwest portion of the open pit at the Barrick Goldstrike deposit, Nevada, United States (Leonardson 2004; Leonardson et al. 2005). A world-class geologic map and model existed in the pit area, and ore controls were understood. However, a deficiency in the model existed in the area of drill-hole logging due to the transitional nature of, and resultant inconsistencies in, the picking of unit and formation contacts and because stratigraphic information from early drill holes was not in the database. As a result, projection of ore-controlling structures outside the existing pit wall was difficult. An 82,300-m (270,000-ft) core and cutting relogging campaign that was primarily stratigraphic in nature but included lithology, structure, and alteration was carried out with team members jointly reviewing their work to ensure consistency. Current bench mapping was included. The greatly improved data were incorporated into the computer-based geologic model of the property, which allowed for the definition of numerous structural/stratigraphic drilling targets. Approximately 300 holes were drilled over a 2-year period, and the property reserve expanded by more than 68 million g (2 million oz) of gold. Significant mining plan changes were made that required pushbacks of the originally planned "final pit wall" that ranged from 154 to 610 m (500 to 2,000 ft) and averaged 305 m (1,000 ft). The work documents the importance of saving core and cuttings, consistency in the geologic work, and the importance of a good geologic model.

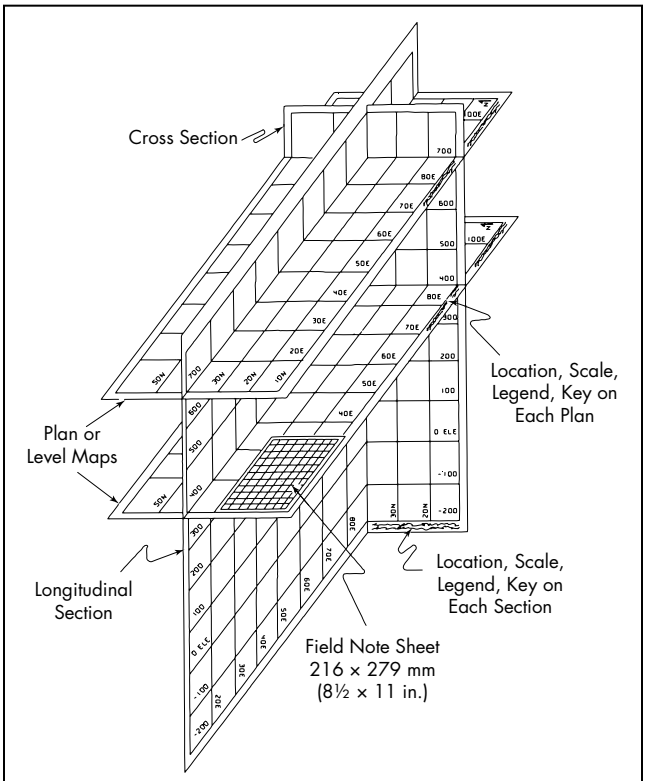
Rivera et al. (2009) further document the importance of maintaining drill core from earlier drilled holes in reporting on a brownfield exploration program in the Chuquicamata District in Chile. Here the "exploration potential was determined by the review of old drill holes" that led to a program that discovered the so-called Toki Cluster of five completely concealed, individual, closely adjacent porphyry centers containing an "oxide and supergene sulfide resource on the order of 1.6 Bt [billion metric tons] of mineralized rock averaging 0.4% Cu."

Gustafson et al. (2001) summarize ongoing geological work on the multiple intrusion/mineralization centers at the El Salvador copper deposit, Chile. These authors reemphasize that porphyry copper deposits tend to cluster, may be closely spaced and overlap (which is difficult to identify and not a widely recognized concept), and require careful mapping (field and core) and mineralization study. They believe that studies of this type are frequently neglected at operating properties and that the failure to recognize multiple, truncated, or incomplete zoning patterns may result in the lack of appropriate additional drilling. The work they describe led to the drilling, discovery, and development of new ore in an existing mine in which ore had first been identified 40 years earlier. Discoveries of this type "within the mining complex" tend to be far more valuable than new discoveries farther removed from an operation.

Future discoveries will be made because old core or cuttings or data were available for examination in the light of new data, new ideas, or other commodities, or, unfortunately, simply because a better or more conscientious geologist was involved. Geology is a continually evolving discipline, and new knowledge and understanding are accumulating at an astonishing rate. Discarding already logged core or cuttings is the equivalent of destroying survey or production records or a computer database after a set of maps or financial algorithms has been completed. It should not be done.

After or in conjunction with the development of a surface geologic map, it is essential that a detailed set of geologic cross sections (and subsequently plan maps) be constructed, preferably at right angles to each other. This is easier if the critical aspect of a resource can be satisfactorily approximated by a set of north-south and east-west sections tied to a coordinate system. Other orientations are possible, although this can introduce measuring and posting problems in relationship to grid coordinates. Coordinates may also be rotated to provide local grids, but this practice may cause serious survey correction problems and difficulties in tying locations to the Public Land Survey System or various state plane-coordinates systems. A reference line to aid in registration and data posting should be drawn on sets of sections, particularly those that do not parallel the coordinate grid system. All data from surface mapping and careful systematic core logging should be posted on appropriate sections and plotted, as indicated by Call (1979), "without interpretation on reproducible sheets. From these, copies can be made [or they can be developed on computer screen displays] for use in interpretation. This process will maintain the distinction between observed facts and interpreted geology." These sections can be constructed manually as the project or drilling proceeds. If an appropriate computer-assisted package is available, data can be entered into an expandable database for rapid factual data posting to provide base maps for interpretation.

As new data are acquired (subject to the appropriate QA/QC measures), they are posted on the factual data sheets. Prints or computer screen displays are produced and new, revised interpretations are developed. Additionally, completed interpretations can be transferred to a second set of reproducible bases (copies of the factual data) so multiple sets of interpretative maps can be reproduced for several users. Drill-hole traces and associated data should be plotted on the sections at a scale sufficient to allow for posting of multiple



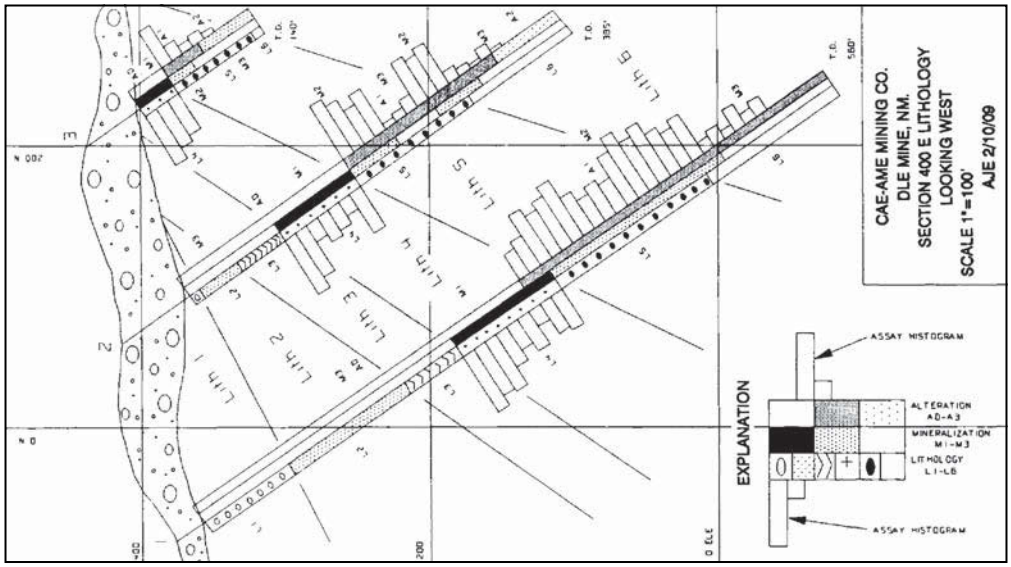
variables along the trace of the hole. The important parameters are lithology, structure, alteration (if present), grade (as a pattern, a color bar, histograms, or numerical values), and perhaps total sulfide or sulfur content. The particular parameters posted depend on the resource being evaluated. This posting of several parameters allows for the determination of critical relationships that normally are of use in guiding interpretation and projections. An extremely risky interpretation is the simple correlation of assays (grade) from hole to hole with no consideration of associated geologic features. This process, which should be avoided, commonly leads to incorrect interpretation, overestimation of resources, and incorrect, usually overly optimistic, evaluation.

Clear cross-sectional construction allows one to determine hole-to-hole relationships and continuity of numerous key geologic features such as lithology, alteration, mineralogy, grade, and structure and, perhaps, features that may influence mining such as rock quality designation or the distribution of varied metallurgical ore types (hardness, alteration, mineral species, or others) requiring different metallurgical processes. The construction of a second set of cross sections at right angles to the first allows for determination of hole-to-hole relationships in two directions and hence section-to-section relationships in three dimensions.

The final step is usually development of a third set of illustrations, plan or level maps (sometimes referred to as slice maps) from the drill-hole pierce points in the plane of the level maps, and projections from the two sets of cross sections. This allows one to conform the sections and plans so all common points have similar XYZ coordinates in the now completed 3-D interpretation and resource characterization. As indicated, multiple sets showing the important relationships of variables—the geologic model—is the product.

In areas of little or no outcrop, such as areas covered by glacial debris or thick overburden, a bedrock geologic map at the subcrop (i.e., at the base of the glacial debris or overburden), rather than a surface geologic map, is commonly constructed. This is carried out in conjunction with construction of the plan maps of the deposit at varied elevations. Data for the subcrop map are derived from the drill holes and consist of the core or cutting information obtained when the drill encounters bedrock. Likewise, interpretations developed during cross-section construction are typically projected to this bedrock surface.

Construction of this set of plans, sections, and illustrations described previously allows one to develop the fundamental geologic understanding of the resource necessary for mine planning and financial evaluation. In the case of coal or uranium, the sets of plans and sections are commonly supplemented or replaced by isopach, isograde, grade-thickness, or structure-contour maps of important features. Of particular significance in this understanding is the determination of ore/resource controls such as lithology, primary structural features, secondary structures, structural intersections, or combinations of features that are directly responsible for the specific localization of the resource. Sufficient understanding, particularly of limiting features, should be developed in the process to allow the input of proper geologic controls in either conventional or computer-assisted resource-estimation methodologies, such as block modeling or the gridded seam technique. This limiting aspect is critical in resource/reserve work to prevent the building of computer-generated reserves in unmineralized areas.



Source: Adapted from Herness 1951.

Figure 4.2-2 Relationship of 3-D plan, section, and field note sheet

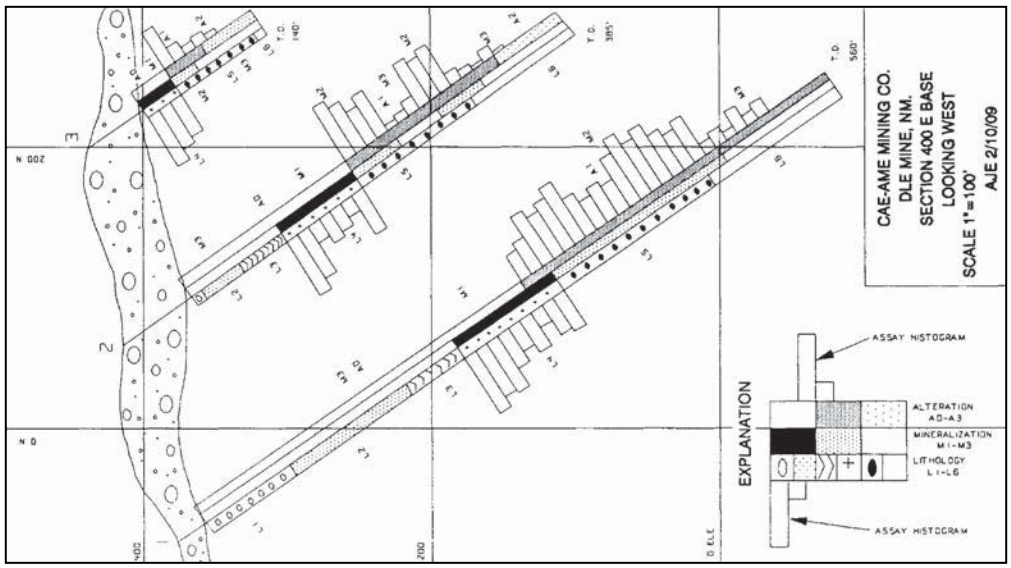


Figure 4.2-2 illustrates the relationships of an orthogonal set of plan maps and cross sections, including the smaller field note sheet subdivisions, used to collect and compile data and support interpretations in the development of a geologic model. Herness (1951) provides a very detailed discussion, illustrations, and recommendations (some dated and others still current) on the essentials of setting up a unified geologic data recording and representation system.

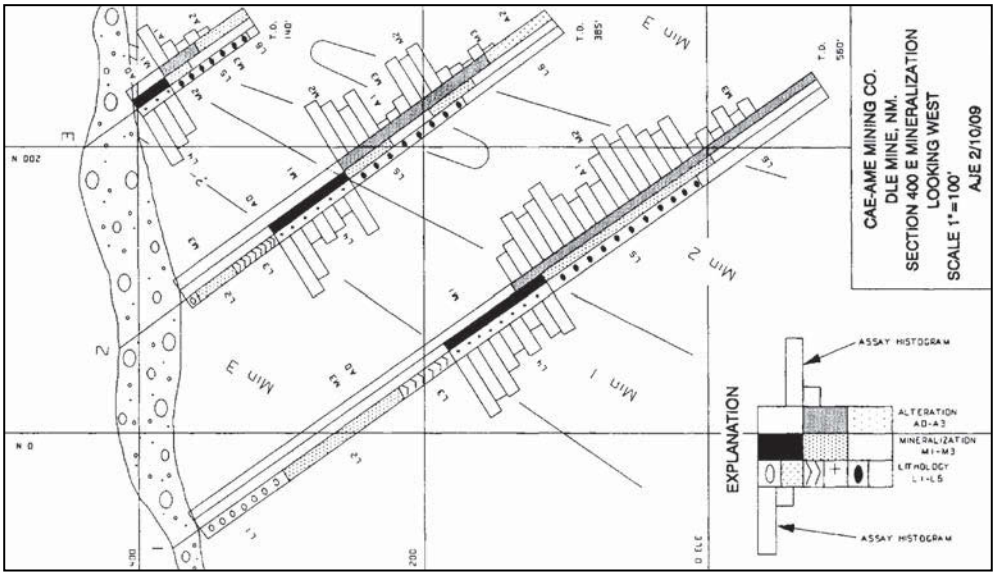
Figures 4.2-3 through 4.2-6 depict the development of factual data and interpretative plans and sections needed to build the geologic model characterizing a particular resource, in this case a VMS deposit. Combination of features such as mineralization and lithology, not shown here, is common. These types of illustrations ultimately form the basis for VMS models (Figure 4.2-7). Figure 4.2-7, which shows mineral and metal distributions and features to be expected in the deposits, portrays one of several idealized models of VMS characteristics developed from studies of numerous deposits.

Figure 4.2-8A is a well-known model that portrays the distribution of alteration, mineralization zones, and sulfide occurrences in a porphyry copper system (Guilbert and Park 1986). This illustration portrays only primary, or hypogene, mineralization and does not show the effects of the secondary, or supergene, processes of weathering (oxidation and enrichment), which are extremely important in these deposits. The effects and changes in the mineral distribution resulting from the action of these secondary processes on the porphyry copper deposits are illustrated (modeled) and discussed elsewhere in

Lithologic interpretation developed from data posted on the cross-sectional base (bottom) of this figure



All factual data manually posted or computer generated from a database on a cross-sectional base showing coordinates, elevations, drill-trace annotated with multiple geologic variables, and histograms representing metal grades

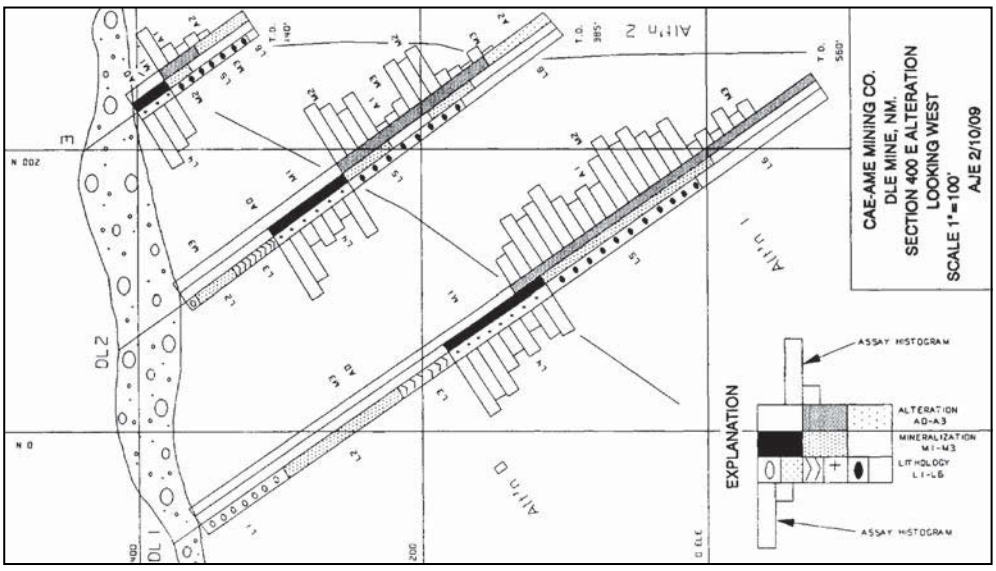


Figure 4.2-3 Idealized cross section—factual data and lithologic interpretation

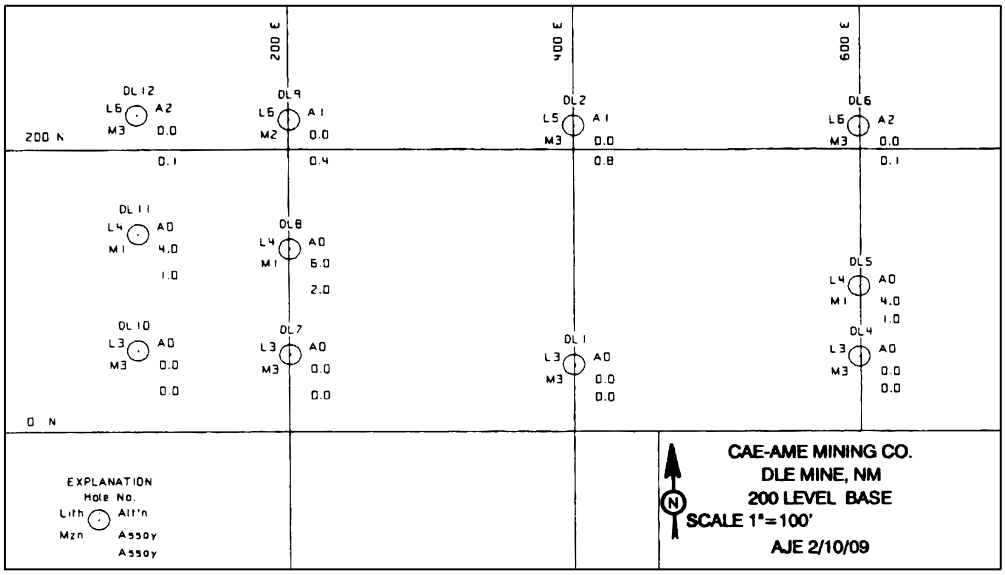
the above-referenced text as well. In addition, Sillitoe (2005) and Titley (2009) provide important reviews, discussions, and illustrations of oxidation and supergene enrichment environments, processes, and resultant products. Figure 4.2-8B illustrates an idealized model of an intrusion-centered porphyry copper–molybdenum–gold deposit and possible other related deposit types that *may* be related to and/or associated with the porphyry deposit (Sillitoe 1995).

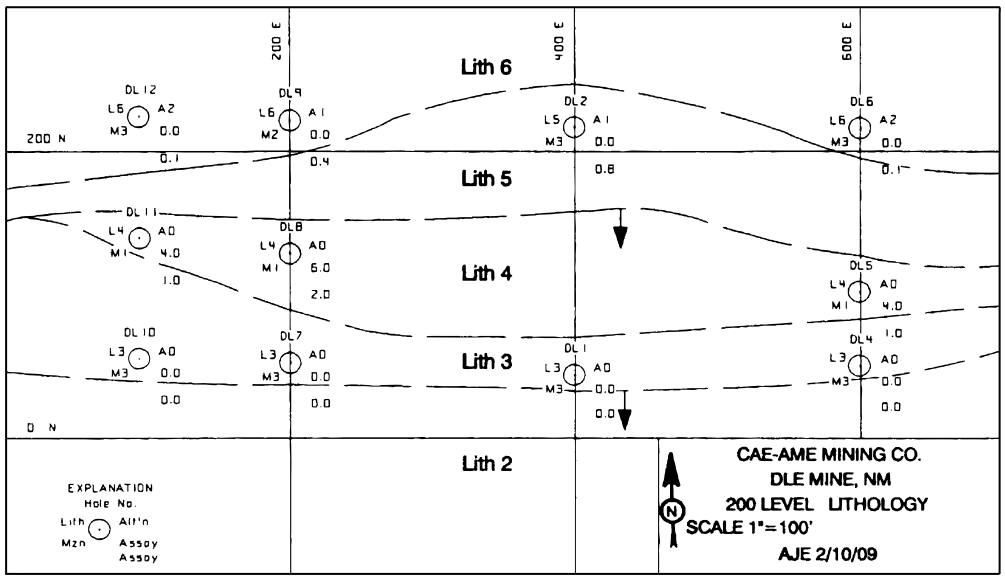
Figures 4.2-7 and 4.2-8 portray idealized models of a VMS and porphyry deposit and potentially occurring deposits in an intrusion-centered mineralization system. It is essential for the geologist to know of, recognize, and understand the mineralogical variations and variability of the deposits represented by these and other deposit-type models—to know where (in what geological zone or subzone) he or she is working, that is, collecting data in a mineralization system.

Mineralization and ore-body interpretation developed from data posted on the cross-sectional base (bottom) in Figure 4.2-3



Alteration interpretation developed from data posted on the cross-sectional base (bottom) in Figure 4.2-3

Figure 4.2-4 Idealized cross section—alteration and mineralization interpretations

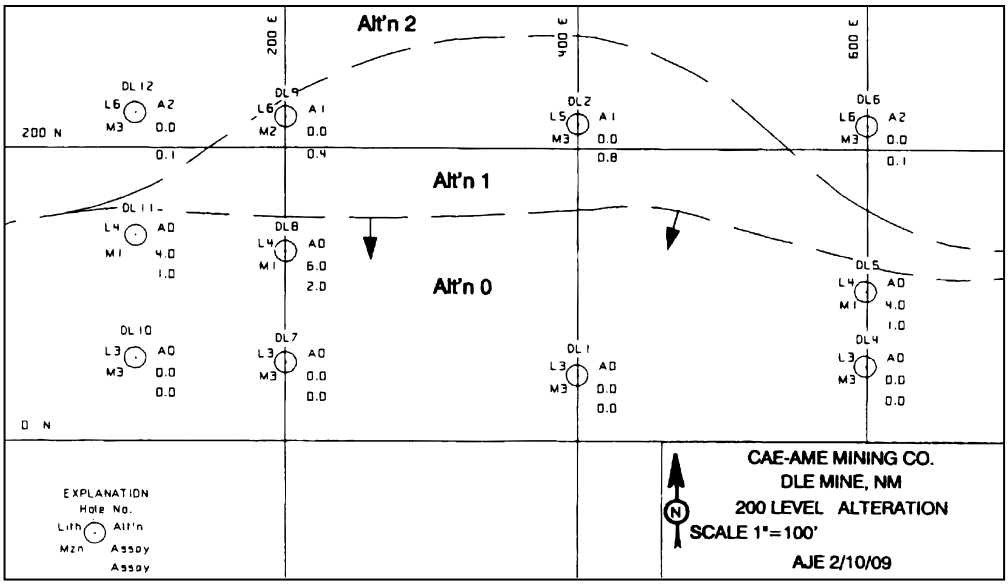


In reality, because of erosion or tectonic events such as folding and/or faulting, the geologist is commonly working on and evaluating only a portion of a total mineralization system, and any model he or she develops from the data should reflect this fact. The geologist in turn must recognize the nature and complications of this situation and the consequences and opportunities it presents.

Purpose

The geologic model is constructed to provide a clear picture of the 3-D geologic relationship of numerous features that limit varied distribution in the geologic resource. The plans and sections used to develop the model form the basis for resource estimation in conventional schemes for calculating reserves. They provide the input for limiting controls, generally as digitized polygons, in computer-assisted methodologies and are the primary standard of comparison between conventional and computer-generated resource estimates. The model provides the limits needed to prevent algorithms from estimating resources in unmineralized areas. A well-constructed model ensures that the algorithms are being used on correlatable units or features.

A. Plan map at the 200 elevation showing factual data in drill holes



B. Lithology interpretation at the elevation of the plan map developed from factual data in the drill holes and interpreted contacts transferred from cross section 400E in Figure 4.2-3 (top)

Note: Only contacts transferred from one cross section are shown, whereas in actual practice, data from many sections would be used.

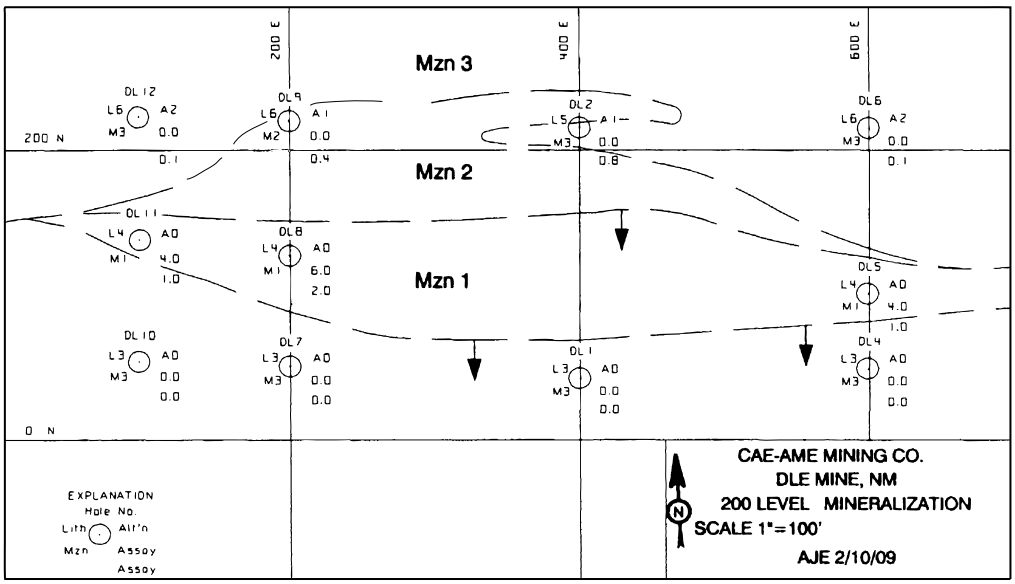


Figure 4.2-5 Level maps—factual data and lithologic interpretation

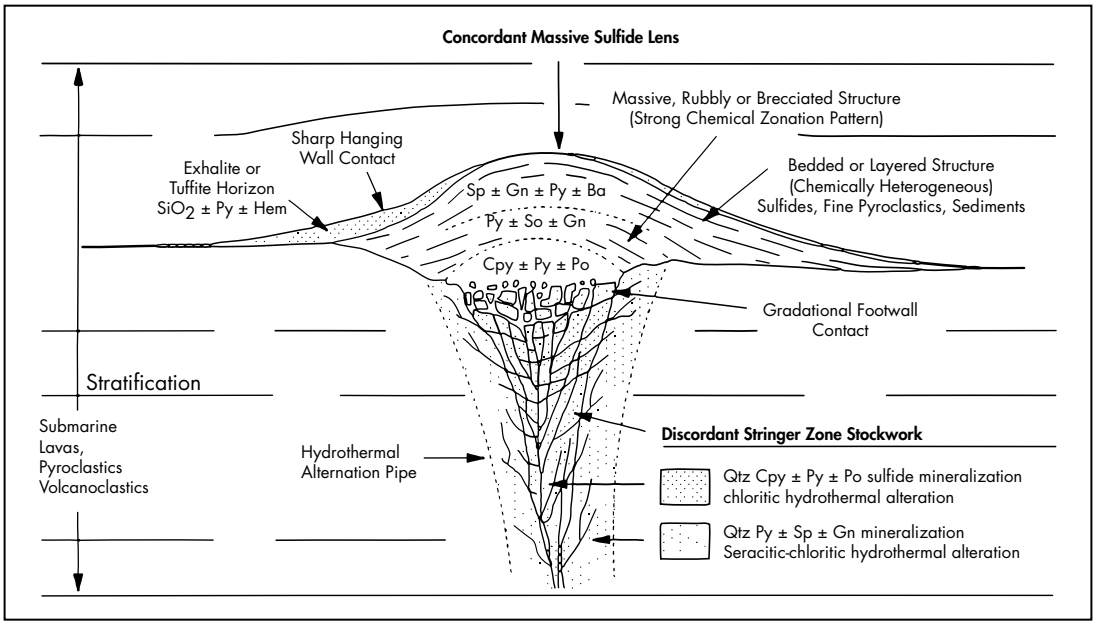
Frequently, simplified illustrations that depict the model and explain the observed geologic relationships are developed. These illustrations show the gross features of the deposit and perhaps the surrounding environment at time of formation. They are used for discussion, illustration, and perhaps comparison with generally accepted models of the type of deposit in question to ensure the appropriateness of the model. Although these simple illustrations are unfortunately sometimes referred to as cartoons, they are extremely useful for conveying concepts in discussions with technical experts involved in deposit evaluation and in management presentations. Figures 4.2-7 and 4.2-8 illustrate this type of display.

It is becoming increasingly apparent as more sophisticated computer-modeling techniques are developed that, assuming correct analytical data and posting are available, the fundamental control of sound geologic interpretation is the most important factor in resource evaluation. Superior models require superior data collection and interpretative work to provide superior resource calculations.

A. Alteration interpretation at the elevation of the plan map developed from factual data in the drill holes and interpreted contacts transferred from cross section 400E in Figure 4.2-4 (bottom)



B. Mineralization and ore-body interpretation developed from data in Figure 4.2-4 (top) in a similar manner to lithologic and alteration interpretations shown in Figures 4.2-5B and 4.2-6A

Figure 4.2-6 Level maps—alteration and mineralization interpretations

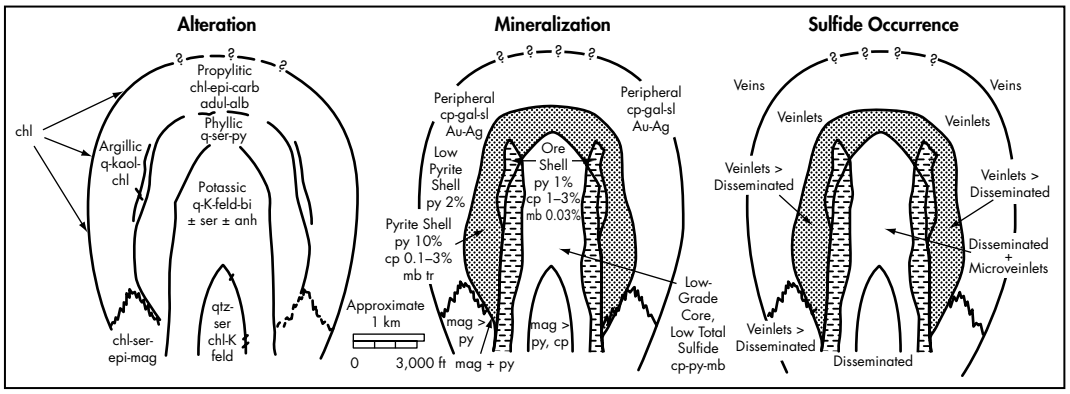
Considering the risk associated with financial commitments in the resource industries, unquestionably, in the evaluation of all but the smallest resource, the best way to handle the massive amounts of data and to test sensitivities as parameters are varied is through computer modeling of the resource. These models, whether block, gridded seam, or others, take considerable work to construct and control and require sound geologic judgment and experience. When the computer model is constructed, the parameters can be rapidly varied and analyzed to determine sensitivities. It is imperative to have a correct resource determination to support evaluation and risk assessment and ensure that the heavy financial commitment required for a new mine will lead to a profitable outcome. The only way to effectively discharge this important geologic responsibility is through construction of an accurate geologic model.

GEOLOGIC REPRESENTATION

Geologic features of mineral resources are highly variable. A nearly constant change in 3-D shapes and relationships is the rule rather than the exception. Many parameters of varying

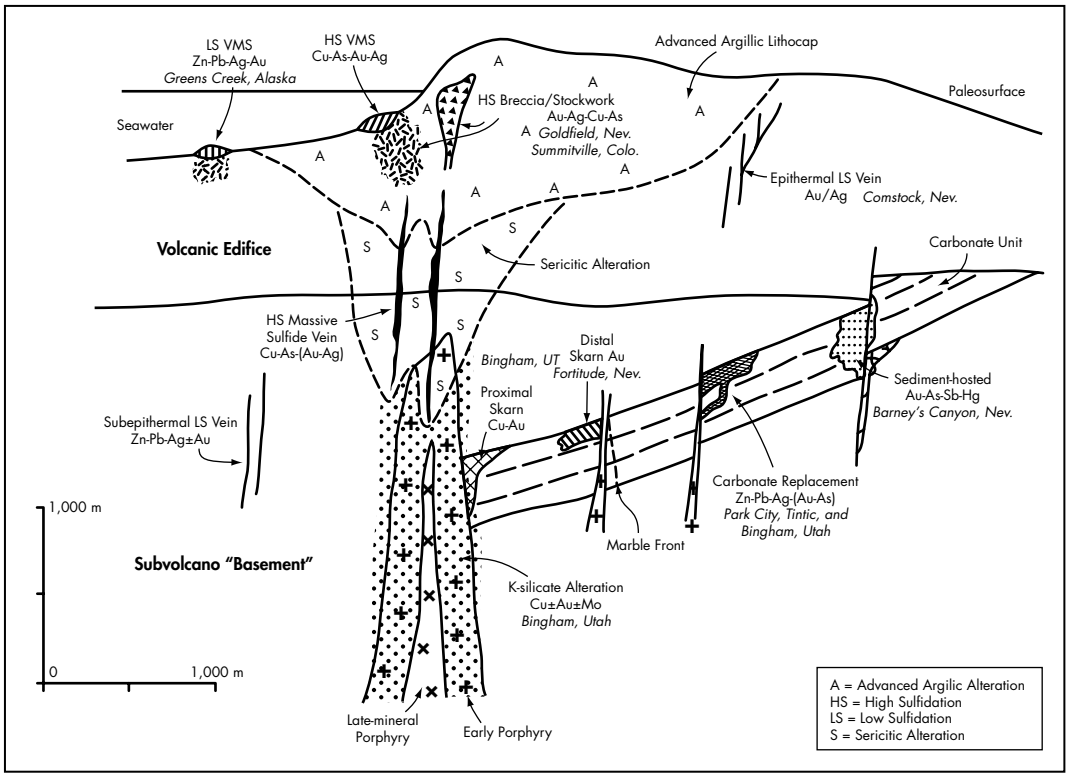
Source: Adapted from Roberts and Sheahan 1988.

Figure 4.2-7 Empirical geologic model of VMS deposit



significance such as lithology, alteration, mineralization intensity, structural complexity, or mineralogical variability perhaps affecting resource recovery must be considered in order to understand the resource and its normally complex geometrical shapes. It is essential that presentations or illustrations (hard copy, computer screen plans and sections or 3-D visualizations) used in describing these complex relationships present sufficient, but not excessive, detail to provide accurate, clear, qualitative, and where possible quantitative, or at least semiquantitative, representations of the important features. The illustrations must be systematic, consistent, preferably simple, and standardized, because professionals from various disciplines (frequently nontechnical) will be using them. Relationships depicted or documented by the illustration should be instantly obvious with a minimal chance for confusion or misinterpretation. The user must be able to quickly grasp the significance of relationships. Additionally, illustrations should be easy to update to ensure that new data can be rapidly assimilated and available to support the decision-making process.

The basic illustrations commonly used to depict important geologic relationships should consist of an integrated set of plan maps and sections showing distributions of lithologies, alteration, and the resource under study. Structural features are commonly shown on all sets. Combinations of various parameters such as mineralization with lithology or perhaps isograde reflecting sulfur distribution within mineable areas of a specific coal seam are common. Almost any feature (parameter) showing variability can be mapped and, if it is important to resource characterization, illustrated to depict the importance of the relationship. Sets of illustrations should have common coordinates and points of origin so they include identical areas. Sheet size should be standardized—neither so small that it prevents adequate coverage of important areas nor so large as to be unwieldy if frequently used. Sheets 760 × 1,070 mm (30 × 42 in.), a standard size readily available, are a good choice for most geologic work. Sheets should have coordinate grid lines with full numerical values of the coordinates identified, not coordinates with some digits removed for ease in posting, as this leads to questions concerning the actual XYZ location of the data point(s) under discussion (e.g., 2,550,000 N should be stated as such and not abridged to 50,000 N). Similarly, elevations on cross sections should not be abridged or modified to reflect anything other than true elevation as related to sea level. Although schemes are used that add or subtract constants to true elevations, they tend to confuse and are best avoided.



Legends or explanations should be complete and should appear on each illustration. The legend should include all symbology and should show the scale as both a bar and ratio or representative fraction. Location name, date, topic and/or subtopic, and a north arrow(s) as appropriate showing true, magnetic, or grid north should be included. Magnetic declination on plan maps may or may not be needed.

As indicated previously and shown in Figures 4.2-3 through 4.2-6, illustrations should be clear and reproducible with sufficient detail included to provide appropriate understanding and with fact clearly discernible from inference. A base reproducible set showing all factual data should be maintained in order to provide easy copies for interpretative work. The interpretative sets, constructed from the base set, are the result of the data analysis process and form the basis for geologic predictions and projections into unsampled areas. Copies, either or both hard paper or as electronic files, of these interpretations and resource estimates should be archived, as they will be needed for review, both as new data becomes available and during the operating life of the mine. These reviews, typically plan versus actual production reconciliations studies—commonly an ongoing process in producing operations—must be based on original data, interpretations, and estimation that should be available in the archived material.

Key simplified sets such as mineralization outlines, grade distribution, perhaps isograde, alteration, or coal thickness with sulfur content contours will typically be made available

Figure 4.2-8 Geologic models

to operating personnel for mine planning and operational support.

Typical scales of illustration may vary as follows.

- For initial data compilation in a base metal deposit: the extremely detailed and seldom used 1:120 (1 in. = 10 ft) or the more common 1:240 (1 in. = 20 ft) or 1:600 (1 in. = 50 ft)
- For interpretive compilations and mine planning: 1:1200 (1 in. = 100 ft) or 1:2400 (1 in. = 200 ft)
- For summary presentations or district or regional overviews: 1:4800 (1 in. = 400 ft), 1:6000 (1 in. = 500 ft), 1:12,000 (1 in. = 1,000 ft), 1:24,000 (1 in. = 2,000 ft), or a scale in which an inch equals a mile (1:62,880 [1 in. = 5,280 ft])

Numerous other types of maps and illustrations can be constructed on an as-needed basis to depict or clarify important geologic relationships. Most useful among these are the following: structure contours or isopachs of geologic units or

parameters, isograde of metal values, total sulfide content, or perhaps dilutents as sulfur or ash content of coals, and ratio maps or combinations of parameters such as grade and thickness, common in uranium work. Any geologic parameter that can be quantified can be mapped or illustrated and may provide extremely useful data on trends, distributions, or variability; hence it contributes to interpretation and a better understanding of the geologic conditions associated with a resource. The key points on the use of any of these are accuracy, clarity, simplicity, and reproducibility.

Herness (1977) discusses subsurface geologic representation and provides a list of essentials for effective field and office representation of geologic data, abridged and summarized as follows:

- Techniques should be easy to master and rapid to use.
- All megascopically recognizable features should be capable of being represented.
- Representation legends should be logical, systematic, chromatic, or geometric sequences clearly depicting trends.
- Systems should be planned to prevent duplication, unnecessary maps, and map overlap.
- Ongoing work maps should be easy to revise.
- Sections and plan maps should be integrated to allow for efficient utilization and prevent data loss in files.
- Note sheets should be uniform in size, kept in a logical available file, and never discarded.
- Office maps should not be excessively large to ensure ease of handling and prevent damage. (However, a good set of large, highly generalized, attractive display maps should be available for presentations.)
- Coordinate grids should be parallel to the edges of note and map sheets, and maps should conform to a district-wide grid and not overlap.
- Maps and note sheets should be clear, neat, and pleasing in appearance. They must have sales appeal because difficult concepts are being portrayed and a project's funding is commonly dependent on clarity of presentation. Impressive, well-executed note sheets and maps generally attest to the quality of the geologic work and of the geologist doing the work.

The variety, types, styles, and purposes of geologic illustration are too varied to allow an example of each. Any of the professional technical geologic journals can be reviewed for style and content. In addition, the following references are particularly good in their content of illustrations: LeRoy et al. (1977), Titley (1982, particularly the included papers by M.T. Einaudi); Dixon (1979), Roberts and Sheahan (1988, very clear and simple, sometimes small), Barnes (1981), as well as the references cited previously in the "Geologic Modeling" section of this chapter.

In summary, there is no substitute for high-quality resource characterization and evaluation based on sound geologic understanding and judgment and presented in an accurate, clear, and lucid manner.

CHAPTER 4.3

Sample Preparation and Assaying

Edwin V. Post, Marc Rademacher, and Walter E. Hill Jr.

The sample preparation and assaying procedures discussed in this chapter apply equally to in-house facilities as well as commercial laboratories. They are applicable to samples derived from reconnaissance exploration through development drilling to mine operations and mineral processing. These procedures assume that the samples submitted were collected properly and a representative portion of the original samples is submitted for preparation and analysis. The character of the material being sampled influences the size of the sample that should be collected and the manner in which it should be prepared for analysis. Ingamells and Pitard (1986) present a good review of the necessity for the collection of appropriate samples as well as techniques for establishing proper sample sizes. Abbott (2007) emphasizes the importance of quality assurance and quality control procedures throughout the life of a project.

The focus herein is on operations in metal mines; indeed, much worldwide mining activity at this writing is concerned with exploration for and development of gold deposits. The requirements for the preparation of samples of many gold-bearing materials are more stringent than those for many other metallic deposits. Thus, the practices described here generally fulfill the requirements for most metallic mineral deposits as well as many nonmetallics.

The preparation and testing of coal samples is a specialized field, and these procedures are summarized later in this chapter. As is true for coal, the preparation and testing of samples of industrial minerals raw materials is highly specialized. For many products, the preparation and testing procedures are end-product sensitive; that is, the preparation and testing procedures to be used are controlled by the properties desired in the final product. One must attempt to select sample preparation and testing procedures that will produce a product comparable to one produced by the actual process procedures to be used. *Industrial Minerals and Rocks* (Kogel et al. 2006) presents perhaps the best overall background on a wide variety of industrial minerals products, although little specifically on sample preparation and testing. Few additional general publications exist, and no specific guidelines can be given here, other than to suggest that sample preparation and testing procedures be established for individual deposits through frequent and close communication among the exploration and mining staff, laboratory personnel, mill managers, marketing staff, and end users.

SAMPLE PREPARATION

Sample preparation is the process of converting samples of geologic materials from the larger sample collected in the field or mine into finely divided homogeneous powders suitable for chemical analysis or other testing. This is accomplished by the screening of soil or sediment samples or the mechanical reduction of pieces of rock to a smaller particle size in a stepwise sequence, alternating with the reduction of sample volume or mass by an unbiased splitting process.

Error can be introduced in many ways during sample preparation. As a consequence, attention to detail and thorough cleaning of equipment between samples is necessary. The desired end result of sample preparation is a powder, or pulp, that contains the elements to be analyzed in the same concentrations and proportions as in the original sample received. The reduction in particle size will be affected by many factors, including particle shape, hardness, specific gravity, lubricity, malleability, residual moisture, and the quantity of clay minerals or organic matter present.

Selecting a Sample Preparation Procedure

Virtually every mineral deposit has its own characteristics, and an individual sample preparation procedure should be developed for each, unless the deposit is known to be fine-grained and relatively homogeneous. Soil and sediment samples typically are dried, sieved through 10-mesh and 80-mesh screens, and in some cases pulverized before analysis. Rock samples routinely are dried if necessary, crushed (in stages if necessary) to –10 mesh, riffle split, and a 250-g to 1-kg portion pulverized to a nominal 150 or 200 mesh.

A "safe" sample preparation procedure is given by Royle (1988) based on a method originally developed by Gy (1977). Similarly, Pitard (1993) presents sampling nomographs that enable one graphically to analyze an existing

Edwin V. Post, Retired, Former President of Skyline Labs, Inc., Wheat Ridge, Colorado, USA
Marc Rademacher, Director, Western Operations, Minerals Services Div., SGS North America, Inc., Denver, Colorado, USA
Walter E. Hill Jr., Former Chief Chemist, AMAX Exploration, Inc., Lakewood, Colorado, USA

sample preparation process and to develop an optimum protocol. Pitard markets programs for personal computers that describe tests to perform on gold ores of unknown characteristics and enable one to plot sampling nomographs from which an appropriate sampling protocol can be developed. In their Chapter 1, titled "Sampling," Ingamells and Pitard (1986) present a good review of the necessity for intelligent sampling, both before and during the sample preparation and analytical stages.

Sample Preparation Equipment

The equipment required to adequately prepare mineral samples for analysis depends to some extent on the nature and quantity of the samples, and even on the climatic environment. In hot desert environments, samples can be adequately air dried under the sun, and a laboratory with only a handful of small rock samples to crush and pulverize per day could do an adequate job with a manual bucking board and muller.

Dryers

Electric or gas-fired ovens are used to remove moisture from samples before crushing and pulverizing. An airflow is maintained through the oven to remove water vapor released from the samples. For routine assay purposes, oven temperatures are usually maintained from 104° to 140°C (220° to 285°F), the higher temperatures being used on clays, although the temperature should not exceed 37°C (100°F) if mercury is to be determined. The submission of larger and excessively wet drill-cutting samples to high-volume minerals laboratories has started a trend toward drying rooms or even buildings equipped to dry large quantities of samples.

Screens

Soil and sediment samples should be screened through screens with both frame and screen as well as a pan made of stainless steel, the screen pressed or welded in, not soldered. Screen sizes typically are 10 mesh to remove coarse fragments and 80 mesh for the final product.

Crushers

Jaw crusher. The first stage of crushing normally is accomplished in a laboratory-sized jaw crusher. Some of these can be choke-fed through a hopper with feed up to 100 mm (4 in.) across, and they will produce a 2.4-mm (–8 mesh) product in one pass while the operator is attending to other duties. A newer double-acting jaw crusher with one jaw top driven and one bottom driven has a 25:1 reduction ratio and will produce a –10 mesh product. Jaw crushers have a relatively high productivity and reduction ratio and are generally easy to clean between samples.

Cone crusher. Normally used in a second stage of crushing, cone crushers produce a uniform-sized product with a smaller percentage of fines, considered better for metallurgical testing, and most can crush to 2 mm (10 mesh). Cone crushers are not effective on clays, but work best on hard, siliceous materials. They have a relatively low productivity and are difficult to clean, especially after clayey samples.

Roll crusher. As an alternative to cone crushers for second-stage crushing, roll crushers have a higher productivity and can produce a 2-mm (10-mesh) product. However, they produce a poorly sorted product with a higher percentage of fines and are noisy, dusty, and difficult to clean. The feed to roll crushers must be sized to 10 or 12 mm (⅜ or ¼ in.), and the feed rate must be controlled to prevent choking.

Hammer mill. Hammer mills have a high productivity rate and the potential to produce a product suitable for splitting and pulverizing in one pass from feed as large as 100 mm (4 in.). However, they are extremely noisy, dusty, hard to clean, and subject to excessive wear when processing tough, siliceous materials. Their product is not well sorted, typically consisting of a large percentage of fines with a small percentage of very coarse fragments. Hammer mills are more often used to crush clays, limestone, coal, and similar softer materials.

Splitters

At some point in the sample size-reduction process, it becomes impractical and unnecessary to further reduce the particle size of the entire sample. The sample volume is then reduced by half or more, depending on the procedure selected for the material at hand, by using a sample splitter.

Riffle splitter. The riffle splitter, or Jones splitter, is most commonly used for sample size reduction. The technique of splitting must be carefully monitored to ensure that statistically valid splits are taken. Splitter chutes should be at least three times as wide as the diameter of the largest particles in the sample, and the delivery pan should be no longer than the distance across all of the chutes. The sample should be evenly distributed along the length of the delivery pan and should be poured along the center line of the splitter—not against one side or the other. The rate of pouring must be slow enough to avoid choking the chutes. The splitter must be cleaned between samples.

Rotating sectorial splitter. The most effective splitter, in terms of sampling error, is the rotating sectorial splitter (Allen and Khan 1970). Shop-made laboratory-sized versions of the rotating sectorial splitter are in use in some sample preparation facilities. One design consists of a rotating circular table driven by a variable-speed motor at about 10 rpm. Four plastic cartons of 1- or 2-L (1-pt or 1-qt) capacity rest on the rotating table. The gaps between the cartons are covered by pieces of angle iron. The sample is fed from a feed hopper by a vibratory feeder. Professionally manufactured rotating sectorial splitters are available that will produce a split of any proportion from 2% to 50% of the original sample.

Pulverizers

After the sample is reduced to an appropriate weight (typically 100 to 500 g, or ¼ to 1 lb), it is then pulverized to a nominal 150 to 75 μm (100 to 200 mesh). Two basic types of pulverizers have been in common use for many years—plate pulverizers and vibratory ring mills or swing mills—although plate pulverizers are being phased out.

Plate pulverizers. Plate pulverizers reduce the particle size of samples through a shearing action as the samples pass between a fixed and a rotating plate. Plates are made of steel, or ceramic if metallic contamination is to be avoided. Controlling the spacing between the plates (and thus the product size) has been a problem and has required almost constant attention by the operator, but newer models of plate pulverizers have better mechanical or even pneumatic controls that maintain a constant plate separation. They can pulverize a large sample and are easily cleaned, but they are dusty and their product is inhomogeneous, requiring

thorough blending before assaying. Mikli (1986) does not recommend plate pulverizers for the final pulverizing of nuggety gold ores, as the plate pulverizer does not significantly reduce the particle size of gold nuggets. Plate wear is high, requiring frequent changing and refinishing or replacing of plates.

Vibratory ring or swing mills. Two basic versions of vibratory mills are made. The ring mill consists of a steel bowl with lid, the bowl containing a cylindrical steel puck plus one or two steel rings that surround the puck. The crushed sample is placed in the open space between the wall of the bowl, the rings, and the puck. The bowl is clamped in a housing which is made to oscillate around a vertical axis by an electric motor carrying an eccentric weight on its shaft. The oscillatory motion causes the puck and rings to revolve in a planetary motion inside the bowl, thus grinding the sample.

The second version of this mill also consists of a bowl with lid but only a single grinding element, a discus or "flying saucer"shaped oblate spheroid of steel with a flat rim. The center of gravity of this steel element is off center so that when the bowl oscillates, the grinding element revolves in a planetary pattern within the bowl. Bowls of this style have a capacity of 800 g to 5 kg (1.8 to 11 lb) of sample, whereas the puck and ring bowls range from 50 to 450 g (0.1 to 1 lb) in capacity. An alternative to the single grinding element is a split discus consisting of two elements with matching concave or convex upper and lower surfaces that oscillate independently in a planetary pattern.

Vibratory mills exhibit the following advantages: they require no operator adjustment, produce a relatively homogeneous product that requires no further blending, create little dust, are available in a variety of materials to avoid sample contamination, have a low noise level (because of a supplied noise-suppressant cabinet), and have a moderate productivity of some 10 to 20 samples per hour. The productivity depends on the character of the samples, with the lower productivity being achieved on high-clay samples, which require just a few minutes to pulverize but several minutes' cleanup time between samples. Vibratory mills have been described by Mikli (1986) as the only type of pulverizer that can actually reduce the particle size of gold nuggets. However, to reduce the particle size of coarse nuggety gold or to pulverize a 2-kg (4.5-lb) or larger sample thoroughly to 150 μm (–100 mesh) or finer can require 10 or more minutes and result in excessive bowl wear. Coarse nuggety gold is best screened out, weighed, and assayed separately from the fine fraction of the sample.

Blenders and Pulp Splitters

Pulps prepared on plate pulverizers, or pulps that have been extensively vibrated during transport, require blending. The most common approach (although not the most effective) is to roll the pulp on a rubberized cloth. Taggart (1945) gives instructions for proper rolling: "Rolling is accomplished by drawing the corners of the cloth horizontally toward diagonally opposite corners, causing the sample to roll over and over on itself. If the corner is lifted instead of drawn horizontally, the sample merely slides along the surface of the cloth and no mixing occurs." Plastic sheeting should not be used for blending because of the static charges that build up, causing retention of some particles and difficulty in cleaning.

A superior alternative to rolling is the use of a mechanical blender; however, small sizes suitable for blending assay pulps are not common. Individual sample blenders are slow. A multisample mechanical wheel blender that meets the productivity requirements of a high-volume minerals laboratory has been described by Gilbert (1987).

A simple approach to splitting a pulp is to roll it on a rolling cloth into a "sausage," flatten the sausage to the height of the scoop being used, and then cut several increments from the sausage using a flat-bottomed vertical-sided scoop until the required weight has been withdrawn. Mechanical rotating sectorial splitters appropriate for splitting pulps are available and are used in some automated sample preparation systems.

Automated Sample Preparation Systems

Mine laboratories that process large numbers of samples of similar materials on a routine basis have invested in automated sample preparation systems. Designed individually for each operation, the systems range from simply crushing and splitting to complex systems involving two stages of crushing, rotary splitting, two stages of pulverizing in continuous flow ring mills, rotary splitting of the resulting pulp, and even weighing into test tubes or beakers for analysis. Automated sample preparation systems cost from several tens of thousands to a few millions of dollars, but their cost is offset by high productivity and dramatically lower labor costs.

ASSAY METHODS

Two basic classes of assay methods historically have been available: geochemical and quantitative, but current instrumental methods of measurement and standardized dissolution techniques have tended to merge the two classes of analysis. Geochemical procedures typically are used in prospecting and the early stages of exploration when results of high accuracy and precision are not as necessary but low levels of detection are required. Quantitative procedures are used during exploration drilling, sampling and analysis for ore reserve estimation, and subsequent stages of mine development and operation. Geochemical methods of analysis in the past have been considered semiquantitative, but most of these now approach quantitative methods in accuracy and precision, and they offer the advantage of considerably lower levels of detection.

The following procedures are not applicable to all materials encountered in the mineral industry. For example, placer samples should be processed by gravity methods (panning, sluicing, jigging) to produce results comparable to the recoveries to be expected from gravity production techniques. Nuggety gold-bearing rock samples are best analyzed either by screen fire assays or by bottle-roll cyanide leach tests of large samples in preference to routine fire assays or wet chemical analyses of smaller samples.

Whether one is establishing an in-house laboratory or selecting a commercial laboratory, there is no substitute for a chemist with experience in the analysis of earth materials. The wide variety of materials to be analyzed, constituents to be determined, and matrix compositions to be encountered pose a myriad of challenges to the minerals analyst. Constructive comments on the art of geochemical analysis are given by Ingamells and Pitard (1986). Many methods of analysis of earth materials are given in publications of the U.S. Geological Survey, the Geological Survey of Canada, and several Australian organizations.

Wet Chemistry

Most analytical procedures today involve wet chemical digestion of the sample, followed by instrumental measurement of the elements of interest.

Digestion Techniques

The most common digestion techniques in current use are aqua regia, four acids (hydrofluoric, hydrochloric, nitric, and perchloric), and fusions using either lithium borate, lithium metaborate, or sodium peroxide followed by acid digestion of the fusion product. Aqua regia digestions may not liberate all elements quantitatively, especially from more resistive minerals, but the acid-leachable results are considered by some to be valuable in geochemical exploration. Fusions followed by acid dissolution produce the most quantitative liberation of a wide suite of elements, but are somewhat slower and more expensive than simple acid digestions. Purposely weak selective leaches are used in some geochemical exploration programs. They include demineralized water, ammonium acetate, hydroxylamine hydrochloride, and sodium pyrophosphate, as well as the proprietary procedures known as Enzyme Leach, Mobile Metal Ion Leach, and Terrasol Leach.

Instrumental Measurement

Instrumental methods of measurement follow the wet chemical dissolution of the sample and have dominated minerals laboratories since the development of the atomic absorption spectrophotometer (AAS) in Australia in the 1950s and the inductively coupled plasma emission spectrometer (ICP-ES) in the 1970s. AASs are used when results for only a few specific elements are desired, whereas ICP-ESs measure a large number of elements either sequentially or simultaneously. The simultaneous instrument is faster for routine work on similar materials, whereas the sequential instrument is more versatile, as it can be tuned for specific elements.

The AAS enables the analyst to measure the concentration of some cations down to a fraction of a part per million and with specialized attachments down to a part per billion. The AAS instrument generally is specific for the element selected, although there are various interferences and operational nuances that the analyst must be aware of and either avoid or compensate for.

ICP-ES instruments utilize the high energy of an argon plasma to excite atoms of various elements in a sample solution that is aspirated into the plasma. The excited atoms emit light that is passed through a spectrometer wherein the energy of light at various wavelengths is measured electronically and converted into the concentration of each element in the sample solution. A more sensitive version of the ICP-ES couples plasma excitation of the sample with a mass spectrometer to measure isotopes of many elements, enabling the reporting of more than 60 elements, in some cases at detection limits of a few parts per billion. ICP-ESs have a linear response over some five to seven orders of magnitude of concentration of the element in question, a much broader operating range than the AAS.

Several other instruments are used for specific determinations in minerals laboratories. Specific ion electrodes, for example, are used to measure the concentration of cyanide in dilute solutions as well as the content of fluorine, chlorine, and several other constituents in earth materials.

Fire Assay

A fire assay is a chemical fusion method for separating, concentrating, and measuring the content of gold and silver in exploration samples, ores, and concentrates. The pulverized sample is weighed, mixed with a lead oxide–alkali carbonate flux and a small amount of a reducing agent such as flour, and fused in a fire-clay crucible. The reduced lead collects the precious metals as it settles down through the melt. The molten charge is then poured into a mold to cool. The lead sinks to the bottom of the mold and is broken from the glassy slag when cool. The precious metals are separated from the lead by cupellation. The lead button containing the precious metals is placed in a cupel of bone ash or magnesia, which is heated in the furnace under oxidizing conditions. The cupel acts as a semipermeable membrane, allowing the lead oxide formed from the button to be absorbed into the cupel, leaving the precious metals in a tiny bead on the surface of the cupel. The bead is weighed, the silver is chemically separated from the gold, and the resulting gold bead is either weighed or dissolved and measured instrumentally. Fire assay is the standard method of the industry. Details, theory, and variations of the method are described in references such as Bugbee (1940), Haffty et al. (1977), and Heady and Broadhead (1976).

Nondestructive Analysis

X-Ray

The X-ray diffractometer is used in some well-equipped minerals laboratories to determine the mineral species present in a sample by recording their characteristic crystallographic patterns. The instruments are not extensively used in mine and project assay work.

X-ray fluorescence spectrometry (XRF) is used for the rapid analysis of silicate rocks and the routine determination of the concentration of selected elements in exploration samples, ores, concentrates, and mill products. XRF analysis is most satisfactory when applied to a continuing series of samples of similar matrix. The method is subject to matrix effects and interelement interferences, most of which can be corrected for in the comprehensive computer software that accompanies all modern instruments. XRF instruments require for calibration previously analyzed standards similar in bulk composition to the unknowns. The instruments are capable of excellent precision, but without proper calibration and intelligent operation, they can be rather inaccurate.

Neutron Activation Analysis

Neutron activation analysis (NAA) is available, principally through commercial laboratories with access to nuclear reactors. Most of the laboratories offering commercial neutron activation analyses of earth materials at a reasonable cost are Canadian based. NAA is indicated when (1) a conventional technique does not have acceptable limits of detection for the element of interest, (2) the sample is unique and cannot be consumed in analysis, (3) only a small quantity of sample material is available, or (4) conventional methods of analysis are unacceptable because of interferences or inherent instrumental errors. The sample typically is pulverized, loaded into a capsule (rabbit), and introduced to a reactor in which it is bombarded by neutrons. After recovery of the capsule from the reactor, the radioactivity induced in the sample is measured and analyzed, thus giving a measure of the concentration of

each element present in the sample. NAA currently has much application in the analysis of vegetation or mull for trace amounts of gold, and in the analysis of the platinum-group elements, the rare earth elements, and uranium.

COAL PREPARATION AND ANALYSIS

The procedures used in the preparation of coal and coke samples for analysis are similar to those of rock samples. The ASTM International standard method of preparing coal samples is ASTM D 2013-07 ("Standard Practice for Preparing Coal Samples for Analysis"; ASTM International 2009). The principal difference in coal sample preparation is the use of lower temperatures and, indeed, even air drying to preclude oxidation as much as possible. Crushing and pulverizing is accomplished with much the same equipment as used on rocks. However, samples are pulverized only to 250 μm (–60 mesh), and only 50 g (0.1 lb) is retained for analysis.

A variety of tests are available for coal samples. Some of these include sieve analyses, washability, Hardgrove grindability, moisture, sulfur, ash content, carbon and hydrogen content, and calorific value. Two of the most common determinations are proximate and ultimate analyses. A proximate analysis, as described in ASTM Standard Method D 3172-07 ("Standard Practice for Proximate Analysis of Coal and Coke") covers the determination of moisture, volatile matter, and ash, as well as the calculation of fixed carbon (ASTM 2009). According to ASTM, the results of a proximate analysis are used to establish the rank of coals, to show the ratio of combustible to incombustible constituents, to evaluate the coal for beneficiation and other purposes, and to provide a basis for buying and selling.

An ultimate analysis, according to ASTM Standard Method D 3176-89 (reapproved 2002), "Standard Practice for Ultimate Analysis of Coal and Coke," when tabulated along with a proximate analysis, provides the data for a cursory valuation of coal for use as fuel and coke for metallurgical purposes (ASTM 2009). An ultimate analysis includes the determination of carbon and hydrogen as well as sulfur, nitrogen, ash, and the calculation of oxygen by difference. Typically moisture is reported as well. The procedures for an ultimate analysis are also specified by ASTM International.

In addition to the analytical procedures described previously, data on the major, minor, and trace elements in coal and coke ash often are of use in the evaluation of coal quality. Accordingly, methods for these determinations are presented in ASTM D 3682-01 (reapproved 2006), "Standard Test Method for Major and Minor Elements in Combustion Residues from Coal Utilization Processes"; ASTM D 4326-04, "Standard Test Method for Major and Minor Elements in Coal and Coke Ash by X-Ray Fluorescence"; and ASTM D 6357-04, "Standard Test Method for Determination of Trace Elements in Coal, Coke, and Combustion Residues from Coal Utilization Processes by Inductively Coupled Plasma Atomic Emission, Inductively Coupled Plasma Mass, and Graphite Furnace Atomic Absorption Spectrometry" (ASTM 2009).

QUALITY CONTROL

The necessity of establishing a quality control program for every project is presented by Abbott (2007). Most laboratories have an adequate quality control program covering their analytical work, and many commercial laboratories currently are certified under the International Organization for Standardization quality control standard ISO 9001:2000, currently being supplanted by ISO 9001:2008. How intensively the quality of sample preparation is controlled is unknown, yet it is just as important as the chemistry, for, as A.G. Royle (1989, personal communication) has commented, "Wait until you see the numbers that show all the horrible things that happen in sample preparation of gold samples!"

During sample preparation, maximum particle size can be readily monitored by screening at various stages as the material is crushed and pulverized. Other parameters are more easily checked by actually analyzing the material. Analysis of several pulps prepared from different splits of the crushed bulk sample will provide data on reproducibility of splitting. Analogously, the homogeneity of a pulp can be checked by taking a number of replicate portions for analysis from the same pulp and calculating the precision of replication. A simple procedure to evaluate the effectiveness of sampling drill cuttings is presented by Schwarz (1989).

Analytical precision and accuracy are best established and maintained through the use of reference standard samples and analytical control samples (Hill 1975). Certified standard samples of mineral materials are available from mineral industry suppliers and some governmental agencies and professional or trade groups in several countries, but such standard materials are expensive and limited in quantity. The elements present and concentration ranges in certified standards may not adequately cover the character of materials that the laboratory is engaged with. Nevertheless, such standard materials may help to provide initial calibration. Matrix-matched control samples to provide batch-to-batch and day-to-day calibration and quality control in the laboratory can be prepared and blended from the reject samples from the project. The analytical development of these in-house control samples can be calibrated to the certified standards. Ideally, every set of analyses produced by the laboratory should have one or more control samples and duplicates included for quality control and assurance. Some governmental agencies that contract out a large quantity of sample preparation and analytical work arrange for 3 of each 20 samples to be controls or replicates. ASTM gives guidelines for evaluating laboratories performing analysis of coal and coke (Method D 4182-97, reapproved 2004, "Standard Practice for Evaluation of Laboratories Using ASTM Procedures in the Sampling and Analysis of Coal and Coke"; ASTM 2009).

When the results of analysis of the controls do not agree with the established values within acceptable limits, the entire group of assays should be rejected, the problem identified and resolved, and the group of samples rerun. The timely realization and resolving of sampling, sample preparation, and analytical problems is the essence of quality control.

CHAPTER 4.4

Ore-Body Sampling and Metallurgical Testing

Philip King

The evaluation and development of an ore body requires the input of many disciplines, including geology and related subjects, mining engineering, process engineering, and environmental sciences, as well as marketing and financial modeling. Work commences during the exploration phase with extensive sampling programs designed primarily to evaluate the grades and tonnages of mineralization present.

In a feasibility study, a deposit's ore reserve grades and tonnages are quoted according to strict accounting procedures such as those of the Australasian Joint Ore Reserves Committee (JORC), its variants in the west, and the State Commission on Mineral Reserves of Russia (GKZ) in the former Commonwealth of Independent States countries. However, methods for evaluating exactly what is recoverable from an ore body are not well defined and it is usually up to the process engineer, with assistance from geologists and mining engineers, to develop a metallurgical test program.

QUALITY MONITORING IN CHEMICAL ANALYSIS

The general quality standards (not specific to laboratories) of the ISO 9000 series developed by the International Organization for Standardization (ISO) are guidelines to ensure that a quality system exists and is followed, but they do not assess actual quality or competence. ISO 17025:2005 specifies general requirements for the competence of laboratories to carry out tests and calibrations, including sampling. It covers testing and calibrations performed using standard, nonstandard, and laboratory-developed methods. It is applicable to all laboratories regardless of the number of personnel or scope of testing activities. It requires a laboratory to state its quality policies and procedures, provide building facilities and equipment appropriate to the tests performed, use suitable methods, recruit and train competent staff, maintain good document control, and keep thorough records.

Laboratories seeking accreditation must prepare a list of the tests they perform and describe the quality control (QC) procedures associated with these tests. An independent national or private organization then assesses the laboratory for accreditation. If the laboratory is accepted, it receives a registration document showing the tests for which it is accredited. Follow-up visits, usually annually, are made to maintain accreditation. Under ISO 17025, prospective clients must confirm that any laboratory that they are considering using is registered to perform their required tests in addition to having overall ISO accreditation. Although ISO 17025 is achieving international acceptance, some countries still maintain their own national systems.

With the drive toward stricter reporting conditions for mineral exploration and the requirement for so-called competent-person reports, the need for laboratories to be accredited is of increasing importance. This applies not only to assay laboratories but also to laboratories providing services such as mineral-processing test work and mineralogy.

Assay laboratories should have written procedures under the following main headings:

- Sample handling
- Sample preparation
- Sample analysis
- Quality control
- In-house QC procedures for both sample preparation and assay
- External control by assay of samples with other accepted laboratories and by participation in round-robin analytical programs such as those organized by Geostats and Canmet
- Sample documentation

Accreditation is not the same as certification. The latter requires an independent third party to give written assurance that a service conforms to specified requirements. In the context of mineral exploration and mining, where companies may have varying requirements, it is probably better that certification of a laboratory (whether external or in-house) be carried out as part of a company's own QC program.

Overall, a comprehensive QC program should increase the number of individual analyses by about 40% compared with the original number of samples being analyzed. The laboratory should maintain tables of its QC performance on all of the above factors, with charts as appropriate, and make these available to current and prospective clients. For in-house mine and

Philip King, Technical Director, Truro, Cornwall, UK

process-plant laboratories, QC data should form part of monthly reports and be open for discussion at management meetings.

Laboratory clients should not rely on only laboratory-produced data. As part of their own QC programs, they may wish to insert duplicates, blanks, and standards as part of their sample batches.

The following terms are used in the analysis of samples:

- **Accuracy:** Closeness of agreement between a measured value and the true value. Lack of accuracy can be measured and quantified in terms of bias or systematic error.
- **Bias:** Statistically significant difference between a measured value and the true value.
- **Precision:** Magnitude of randomly distributed variations in the measurement procedure.

GEOSTATISTICS

Geostatistics is a branch of statistics concerned with analysis of not only data values but also the positions of data samples and time-related data variations. Although originally developed in the mining industry, it is now widely applied in a range of disciplines.

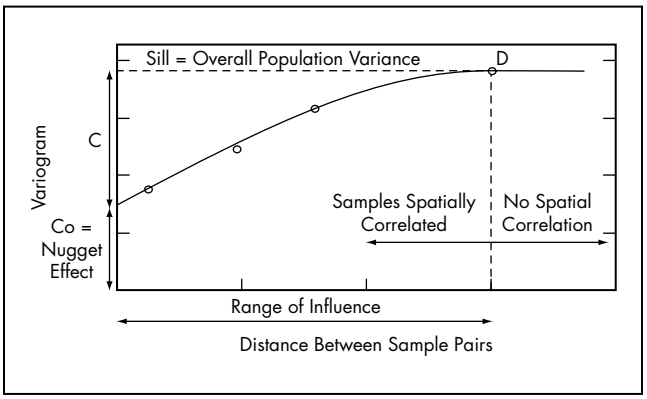
Basic Principles

The basic principles of geostatistics involve summary statistics, variance, variograms, and kriging.

Summary Statistics

Normal analysis of any geological data usually starts with the production of summary statistics to provide an initial view of the data ranges and distributions. Summary statistics include not only the mean, standard deviation, variance, median, and mode, but also the coefficient of variation (standard deviation/mean) and log estimates of the mean. Graphical analysis usually includes histograms, log histograms, and log probability plots that enable analysis of whether different populations are present and whether some sort of domaining is necessary. A decile analysis can also be helpful in assessing outlier grades; the data set is ordered by grade, then the metal content contained in each 1/10th of the data set is calculated and 1/100th parts for the top-most decile are analyzed.

Variance



For the purposes of estimation, the variance of grade distributions is as useful, if not more, than the mean. Variance is a fundamental measure of variability and precision.

Variance between pairs of samples a specific distance apart is a measure of the interdependence of grades for points separated by this distance. Points closer together are normally more closely related (have lower variance) than are points farther apart. For pairs of samples formed by, for example, check-sampling from different laboratories, specific techniques exist for the analysis of variance (ANOVA).

Variance also depends on the size of a sample, so composites usually have a lower variance than do raw samples. As many geostatistical processes are involved in ANOVA, irregularly sized samples must usually be composited to a regular length (greater than the majority of raw sample lengths) so that the composites have the same approximate size (support) for subsequent analysis.

Variograms

In comparisons of a large number of sample pairs, some differences are positive and some are negative. Squaring these differences gives a new set of all-positive values. Differences measured between samples separated by similar distances can then be averaged, giving a variance. A graph called a variogram can be developed of variance versus distance of separation (lag) between points. Figure 4.4-1 shows a sample variogram (strictly it should be called semivariogram, as it is the variance/2), fitted with a spherical model variogram. The distance at which the variogram levels off is called the range of influence; samples separated by more than this distance are uncorrelated.

Courtesy of Adam Wheeler.

Figure 4.4-1 Sample variogram

Different variograms can be created and modeled in different directions, enabling measurement of the anisotropy of mineralization. The position where the variogram cuts the y-axis gives a measure of the so-called nugget effect (designated Co), which describes how well the sampling results can be reproduced by repeated sampling at the same location. This measure incorporates the natural inherent variability of the deposit plus the variability due to sample size, preparation, and analysis. A very high nugget effect relative to sill height may therefore indicate poor data quality, as might result when sample data stems from a mix of different laboratories over many years. A low (or near-zero) nugget effect indicates very homogeneous mineralization.

Kriging

An important use of variogram parameters in grade estimation is the so-called kriging method of estimation. Kriging involves the following steps:

1. Perform a structural study of the sample data to determine the variogram.
2. Select samples to be used for evaluation of a particular block.
3. Calculate variogram values between all selected samples as well as between each sample and the block itself to set up a kriging system of equations.
4. Solve the kriging system of equations to obtain weighting coefficients for each sample.
5. Estimate the block grade from the weighted average.

In mining and geostatistical software systems, model variogram parameters and search parameters are user defined. The search parameters themselves, particularly the distances involved, also largely stem from the variography analysis. The model software uses the parameters to complete the previous kriging steps and produce a separate kriged grade for each block of a supplied block model.

Drilling and Sampling

During a geostatistical study, variogram ranges and other derived model parameters can be helpful in determining the minimum spacings required for future drilling or sampling. If different ranges exist in different directions (anisotropy), this information can be used to guide different drilling spacings in the corresponding directions.

Ore-Body Modeling

Computer-based resource estimations usually involve the generation of block models. Each cuboid block represents a volume of ground and has a number of numeric (typically grades, densities, or metallurgical parameters) or alphanumeric (rock-type) attributes assigned to it. A parent block size is usually assigned; the size is established when the model is initially generated, although some mining software systems also allow sub-blocks to be generated within the same framework so that more complicated geological or topographical features can be accurately represented.

Volumetric Modeling

The first stage in resource modeling is generally to build a volumetric block model that uses topographical and geological surfaces and envelopes to split and code blocks. This process often involves modeling mineralized zones into which grade values are subsequently interpolated. Mineralized-zone boundaries can stem from drill-hole or other sample data and can take into account cutoff grades, lithological differences, and extrapolation of other geological features. Some mining software offers advanced facilities for extrapolating geological and ore-body features.

Grade Estimation

The next stage is generally to use grades stemming from the sample data in order to estimate grades in the mineralized-zone blocks. Often the boundaries used to define mineralized zones have also been used to set corresponding codes onto the sample data. These data can then also be composited, either into regular lengths (for large ore bodies) or cross-intersection composites (for veins or seams). Search parameters need to be defined to control which composites or samples are used for each block estimate. Generally, geostatistical analysis helps set these search parameters. An estimation method is then applied to assign weights to each selected composite/sample during a block's estimate. The block value is derived from a weighted average.

The following are commonly applied estimation methods:

- **Indicator methods.** Instead of grade values being weighted directly, composites are first set to either 0 or 1, depending on whether they are above or below a specified cutoff grade. A series of different indicator 0/1 values (for a range of cutoffs) is estimated for the block model, possibly by means of kriging. These interpolated indicator values (decimal numbers between 0 and 1) are reconstituted into a block-model grade value. A number of indicator methods and variants are available, including multiple-indicator kriging.
- **Inverse-distance weighting.** Weights are assigned that are inversely proportional to the distance between the sample and block. The distance can optionally be raised to a power (typically 2 or 3) before weights are assigned. The method is easy to apply, but does consider clustering of sample data and generally performs poorly beyond the edge of the available sample data.
- **Kriging.** Parameters defined by the model variogram are used, and the resultant weights are dependent on the sample pattern and spacing. Clustered samples automatically have their individual weightings reduced. Many variants of kriging are available, the commonest of which is probably ordinary kriging.
- **Nearest-neighbor (polygonal) weighting.** The block grade is set to the grade of the nearest available sample/composite. Results are similar to those produced by sectional evaluation, where polygons are assigned sample/composite grades.
- **Simulation methods.** In a derivative of kriging called conditional simulation, a number of alternative block models are generated, which are smaller than those used for conventional estimation methods. Grades differ for each block but can be thought of as equally likely outcomes for the same input sample/composite data. The types of grade pattern produced by this method are generally more realistic, on a smaller scale, than are those produced by conventional methods. Having a series of block-model outcomes enables good probabilistic assessment of results that can be used for resource classification, mine design, and prediction of production tonnages and grades.

Model Validation

Regardless of the estimation method used, it is recommended practice to complete a number of validation steps before performing final resource calculations, as a check on the model-generation procedures. Validation steps can include the following:

- **Visual examination.** Superimpose the sample or composite data onto sectional views of the block model and coloring and/or annotating grade data.
- **Global-average comparisons.** Determine the average grade of samples and composites within principal divisions of the mineralized zones, and compare these with corresponding average grade values from the block model.
- **Local-average comparisons.** Depending on the geometry of the ore body, capture sample and model data onto regular parallel slices (e.g., vertical sections or benches), then produce graphs depicting the variation in grade by slice position (e.g., easting). Variations in average grade from samples, composites, and models can be compared in the form of model grade profiles (swath plots) that can include principal grade fields (estimated, for example, by kriging) and also alternatively derived grades (estimated perhaps by inverse-distance or nearest-neighbor weighting).
- **Historical comparisons.** When older estimates are available, compare these with newer revised estimates to help understand differences in the updated procedures and/or data.
- **Test-block analysis.** Isolate particular blocks in the block model and study the associated grade estimates in more detail. Retrieve the sample/composite data used for estimation and plot it along with the weightings that the estimation method applied. If kriging was used, determine other parameters associated with the estimation process

along with the resultant block grade, and from these assess how "well informed" that particular block may be. Analysis parameters can include kriging variance, which is the expected value of the squared error between the actual and estimated grades and is a useful indication of the geostatistical confidence in a given block with respect to the sample data configuration. Analysis can also include comparison with reconciliation data (planned and produced tonnages and grades) when available.

Resource Evaluation

The following terms are used in ore-body assessment:

- **Average grade:** Average quantity of an ore's valuable constituents; the average relative quantity or percentage of ore, mineral, or metal content in an ore body
- **Bulk density (dry or wet):** Dry or wet weight of an object or material divided by its volume including pore spaces, often expressed in metric tons per cubic meter, or t/m^3 (for dry bulk density, the sample must have been oven-dried to a constant weight at 105°C)
- **Contained metal:** Weight of a given metal contained within a unit amount of ore or mineral-bearing material
- **Density:** Ratio of the mass of a substance to its volume
- **Specific gravity:** Ratio of the weight of a unit volume of a substance to that of water, based on the volume of solid material, excluding pore spaces
- **Stripping ratio:** Unit amount of spoil, overburden, or waste that must be removed to gain access to a unit amount of ore or mineral-bearing material, generally expressed in cubic meters of overburden to raw metric tons of mineral material (m^3/t)

Resource Classification

Along with estimated grades, some assignment of resource categories is necessary so that results can be reported according to normal resource-estimation practice. In most international systems, resource categories are measured, indicated, and inferred, reflecting decreasing levels of confidence. Only measured and indicated resources should be used as the basis for mine design and resultant ore reserve calculation.

These class categories can be set as attributes directly in the block model. Alternatively, separate physical limits can be constructed, again so that block-model evaluation can be subdivided into classes. Criteria involved in assigning classes should include the following:

- Drilling, sampling, and assay integrity
- Sample spacing and patterns
- Mineralization continuity, often described by means of model variogram parameters
- Estimation method and block size
- Samples/composites encountered during estimation; for each block, the number found and proximity to the nearest and general coverage are important
- Sample types; in some instances, older less-reliable data sets might have been used for inferred resources only
- Other modeling parameters (such as maximum distance of extrapolation)
- Reliability of other supporting measurements (such as density)
- Likely mining dimensions, as resources must be reported to a realistic degree of selectivity

Other more sophisticated procedures relevant to resource classification might include use of results from kriging operations, such as maps of kriging variance, or other forms of risk assessment (such as use of conditional simulation). For producing mines, the ore production rate may also be used such that the confidence associated with measured, indicated, and inferred resource categories corresponds to the confidence associated with tonnage/grade predictions in short-term, medium-term, and long-term mine planning.

Evaluation Methods

For ongoing or future mine development, the resource block model usually becomes the main tonnage and grade reference source for mine planning. All embedded attributes, grades, resource classes, and resource properties are useful. For open-pit mines, the model is useful for pit optimization and determination of future exploration-drilling requirements. For underground mines, the model is useful for stope optimization. Mining software provides a variety of planning tools for interactive design work using the block model as a three-dimensional backdrop.

After a resource block model has been set up with some means of resource classification, it can be evaluated in various ways. Resource evaluation can be subdivided by rock or ore type, resource classification, cutoff grade interval, or model increment such as benches. The model can be evaluated as a whole or by retrieval within defined bounds: physical bounds in the case of a mine design or a particular zone or range defined by coordinates.

Evaluation results are commonly displayed by means of grade–tonnage curves that show the available tonnage and average grade of that tonnage for a range of different cutoff grades. Figure 4.4-2 shows a sample curve. According to the figure, for a Zn cutoff grade of 4%, 11,500 t are available with an average grade of 7.6% Zn.

In these curves, the x-axis represents the cutoff grades applied. Generally the left-hand y-axis represents the tonnage above cutoff and the right-hand y-axis represents the average grade above cutoff.

It is important to be aware of the selectivity associated with a grade–tonnage curve. If the curve is produced directly from a block model, selectivity is a function of the block size and the grade-estimation parameters used. Curves produced from mining blocks defined by polygons or three-dimensional shapes may differ in shape and selectivity. Thus different curves can exist for the same deposit at different levels of selectivity.

When an economic mineral has a specific gravity that is significantly higher than those of the waste or gangue minerals, the relationship between ore density and grade should be evaluated. This can be readily achieved by plotting ore grade versus density as a scattergram and then performing regression analysis. The density of an ore containing two minerals of different specific gravities is

$$100/\Delta = x/\delta_A + (100 - x)/\delta_B$$

where

Δ = density of the ore
x = percentage of mineral A
δ_A = density of mineral A
δ_B = density of mineral B

This equation can be expanded for more than two mineral phases.

OBJECTIVES OF A METALLURGICAL TEST PROGRAM

The main objectives of a metallurgical test program are to

- Define the recoveries of the metals or minerals to a salable product;
- Determine the grade or quality of the products;
- Conduct a liberation analysis process;
- Develop one or more flow sheets for ore processing;
- If reserves are to be declared, demonstrate the economic viability of the process;
- Specify and size process equipment;
- Estimate capital and operating costs; and
- Evaluate the characteristics of tailings or waste products.

The stage of the study determines the level of detail and degree of accuracy required for a metallurgical test program. For example, a conceptual study typically has relatively little measured ore resources and only conceptual mining and process plant flow sheets, and therefore capital and operating cost estimates might be accurate to within only ±30%. In contrast, a detailed feasibility study typically has detailed design criteria including balanced process flow sheets and completed equipment designs based on firm supply quotations, and estimates might be accurate to within ±10%. The detailed study then provides the formal basis for the final contractual design of the process and the selection and sizing of plant equipment and other associated facilities. It also includes all operating criteria, including throughputs, operating schedules, design capacities, feed characteristics, and mass balances.

TYPES OF SAMPLES USED FOR METALLURGICAL TESTING

Samples for metallurgical studies can be obtained from a variety of sources, including drill cores (of diameters up to ~200 mm), trenches, small pits, and channel samples. Residual samples from initial exploration programs or from dedicated metallurgical sampling exercises can also be used.

Field-Sampling Methodologies

The prime objective of field sampling is to create a sample that is suitable for laboratory processing and representative of its source. This is the most critical step in the development of a sampling flow sheet. Errors incurred at this point are usually large (have great variance) and cannot be rectified by subsequent treatment. Major types of error include splitting in the field, loss of sample, and contamination.

Assay Pulps

The ore body at this point has been subjected to a sampling program to determine the grades of metals or minerals present, and a considerable amount of sample material often remains from this exercise. Such material can be in the form of a dry solid called an assay pulp, either moderately crushed (~12 mm), finely crushed (~1 mm), or pulverized (~75 μm). The latter is of little use in a metallurgical test program, but the crushed materials have some value. An advantage of using assay pulp is that it is usually plentiful and reasonably representative of the deposit. A disadvantage is that minerals may have deteriorated during storage, and testing based on whole-rock response (e.g., crushability) is precluded.

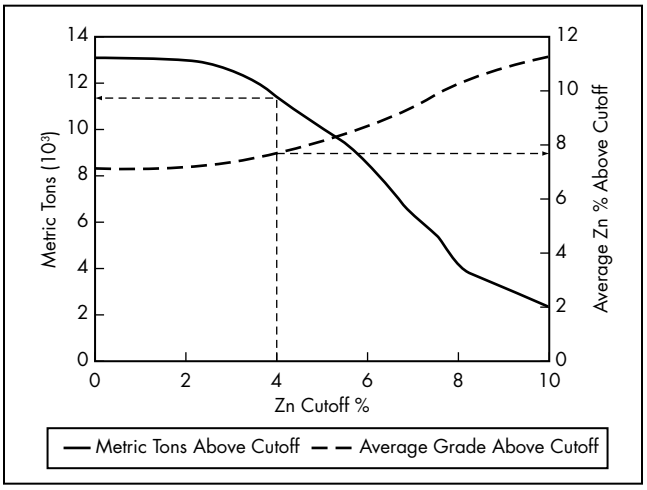


Figure 4.4-2 Sample grade–tonnage curve

Split Core

In an exploration program, diamond-drill core samples are generally cut in half. One half is sent for chemical analysis; the other half is then generally quartered, and one quarter subjected to metallurgical testing and the other quarter kept for reference.

Trenching and Pitting

Near-surface ore bodies can be sampled by means of pitting or trenching. Both are relatively inexpensive means for obtaining bulk samples for testing. A disadvantage is that the samples taken may not represent the mineralization below the level of pitting, particularly where the ore body has been subjected to weathering near the surface.

Channel Sampling

Where there is access to the ore body, the mineralized face can be channel sampled. This involves cutting a channel over the mining width without preferential recovery of highly mineralized or softer minerals. The width of the sample can be extended into the footwall or hanging wall so as to include mining dilution.

GY'S SAMPLING FORMULA

Gy's sampling formula (Gy 1979) is widely used when subsampling particulate material for a metallurgical test program. The formula predicts sampling errors incurred when a subsample is taken from a known weight of crushed or ground material. It also determines to what size a sample must be crushed and the size of subsample that must be taken to achieve satisfactory sampling accuracy. However, the formula does not determine the size of sample that should be taken when sampling an ore body, drill-core sample, or mine face.

Gy's sampling formula can be simplified to

$$M = Cd^3/s^2$$

where

M = minimum sample weight
C = sampling constant
d = top size of the material being sampled
s = a measure of the statistical error incurred during sampling

The formula considers particle size, mineral content, degree of liberation of the minerals, and particle shape. The sampling constant C depends on the material being sampled and takes into account the mineral content and its degree of liberation. It may vary with d, and often must be experimentally calibrated for the material being sampled. The term s can be used to measure the confidence in the results of the sampling exercise.

Applications of the formula involve the introduction of sampling constants, shape factors, size-range factors, liberation factors, and mineralogical factors, and the concept of fundamental error. The formula is also widely used in the sampling of alluvial material. Alluvial deposits generally contain very low levels of economic minerals and the formula can determine the size of sample that must be taken to achieve a given degree of sampling accuracy. The required size is often such that a small-scale or pilot gravity processing plant must be constructed on-site.

SAMPLE SELECTION FOR METALLURGICAL TESTING

If the style of mineralization is the same throughout an ore body, with the same minerals present in the same proportions with no significant degree of alteration, then a single composite sample can be taken for testing.

If the style of mineralization is not the same or if some doubt exists regarding ore consistency, then several samples should be taken and subjected to a range of basic mineralogy and scoping beneficiation tests. If all samples yield the same test results, the samples can be combined into a single composite sample for testing. However, it is more likely that mineralization is variable, with different styles and processing characteristics. The most common examples of this are gold and base-metal ores that have both primary and oxide ore zones, often separated by a transition zone. Mineralization within these zones is clearly different, and each zone must be tested separately. Other examples of ore-body variability include mineralization hosted within different lithologies; spatial variation in grade, either with depth or laterally; mineral alteration; and variation in the ratios of economic minerals where more than one is present.

The distribution of deleterious elements can also affect the selection of test samples. Classical related pitfalls of sample selection include the following:

- The sample is not representative of the mineralization being sampled.
- The mineralization being sampled is not representative of the rest of the deposit.
- The sample represents the average characteristics of the deposit but does not consider factors such as range of head grades, mineralogy, and physical characteristics.

LABORATORY TEST PROGRAMS

Laboratory test programs are undertaken in a number of phases, each of increasing detail, complexity, and cost.

Scoping Test Program

The first level of testing, scoping testing, identifies the processing characteristics of the ore and any potential factors that may hinder realization of its perceived economic value. The aim at this point is to identify minerals of economic interest and broadly define the processing characteristics of the ore while minimizing testing costs.

If test results are favorable and the ore body is deemed potentially viable, more detailed test programs are then undertaken. The scale of testing increases as knowledge of the deposit and confidence in the ore reserves increase.

Scoping tests can be undertaken on samples weighing as little as a few kilograms. In particular, basic optical mineralogy can reveal the limits of recoverability of certain mineral phases or the grade of mineral concentrate that can be produced. Mineral phases or elements that are deleterious to final product quality can also be identified and quantified at an early stage.

Preliminary Test Program

The second level of testing, preliminary testing, defines more clearly the processing characteristics of the ore and provides basic test data needed to size crushers, primary grinding mills, beneficiation plants, and thickeners. Preliminary testing involves more detailed analytical, mineralogical, and beneficiation tests, often on a range of samples taken from different areas of the deposit.

Preliminary tests investigate the ore's response to processing at a range of grind sizes determined from the mineralogical analysis. Beneficiation tests are performed using a range of techniques appropriate to the minerals to be recovered.

For gravity and flotation testing, initial batch tests can take the form of so-called rougher tests where the sample is processed in a single stage to produce a number of products of varying grades. Depending on the beneficiation method used, concentrates from a rougher test can then be subjected to cleaning tests to determine final product quality. A batch test does not give a final measurement of either quality or recovery, as some mineral values are lost with material rejected during cleaning. In a continual process, these cleaner tailings are normally recirculated to some degree, which increases product recovery but may well reduce the final product grade.

Physical tests performed at this stage are normally limited to the Bond ball mill work index test.

Detailed Test Program

The third level of testing, detailed testing, is normally undertaken as part of a full feasibility study. At this stage, the grade of ore to be processed should be known to a high degree of confidence. A mining plan should also have been established, although it is in the nature of feasibility studies that mine-plan optimization is normally run concurrently with the final stages of metallurgical testing and plant design.

It is important that dialogue be maintained among geologists, mining engineers, and process engineers, as mine plans can often change rapidly when computer mine-modeling systems are used. Mining engineers determine the optimum ore extraction rate and convert the geological resources into mining reserves by applying mining-recovery and dilution factors as well as conceptual mine-design and commodity-price considerations.

Samples of the products from the test program may be sent for vendor testing, particularly if performance guarantees are to be sought, and such tests are often undertaken for dewatering of tailings or concentrates. Laboratory settling tests, using measuring cylinders, can readily be undertaken on relatively small samples. Similarly, vacuum filtration tests can be undertaken using standard laboratory filter leaf tests, although tests for pressure filtration require considerably larger samples than are normally generated in a laboratory bench-scale test program. Bulk samples of concentrates or tailings for such

tests may be produced from pilot-scale testing, but if no such samples are available, vendors can size equipment based on their experience with other operations.

Bulk samples of concentrates or tailings can be produced from pilot-scale tests. If no such samples are available, vendors can size equipment based on their experience with other operations.

Variability testing should be undertaken on a range of samples to determine how the processing characteristics of the ore body vary. It may be advisable to test composite samples that represent the ore that will be treated during the crucial first 2 years of production.

TEST-PROGRAM STAGES

Test-program stages include sample preparation, chemical analysis, and mineralogical analysis.

Sample Preparation

Sample preparation generally involves the preparation of one or more composite samples, often from many individual samples. Samples may require drying and crushing to improve representivity and to initiate the comminution process.

Drying should be undertaken at a temperature that does not alter the physical or chemical nature of the minerals and can be undertaken under ambient conditions (air drying) or in an oven. Some minerals may need to be dried in an inert atmosphere.

Crushing of a dried sample is generally done with jaw, cone, or roll crushers. The crushed material is then thoroughly mixed, either manually or by rotating drums. The mixed material can be divided into subsamples by means of a Jones riffle splitter or rotary splitter or by cone and quartering techniques.

Chemical Analysis

The following are techniques for determining the major chemical elements of interest in a sample:

- Atomic absorption spectroscopy is widely used to analyze base metals and is also suitable for analyzing precious metals.
- Fire assay is the most widely accepted technique for analyzing gold and platinum group metals.
- Inductively coupled plasma is used as the main analytical method and can also produce reasonably accurate semiquantitative scans of minor and trace elements.
- X-ray fluorescence can detect major rock-forming elements and is a preferred method for analyzing niobium, tantalum, tin, tungsten, and other elements that are difficult to dissolve in acid.

Mineralogical Analysis

Optical microscopy is used initially to determine the mineralogical composition of a sample in order to identify the economic minerals present, identify the gangue or other rock-forming minerals, estimate the likely liberation size of the minerals of interest, and evaluate the degree of alteration of the minerals.

X-ray diffraction (XRD) can also be used to identify minerals, although the method is, at best, only semiquantitative. Scanning electron microscopy (SEM) can be used to identify minerals that cannot be identified optically. Electron probe microanalysis can be used for chemical analysis of mineral grains to a low level of detection.

In recent years, automated SEM image analysis has become possible due to the advent of QEMSCAN (Quantitative Evaluation of Minerals by Scanning Electron Microscopy) and Mineral Liberation Analyzer systems. These systems rapidly scan a sample with an electron beam and analyze the resulting X-rays to identify mineral composition. Data output includes mineralogical maps of the sample and information on grain size, shape, and mineralogical associations. The output can be used to produce limiting grade–recovery curves that can assist in determining the maximum degree of separation efficiency for a particular sample. Analysis is usually performed on discrete size ranges, and large amounts of data can be generated from even a single sample. Careful interpretation of the data is required to gain maximum benefit from this developing technology.

BENEFICIATION TESTS

After chemical and mineralogical testing is completed, a beneficiation test is usually performed. Beneficiation tests exploit chemical and physical differences between the one or more minerals to be recovered and the host rock or gangue minerals.

Beneficiation testing can include froth flotation, gravity, hydrometallurgical processing, magnetic, electrostatic, pyrometallurgical, and screening tests.

PILOT-PLANT TESTS

After laboratory testing is complete, it may be necessary to perform continuous pilot-plant tests. Pilot-plant tests become practical in any of the following situations: (1) the test process is technically complex and involves the recycling of product streams, (2) the test process is technically straightforward and pilot test facilities can readily be sourced, or (3) plant capital expenditures are high.

Contract pilot-plant testing is expensive, and relatively few facilities offer the service. There is clearly little point in performing pilot-plant tests unless a truly representative sample can be obtained. Access to the ore body is normally required unless sufficient material is available from drilling programs. Furthermore, contract facilities may not have the correct sizes of equipment for the flow sheet being tested and compromises are often made. A high degree of operator knowledge is required or else the exercise becomes one of testing the pilot plant itself rather than the process.

Pilot testing can also be undertaken by treating bulk samples through an existing facility that uses a flow sheet similar to that being proposed for the new operation. This might be the case when an ore body is being developed near an existing operation that is treating a similar ore type.

For larger-scale projects, it may be possible to justify purchasing a pilot plant and performing tests on-site. Doing so enables evaluation of site-specific conditions such as water quality, temperature, and atmospheric conditions, and allows local operators to be trained. Although it may be possible to purchase secondhand equipment, on-site testing is almost always expensive. It is important to ensure that equipment used in pilot-plant testing is well matched and capable of the required throughput.

Pilot-plant testing enables the testing of specific equipment such as that required for pressure filtration, high-rate thickening, column flotation, and developing technologies that cannot be readily evaluated on a laboratory scale. It also enables production of bulk samples of concentrate for marketing purposes or for further specialized testing. Bulk samples

of tailings can also be produced for backfill, paste, or liner tests.

Pilot-plant test data requires careful evaluation and should, whenever possible, be audited by independent observers. A thorough review of metallurgical balances is required to ensure that data was obtained at steady-state operating conditions. Chemical analyses should also be audited and check samples should be submitted to reputable assay laboratories.

Whether or not to perform pilot-plant tests is a complex decision but ultimately comes down to the question of risk. Constructing and operating an on-site pilot plant is expensive but, if testing is performed to a high standard, minimizes technical risk. A concentrator designed on the basis of small-scale batch laboratory tests undertaken on a few kilograms of material probably has a relatively high chance of failure, depending on the commodity being investigated.

Notably, gold ores are rarely pilot-tested, as the tests involved are well understood and can easily be performed on relatively small samples. In recent years, even complex sulfide ore flotation flow sheets are less likely to be pilot-tested because locked-cycle tests (explained in the following section) can be used to simulate continuous flotation performance accurately.

SPECIFIC TEST METHODOLOGIES

The following tests are related to minerals-processing test work.

Physical Testing

Physical tests evaluate the resistance of ore to breakage and determine the crushing and grinding power required during comminution. Abrasion tests determine the consumption of grinding media and liners during grinding. The following tests are available:

- **Bond abrasion index (Ai) test.** Each test requires at least 1,600 g of 19 × 13 mm (0.75 × 0.50 in.) material. The test provides an index from which the wear rates of grinding media and liner wear rates can be determined.
- **Bond ball mill work index test.** Each test requires ~10 kg of sample, stage-crushed to pass 3.36 mm. The test uses a closing screen size of 100 μm and a range of factors to determine the grinding power required to achieve a given product d_{80} (80% passing size).
- **Bond low-energy crushing work index (Wi_c) test.** Each test requires at least 20 pieces sized between 51 and 76 mm.
- **Bond rod mill work index test.** Each test requires ~15 kg of sample, stage-crushed to pass 12 mm.

Autogenous grinding (AG) and semiautogenous grinding (SAG) milling tests can also be performed. Several types of tests can be undertaken to evaluate how an ore will respond to milling:

- **Advanced media competency test.** A suite of tests covers impact crushing, rod and ball mill work indices, abrasion index, and uniaxial compressive strength tests to determine whether a material is suitable for autogenous or semiautogenous milling. An advantage of this test suite is that it can be used on PQ core material (85 mm).
- **Autogenous media competency test.** Each test requires 200 kg of material in discrete size ranges from 152 × 140 mm down to 114 × 102 mm. The sample is loaded into a drum (1.83 × 0.3 m) and rotated for 500 revolutions while power draw is measured. A range of Bond crushing, rod, and ball mill tests are performed on the mill product and on fresh ore.
- **JK Tech drop-weight test.** Each test requires 100 kg of crushed ore in the size range 75 to 12 mm. If diamond drill core is used, the core diameter should be at least 50 mm. The test measures impact-breakage and abrasion-breakage parameters. The former is determined by a tumbling test, the latter by a high-energy impact device called a JK drop-weight tester. These parameters are then used in a computer model (JKSimMet) to predict AG and SAG mill performance.
- **MacPherson autogenous work index test.** Each test requires 250 kg of material, stage-crushed to pass 32 mm. The test is performed in a mill (of diameter ~46 cm or 18 in.) as a dry grinding process with cyclone classification. It does not evaluate the competence of the ore at the coarse sizes used in autogenous or semiautogenous milling but gives a preliminary indication of whether the ore is better suited to autogenous or semiautogenous milling.

The number and type of samples submitted for testing depend on the complexity of the ore body and the associated host rocks. It is important that the samples include mining dilution. For an underground mine, it is also important to consider the expected proportions of hanging-wall and footwall dilution.

When designing comminution circuits for a concentrator, it is important to know not only the average value of the ore's hardness (resistance to breakage) but also the range of values that will be experienced throughout the life of the mine. It is therefore important to test a range of samples to determine how energy requirements and plant throughput will vary. The choice of these samples should generally be made based on the lithology of the rock types present rather than the ore mineralogy, particularly if the economic mineral is a relatively minor component of the ore.

The final value of the work index used for plant-design purposes depends on the nature of the ore body and the mine plan. For example, in an open-pit mine, if the ore body has a work index that is lower at the top and higher at the bottom of the pit, then it is clearly necessary to design the comminution circuits to treat the harder ore at the bottom.

In an underground mine, ore may vary in hardness, but in practice it is likely to be produced from several stopes in different parts of the ore body, in which case it may be adequate to design not for the hardest ore type but rather for a calculated blend based on the predictions of the mine plan. Comminution circuits are normally designed based on a stated average value of work index as well as the range of values with which the plant is expected to cope.

Gravity Testing

High-density minerals can be recovered by means of gravity processing. The following test methods may be appropriate.

Heavy Media Separation Test

Some ores are amenable to preconcentration using heavy media separation (HMS). HMS can be used to reject a significant portion of ore at a relatively coarse crush size with low loss of mineral value. Tests are performed with heavy liquids, typically with densities in the range 2.6–3.3 g/cc. Crushed ore

is screened into size ranges, and each size fraction is subjected to sink–float separations within closely sized density ranges.

Heavy-liquid test results are usually sufficient to evaluate the efficiency of most HMS processes. It is not necessary to perform pilot-plant testing unless bulk samples of HMS product are required for subsequent processing.

Spiral Test

Gravity separations can be performed using spirals on material in the size range 1.5–0.05 mm. A full-size spiral requires a minimum of 30 kg of material although smaller units can be used. Tests are normally performed in a closed circuit with products periodically removed and fresh material added.

Table Test

Shaking table tests are usually performed in an open circuit. The feed material should be reasonably closely sized. Products can be subjected to further cleaning, and computer models can determine the effect of recycling these products.

Gravity-Recoverable Gold Test

The use of centrifugal concentrators such as those made by Falcon and Knelson is a well-established method for treating gold ore. Concentrators are often installed within a grinding circuit for treating a portion of the circulating load (cyclone underflow).

A standard gravity-recoverable gold test involves stage-grinding a sample (10 kg) and performing a gravity separation after each grinding stage. The gravity concentrate is generally cleaned using a Mozley table or other laboratory panning device, and the gravity tailings are combined and ground to liberate further values. This method simulates gold recovery in a grinding circuit and recovers gold as soon as it is liberated so as to prevent overgrinding.

Gravity concentrate should be cleaned to the point that it is either salable or readily processed by smelting or further processing methods such as intense cyanidation.

Flotation Testing

Froth flotation is a widely used beneficiation method. The response of an ore to froth flotation can be readily tested in the laboratory using bench-scale flotation machines. Samples (typically 1 kg) are ground in a laboratory rod or ball mill and subjected to batch tests in which samples of concentrate are collected for timed periods.

A flotation test program generally involves the following stages:

1. Determining the relationship between mineral recovery and grind size
2. Collector screening
3. Testing the effect of pH
4. Testing modifiers to reduce or increase the floatability of minerals
5. Regrinding rougher or scavenger concentrates
6. Performing cleaning tests

A test program often culminates in a series of locked cycle tests. This laborious procedure involves a series of identical tests, or cycles, in which intermediate cleaner tailings products are added at the appropriate point in the subsequent cycle to simulate closed-circuit cleaning. The tests predict how mineral values that report to the cleaner tailings during the cleaning stages will be redistributed between the final products and tailings during continual processing. The locked cycle test generates a final metallurgical balance for the process and determines the final product concentrate grades and recoveries. Undertaking such tests requires experience, and it is essential that the test be kept in balance or equilibrium such that the weight of metal in the final products of each cycle matches the input of new material.

Gold Ore Testing

The testing of gold ores is often complicated by the low levels of gold present. Sampling errors increase as the grade of gold decreases and the gold particle size increases.

Cyanidation remains by far the most common method of processing gold and is used increasingly in conjunction with gravity processing. The following cyanidation tests are available.

Diagnostic Leach Test

The diagnostic leach test determines the gold mineralogy or gold associations within an ore. The test is actually a series of tests in which the gold in the sample is progressively recovered. Test stages might include the following:

1. Gravity testing and amalgamation to determine free gold
2. An initial cyanidation test to determine cyanide-recoverable gold
3. Treatment of the cyanide tailings with warm nitric acid to break down sulfide minerals, followed by filtering, thoroughly washing of the residue, and a further cyanidation test to determine gold associated with sulfides
4. Fire-assay analysis of the residue to determine gold encapsulated within silicate minerals

There are no standard test methods. Rather, tests are usually tailored for a particular ore type based on the basic mineralogy of the sample.

Bottle Rolls Test

Preliminary cyanidation tests often involve bottle-rolling. A sample is ground wet, often without measuring particle size, and placed in a bottle with lime and cyanide. The bottle is then rolled, typically for 24 or 48 hours, and the amount of soluble gold is determined. Analysis of the solid residue determines the gold recovery. The test is often undertaken by assay laboratories to give an initial indication of the feasibility of using cyanidation for gold recovery. However, the test is generally not sophisticated, and the levels of cyanide and oxygen present, both of which are essential for leaching to proceed, are sometimes not measured.

Agitated Leach Test

Laboratory cyanidation tests can also be performed in a stirred vessel where the pulp is agitated by a mechanical stirrer. The test is akin to industrial methods of processing; it enables air or oxygen to be sparged through the pulp and it is easy to monitor pulp conditions throughout the test.

The main process variables are grind size, pulp density, cyanide concentration, pH, and air requirement. The test determines whether it is advantageous to add carbon during the leaching process (carbon-in-leach) to minimize the effect of preg-robbing, in which soluble gold is adsorbed onto organic carbon that may be present in the ore.

The test can be performed with impellers and reaction vessels that give known scale-up factors. The dimensions and

speed of the impellers should be carefully controlled and the reaction vessel fitted with baffles to improve mixing.

Carbon Adsorption Test

Carbon adsorption tests determine the gold and silver loadings that will be achieved during continuous processing using carbon-in-pulp technology. The test involves adding varying amounts of carbon to samples of leached pulp and determining how the levels of precious metal decrease with time. Test results can predict the number of carbon adsorption stages required.

Column Leach Test

Column least tests determine the feasibility of using heap leach technology to recover gold. The static tests are performed in vertical columns typically ranging from 0.15 to 0.30 m in diameter, although pilot-plant tests may be performed in vessels several meters in diameter.

The ore sample is crushed and placed in the column, often on top of a filter medium consisting of crushed rock and hessian. If the sample contains clay, it may be necessary to agglomerate the ore using cement. In the laboratory, agglomeration is normally performed by rolling the sample in a cement mixer, adding measured amounts of cement and water, and curing for 24 to 48 hours before testing. Cyanide solutions are pumped into the top of the column by peristaltic pumps. The solutions percolate down through the bed of material, leaching gold and silver minerals. They are collected and measured daily and assayed for metal content, pH, and cyanide concentration, then passed through carbon columns to recover the precious metals. The barren solutions are pumped back through the column.

Environmental Testing

Tightening requirements for obtaining environmental permits for mining projects are resulting in similarly increased requirements for testing of tailings, low-grade ore, and other waste products. Test objectives are generally to determine the nature of the products arising from long-term degradation of mineral species.

Tailings Characterization Tests

Tailings characterization tests can involve the following analyses:

- Chemical analysis (major and trace element analysis)
- Mineralogical analysis using optical methods and XRD
- Particle size analysis

Chemical and mineralogical tests and particle size analysis were discussed previously; the goal of these tests is to gain a basic understanding of the nature of the tailings. Chemical analysis should identify the presence of elements that are potentially toxic and have the potential to enter the environment.

Acid–Base Accounting Analysis

Acid–base accounting (ABA) seeks to determine the acid-producing potential of tailings material. The method involves determining the total sulfur and sulfate sulfur contents of a sample and calculating the sulfide sulfur content by difference. The levels of sulfide sulfur indicate the acid-generating potential of the material, it being assumed that all sulfide sulfur present converts to sulfuric acid. Some methods involve only total sulfur analysis and assume that all sulfur present converts to sulfuric acid over time.

The acid-neutralizing potential of a material is determined in a separate test that involves reacting a known weight of sample with hydrochloric acid and determining the amount of acid consumed by titration.

The net generating potential is the difference between acid-generating potential and acid-neutralizing potential, and is normally quoted in metric tons of calcium carbonate per 1,000 t of material.

An alternative ABA method is the net acid generating test, which uses hydrogen peroxide to oxidize sulfide minerals. The pH at the end of the test is regarded as a measure of the sample's ability to generate acid.

There are several variations of ABA procedures, and the methodologies are continually being refined.

Leachate Analysis

Two types of leachate analysis are appropriate:

1. Synthetic precipitation leaching procedure (SPLP) test. The test determines the mobility of toxic organic and inorganic materials into groundwater. It involves shaking a sample (100 g) with a very dilute acid that represents rainwater, and analyzing the filtered leachate for a range of determinands. The strength of the acid used in the test should match the perceived levels of pollution.
2. Toxicity characteristic leaching procedure (TCLP) test. The test determines the mobility of the organic and inorganic phases in a material. It involves shaking a sample (100 g) with an acid buffer for a prescribed period of time; the pH of the buffer depends on the pH of the sample. The pulp is filtered and the leachate analyzed for a specified suite of 40 determinands, although this can be modified depending on the material being tested.

Humidity Cell Test

The humidity cell test is an accelerated weathering test in which a sample (1 kg) is placed in a cell and subjected to the following cycle: 3 days of dry-air permeation followed by 3 days of humid-air permeation and 1 day of washing with a fixed volume of water. The water samples are collected, carefully stored, and analyzed for a range of determinands. The test period can range from 20 weeks to 2 years.

CHAPTER 4.5

Mineral Resource Estimation

Alan C. Noble

Mineral resource estimation is the process of estimating the tonnage, grade, size, shape, and location of mineral deposits. The *ore reserve estimate* follows the resource estimate, and generally requires at least a prefeasibility study to establish quantity and grade of a mineral that may be profitably and legally extracted from the deposit. Estimation of ore reserves involves not only evaluation of the tonnage and grade of a deposit but also consideration of the technical and legal aspects of mining the deposit, beneficiating the ores, and selling the product.

Estimation of the mineral resource generally involves only the geologist and a resource estimator who may be a geologist, geostatistician, or mining engineer that specializes in resource estimation. This team works together to define a resource model that defines the in-situ characteristics of the mineral deposit. The mineral resource model does not generally require consideration of mining costs or mining method, but it may be convenient to incorporate some mining features such as bench height in a deposit that will be mined by open pit, or minimum mining width for an underground vein mine. Reporting of the mineral resource is a different matter, however, and at least minimal consideration of project economics will be required to determine a cutoff grade above which resources are reported. The standards for reporting resources and reserves are different for the various countries, and the resource estimator must be careful to follow the appropriate regulations. Some examples of reporting requirements and standards include the Securities and Exchange Commission *Industry Guide 7* for the United States, NI 43-101 for Canada, the JORC Code for Australia and New Zealand, and the SAMREC Code for South Africa (SEC 2007; National Instrument 43-101 2005; AusIMM 2004; SAMREC 2007).

RESOURCE ESTIMATION METHODOLOGY

A resource estimate is based on prediction of the physical characteristics of a mineral deposit through collection of data, analysis of the data, and modeling the size, shape, and grade of the deposit. Important physical characteristics of the ore body that must be predicted include the size, shape, and continuity of ore zones; the frequency distribution of mineral grade; and the spatial variability of mineral grade. These physical characteristics of the mineral deposit are never completely known but are projected from sample data. The sample data consist of one or more of the following:

- Physical samples taken by drilling, trenching, test pitting, and channel sampling
- Measurement of the mineral quantity in the samples through assaying or other procedures
- Surveys to determine the location of the samples in three-dimensional (3-D) space
- Measurement of in-situ rock density
- Direct observations such as geologic mapping and drill core logging
- Metallurgical testing to define the amenability of the minerals for upgrading and extraction

Estimation of the resource requires analysis and synthesis of these data to develop a resource model. Methods used to develop the resource model may include

- Compilation of the geologic and assay data into maps, reports, and computer databases;
- Delineation of the physical limits of the deposit based on geologic interpretation of the mineralization controls;
- Compositing of samples into larger units such as mining bench height, seam thickness, or mineable vein width;
- Modeling of the grade distribution based on histograms and cumulative frequency plots of grades;
- Evaluation of the spatial variability of grade using experimental variograms; and
- Selection of a resource estimation method and estimation of quantity and grade of the mineral resource.

The estimation procedure must be made with at least minimal knowledge of the proposed mining method because different mining methods may affect the size, shape, and/or grade of the potentially mineable ore reserve. The most important mining factors for consideration in generating an ore reserve estimate from a mineral resource estimate are

- The range of likely cutoff grades,
- The degree of selectivity and the size of the selective mining unit for likely mining methods, and

Alan C. Noble, Principal Engineer and Owner, Ore Reserves Engineering, Lakewood, Colorado, USA

- Variations in the deposit that affect the ability to mine and/or process the ore.

These mining factors often determine the degree of detail that is required for the resource model. For example, a disseminated gold deposit may be continuous and regular in shape, if mined by bulk open-pit methods. The same deposit may be discontinuous and difficult to estimate, however, if mined by more selective underground methods at a higher cutoff grade. Such large differences in deposit shape due to variations in cutoff grade and mining method may require different ore reserve estimation methods for different mining methods.

DATA COLLECTION AND VERIFICATION

Data that must be collected and compiled for the resource estimate are as follows:

- Reliable assays from an adequate number of representative samples
- Coordinate locations for the sample data
- Consistently recorded geologic data that describe the mineralization controls
- Cross sections or plan maps with the geologic interpretation of the mineralization controls. The geologic interpretation may be developed interactively on the computer using 3-D modeling methods, in which case paper plans and sections may not be required.
- Tonnage factors or specific gravities for the various ore and waste rock categories
- A surface topographic map, especially for deposits to be surface mined
- Metallurgical testing for samples representative of the various types of mineralization in the deposit

Although small deposits may be evaluated manually using data on maps and in reports, manual methods of resource estimation are nearly obsolete. Resource estimations are primarily done using computer methods with the resource data entered into a computer database. Computer programs can then be used to retrieve the data for printing reports, plotting on digital plotters, statistical analysis, and resource estimation. The minimum information that should be included in a drill-hole database are

- Drill-hole name, number, or other unique identification;
- Hole length, collar coordinates, and down-hole surveys;
- Sample intervals and assay data;
- Geologic data such as lithology, alteration, oxidation, etc.; and
- Geotechnical data such as rock quality designation.

Entry of data into a computer database is a process that is subject to a high degree of error if not carefully controlled and checked. Some procedures that may be used to ensure that the data have been entered correctly are as follows:

- Verification of the data using independent entry by two persons. This may also include importing of the data by two persons/methods and electronically comparing the results.
- Manual comparison of a random sample of hard-copy data sheets with data in the database.
- Scanning the data for "outlier values"; for example, drill locations outside the project limits, high and low assays, and sample intervals that overlap or are not continuous.
- Comparison of computer-plotted data with manually plotted maps of the same data. Collar location maps and cross sections are especially useful to rapidly locate inconsistent collar locations and downhole surveys.
- An independent audit of the data as part of statutory requirements, which may be required by some regulatory bodies.

Assay data are generally transferred from the analytical laboratory to the client using electronic means (such as e-mail) to transfer the data in electronic format. Although this dramatically reduces data entry errors compared to manual keyboard entry, it creates a new set of problems. A particular issue is that the laboratory may change the reporting units (for instance, from parts per million Au to ounces Au/t, or parts per million to parts per billion) from one report to the next, or even within the same report.

The recent practice of surveying collar coordinates using Global Positioning System (GPS) methods is also a frequent source of errors. Particular problems include reporting using different datum, improper units, incorrect conversion from GPS units to a local survey, and use of a low-resolution, inaccurate consumer handheld GPS units. The geologist or resource estimator should always ensure that the survey method, survey datum, data postprocessing methods, datum conversions, and the type of instrument are reported with the survey data.

Additional care and attention to the detail and accuracy of the resource database are essential. A database with a large number of errors may result in a resource estimate that is inaccurate and requires a complete revision to provide defensible results.

GEOLOGIC INTERPRETATION

The sample database represents a large 3-D array of point locations in a deposit. The sample data are quantitative and have been subjected to minimal reinterpretation after the original measurements. There is another body of geologic knowledge, however, that does not fit this description. This is the interpretation resulting from the geologist's assimilation of the geologic data. These interpretative data are often represented on plan maps or cross sections that show outlines of the geologic features or iso-grade contours that define mineral zones.

The current industry practice is to create a 3-D model of a geologic interpretation known as a "wireframe" model. The wireframe model is created by displaying a slice through the deposit on the computer screen and interactively digitizing the outlines of the geologic feature. The digitized line is frequently attached, or "snapped," to points on drill holes, such as contacts and grade-zone boundaries, to provide a more precise location of the line relative to the locations established by the drilling.

The interpretation process is continued on an adjacent slice through the deposit to extend the interpretation. Adjacent lines are then connected using a mesh of triangles to form a continuous 3-D ribbon of triangles that links the two lines. After this process has been completed across the extent of the deposit, the interpretation is a series of adjacent, connected ribbons that are built from a mesh of triangles. The visual appearance of the resulting object, the wireframe model, is that of a triangular network of wires connecting an irregular set of points. A significant body of mathematical tools has been developed by computer software developers

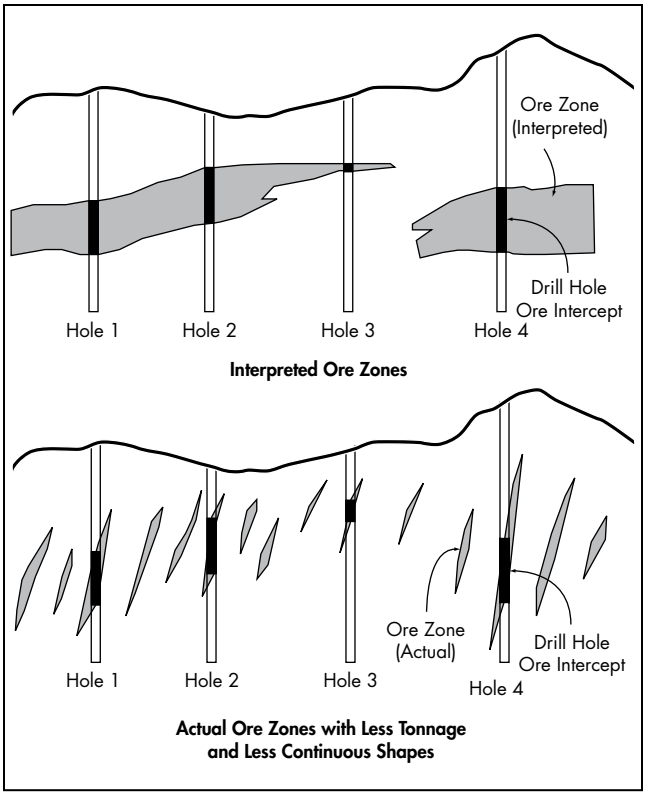

Figure 4.5-1 Overestimation of the size of a mineral deposit based on a geologic model that is more continuous than the actual ore zones

to provide for manipulation and analysis of wireframe models as solid objects for use in resource estimation.

These interpretations provide an interpretative geologic model that is one of the most critical factors in the resource estimation. Failure to develop an appropriate geologic orebody model is the most common reason for large errors in the resource estimates. As shown in Figure 4.5-1, an inappropriate geologic model may lead to errors greater than an order of magnitude.

The geologist's interpretation of the ore body should be used as much as possible in developing the resource estimate. There are, however, practical limits to the amount of complexity that can be included in the resource model, and the geologic interpretation will be limited to critical inputs that define the shape and trends of the mineral zones at different cutoff grades and the character of the mineral zone contacts.

Examples of geologic features that are often modeled include

- Receptive versus nonreceptive host rocks;
- Alteration types that accompany mineralization or create problems in beneficiation;
- Faulting, folding, and other structural modifications;
- Multiple phases of mineralization; and
- Post-mineral features such as oxidation and leaching.

Changes in lithology are often important variables in resource estimation as mineralization can vary because of physical or chemical attributes of the host rocks. The differences may be distinct, such as the sharp contact between a skarn ore body and an unmineralized hornfels country rock. They also may be gradational, such as the gradual decrease in grade that is often observed between a favorable and slightly less favorable host in a porphyry copper deposit. Other important lithologic controls include barren post-mineral intrusive rocks, nonreceptive shale beds, and other unmineralized materials that are contained within the mineralized zone.

The effects of faulting will vary according to whether the faulting occurred before or after the mineralization and what processes accompanied the faulting. A simple post-ore displacement may create a discontinuity in the mineralization trends, preventing simple interpolation across the fault. The same type of fault occurring prior to mineralization may have little or no effect on the mineralization on either side of the fault, or may localize high-grade, vein-type mineralization that must be modeled independently of a more uniformly disseminated ore body. It is also important to determine whether the fault is a thin, well-defined structure or many smaller structures in a complex, wide shear zone. In the first case, the fault is modeled as a simple surface with zero thickness; in the second, the fault zone must be defined and modeled as a volumetric unit distinct from the adjoining rock units.

Folding is particularly significant in sedimentary and stratabound deposits. Modeling of folding depends on whether folding happened before or after ore deposition, on the tendency of the mineral zoning to follow the stratigraphy, on any remobilization that occurred with the folding, and on the creation of mineral traps or other favorable structures. In addition to defining the shape of the folds, it is important to determine whether the mineralization follows the contours of the folds or is independent of the fold geometry.

Multiple phases of mineralization must be defined individually, particularly where they complicate the mineral zoning pattern through overlapping, discordant trends and through post-mineral oxidation or leaching. Secondary enrichment and oxidation will almost always require delineation of these enrichment features as modified ore zones.

The character of the ore zone contact must be determined and input into the resource model. A sharp contact will be handled as a discontinuity (a hard boundary) and the data used independently on either side of the contact. A transitional contact, however, is a broad, gradational boundary (a soft boundary) that may require data selection from zones of 5 m to more than 30 m to achieve true differentiation between the different grade zones. As a transitional zone becomes thinner, it will eventually approach a sharp contact. For practical purposes, any transitional boundary thinner than the smallest selective mining unit will be modeled as a discontinuity.

In addition to definition of these physical ore controls and post-mineral modifications, a clear understanding of ore genesis will always be beneficial in creating a resource model. In the simplest case, the ore genesis will give clues to the behavior of the grade distributions and variograms; in other cases, the genetic structure is so dominant that it can be used as a direct control in the estimation of mineral resources.

Grade zoning is another common method for adding geologic control to the resource model. Grade zones are usually created by manually drawing grade contours on plans or sections through the mineral deposit. Correctly drawn grade zones will synthesize all of the known geologic controls and the assay grade distribution to define a shape for the deposit that is much more informative than just the grades themselves. The grade zone contours may then be wireframed to form 3-D grade shells for use in coding the block model and selecting

assay data for estimation. Some general rules for grade zoning are as follows:

- Grade zones should be fairly smooth, continuous lines. If it is necessary to draw very irregular lines to contour the sample data, grade zoning is generally not appropriate.
- Unless the grade-zone boundary is coincident with a natural break in a grade distribution, the grade-zone boundaries should not be treated as strict hard boundaries for grade estimation. Mineralization is usually gradational across a grade-zone boundary, and it is generally appropriate to treat adjacent grade zones as soft boundaries and nonadjacent grade zones as hard boundaries.
- Defining a grade zone based on the anticipated mining cutoff grade and using that grade zone as a hard boundary is incorrect unless the mining cutoff grade is coincident with a natural break in the grade distribution. The use of the grade zone as a hard boundary in this fashion will create an estimate that is a polygonal estimate along the boundary, and additional dilution is usually required to create an unbiased estimate of the resource grade.

COMPOSITING

Compositing is a procedure used in developing resource estimates in which sample assay data are combined by computing a weighted average over longer intervals to provide a smaller number of data with greater length. Compositing is usually a length-weighted average. If density is extremely variable (e.g., massive sulfides), however, compositing must be weighted by length times density (or specific gravity).

Some of the reasons for and benefits of compositing include the following:

- Irregular length assay samples must be composited to provide equal-sized data for geostatistical analysis.
- Compositing incorporates dilution such as that from mining constant-height benches in an open-pit mine or from mining a minimum height/width in an underground mine.
- Compositing reduces wild variations caused by erratic high-grade values (the nugget effect).

Several methods for compositing may be used depending on the nature of the mineralization and the type of mining. Common compositing methods are (1) bench compositing, (2) constant length, downhole compositing, and (3) ore-zone compositing.

Bench compositing is a method often used for resource modeling for open-pit mining and is most useful for large, uniform deposits. Composite intervals for bench compositing are usually chosen at the crest and toe of the mining benches. Bench compositing has the advantage of providing constant elevation data that are simple to plot and interpret on plan maps. In addition, the dilution from mining a constant-height, constant-elevation bench is approximated by the bench composite.

Downhole composites are computed using constant length intervals that generally start from the collar of the drill hole or the top of the first assayed interval. Downhole composites are used when the holes are drilled at oblique angles (45° or less) to the mining benches and bench composites would be excessively long.

Downhole composites should also be used where the sample interval is long compared to the composite interval. For example, if the composite interval is 10 m and the sample interval is also 10 m, it is possible for a bench composite to straddle two sample intervals. In the worst case, the composite will be composed of two 5-m sections of the 10-m sample intervals and the resulting composite will have exactly the same grade as a 20-m composite and will contain significant excess dilution.

Where the drill holes are drilled in many directions with respect to the ore zone, the composite length may need to be varied based on the orientation of the drill relative to the ore zone. For example, when mineralization in a tabular structure has much better continuity along the structure than across the structure, drill holes oriented perpendicular to the structure should be composited to a short interval, while drill holes oriented parallel to the mineralization should be composited to a longer interval. The ratio of the length of the composites should respect the relative continuity of mineralization in each direction.

Ore-zone compositing is a method of compositing that is used to prevent dilution of the composite when the width of the contact between waste and ore (or low-grade and high-grade mineralization) is less than the length of a composite. Use of bench compositing or downhole compositing in this case may distort the grade distributions by adding low-grade mineralization to the ore population and high-grade mineralization to the waste population, resulting in underestimation of ore grade and overestimation of waste grades.

Ore-zone composites are computed by first identifying the interval containing each ore zone in the drill hole. Each ore zone is then composited individually as follows:

1. The length of the ore zone is divided by the desired length of the composite to estimate the number of composites that will be created;
2. The number of composites is rounded up or down to provide the composite interval that is closest to the desired composite length; and
3. The ore zone is composited using length composites starting at the beginning of the ore zone and length as determined in the previous step.

Geologic codes are usually assigned to composites according to the rock type, ore zone, or other geologic feature. This is often a simple procedure, since most composites will be computed from samples taken from a single geologic unit. Assignment of geologic codes to composites that cross geologic contacts is more complex, since the composite will be computed using data from multiple geologic units. In most cases, the geologic code for the composite is assigned according to the dominant code within the composite.

A special case of ore-zone compositing is encountered in a vein or bedded deposit in that the width of the ore zone is determined by a combination of minimum mining thickness (height) and assay limits. In these situations, composites must be computed for each combination of assay cutoff grade and minimum mining thickness that is used for the resource model.

If the geologic contact is transitional and does not separate contrasting grade distributions, it is appropriate to assign the geologic codes according to the majority rule. If the composite crosses a sharp boundary between contrasting grade distributions, it is best to use geologic unit compositing or to assign the composite to the geologic unit with the most similar grade.

If some sample intervals in the data are missing assays, it is important to determine the reason for the missing data and account for it appropriately. Typical examples follow:

- The missing zone was not assayed because it was low grade or barren by visual inspection, or the sample was missing because of poor core recovery in a barren zone. *Action:* Composite using the average of the barren unit or zero grade for the grade of the missing assay.
- The sample was missing because of poor core recovery in a narrow post-mineral fault. *Action:* Ignore the missing interval when computing composites. The volume of the fault zone is small and the grade will be similar to the grades in the country rock.
- The sample was missing because of poor core recovery in a vein that is higher grade and less competent than the surrounding country rock. *Action:* Ignore the missing interval when computing composites, but retain the length of the interval for use in estimating the width of the vein.

BASIC STATISTICS AND GRADE DISTRIBUTION

Computation of basic statistics and evaluation of grade distributions are the first quantitative analyses of the grade data and are basic tools to provide both feedback to the geologic analysis and input to the resource modeling. Important factors in these basic studies include

- Detection of high-grade or low-grade outlier values,
- Evaluation of different lithologies to determine which are favorable and which are unfavorable host rocks for mineralization,
- Differentiation of complex grade distributions into simple populations for resource modeling, and
- Identification of highly skewed and/or highly variable grade distributions that will be difficult to estimate.

Basic statistics should be computed for sample and/or composite grades in each geologic domain that is suspected to have different characteristics. This may include different lithologies, alteration types, structural domains, grade zones, or other grouping of data that has been recognized (or suspected) to have different grade distributions. Statistics that should be compiled include

- Number of data (samples or composites);
- Average grade, thickness, etc. (mean);
- Standard deviation (std. dev.) and/or variance;
- Coefficient of variation (COV), the standard deviation divided by average grade;
- Histogram of grades; and
- Cumulative frequency distribution (probability plot).

The first item reviewed is the number of data; generally, at least 25 data points are required to make comparisons between different geologic domains. If sufficient data are available, average grades and COVs will be compared among the various geologic domains. General rules for evaluating differences in average grade and guidelines for analyzing COVs are shown in Tables 4.5-1 and 4.5-2, respectively.

Distributions with COVs greater than 25% often have a lognormal grade distribution, and the basic statistics will also be compiled for the natural logarithms of grades. For a perfectly lognormal distribution, the lognormal statistics are related to the normal statistics as shown in Equations 4.5-1 through 4.5-4:

Table 4.5-1 General rules for evaluating differences in average grade

Grade Difference, %	Interpretation
0 to 25	Grade populations that do not usually require differentiation for resource modeling.
25 to 100	Grade populations that require differentiation for resource modeling if divided by a discontinuity such as a fault or if variograms or grade trends are dissimilar.
>100	Grade distributions must be separated for modeling. Differences of 1,000% or more may be observed when barren, mineralized, and/or high-grade populations are present.

Table 4.5-2 Guidelines for analyzing coefficient of variation

COV, %	Interpretation
0 to 25	Simple, symmetrical grade distribution—Resource estimation is easy; many methods will work.
25 to 100	Skewed distributions with moderate difficulty in resource estimation—Distributions are typically lognormal.
100 to 200	Highly skewed distributions with a large grade range—Difficulty in estimating local resources is indicated.
>200	Highly erratic, skewed data, or multiple populations—Local grades are difficult or impossible to estimate.

$$\text{mean} = e^{\alpha + \frac{\beta^2}{2}} \tag{4.5-1}$$

where

α = average of the natural logarithms of grades
β^2 = variance of the natural logarithms of grades

$$\text{median} = e^{\alpha} \tag{4.5-2}$$

$$\text{COV} = \sqrt{e^{\frac{\beta^2}{2}} - 1} \tag{4.5-3}$$

$$\text{std. dev.} = \text{mean} \times \text{COV} = \text{mean} \times \sqrt{e^{\frac{\beta^2}{2}} - 1} \tag{4.5-4}$$

Close agreements between the mean, standard deviation, and coefficient of variation when estimated using both normal and lognormal statistics are indicative of a lognormal population and are required to use lognormal statistics.

GRADE DISTRIBUTION AND GEOLOGIC PARAMETERS

The grade histogram and cumulative frequency distribution are also used to study the relationship between the statistical grade distribution and geologic parameters. The analysis is usually begun with a histogram of sample or composite grades. If the histogram is bell shaped and symmetrical, a normal distribution is indicated and the cumulative frequency will be plotted as a normal probability graph. Normal distributions are not usually found in mineral deposits except for those that are very continuous and have low variability.

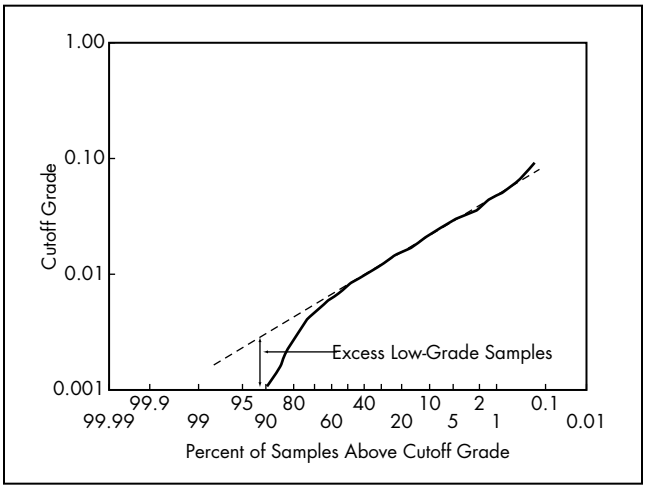

Figure 4.5-2 Cumulative frequency plot showing excess low-grade samples

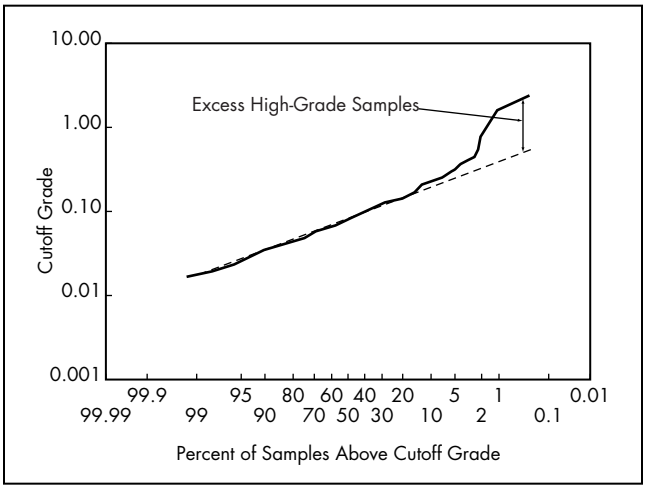

Figure 4.5-3 Cumulative frequency plot showing excess high-grade samples

If the histogram is skewed to the right so that the high-grade side of the histogram is larger than the low-grade side, a lognormal distribution is indicated and the cumulative frequency distribution will be plotted as a lognormal probability graph. Lognormal distributions, or combinations of lognormal distributions, are common in mineral deposits.

A normal probability plot is a specialized plot where one axis (usually the y-axis) is the cutoff grade and the other axis (usually the x-axis) is the cumulative frequency distribution (the percentage of samples above, or below, the cutoff grade). The cumulative frequency axis is scaled so that a normal distribution will plot as a straight line, the slope of the line is proportional to the standard deviation of the distribution, and the 50th percentile is the average of the samples.

A lognormal probability plot is similar to a normal probability plot except that the axis for the cutoff grade is scaled according to the logarithm of cutoff grade. The slope of the line is proportional to the standard deviation of logarithms of grade β, and the 50th percentile is the average of the logs of grades α. A probability axis is generally available in most technical graphing software.

The probability graph may be used to estimate the log–standard deviation based on probabilities from the normal probability distribution, as shown in Equation 4.5-5:

$$\beta = \frac{[\ln(g_{98\%}) - \ln(g_{2\%})]}{4.11} \tag{4.5-5}$$

Often the probability graph will not be a straight line but will be composed of multiple straight lines or curves. A typical deviation from a straight line is a downward curve at the low end of the graph, as shown in Figure 4.5-2. This curve represents excess low-grade samples and in porphyry systems is often attributed to weakly mineralized late intrusions or to post-mineral, barren dikes. On low COV deposits, this type of graph may also represent a normal distribution that has been plotted on lognormal probability paper. The data should be examined to determine the source of the low-grade material and to determine whether that population has been or can be mapped geologically and estimated separately.

Another common deviation from a straight line on the probability plot is a steeper slope at the upper end of the curve, as shown in Figure 4.5-3. This represents excess material in the high-grade population and may be caused by two superimposed populations, such as high-grade veins within lower-grade disseminated or stockwork mineralization. Other causes of excess high-grade assays include small zones that are highly favorable to mineralization because of higher permeability, favorable chemical properties, secondary enrichment, or metamorphic remobilization. Since the high-grade mineralization usually has less continuity than the lower-grade mineralization, the high-grade samples are usually capped to prevent overestimation of the grade of the resource. If the high-grade samples show sufficient continuity to define a continuous volume, a separate high-grade domain may be defined and estimated separately from the lower mineralization.

VARIOGRAM MODELING

The variogram is the fundamental tool used by the geostatistician and geologist to measure spatial continuity of grade data. The variogram (also called the semi-variogram) is usually presented as a graph showing the average squared difference between samples versus the distance between samples. It is computed by averaging the squared differences between pairs of samples that are a given distance apart as follows:

$$\gamma(h) = \text{variogram for distance } h$$
$$= \frac{1}{2N}\sum(g_i - g_{i+h})^2,\ i = 1, 2, 3, \ldots N \tag{4.5-6}$$

where

h = distance between samples
N = number of pairs at distance h

The variogram function, $\gamma(h)$, is computed for a number of different sample distances to provide an experimental variogram that typically looks like the graph in Figure 4.5-4. The most important features of the variogram are the nugget, range, and sill. The nugget value is identified as the y-intercept of the variogram curve and represents random and short-distance variability factors such as sampling error, assaying error, and erratic mineralization. High nugget values are commonly found in mineral deposits where short-distance variability is extremely high, where accurate sampling and assaying of ore is difficult, or where

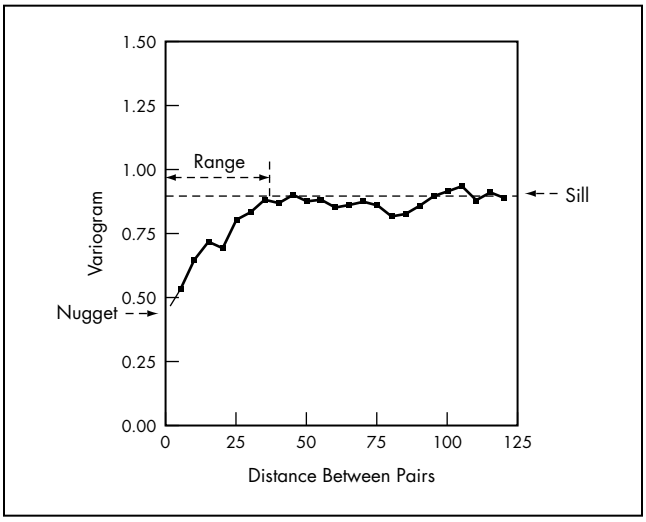

Figure 4.5-4 Typical variogram plot

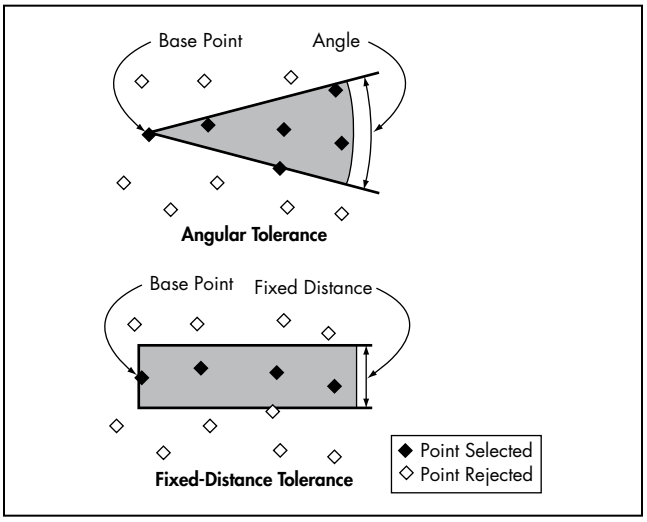

Figure 4.5-5 Simple angular and fixed-distance tolerance geometries for computing variograms

poor sampling and assaying techniques are employed. High nugget effects are found in many gold deposits because of random gold particles that cause large grade changes over small distances. (Note: A "large" gold particle may be as small as 0.25 mm). Similar high nugget values are often found in molybdenum deposits; these are caused by small pockets of pure molybdenite in a disseminated or stockwork mineralization.

Small nugget values suggest good sampling techniques and locally continuous mineralization, and imply that the assays can be used reliably for geologic interpretation and resource estimation. Low nugget values are typically found in many types of deposits, including hypogene porphyry copper, iron ore, and coal. High nugget values have also been found for each of these types of deposits, so each deposit must be analyzed individually. In addition, salting of samples to fraudulently upgrade a deposit may cause a false low-nugget value if a constant amount of finely dispersed mineral is added to samples before assaying. A similar effect has been observed in samples salted by downhole contamination in reverse-circulation drilling.

Most variograms increase in value from the nugget for some distance and then level off to a constant value. This distance is called the range of the variogram, and the variogram value is called the sill. The range is equivalent to the geologist's concept of range of influence; that is, the distance beyond which samples are not correlated with other samples and beyond which grade trends should not be projected. The sill value is usually equal to the sample variance. If the sill is higher or lower than the variance, zonal effects or multiple grade distributions are usually indicated.

The slope and shape of the variogram often vary in different directions, with the range increasing in the direction of greatest continuity of the mineralization. This behavior is referred to as a geometric anisotropy.

Computing an Experimental Variogram

Computing an experimental variogram from a set of randomly spaced data involves finding pairs of data that are oriented in the specified directions, determining the distance between the samples, and then summing the squared differences of the

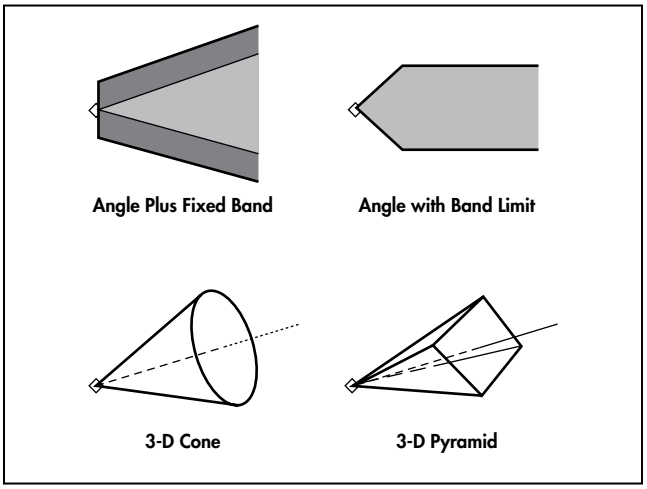

Figure 4.5-6 Composite and 3-D geometries for computing variograms

grades. Since the data are usually sparse, it is necessary to use tolerances for both the directional and distance increments. The directional tolerance is usually achieved with a window angle or a fixed distance, as shown in Figure 4.5-5. These methods may be combined and/or generalized into three dimensions, as shown in Figure 4.5-6. The distance tolerance is a fixed-distance increment (cell size) selected so a reasonable number of samples fall in each cell.

The following list offers some guidelines to aid in computing experimental variograms.

1. Variograms must be computed within continuous zones of mineralization. Contacts should not be crossed between different geologic domains.
2. The maximum distance used should be less than one-half the length of the mineralized zone in the direction of the variogram.
3. The maximum search distance perpendicular to the direction of the variogram must be less than one-fourth the range of the variogram in the perpendicular direction.

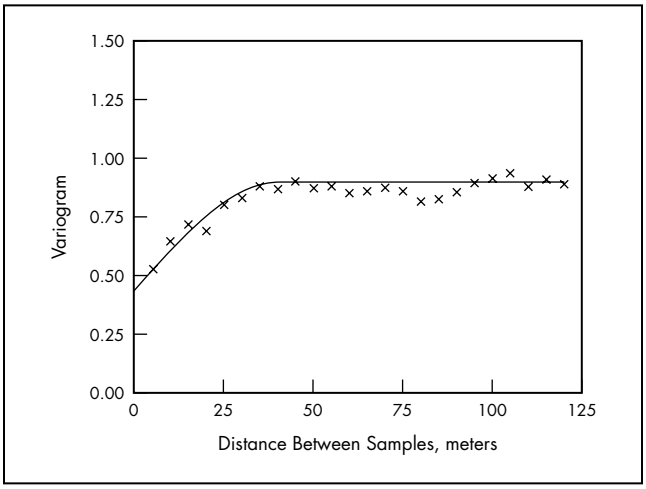

Figure 4.5-7 Spherical variogram model

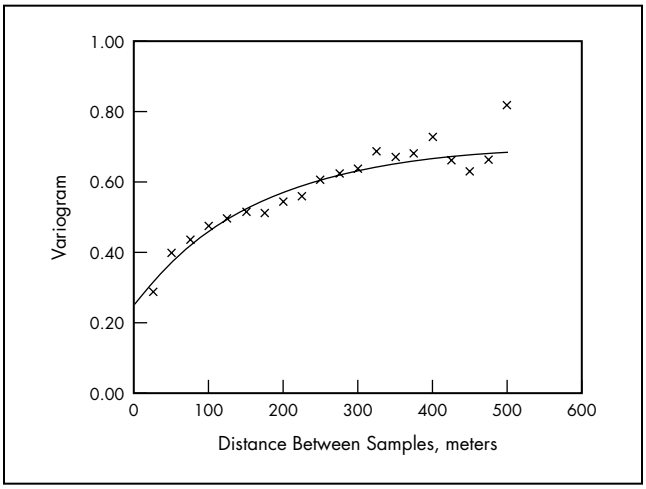

Figure 4.5-8 Exponential variogram model

This is particularly important for planar or bedded deposits that often have much greater continuity parallel to the dominant plane compared to the perpendicular/across-bedding direction.

4. The distance increment should be approximately equal to the average spacing between samples in the direction of the variogram.
5. At least 30 pairs of samples are required to compute a valid variogram. More pairs produce a more stable variogram.
6. All samples must be the same size and should be obtained by the same or similar sampling methods.
7. Where the samples are not evenly spaced, particularly where more samples have been taken in higher-grade areas, data should be declustered before computing the variogram. In addition, a few twin holes in a higher-grade area may give a misleading impression of the nugget effect. The simplest method of declustering is to randomly remove some of the clustered samples. Other methods compute areas of influence for the clustered samples that are used to create weighted averages for statistical analysis and variogram modeling.

A model, or equation, is fitted to the experimental variogram for further geostatistical evaluations such as kriging. The most common variogram models found in mineral deposits are the spherical model, shown in Figure 4.5-7, and the exponential model, shown in Figure 4.5-8. Another model that is rarely seen in mineral deposits but may be useful for classifying resources is the linear model, shown in Figure 4.5-9. Most geostatistical software packages provide functionality for variogram modeling, varying from interactive graphics fitting of the variogram curve to least-squares fitting of the variogram in multiple directions.

Because many mineral deposits have lognormal assay distributions, a proportional effect will be present and grade variability will be higher in high-grade areas than in low-grade areas. This may be dealt with by dividing the raw variogram in each variogram cell by the square of the mean of the samples that were used in the variogram for that cell. The resulting variogram is known as a relative variogram. If the data distribution has been shown to be lognormal during statistical

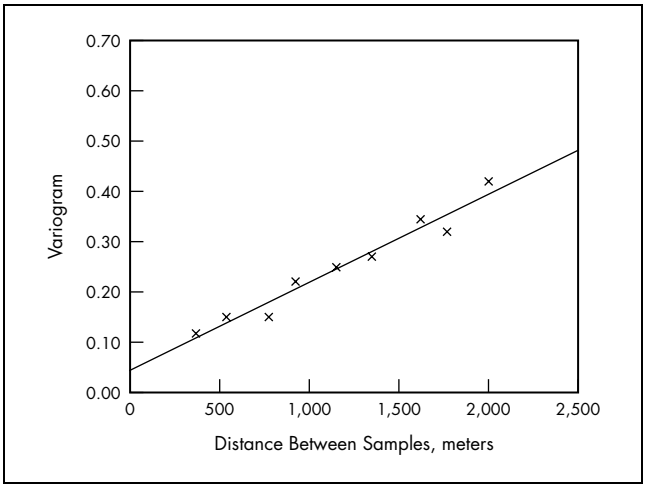

Figure 4.5-9 Linear variogram model

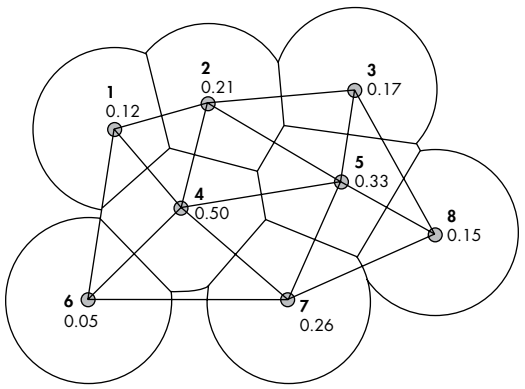
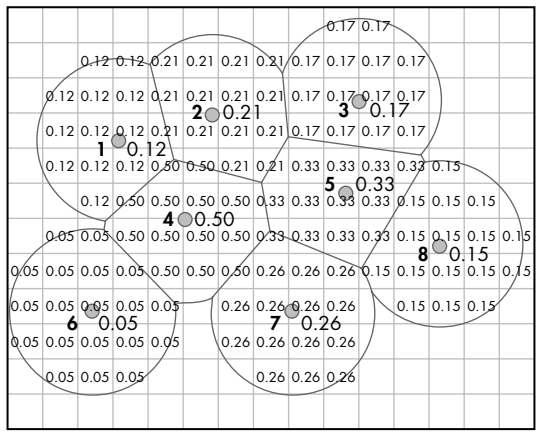


analysis and grade-distribution studies, the variogram may be computed using the logarithms of sample grades. The resulting variogram is often less erratic and more easily interpreted than the variogram of untransformed values. This variogram may be used directly for lognormal geostatistics or may be transformed to a relative variogram as follows:

$$\sigma_R^2 = \text{relative variance} = e^{\beta^2} - 1 \quad (4.5\text{-}7)$$

$$\gamma_R(h) = \text{relative variogram} = \sigma_R^2 - e^{(\beta^2 - \gamma\ln(h))} + 1 \quad (4.5\text{-}8)$$

where $\gamma\ln(h)$ is the log-transformed variogram for distance h.



As shown in the above transformation, the lognormal covariances are transformed using the lognormal-to-relative transformation rather than the raw lognormal variogram. Conversion of the lognormal variogram to a relative one is very important, since the nugget/sill ratio is always higher for the relative variogram than for the lognormal variogram. In addition, caution must be exercised when using the lognormal variogram because small deviations from lognormality may have large effects on the transformation to a relative variogram.

Hole	Grade	Area
1	0.12	39.4

RESOURCE ESTIMATION (MODELING)

Methods for resource estimation or modeling are generally divided into the traditional geometric methods that are done manually on plans or sections and interpolation methods such as inverse-distance weighting and kriging that require the use of a computer.

Geometric Methods

Manual resource estimations are usually done on plan maps or cross-sectional maps that cut the deposit into sets of parallel slices. Data plotted on the maps include drill-hole locations, assay values, and the geologic interpretation of the mineralization controls. True manual estimates on paper are seldom done anymore because of the widespread availability of computer software for resource estimation. Frequently, the computer performs the same calculations as were used for the original manual methods and the results are comparable. The two basic geometric methods are area averaging and polygonal/cross-sectional estimation.

Area Averaging

The area-averaging method is among the simplest of all reserve estimation methods, involving only a geologic interpretation of the shape of the ore and averaging of the grades within that shape. The tonnage is estimated by multiplying the density of the mineral and the volume of the zone. Volume is estimated by multiplying the thickness of the plan/section and the area defined within the interpreted line.

The method may also be implemented in three dimensions using a wireframed volume, in which case the average grade is estimated based on the samples inside the wireframe and the wireframe volume is calculated directly by the software.

Despite its simplicity, the area-averaging method provides excellent estimates where the drilling pattern is uniform, grades are continuous, and ore boundaries are distinct and sharp. Problems may arise, however, when the drill pattern is not uniform. With a nonuniform drill pattern, a cluster of holes in a high-grade zone will cause overestimation of grade. Area-averaging methods also may be difficult to implement on deposits with discontinuous or spotty ore zones, especially if the ore contacts are gradational and multiple cutoff grades are desired.

Polygonal Methods

Polygonal methods involve drawing a polygonal area of influence around each sample intersection, measuring the area of the each polygon, and then calculating the average grade by weighting each sample grade by the corresponding polygonal area. Tonnage is then computed using the same procedure as was used for the area-averaging method, except that the areas used to compute tonnage are the area of each individual polygon.

The classical manual polygonal estimate was done by drawing polygons on plan maps based on the perpendicular bisectors of the line between each drill hole, as shown in Figure 4.5-10. The current computer-based approximation of the polygonal method is the nearest-neighbor estimation. This method requires superposition of a rectangular grid of blocks over the drilled area, as shown in Figure 4.5-11. The grade of the nearest sample is then assigned to each block. This method will closely approximate the polygonal method if the block size is no more than 25% of the average drill-hole spacing.

The polygonal/nearest-neighbor method has the advantage of simplicity and ease of implementation. It is also independent of interpretation bias and provides an unbiased estimate of the average grade of a deposit at a zero cutoff grade. This unbiased estimate of the average grade of the deposit is very useful for validation of an inverse-distance power, kriged, or other advanced estimate.

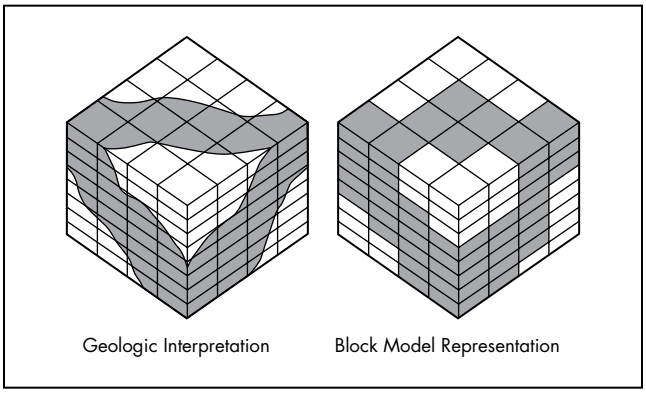

Figure 4.5-12 Geologic feature coded into a block model

The most common problem with geometric methods is that they may imply more selective mining than may be achieved by the mining method. This results from estimating the resource from samples the size of a drill hole but mining larger, less-selective volumes. High-grade blocks usually include lower-grade material when they are mined, and low-grade blocks usually include some higher-grade material. The resulting mined grades are different from the predicted distribution; for cutoff grades below the average grade of the deposit, the mined grade will be lower and the tonnage will be higher. If the cutoff grade is significantly higher than the average grade of the deposit, however, both the mined grade and tonnage can be lower, resulting in a severe overestimation of contained metal.

Moving-Average Methods

The moving-average methods, inverse-distance weighting and kriging, are the most widely used procedures for computer-assisted resource estimation. The basic procedure for both of these methods is as follows:

1. Divide the ore body into a matrix of 3-D, rectangular blocks, as shown in Figure 4.5-12.
2. If geologic controls are present and will be used to control or modify grade assignment, a geologic code must be assigned to each block.
3. Estimate the grade of each block by searching the database for the samples surrounding each block and computing the weighted average of those samples. The weighted average is computed using the following equation:

$$g^* = \text{estimated grade} = \sum w_i g_i, i = 1, 2, 3, \ldots N \quad (4.5\text{-}9)$$

where

w_i = weight assigned to sample i
g_i = grade of sample i
N = number of samples used for estimation

Practical Considerations for Moving-Average Methods

The determination of block size, anisotropies, and sample selection criteria are common considerations for either kriging or inverse-distance estimation. These factors are often the most critical factors in developing a satisfactory resource model because the geologic controls are introduced via these mechanisms. Poor selection of these parameters commonly results in an unsatisfactory resource model with significant overestimation or underestimation of ore tonnage or grade.

Block size. Factors that must be considered when determining block size include the size of the resulting model, drill-hole spacing, mining method, and geologic controls. General rules for block size determination are as follows.

1. The largest block size possible should be used to minimize the size of the block model and reduce computational time and disk storage requirements.
2. The block is normally one-half to one-fourth the average drill-hole spacing. A bigger block may be used if the drilling is extremely dense. Smaller block sizes provide minimal improvement in the estimation unless strong geologic controls are present.
3. The block size must be at least one-half the size of the smallest geologic feature that will be modeled. Larger blocks will destroy the location and/or size of small features.
4. Block size may be related to a proposed mining method. The block height is usually the same as the bench height in a deposit that will be mined by open-pit methods.
5. Most commercial software packages for resource estimation allow each dimension of the block to be a different size and may allow rotation of the entire model to an orientation other than north-south.

Anisotropies. Strong anisotropies, or trends, are often observed in mineral deposits that have ore zones with greater continuity in favorable orientations. Anisotropies can often be identified and are commonly shown by variograms with longer ranges in certain directions.

Sample selection criteria. The purpose of the sample selection step is to provide a subset of the data that is representative of the region around the block. Weighted moving-average methods may be very sensitive to sample selection. The following rules can assist in defining a sample selection search.

1. Samples must be selected from geologic domains similar to that of the block.
2. The maximum radius should be at least equal to the distance between samples to prevent discontinuities in the weighted average as samples drop in and out. (For a square grid, the maximum radius is the diagonal.)
3. The maximum number of samples is usually on the order of 8 to 12. More than 12 samples rarely improves the estimate; fewer than 8 samples may cause discontinuities in the estimated grades.
4. A minimum distance to the nearest sample may be used to prevent excessive extrapolation.
5. A search ellipse or other anisotropic pattern may be used to align the search with trends in the ore, as shown in Figure 4.5-13. The axes of the search ellipse should be oriented parallel to grade trends. The length of the ellipse axes should be proportional to the range of continuity in the respective directions. The variogram ranges and visual appraisal of the grade zones on plans and sections are both used as guides to determining the orientation and length of the search axes.
6. Three composites are usually the maximum required from a single drill hole. More than three provides redundant data and may cause strange kriging weights. For example, the outermost composites in a group of five from the same hole may have larger weights than the inner points.
7. Search patterns may be modified to select data with quadrants or other geometric limits as shown in Figure 4.5-14.

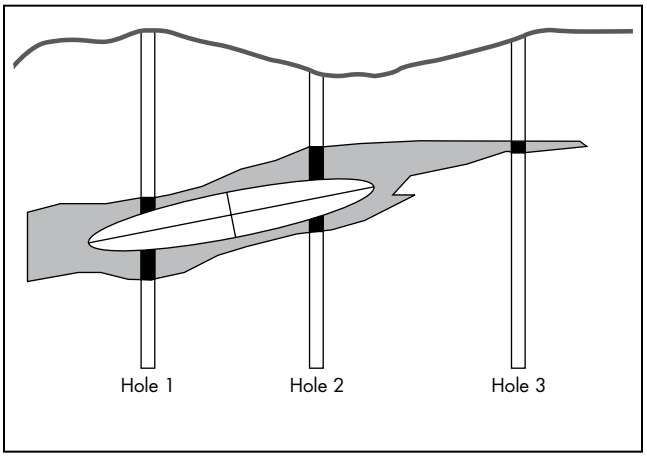

Figure 4.5-13 Anisotropic search ellipse oriented parallel to a mineral zone

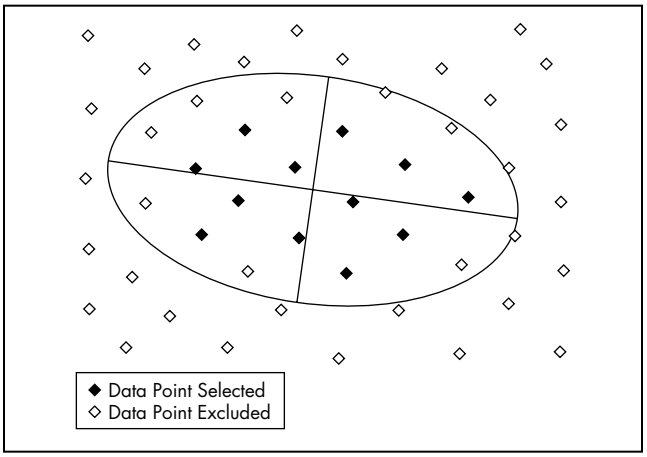

Figure 4.5-14 Oriented, anisotropic search ellipse with a quadrant search limit

Use of a quadrant search will improve estimations if data are clustered.

8. The search pattern should be sketched on plan maps and/or cross-sectional maps in both well-drilled and sparsely drilled areas. This will aid in visualization and ensure that the search pattern is appropriate. Computer software may also provide a direct visualization of the 3-D search ellipse, which is very helpful.

Inverse-Distance Estimation

Inverse-distance weighting, one of the earliest interpolation methods, is based on an empirical observation that the weight of each sample in Equation 4.5-10 is proportional to an inverse power of the distance from the location of the estimate to the sample. The inverse-distance estimate is thus a weighted average with the individual weights computed as an inverse power of distance as follows:

$$w_i = \text{weight for sample } i = \frac{d_i^{-p}}{\sum d_i^{-p}} \qquad (4.5\text{-}10)$$

where

d_i = distance between sample i and the location being estimated
p = weighting power

Care must be taken with an inverse-distance estimate to ensure that none of the distances d_i are very small or equal to zero, resulting in division by zero, or floating point overflow. This problem may be alleviated either by adding a small constant to each distance or by assigning the value of the closest point to the estimate if the distance is less than some threshold, depending on the resource estimation software.

Although it is common to use an arbitrary power like 2 or 3 for inverse-distance weighting, the estimate can be improved by using geostatistical methods to calibrate the estimation as follows:

1. Compute the average variance of samples in blocks that are the same size as the selective mining unit that will be used for mining. The average variance in blocks is referred to as the F-function and is generally available in geostatistical software.
2. Using Krige's relationship, the variance of selective mining units (SMUs) is as follows:

$$\sigma^2_{\text{SMU}} = \sigma^2_{\text{samples in deposit}} - \sigma^2_{\text{samples in SMU blocks}} \qquad (4.5\text{-}11)$$

3. The inverse distance estimate can be adjusted so the variance of estimated blocks is equal to the variance of SMU blocks by adjusting the power, the size of the search ellipse, or the number of points.
4. The variance of estimated blocks is reduced by using a lower power, increasing the radius of the search ellipse, and/or increasing the number of points used in the estimation.
5. The variance of estimated blocks is increased by using a higher power, reducing the radius of the search ellipse, and/or decreasing the number of points used in the estimation.

A certain amount of trial-and-error and experience is required to optimize the estimation parameters. In addition to the above procedure for matching the variance of estimated blocks to the estimated SMU variance, it is also useful to compare the cumulative grade distribution to the grade distribution from production results, and to plot the estimated values and visually verify that the estimation makes sense.

Kriging

Kriging is the geostatistical estimation method developed to provide the "best linear, unbiased estimate" for grade based on a least-squares minimization of the error of estimation, or kriging error. Kriging and its variants have had much theoretical development and are well described in the geostatistical literature. For a more detailed discussion of kriging, the reader may refer to any geostatistical textbook. Similarities and differences between kriging and inverse-distance power are as follows:

- Both methods are weighted moving-average methods and the summation of weights is set equal to 1 so that the estimate is unbiased.
- The kriging weights are determined by solving the kriging equations, which uses as input the covariances between the samples and the estimated block and between each pair of samples. Because the covariances are determined by the variogram, sample weighting is dependent primarily on the variogram rather than trial and error.
- Because the kriging equations consider the covariances among the samples, kriging will reduce the weights of a

cluster of samples, minimizing the effect of variable sample spacing. Inverse-distance-power estimation, however, may be strongly impacted by irregular sample spacing.

Kriged estimates, however, are often "oversmoothed," and the variance of estimates is lower than expected for the variance of SMU blocks. If the estimate is unbiased, the variance of the estimated blocks is the primary factor that determines the shape of the grade distribution, and oversmoothing may cause a significant bias in the tonnage and grade above a cutoff grade. (Generally the tonnage is higher and grade is lower for an oversmoothed estimate.)

Because the kriged estimate is mostly dependent on the variogram estimate, it is difficult to correct for smoothing of the estimates. If the degree of oversmoothing is small, reducing the search radius and the number of samples may be helpful. Although not justified by geostatistical theory, reducing the nugget effect and/or using point kriging instead of block kriging may also be helpful in minimizing oversmoothing of estimates.

Other Types of Kriging

Because of the previously mentioned problems with ordinary kriging, a number of improved kriging methods have been developed in an effort to define not only the local grade, but also to estimate accurately the tonnage–grade distribution. These advance techniques include indicator kriging, multiple-indicator kriging, disjunctive kriging, and uniform conditioning. All of these methods require a highly skilled professional for reliable estimation and are beyond the scope of this handbook.

Dilution and Ore Losses

Dilution and ore losses are a key factor in the conversion of mineral resources to ore reserves. In general, dilution and ore losses are related to either volume–variance effects or geometric effects. Volume–variance effects relate to the decrease in the variance of mining blocks, or SMUs, as the size of blocks becomes larger. The general relationship between the variance of SMUs and samples was shown previously by Krige's relationship (Equation 4.5-11). Some general rules regarding volume–variance effects on resource estimates are as follows:

1. Where the deposit grade distribution is entirely above the mining cutoff grade, volume–variance effects do not need to be considered.
2. Where the estimated variance is higher than the SMU variance, such as with a polygonal estimate, cutoff grades below the median grade tend to underestimate tonnage and overestimate grade. This is corrected by adding dilution tonnage with a grade that is lower than the cutoff grade. The amount of dilution and grade of the dilution is difficult to estimate without production experience with the particular deposit or similar deposits. At cutoff grades higher than the median grade of the deposit, the average grade and tonnage may both be overestimated, and the resource may need to be adjusted with both a dilution and tonnage reduction factor.
3. Where the estimated variance is lower than the SMU variance, such as with a kriged estimate, cutoff grades below the median grade tend to overestimate tonnage and underestimate grade. Where the cutoff is above the median grade, both tonnage and grade may be underestimated. Kriged distributions are difficult to correct for oversmoothing of the grade distribution, which has been the driving force for development of the advanced kriging methods such as multiple indicator kriging and uniform conditioning.

Geometric dilution and ore losses are due to the inability of the mining method to follow accurately and to segregate small isolated pods and small irregular offshoots from the main ore body. Geometric dilution is most significant in deposits with sharp contacts between high-grade ore and barren waste and least significant in deposits with gradational contacts between ore and waste. Dilution tonnage is estimated according to the quantity of waste mined with the ore based on the mismatch between ore body and mining geometry, overbreak in blasting, or lack of accurate location of the ore–waste contact, as shown in Figure 4.5-15. Care must be taken in estimating dilution that the actual ore–waste contact is not more irregular than the model, given that dilution will be underestimated, as shown in Figure 4.5-16. Dilution grade is estimated as the grade of the waste at the ore–waste contact. Mining losses and grades are estimated according to similar procedures.

Selection of Resource Estimation Methods

Selection of an appropriate resource estimation method depends on the geometry of the deposit, the variability of the grade distribution, the character of the ore boundaries, and the amount of time and money available to make the estimate. Deposit geometry determines the amount of detail that must be interpreted and input to the reserve estimation; the variability of the grade distribution determines the amount of smoothing required to estimate mineable blocks; the character of the ore boundaries determines how grade will be estimated at the borders between different grade zones; and the available time and money determine the detail and effort that will be expended on the estimate. Considerations for selection of a resource estimation method are summarized in Table 4.5-3.

Cost

Simple, manual methods such as polygonal and cross-sectional estimations are the least expensive and quickest methods for the estimation of resources when the quantity of data is small. This is usually the case for preliminary evaluations at the exploration stage. As the amount of data increases and a more detailed estimate is desired, computer-assisted methods should be used in order to save time and money. The least expensive computer-assisted methods are automated polygonal or nearest-neighbor methods, and the most expensive methods involve extensive definition of geologic controls in conjunction with the more complex geostatistical methods.

Ore Boundaries

The appropriate reserve and dilution estimation method is determined by the character of the ore–waste contacts. Sharp, simple boundaries are modeled with linear outlines defining discrete mineral zones. Individual estimations are made for each mineral zone; dilution is estimated based on the intersection between the shape of the mineral zones and the shape defined by the geometry of a mining method. A sharp, irregular

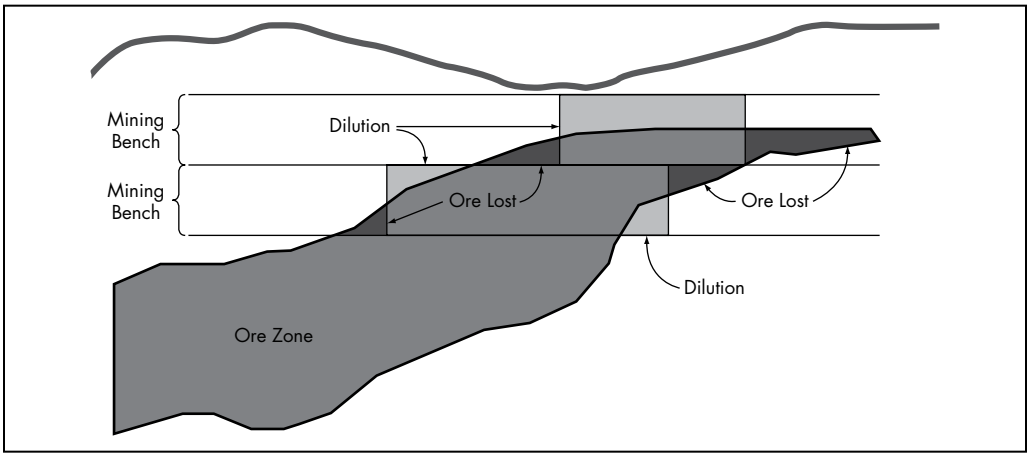

Figure 4.5-15 Dilution and ore losses caused by geometric mismatch between mining geometry and ore-zone geometry

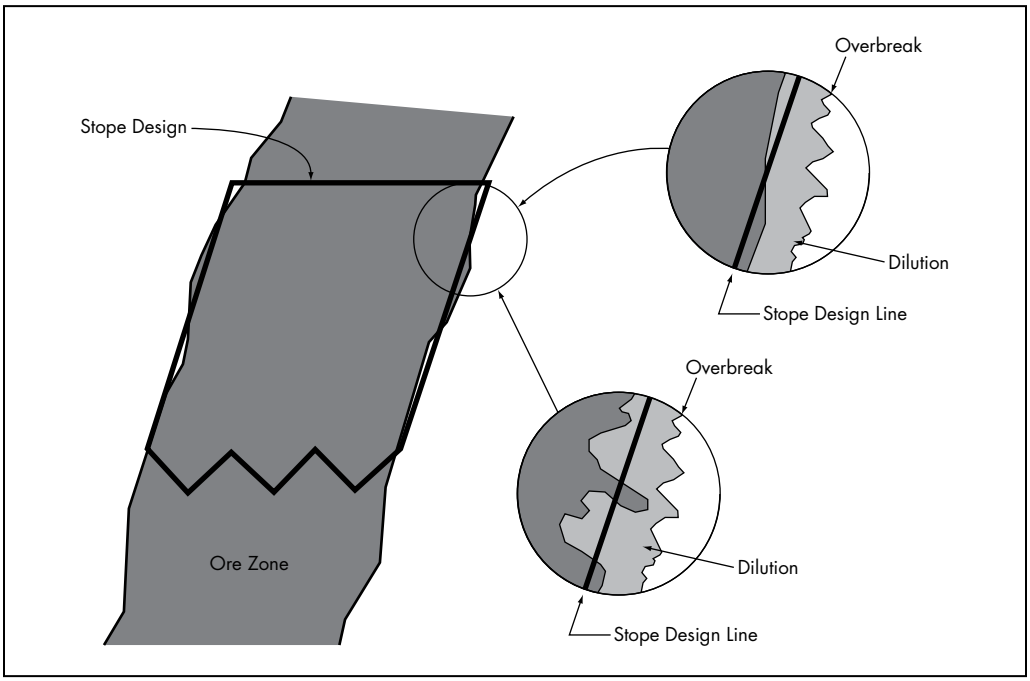

Figure 4.5-16 Underestimation of dilution because of an irregular ore–waste contact

boundary is also described with linear boundaries defining mineral zones; the actual ore–waste contact will be much more irregular than the interpreted boundary, and dilution must be increased accordingly. Geometric methods are usually appropriate for ore bodies with sharp contacts, although kriging or inverse-distance methods may be used within the zones if supported by sufficient data.

Gradational boundaries are handled as transitional between different mineral zones; kriging or inverse-distance methods are most appropriate to model ore bodies with gradational contacts. Sufficient dilution for a gradational contact is usually incorporated in the modeling method.

Extremely erratic, irregular boundaries are difficult to define accurately and are most appropriately estimated using methods such as indicator kriging.

Deposit Geometry

Simple geometry is often found in tabular, stratabound deposits, veins, and structural zones. The geometry of these deposits is easily described using two-dimensional (2-D) methods such as contouring of thickness and elevation. Few additional controls are required other than boundaries to limit the lateral extent of the mineral zones.

Deposits with *moderately complex geometry* include both deposits with simple geometry that have been moderately folded or faulted, and deposits with large, simple, massive shapes such as porphyry copper and molybdenum. Definition of deposit geometry will include definition of fold axes, fault boundaries, and zoning of trends within the deposit. Although these controls are not usually difficult to define, their definition is necessary to provide accurate resource estimates.

Table 4.5-3 Selection of estimation method based on deposit geometry and variability

	Low Variability (COV <0.25)	Moderate Variability (COV 0.25–0.75)	High Variability (COV >0.75)
		Simple Geometry	
Deposit description	Tabular, continuous grade and thickness. Flat or constant dip.	Tabular, large ore pods. Moderately variable grade.	Tabular, small ore pods. Highly variable grade.
Example deposits	• Evaporite • Sedimentary iron • Limestone • Coal	• Stratiform copper • Mississippi Valley lead • Simple porphyry copper, molybdenum	• Gold veins • Gold placers • New Mexico uranium • Alluvial diamond
Estimation methods	Grade and thickness using any 2-D method: polygonal, contouring, inverse distance, kriging. Geometric controls for boundaries of ore zone, faults, and fold axes.	2-D methods. Inverse distance or kriging. Polygonal or cross-sectional with 5% to 15% dilution.	2-D methods. Inverse distance or kriging with recovery functions. Polygonal with 15% to 35% dilution.
		Moderately Complex Geometry	
Deposit description	Simple, bedded. Uniform grade but erratic thickness, gentle folding, or simple faulting.	Simple 3-D geometry. Moderately variable grade.	Simple 3-D geometry. 2-D with smaller, more erratic ore pods. Simple folding, faulting.
Example deposits	• Bauxite (variable thickness) • Lateritic nickel (variable thickness) • Salt dome	• Porphyry copper • Porphyry molybdenum	• Stockwork and Carlin-type gold • Volcanogenic base metals
Estimation methods	Estimate grade, thickness, and elevation using any 2-D method. Must define structural geology (faults, fold axes). Variability of thickness may be difficult to predict.	Inverse distance or kriging with external controls to define the shape and grade trends. Polygonal and cross-sectional methods may be used but will require dilution/volume–variance correction.	Inverse distance or kriging with recovery functions. Polygonal or cross-sectional with 15% to 35% dilution.
		Very Complex Geometry	
Deposit description	Otherwise simple deposits that have been severely folded and faulted.	Complex geometry due to faulting, folding, or multiple mineralization controls. Moderately variable grade.	Deposits with extremely variable grade and highly contorted, complex ore shapes. Typically little continuity between individual ore zones. General mineral envelope definable but with 50% or less ore.
Example deposits	• Talc • Gypsum (deformed)	• Tungsten skarns (folding/faulting) • Base metal skarns (erratic shape) • Copper porphyry combined with local skarns or replacements (multiple controls)	• Archean gold deposits • Roll-front uranium
Estimation methods	Cross-sectional methods with detailed definition of structural geology. Difficult to define geometry for 3-D block models and geostatistical methods.	Cross-sectional methods with detailed input to describe structural geology and ore zones. Geostatistical methods may be appropriate but difficult to implement because of geometric complexity.	Estimation very difficult. Size, shape, and grade not locally predictable. Cross-sectional, area-outline methods, indicator kriging applicable. Errors of 50% to 100% not unusual. Tonnage often overestimated because of incorrect geologic model.

Deposits with *very complex geometry* are usually associated with structural deformation and are folded, faulted, stretched, and twisted to form extremely discontinuous shapes that are difficult to describe and model. Multiple ore controls such as a combination of stratigraphic and structural controls or multiple, overlapping pulses of mineralization also commonly form very complex shapes. Definition of deposit geometry requires detailed examination of structural geology and ore controls to provide cross sections or plan maps that define the shape and location of mineral zones. These sections or maps may then be used directly for manual resource estimation or may be digitized to provide control for a computer block model or 3-D wireframe model. Deposits with complex geometry are prone to large estimation errors because of misinterpretation of deposit geometry and ore controls; order-of-magnitude errors are not infrequent.

Grade Variability

Deposits with low variability may be estimated with many methods. Common methods include automatic contouring and polygonal methods with cross-sectional estimation or area-averaging techniques for more complex geometry.

Weighted averaging methods (kriging and inverse-distance) are most commonly used for estimation of deposits with moderate variability, although polygonal or cross-sectional methods are also used. Weighted averaging methods may require recovery functions and polygonal methods may require dilution to compensate for volume–variance effects, although in most cases the adjustments are small, on the order of 5% to 15%.

Weighted averaging methods are most commonly used for estimation of deposits with high variability. Other appropriate methods may include indicator kriging, polygonal, and cross-sectional methods. Volume–variance effects are often large with these deposits and must be compensated for with recovery functions for weighted averaging methods and large dilution of polygonal and cross-sectional reserves. For COVs above 2.0 or 3.0, local grade estimates are extremely difficult and must be tempered with judgment and caution.

CHAPTER 4.6

Valuation of Mineral Properties

Bernard J. Guarnera and Michael D. Martin

INTRODUCTION

The valuation of mineral properties or mining companies involves the integration of geology, mining, processing, mineral markets, society, and the environment Accordingly, it is common for a multi-disciplinary team to work on valuation efforts and their findings to be incorporated into the valuation. It is essential, however, that any effort be led by an experienced valuator who assumes responsibility for the valuation report.

What Is a Valuation?

How does a *valuation* differ from an *evaluation*? An evaluation simply focuses on the technical aspects of an asset or assets, whereas a valuation focuses on the worth of the asset. Two major factors are considered:

1. **Highest and best use:** Although all mineral-containing properties have an inherent value, which in itself does not indicate that a valuation of the minerals is required, the valuation performed must be based on the highest and best use of a property. An example would be a mineral deposit suddenly discovered on an undeveloped property in the middle of an area with developed residential or commercial real estate. It is possible that the value of the real estate would exceed the value of the minerals (the highest use) or, if it did not, that real estate development was the only possible use of the property because of zoning or environmental factors (the best use). Therefore, unless the valuation was for a condemnation proceeding specifically to value the mineral interest, the highest and best use would be deemed to be real estate development.
2. **Fair market value (FMV):** The valuation should always be based on the FMV of the asset, which is the price an asset would be exchanged for with the parties being a willing buyer and seller, with both parties having access to the same information about the asset, and with neither party being under compulsion to buy or sell the asset.

Types of Properties

Valuation methods vary in type and effectiveness for both undeveloped properties and properties already in operation. Properties warranting or requiring a valuation can range from raw land, where the presence of minerals is only suspected, to large developed properties that have been mined for many years. The commodities can include metallic minerals, nonmetallic minerals, energy minerals, and gemstones.

Valuation Assumptions

Before a valuation is undertaken, certain basic assumptions must be satisfied:

- Mineral development is the highest and best use of the property (unless the valuation is for condemnation purposes).
- A fair market value is attainable.
- All lands have an inherent value for minerals that might occur on them.
- A market exists for the mineral or minerals that may be on or under the land.
- Economic realism must be employed (e.g., a granite deposit under an ice cap would have no value, whereas one adjacent to a major city could be developed for aggregates or dimension stone).

Existing Mineral Valuation Codes

Although valuations of assets have many things in common, it is recognized that the valuation of mineral deposits, properties, or mining companies requires expertise beyond that offered by the typical appraiser. In recognition of these differences, specific codes governing the valuation of mineral deposits and properties have been developed by professional mining associations in countries where mineral resources significantly contribute to the economy:

- **VALMIN code**—Australasian Institute of Mining and Metallurgy. This code is statutory in Australia.
- **CIMVAL code**—Canadian Institute of Mining, Metallurgy and Petroleum. This code is due to become statutory in Canada.
- **SAMVAL code**—South African mining associations. This code is statutory in South Africa.

The Mining and Metallurgical Society of America is in the process of developing recommended standards for mineral

*The income approach may or may not be applicable at the feasibility stage, depending on the reliability of the available information at the time that the valuation is required.

property valuation in the United States. The International Valuation Standards Council is also developing guidelines for the valuation of mineral properties. These are anticipated to focus on market factors and will potentially be in conflict with the above three codes.

Unless specifically requested otherwise, mineral property valuations should be carried out in accordance with one of the VALMIN, CIMVAL, or SAMVAL codes/standards. The choice of code will depend primarily on the reporting location of the company as well as the property, the party requesting the valuation, and the party carrying out the valuation.

TYPES OF VALUATION METHODS

There are three primary methods of valuations:

1. The income (cash-flow) approach, whereby the cash flow resulting from a financial model is discounted at an appropriate rate to yield a net present value (NPV)
2. Market-related approaches, which develop a value based on recent related transactions, and the market multiples approach for publicly traded companies or from recent transactions
3. The replacement cost approach, in which the cost required to duplicate the asset being valued is assessed

Secondary methods include option/real option pricing valuations and Monte Carlo simulations. Table 4.6-1 lists the six valuation methods, together with the types of properties to which they are applicable. The methods themselves are described later in more detail.

In contrast to the other methods listed in Table 4.6-1, the income approach should yield a "true or long-term value" over the life of the asset, provided that the inputs to the cash-flow model are realistic. The market-related transaction or market multiples approach, on the other hand, provides a snapshot value at the time of the valuation; the derived value will likely be higher than the income approach value in prosperous times and lower in difficult times.

The market multiples approach differs from the market-related transaction method in that, rather than comparing the asset against one that was recently sold, it is based on the value ascribed by public markets to units of production of specific commodities. An example would be to base the valuation solely on the pounds of copper or ounces of gold recoverable from the property.

When market valuation methods are used, it is essential that they be adjusted to reflect the realities and characteristics of the asset or company being valued. Failure to allow for these differences will result in incorrect valuations. Thus a property containing 1 million ounces of recoverable gold with the capability of achieving full (cash plus capital) production costs of $200 per ounce is clearly worth much more than another million-ounce property whose full production costs are forecast to be $400 per ounce. Similarly, an underground gold property with a refractory ore would be negatively viewed when compared with an underground gold property with an ore that would only require simple flotation and concentration.

The replacement cost approach can be used as a check on one of the other methods, or alone if none of the other methods is particularly applicable. This method puts a value on finding another similar mineral property and replacing similar infrastructure that previously existed. This method is most commonly used for valuing early-stage exploration properties or properties that have ceased operations but still have resources or reserves. When using this approach, it is essential to consider improvements in technology.

The option/real option pricing valuation approach should be used only to value a company with multiple operations, rather than an individual property. This method is described later in this chapter.

The Monte Carlo simulation approach is a method of analysis based on the use of random numbers and probability statistics to investigate problems with variable potential outcomes. In financial analysis and valuation there is a fair amount of uncertainty and risk involved with estimating the future value of financial numbers or quantity amounts because of the wide variety of potential outcomes (i.e., grade of deposit, reserve tonnage, commodity price, operating costs, capital costs, etc.) The use of Monte Carlo simulation is one technique that can be applied to evaluate the uncertainty in estimating future outcomes and allows for the development of plans to mitigate or cope with risk.

Typically with conventional spreadsheet models, the engineer, geologist, or analyst creates models with the best-case, worst-case, and average-case scenarios, only to find later that the actual outcome was very different. With Monte Carlo simulation, the analyst explores thousands of combinations of the what-if factors, analyzing the full range of possible outcomes—an iterative process yielding much more accurate results with only a small amount of extra work, thanks to the numerous choices of Monte Carlo simulation software that are available. The Monte Carlo simulation cannot eliminate uncertainty and risk, but it does make them easier to understand by ascribing probabilistic characteristics to the inputs

and outputs of a model. The determination of the different risks and factors affecting forecasted variables can lead to more accurate predictions—the desire of all mining managers.

Reviewing Table 4.6-1, one can observe the four stages in the life of a mineral property and the likely applicable valuation methods for each one. Early-stage exploration properties are the hardest to value, whereas operating-stage properties are usually the easiest. In between those two stages, more than one method can usually be employed, with a weighted average value based on the strength of each method used or range of values developed from which a preferred value can be derived. It is also possible for a given property to be in more than one stage at any given time. One such example is a property with undeveloped resources undergoing exploration very near an operating mine.

Valuation Methods for Developed or Operating Properties

Properties that are developed (i.e., ready to operate) or are operating and have a financial history, are usually valued by the income approach. This approach employs the life-of-mine production schedule, forecast or actual operating costs, forecast sustaining and replacement capital costs, and reclamation/closure costs. On the assumption that these have been correctly forecast and projected, the only parameters that would be subject to dispute in this method are the commodity prices and the discount rate used in the valuation.

Some other valuation methods used for developed or operating properties include

- Liquidation value,
- Market-related values,
- Replacement value, and
- The value of a royalty stream if the property is being valued for a lessor.

Income (Cash-Flow) Approach

The income, or cash-flow, method involves constructing a financial model of the cash flow covering the expected life of the mine, generally up to the first 20 years of production. The financial model should be based on constant dollars, where product selling prices, cash operating costs, and future capital requirements are not inflated (varied). It is appropriate to change future operating costs over time by reflecting changing physical conditions, such as longer haul-truck cycles, reduced metallurgical recoveries because of a change in the character of the ore body, and similar measures that the mining professional can predict.

To perform an accurate valuation using this method, the following inputs are required:

- Ore reserves over the life of mine. Resources can be included if factored for their probability of conversion to reserves; however, the valuator should be cognizant of regulatory requirements, such as those of the TSX Venture Exchange (a Canadian stock exchange) that precludes the inclusion of resources in a cash-flow model.
- Production rates
- Operating costs, including on-site general and administrative (G&A) costs, ongoing development costs, and nonincome taxes
- Capital costs—preproduction and sustaining/replacement
- Environmental and reclamation costs
- Commodity prices
- Discount rate

The commodity prices and discount rate utilized in the cash-flow valuation are two critical items that are based on the valuator's experience and judgment. Because of the critical impact these two inputs have on the income approach valuation, they should be developed by the valuator from first principles.

Commodity price selection. While valuations are forward-looking, income approach valuations should normally incorporate a constant commodity price based on long-term historical data. Commodity prices should reflect the up-and-down cycles, which are common to the mineral industry. It is the authors' experience that a 10-year period would normally incorporate both cycles. When valuing an operating property or one near operating status, however, it is acceptable and appropriate to include consensus pricing for the first 2 or 3 years of operation prior to returning to the long-term price. As an example, when an examiner values an operating copper property, if the copper price for the last 10 years has averaged $1.75 per pound, but the current price is $3.50 per pound, the consensus view might be to use $3.50 per pound for year 1 of the cash flow model, $3.00 per pound for year 2, $2.25 per pound for year 3, and then level off at the 10-year average price of $1.75 per pound for the remainder of the mine life.

Discount rate determination. The discount rate essentially reflects the risks present in an investment and is the rate at which the cash flow from a mining property or of a mining company will be discounted. It is never appropriate when conducting a valuation to arbitrarily assign a discount rate; rather the discount rate should be derived from first principles.

Three methods are employed for deriving a suitable discount rate; the method selected is based on the nature of the asset being valued.

1. Weighted average cost of capital (WACC) method
2. Capital asset pricing model (CAPM)
3. Risk buildup method

Weighted average cost of capital discount rate derivation. The WACC method is based on the proportional cost of equity and debt for a particular corporation at a specific time. It should be used as a discount rate only for companies; it is not appropriate for valuing single projects. The key strength of the WACC method is that it incorporates the global risks of all of a company's operations and projects into a single rate, which should reflect the melded risks of the company's assets.

Capital asset pricing model. The CAPM was developed as a valuation tool for shares of publicly traded stocks. It incorporates various elements of an investment, including the risk-free rate of return offered by U.S. Treasury bills and notes, the greater risks inherent in stocks versus other investments, and the volatility of the shares of a company compared to the average company's shares as measured by its beta. (Note: Beta is a measure of a stock's price volatility in relation to the rest of the market. In other words, it is a guide on how a stock's price is likely to move relative to the overall market. Beta is calculated using regression analysis. The whole market, which for this purpose is considered to be the Standard and Poor's 500 (S&P 500), is assigned a beta of 1. Stocks that have a beta greater than 1 have greater price volatility than the overall market and are more risky. Conversely, a beta lower than 1 denotes less volatility than the market and therefore less risk. For example, if the market with a beta of 1 is expected to

return 8% annually, a stock with a beta of 1.5 should return 12%. Young technology stocks will always carry high betas; many utility stocks, on the other hand, carry betas below 1.) The CAPM method is appropriate only for valuing companies; it is not appropriate for establishing the discount rate for individual mining projects or properties. Importantly, the discount rate derived is after-tax for a seller of the shares, and pretax for a buyer of the shares.

Risk buildup discount rate derivation. The risk buildup method is preferred by the authors of this chapter as it reflects the values relevant to the specific properties. In form it is similar to the CAPM method; however, it is differentiated by its inclusion of the technical and other risks associated with the typical mining project. Essentially it adds the components of risk at the project to arrive at an overall risk rate for a given specific property or group of properties. The usual components incorporated are

- The real risk-free rate of return;
- The risk premium expected by an investor who would invest in mining projects which can be assumed to be the same as that for a publicly traded company. There would be additional premium if the project being valued would have a market capitalization of a "small cap" (i.e., less than $200 million);
- Mining industry specific risk; and
- Site-specific risk for individual properties.

The real risk-free rate of return is the difference between the interest rate on U.S. Treasury notes of a maturity approximating that of the project life and the current inflation rate and is measured by the following formula:

$$Rfr = \frac{(1 + Rfn)}{(1 + Ie)} - 1$$

where

Rfr = real risk-free rate of return
Rfn = nominal risk-free rate offered by U.S. Treasury notes
Ie = expected inflation rate

Accordingly, assuming a 10-year mine life and 10-year U.S. Treasury notes yielding 4% with inflation at 1.5%, the real risk-free rate of return is

$$\frac{(1 + 0.04)}{(1 + 0.015)} - 1 = 0.025 \text{ or } 2.5\%$$

With a public company risk premium, investors clearly require a greater return on their investment than that provided by risk-free U.S. Treasury notes. They are willing to accept additional risk for the expectation of a greater return.

If the company involved is a large one (S&P500), the risk premium for such shares can be found at the Ibbotson Associates' Web site. The risk in 2007 was about 7%.

If the company has a market capitalization of less than $200 million (i.e., small cap), an additional risk premium is warranted. In 2007, this was an additional 3% for a total public company risk premium of 10%.

With mining industry risk, based on historic company and industry returns on equity, there is an above-average risk premium for certain industries. These include the aggregate, mining, and petroleum industries, all of which are dependent on the vagaries of natural resources. In 2007, the industry risk premium for the mining industry was 2.5%.

With site-specific project risk, multiple risk factors exist at mining properties ranging from reserve risk through processing, environmental, political, and geotechnical risk. Following are some of the factors that need to be considered:

- **Project status**—This involves exploration, development, or in operation. As a project advances through these stages, the risk factor will normally decrease. For a mature operating property that is performing up to forecasts, the risk will be lowest.
- **Quality of analytical data**—If the quality of the data derived from the drilling, sampling, and assaying of the ore body is suspect, the project risk must reflect this uncertainty.
- **Processing-related risk**—This risk can be high if adequate metallurgical test work has not been performed on samples truly representative of the whole ore body or if new, unproven technology is being employed.
- **Infrastructure-related factors**—Risks can occur if there are unusual circumstances that might cause interruption to the power and water supply or cause access to the property to be lost.
- **Environmental considerations**—In contrast to projects 20 or more years ago, a project located in a sensitive environmental setting must be given a risk rating higher than one that is isolated and insulated from likely environmental damage; government, regulatory, and permitting risks are thus assessed.
- **Operating and capital costs, and working capital**—Poorly predicted figures for these three items introduce substantial risk. The most common of these is an underestimation of total project capital.
- **Prices and markets**—Price projections on which the project economics are based must be realistic, and there must be a market for the product produced.
- **Labor/Management issues**—The availability, education, and trainability of the required labor force in less developed countries is an issue. Union activism poses a risk to some projects. The quality and experiences of the company's management must be considered.
- **Political and social issues, and the social license to operate**—The lack of perceived support from the local inhabitants and government bodies is a major risk.

It is not always possible to secure good information on all of these factors affecting site-specific project risk. If possible, a matrix should be constructed with a ranking from 1 to 10 assigned to each factor. From this, an overall risk factor can be assigned. For an exceptionally low-risk project, a factor of 1% or 2% may be chosen; for one with many uncertainties, the factor is likely to be 5% or higher.

Summary of risk-buildup discount rate. Table 4.6-2 is an example of a risk-buildup discount rate, showing both pretax and after-tax figures. Since the discount rate developed is pretax, it must be converted to an after-tax basis.

Other factors to be considered in the income approach valuation method. Two other factors should be taken into account in an income approach valuation of a property or properties.

The first, and more important of the two, comes into play if an acquisition is involved and if the acquirer will end up being in control of the property, properties, or company. Given that the acquirer will be in charge of his or her own destiny, he or she is not subject to the bad decisions of a senior owner. If

Table 4.6-2 Summary of risk buildup discount rate

Item	Rate, %
Real risk-free rate of return	2.5
Public company risk premium	7.0
Small cap premium	3.0
Industry-specific risk	2.5
Site-specific risk*	3.0*
Total (pre-tax)	18.0
Total (after-tax)	12.0†

*A low-average risk rate of 3% has been chosen for this example.
†From Lerch 1990; the example assumes a tax rate of 33.3%.

the acquirer is in charge, a "control premium" should be added to the total valuation obtained from the income approach method. The amount of this premium cannot be standardized and depends on the type of company and its position in the development/operating chain. During 2007, the control premium for acquisitions of large properties and companies frequently exceeded 30%.

The second factor to be considered is a terminal value of the free cash flow for operations that have a life exceeding that of the financial model. A terminal value is commonly arrived at using the assumption that ongoing operations will mirror the conditions that applied to the last 5 years of the cash-flow valuation, unless there is good reason to expect an ore-grade change or a metallurgical recovery change, and so forth, to occur. The terminal value is measured by the following formula:

$$Tv = \frac{FCF_{N+1}}{(D - G)}$$

where

Tv = terminal value
FCF_{N+1} = annual free cash flow in the residual years after the final year in the financial model
D = discount rate used for the terminal value
G = annualized rate of growth of the enterprise over the life of the financial model

The discount rate used may be higher than that used in the financial model as the inputs to the model would be less certain in the terminal value years.

It is not uncommon for the terminal value to be a significant part of the NPV determined by the financial model.

Market-Related Transaction

On the surface, the market-related transactions or comparable sales approach valuation method should be the simplest to understand and the easiest not to fault. One can simply find several recent transactions with their documented purchase prices and then compare the price paid per pound or ounce at that property with the one requiring the valuation. Unfortunately, it is not that simple. No two mining properties are even remotely identical due to differences in all the parameters that were itemized in the site-specific project risk discourse previously discussed. Even parts of the same mineral deposit can be different. Nevertheless, because of the perceived simplicity of the method, this is a frequently used valuation method and is a preferred technique by the International Valuation Standards Council.

To achieve even relative comparability, all transactions considered must be adjusted in relation to the property being valued. For example, if both are narrow-vein, underground gold properties and one has a grade of 0.6 ounces per ton and the subject property has 0.3 ounces per ton, the value of an ounce at the subject property will obviously be lower than the property it is being compared with. Similar adjustments need to be made for mining costs, processing costs, political factors, geography, and so on.

Market-related transactions, as applied to exploration properties. Generally little information is available about exploration properties due to the early stage of the property in the mine development cycle. Assuming that results are positive, the value of exploration properties increases with the level of work performed. Frequently a "prospectivity factor" is added or deducted to the value based on known results, regional settings, and history.

By the time that a property has either been fully explored, reached the development stage, or started production, there are likely to be other transactions that can be used for developing a market-related transaction valuation, provided that the individual differences between the properties are taken into account.

Market-related transactions, as applied to development or operating properties. When a property is either in development or operating, there will be much credible information available for it, and, unless the commodity is an unusual one, there are likely to be several fairly recent comparable transactions to reference for the valuation. Even so, care must be taken in two areas:

1. The transaction prices for the comparables must be adjusted to present-day conditions when either or both metals prices and costs of production may have changed; and
2. The transaction prices must be adjusted to reflect the different variables that will have affected the price paid for each property, including the relative size of the mineral deposit; differences in ore grade, mining method, and processing recoveries and methods; and the amount and cost of required infrastructure, operating and capital costs, environmental and social issues, tax regimes, and political risk.

Market Multiples Valuation

The market multiples valuation method has similarities to the market-related transactions valuation method and has some of the same drawbacks (principally property or corporate differences). It also has the "advantage" wherein other transactions (comparable existing properties) do not have to be identified and evaluated.

Market capitalization, which is the quoted share price multiplied by the number of issued shares, can be divided by many factors to derive a value per ounce or pound of proven and probable ore reserves or resources, the value per pound or ounce of annual production, the multiplier given to earnings, and so forth. These different metrics constitute a market multiples valuation, and these can then be used to develop a generic value for the company. Such figures are available for many mineral companies, enabling an average valuation per unit of the metric to be established.

A market multiples valuation can also be based on

- A multiple of average annual cash flow, and
- A multiple of earnings before interest, taxes, depreciation, and amortization.

Again, adjustments must be made to ensure that the value developed is truly based on comparable factors. For example, a market capitalization value for a major mining company with several producing mines should not be used to develop a market multiples value for a junior company with only one producing mine.

Replacement Cost Valuation

Replacement cost valuations are simply the expenditure that would be required in current dollars (or other currency units) to duplicate a prior effort. Replacement cost valuations are most commonly used for

- Exploration properties at various stages, and
- Operations that have been shut down with remaining resources or reserves.

For exploration properties, the costs of land acquisition, duplicating any geological, geochemical, or geophysical work, duplicating the prior drilling and assaying performed, and so forth, are determined as the basis of the property's value. Any negative results must be considered, and, using the appraiser's judgment, they may be subtracted entirely or included in a factored manner.

When being applied to operations that have been dormant for a period of time but which still have facilities in place, the replacement cost valuation focuses on the current cost required to replicate the facilities. A factor that must be considered is whether new technology has made the original equipment obsolete. If such is the case, the cost of the new technology must be included, although it is possible that this would overvalue the property. Another factor that should be considered is whether there has been any change in the markets for the commodity that was previously produced.

If the property is being valued by the replacement cost method and resources and/or reserves are still present, the value could be based on the cost of replacing those ounces, pounds, or tons present.

Option/Real Option Pricing Valuation

Although used less frequently than the methods already described, the option/real option pricing valuation method is one that can be used for valuing mining companies with multiple operating properties. The philosophy behind options is based on the formula developed in 1973 by Black and Scholes to be used in the valuation of equities. As currently applied to mineral properties, option valuations are based on the following premises:

- The income approach valuation method may undervalue both producing and nonproducing mining assets. This is generally true in "boom" times, but incorrect in difficult times.
- Mining properties offer the opportunity to be shut down when economics are negatively affecting cash flow and reopened when economic factors are positive. Although this is true in concept, in practice, closing and reopening mines based on volatile economic changes is impractical and would potentially be financially ruinous if attempted by mining companies. The cost of shutting down, maintaining the property on a standby basis, and the time it would take to reopen and ramp-up production is not considered in option theory.
- Mining properties offer a call option on increases in metals prices. (If the gold price is, for instance, $300 per ounce, then a property requiring a price of $350 per ounce to generate a positive cash flow has a finite value.) Note: For readers not familiar with the concept of options, reference is made to puts and calls on 100 shares of a stock on a major stock exchange. Simply, each call gives the call owner the right to purchase 100 shares of the stock in question at a fixed price for a fixed period of time. (The lower the fixed price and the longer the period of time, the higher is the price of buying the call.) For example, if Party A owns 100 shares of a stock currently selling at $100 per share and the calls on a price of $110 per share expiring 2 months in the future are trading at $3 per share, then Party A can sell a call on his or her stock and immediately pocket a check for $300. If the stock does not reach the call price of $110 per share in the next 2 months, Party A will have made $300 and will still have the stock. In the meantime, Party B has bought Party A's call for $300, but if the stock does not reach $110 a share within the 2-month time period, Party B will have lost their $300. However, should the price of the stock rise to, for instance, $116 per share before the 2 months are up, Party B will have doubled their initial investment of $300. (Party B's call gives them the right to buy the stock at $110 per share and they can turn around and immediately sell it for $116 per share, thus realizing a net profit of $300.)

When considering the use of option valuations, it is also important to recognize that

- The longer the option period, the higher the value will be;
- The greater the volatility of the commodity price, the higher the value will be;
- This valuation method will always produce the highest (and probably unrealistic) value; and
- This method is applicable to valuations of companies, not single properties.

Monte Carlo Simulation

The Monte Carlo simulation method can be used for any properties that are at least at the advanced exploration phase. Monte Carlo simulations allow for multiple variables to be changed simultaneously while a specific operation is mathematically performed literally thousands of times. The probabilistic value results from a range of probabilities assigned to each variable in the analysis (i.e., capital and operating costs, and commodity prices) to arrive at a most likely value, or range of values, as based on iterations of cases that sample the distributions of each variable.

Alternative Valuation Methods for Undeveloped Properties

Undeveloped properties include those with blocked-out resources or properties with drill holes that have "ore grade" intercepts. Although the lack of concrete information makes the valuation of such properties more difficult, a "probability" approach, such as the risk-adjusted income approach, can be used. The approach entails the construction of a financial model of the property using likely production rates, ore grades, mining and processing methods, and capital and operating costs.

A justifiable commodity price is chosen, the real risk-free rate of return is used for the discount rate, and the discounted cash flow is calculated. The valuation for an example property then becomes the calculated NPV (say, $100 million), as adjusted for the percentage probability that the items incorporated in the financial model, such as ore reserves, costs, and environmental risks, have been correctly estimated. If the risks for the stated items are, respectively, 80%, 90%, and 50%, the valuation would be $36 million ($100 million × 0.8 × 0.9 × 0.5).

Alternative Valuation Methods for Exploration Properties

Exploration properties include those where no work has been performed and those where some work has been performed.

For properties where no work has been performed, two methods are commonly used:

1. The valuation is a percentage of the surface value of the property. For no work of any kind in a mineralized or unmineralized area, the percentage is 5%. For raw property, but where initial reconnaissance has indicated favorable potential, the percentage is 10%.
2. The valuation is the money that has been spent in staking/leasing and maintaining the property.

For properties where some exploration work has been performed, the following methods are commonly used:

- Modified cost of work performed, with prospectivity factors included
- Geoscience matrix valuation

In the modified cost of work valuation method, the direct costs of work performed are added to valid G&A costs to arrive at a base value. If there have been some highly favorable exploration results, some enhancement of the base valuation is appropriate. Similarly, if results on or at nearby similar properties have been negative, a negative prospectivity factor is applied.

The geoscience matrix valuation method was developed by Lionel Kilburn for the British Columbia Securities Commission to assist them in validating the values being assigned to exploration properties by junior mining companies. Five major criteria are considered, which are divided into nineteen possibilities:

1. The location of the property with respect to off-property mineralization;
2. The presence of any on-property mineralization;
3. The location of the property with respect to off-property geochemical/geophysical/geological targets;
4. The presence of any on-property geophysical/geochemical targets; and
5. Geological patterns on the property associated with known commercial deposits.

The starting point, or base value, for the valuation is the per-acre or per-hectare cost of acquiring the right to a mineral property, usually the cost of staking and maintaining a claim for 1 year. The property is then rated on the basis of its score from the matrix, and this rating is then used to adjust the base value. The value from the matrix is arrived at by assigning points in the five categories, based on whether the property is above or below average. Table 4.6-3 illustrates how the matrix rating is derived.

Table 4.6-3 Categories used in matrix valuation

	Category	Rank	Value Factor
A.	Location with respect to off-property mineralization		
	Sub-ore grade in two horizontal directions	17	1.5
	Ore grade with two horizontal dimensions	13	2.0
	Sub-ore grade with three dimensions known	12	2.5
	Ore grade with three dimensions known	8	3.0
	A past or present producing mine	5	4.0
	A major past or present mine	4	5.0
B.	Location with respect to on-property mineralization		
	Interesting but sub-ore grade with two horizontal directions	13	2.0
	Ore grade with two horizontal dimensions of economically interesting size	8	3.0
	Interesting but sub-ore grade in three dimensions	4	5.0
	An economically interesting ore-grade zone in three dimensions	3	6–8
	Past producer with ore grades measured in three dimensions	2	7–8
	Major past or present producer with ore grades measured in three dimensions	1	9–10
C.	Location with respect to off-property geochemical/geophysical/geological targets		
	One target or two, based on different methods	19	1.3
	Three or more targets	17	1.5
D.	Location with respect to on-property geophysical/geochemical targets		
	One target	13	2.0
	Two or three targets	8	3.0
	Four or more targets	7	3.5
E.	Geological patterns associated with known commercial deposits		
	One or two patterns	13	2.0
	Three or more patterns	8	3.0

RULES-OF-THUMB VALUATIONS

In the rules-of-thumb valuation method, the valuation is based on a percentage of the commodity's price, with the percentage dependent on the state of advancement of the particular property. Table 4.6-4, based on more than 500 transactions analyzed by Frank Ludeman in his publication, *A Decade of Deals*, gives the range of percentages for the different stages of properties (Ludeman 2000).

The rules-of-thumb values provided in Table 4.6-4 should be considered as generic, and the actual percentage a property will value varies with the tenor of the mining industry. The 500 properties studied provided an average value, and the percentage of the commodity price assigned to a property should be based on its characteristics versus that of the "average" property.

REQUIRED QUALIFICATIONS FOR A VALUATOR

The required qualifications for a valuator will depend to some extent on the complexity of the property to be valued, as well as on the type and number of the methods to be employed. The greater the complexity and the number of methods to be

Table 4.6-4 Rules-of-thumb values

Property Stage	Precious Metals (%-per-ounce price)	Base Metals (%-per-pound price)
Early exploration	1.5–2.5	1.0–2.0
Inferred resources	2.5–5.0	2.0–3.0
Measured and indicated resource	5.0–7.5	3.0–5.0
Feasibility	10.0–15.0	5.0–7.50
Production	20.0+	10.0+

Source: Data from Ludeman 2000.

used, the greater must be the knowledge and experience of the valuator (who may be one individual with all the necessary skills and experience or a small team whose combined expertise covers all the skills needed).

The principal qualifications, not necessarily in order of importance, are

- A total lack of bias as to the outcome of the valuation,
- Knowledge of and previous experience in the valuation method(s) to be used, and
- Familiarity with all relevant aspects of the minerals industry.

Sometimes in special circumstances, the valuator or the head of the valuating team may be required to be a member of an accredited appraisal association or professional society. The valuator and the members of the valuation team should hold degrees in geology, mining engineering, or metallurgy; however, overall experience in, and a working knowledge of, the minerals industry is the most important qualification.

CHAPTER 4.7

Mineral Property Feasibility Studies

Richard L. Bullock

Mine feasibility studies are nearly as old as the industry itself. In the first recorded writing on mining by Agricola (1556), he gave many clues as what to look for in evaluating a mine. Most mineral engineers, geologists, mineral company executives, and mineral development lending agencies think of the feasibility study as the formal methodology that brings the necessary information on a property's raw mineralogical data through the feasibility and preliminary design process and to the point where a comparable economic analysis of the envisioned project can demonstrate financial viability. But the feasibility studies have to be completed by many people evaluating different commodities for many different types of mines and process plants in many different climatic, political, and social environments. Yet, in the end, all of the feasibility studies must accomplish the same thing: demonstrate comparable financial opportunity of investment potential. Thus, the need for a consistent, systematic methodology in performing evaluation and feasibility work is clear.

WHO SHOULD PERFORM FEASIBILITY/ EVALUATION STUDY?

The first focus is who should do the feasibility study. Some might argue that the very people who found the resource obviously know the most about it and therefore those within the exploration group should perform the early feasibility study and even the early bulk sampling or test mining. However, there is no way that the discoverer of a new mineral resource can view the outcome of developing that resource with totally unbiased beliefs, any more than a mother could sit on the jury of her son being tried. This is not to say that the exploration group should not have a large role in the early input, but, from that point on, the project team must be organized with persons of multi-disciplinary backgrounds.

Building this multi-disciplinary project team will be discussed in a later section, but for now, consider the organization that has the responsibility of performing all of the project feasibility and evaluation studies. Sometimes referred to as project development or mine evaluation and development, this organization should perform—or supervise consulting organizations performing—evaluation studies of mineral deposits and mineral processing facilities for projects discovered or acquired, wherever that project is located.

The assignment of evaluation studies of all types to a central headquarters has the following advantages:

- It ensures that all of the projects are studied and evaluated in exactly the same manner for that phase of the study and are treated uniformly and objectively.
- It ensures that all projects will have people of specific disciplines available to work on every aspect (thus each phase will be technically evaluated properly for that depth of study).
- It ensures centralized project planning and scheduling.
- It provides an experienced base group to consider the results of all candidate projects.

STAGES OF PROJECT

Because mining is a business that is constantly depleting assets, mining companies must constantly increase their mineral reserve assets through exploration or acquisition. This generally means that most successful companies will have numerous potential prospects that they are considering, either from a raw exploration point of view or through acquisitions. Thus a growing mining company might have between six and twelve active projects in its portfolio at various stages of exploration, evaluation, or development. These several projects to be evaluated

- May be for different commodities;
- Will probably involve different individuals doing the evaluations;
- Will probably start at different times;
- Will most likely have unequal mine lives; and
- May be located in different countries.

The most important element in doing complete property evaluations for a company is that each one is done exactly like every other evaluation within that company so that a decision is based on comparable economics. *Therefore, a company must put into place a system that will require different evaluators to follow the same procedures on different properties and develop equivalent feasibility studies that can be compared.*

Richard L. Bullock, Professor Emeritus, Mining & Nuclear Engineering, Missouri University of Science & Technology, Rolla, Missouri, USA

This is the single most important principle that must be faithfully followed by any company doing property evaluations. Likewise, it would help investment houses if all of their potential clients had projects that had equivalent feasibility studies that were more or less comparable, at least with respect to completeness. One of the primary purposes of this chapter is to instill in each reader the concept that there must be a strictly regimented method of complete property evaluations leading to feasibility reports.

WHAT MUST BE CONSIDERED FOR A PROPER FEASIBILITY STUDY?

For a properly documented property evaluation, quite simply everything must be considered. However, that does not really help much in knowing how to start and what to look for. More specifically, there must be an examination of the potential mineral operation, such as

- Determining the mineral resource (and reserve estimate, if there is one),
- Determining a mining method based on the measured and indicated resource,
- Reviewing the mineral extraction flow sheet,
- Performing a market analysis,
- Determining infrastructure needs,
- Quantifying the environmental and socioeconomic impacts and mitigation required,
- Estimating the costs of these factors, and then
- Performing an economic analysis of the assumed revenues versus the costs to determine if the project meets the company's objectives.

Objectives of Mineral Property Feasibility Study

It is often assumed that the feasibility study's objective is to demonstrate that the project is economically viable if it is developed and exploited in the manner laid out by the study. But this assumes that every mineral deposit evaluated can be profitable. Of course, this is not true; development of most of the earth's mineral deposits is not currently viable.

So what should be the objective of mineral property feasibility study? It should be to maximize the value of the property to the company by determining either to exploit it, sell it, wait for a technology or market change, or do nothing. It should also be the objective to reach that decision as early as possible, with the least amount of money spent. But how can this be done? How does a person know when they have studied each of the hundreds of items of information enough so that they have confidence in the feasibility study and the economic analysis based on that study? One learns to perform a feasibility study by a phased approach to mine evaluation. Several authors (Hustrulid and Kuchta 1995; Gentry and O'Neil 1992; Stone 1997; Taylor 1977) and, in fact, most mineral companies take a similar approach to mineral property evaluation.

INDUSTRY APPROACH TO FEASIBILITY STUDIES

On rare occasions, the activities required in a feasibility study are often described as a single, continuous process—from the time the resource is identified until a decision can be made to develop the property. This one-step approach, in which single feasibility leads directly to development, may sometimes be correct for extremely high-grade ore bodies or if the company requires development for some reason in a specific time frame. But the one-step approach is risky from a technical and an economic point of view. Such methods will usually develop an operation that is, in fact, suboptimal, even though it still may meet the company's needs. Furthermore, it may cost the company far too much money to find out that the project economics prove inadequate. Most companies and books on the subject recommend a phased approach to mineral property evaluation.

Content of Classic Three-Phased Approach

Lee (1984) describes a classic three-phased approach as follows:

> **Stage 1: Conceptual [Scoping] Study**
> A conceptual (or preliminary valuation) study represents the transformation of a project idea into a broad investment proposition, by using comparative methods of scope definition and cost estimating techniques to identify a potential investment opportunity. Capital and operating costs are usually approximate ratio estimates using historical data. It is intended primarily to highlight the principal investment aspects of a possible mining proposition. The preparation of such a study is normally the work of one or two engineers. The findings are reported as a preliminary valuation.
>
> **Stage 2: Preliminary or Prefeasibility Study**
> A preliminary study is an intermediate-level exercise, normally not suitable for an investment decision. It has the objectives of determining whether the project concept justifies a detailed analysis by a feasibility study, and whether any aspects of the project are critical to its viability and necessitate in-depth investigation through functional or support studies.
>
> A preliminary study should be viewed as an intermediate stage between a relatively inexpensive conceptual study and a relatively expensive feasibility study. Some are done by a two- or three-man team which has access to consultants in various fields; others may be multi-group efforts.
>
> **Stage 3: Feasibility Study**
> The feasibility study provides a definitive technical, environmental and commercial base for an investment decision. It uses iterative processes to optimize all critical elements of the project. It identifies the production capacity, technology, investment and production costs, sales revenues, and return on investment. Normally it defines the scope of work unequivocally, and serves as a base-line document for advancement of the project through subsequent phases.

Frequent Problems in Classic Three-Phased Approach

However, some pitfalls are associated with using the classic approach. As used by much of industry, this approach is a nonuniform, nonsystematic, nonstandarized approach to feasibility.

Conceptual/Scoping Study

A conceptual or scoping study can be extremely misleading. Nearly every exploration project that is even slightly submarginal can be shown to be worthy of further development based on casual educated guesses and optimistic, simplified,

or even biased evaluations. Back-of-the-envelope approaches to a mine feasibility study need to stay on the backs of envelopes and out of formal, official-looking reports. At its worst, this type of report can be performed by the exploration firm or project sponsor to try to sell the project to someone else. However, when an independent third party does the conceptual/scoping study, it can be employed as a useful tool for the potential investing company to determine if it wishes to proceed to the next phase of feasibility study or to calculate what the project might be worth on the open market. Also, this approach might be appropriate when looking for commodity targets for the exploration group, but not for further in-house decisions to move the project to the next level, based on the exploration group's mining and milling judgments.

This is not to say that conceptual, unclassified screening studies do not have their place in justifying other types of work, but care and caution are needed so the conceptual study is not dignified beyond its engineering basis. In fact, some countries' security exchange agencies, such as the Canadian Securities Administrators (CSA), allow and specify such a preliminary study, which they call a preliminary assessment. As identified by the CSA, such a report includes a statement that this "assessment is preliminary in nature, that it includes inferred mineral resources that are considered too speculative geologically to have the economic considerations applied to them that would enable them to be categorized as mineral reserves, and there is no certainty that the preliminary assessment will be realized; and states the basis for the preliminary assessment and any qualifications and assumptions made by the qualified person." It is completed without substantial engineering studies.

In a conceptual or scoping study, the accuracy of the cost estimates are most often assumed. In fact, the accuracy of all levels of feasibility studies depends on how much good engineering has been performed on the specific project. If none, then the project's related cost and economics are not likely to be accurate, and the study is likely to be misleading. Typically, at this stage, one might do 1% or 2% of the total engineering on the project. Bear in mind that, for a small project, this may amount to 1,800 to 2,400 hours of engineering work. But, for a large project, this percentage may amount to 9,000 to 18,000 hours of engineering. Then, using good engineering judgment, experience, and cost on similar projects, the accuracy of the scoping study feasibility may be in the ±45% range. Other authors claim that an accuracy of 30% is achievable for a conceptual/scoping study (White 1997). However, this accuracy will likely not be achieved unless the project is being developed in an old district where a mine or plant has recently been built and the new installation is similar to the existing one. The 30% accuracy will only be attained after 10% to 12% of the engineering has been completed.

Prefeasibility Study

The problems that have been found with many prefeasibility studies that followed conceptual or scoping studies as outlined is that often this phase simply follows the path set by the conceptual study. There is a reluctance to spend the time and money for a feasibility team to go back and justify the concepts chosen for the mining method, processing method, necessary infrastructure, waste disposal method, and overall size of the operation. Likewise, there is a reluctance to spend the time to optimize any of the functional operations at a time when the project team is small.

Another observed problem is that some of the elements or activities of the prefeasibility study will be taken too far in application, and the project's proponents will invariably proclaim to others in management and the investors that "the study is really more than a preliminary feasibility study." Although this is probably not so, it will give members of management (and possible financiers) some unjustified overconfidence in the project.

Another critical failure that often occurs in this system of feasibility progression is that the preliminary study is the chance to find the "fatal flaws" of the project, if it has any. Sometimes this does not happen or the flaws may be found in the scoping study. One definitely does not want fatal flaw discovery after a large engineering group has been assembled to work on the final feasibility study, because by this time the project's momentum is huge, and it will cost a lot to stop the project.

If the project is being undertaken by a company listed on the Canadian or U.S. stock exchange, then inferred mineral resources may not be used for mine planning purposes, except if a small zone of interburden exists between measured or indicated resource material that must also be mined.

Final Feasibility Study

When using the classic approach, by the time one gets to the final feasibility study, the project direction of each element has usually been set. For all aspects of the project to proceed at the same pace from this point, there is little opportunity to stop and examine the many interrelated operating variables that should have been examined at an earlier stage of the study. Thus it is likely that a nonoptimized design will emerge from this type of study. As a result, the mining industry is full of nonoptimized mines and plants that have been built because those optimization studies did not take place at the proper time, which in this case was during a prefeasibility study. Sometimes toward the end of a final study, the operating management realizes that certain aspects have not been optimized, and subsequently major last-minute adjustments are implemented in an attempt to mitigate these errors. Usually, such actions are based on less than the amount of engineering analysis that went into the original planning, and the accuracy of such last-minute changes and the ripple effect to all other aspects of the project (particularly the environmental and regulatory engineering) damage the credibility of the entire project.

RECOMMENDED APPROACH

Because of the problems outlined previously regarding industry abuses to the nonuniform, ill-defined, classical three-phased approach, a more rigid, uniform, engineered, and systematic three-phased approach to mineral property feasibility is recommended. In a more general way, this has been suggested by Hustrulid and Kuchta (1995) and by Gentry and O'Neil (1992), using the work of Gocht et al. (1988) and Taylor (1977). But what is considerably different as defined here than what has been suggested by others is the sheer magnitude of details enumerated by engineered task. Rigorously following the details—a description of which is contained in the iteration of each phase—makes this method unique and bankable. Nowhere else has this amount of detail of the tasks required in a mineral property feasibility study been documented and published in publicly available literature. Many of the larger mineral groups, such as BHP Billiton, Rio Tinto,

and Anglo Gold, probably have equally as well documented activity lists for each step of the feasibility studies, but they have not been publicly published.

The need for such an approach was imperative because many companies have eight to twelve mineral project feasibility studies to manage at one time. It would not be unusual for such studies to address four or five different mineral commodities located in four or five different countries, all having different starting dates and mine life, and being studied at one time by several different project teams. It is only by formalizing the feasibility study process that management can be assured that items will not be left out or that some activities would not be studied in too much depth. Although some companies may not have a dozen projects going at one time under the conditions described, the established procedure will serve any user of the system well and yield project results that are comparable for financial decisions.

This chapter examines the engineered, systematic three-phased approach to a mine feasibility study. Although not the only system available, many believe it is the safest and most prudent method. As different situations arise on different commodities, the project manager may believe that some steps can and should be omitted. However, one must also be aware of the potential consequences when taking shortcuts, particularly if the company's experience is weak in this type of new project. While looking at the details of the long lists of items that need to be studied in the different phases (described in the next section), the reader may believe there are far too many activities and the time and expense required to accomplish them is too great. Some may choose to combine many of the activities of the preliminary study with the intermediate study. This may be possible and is discussed later. However, one must be careful that this combination does not dilute the preliminary/intermediate study such that a financial decision can't be made with confidence. Some may believe that items can be eliminated or that the study of certain items is not applicable. But a great amount of caution should be used in eliminating any study aspect unless the company has so much experience and data on that particular aspect that the study is simply not necessary.

The three steps of feasibility studies recommended here are

1. Preliminary (or conceptual) feasibility,
2. Intermediate (prefeasibility) feasibility, and
3. Final feasibility.

Although these appear similar to some of the systems previously mentioned, they are not the same. Learning the content of these three studies and how to apply the work from one level of effort to the next are important parts of this chapter. What will be covered is a brief description of the activities at each level of study and how to move a project from exploration through the feasibility phase and then to engineering design—or to the back burner or for sale.

Work Breakdown Structure

Another important aspect is to apply controls to portions of the study. To do this, one must first organize a list of work categories and assign numbers to them. This is known as a work breakdown structure (WBS). No two people will develop identical WBSs; the important thing is to get the work organized so that it can be tracked—both from an accounting and scheduling point of view—and to track it on a computer.

Table 4.7-1 Typical work breakdown structure numbering system

Numbering Sequence	Project Study Level or Project Execution Phase
1XXXX	Preliminary feasibility study
2XXXX	Intermediate feasibility study (may include the test mine/bulk sample)
3XXXX	Final feasibility study (including the design basis document)
4XXXX	Engineering design (includes all preconstruction activities)
5XXXX	Construction/mine development
6XXXX	Mine/plant operations

Within each of the three levels of the feasibility study are 50 to 150 major activities. For each major activity, there are 10 to 20 elements, or work types. A large mining company trying to grow, or even holding on to its depleting asset, may have as many as eight to twelve projects going at any one time, at various levels of study. Because of the complexity of accounting for everyone's time and charging expenses to ongoing work, a numbering system to keep track is essential. In addition to the billing and accounting, a robust WBS ensures that all activities can be handled and scheduled on a computer. This is no small task because many of the activities feed information to other activities before they can begin.

All major projects use such a system, and all U.S. government projects require a WBS. As defined by the American Association of Cost Engineers, a WBS is a product-oriented family tree division of hardware, software, facilities, and other items that organizes, defines, and displays all of the work to be performed in accomplishing the project objectives. An additional advantage is that if the WBS is written in a generic way, all of the projects within a single company can follow the same structure, thus ensuring comparable completeness for any future level of study.

The WBS method outlined in Table 4.7-1 is a generic WBS that could be used on any number of mineral projects. It also uses the project phase as part of the identification. Writing a WBS for each project is possible, but the comparison between all of the projects would be more difficult and possibly less accurate.

The WBS number system carries through the six steps from the preliminary study through the project design, construction, and into operations. The WBS illustrated here is in two parts: (1) in Table 4.7-1 where the first number of each line signifies the phase or step that the project is in when the activity occurred; and (2) in Table 4.7-2 where the numbers on each line refer to the various types of chargeable activities that occur in all of the phases. Thus, for a market investigation and planning activity in the mine/plant operation phase, the WBS number would be 61300, but if the market investment and planning study occurred in the final feasibility study, the WBS number would be 31300. It can be seen that a screening project is not included, because it only officially becomes a project when it passes a screening activity. Within each project phase, a further breakdown of the numbering sequence identifies major areas of work. An example of how this might be broken down is shown in Table 4.7-2.

The feasibility study definitions of each activity serve as a checklist and, with time elements applied to each activity and subactivity, form the basis for building a project schedule. Each project will have unique characteristics that will require

Table 4.7-2 Example WBS numbering system

Work Area Numbering Sequence	Areas of Work
XX100	Preparation for reviews and management approval
XX200	Land and water status and mapping
XX300	Geology and predevelopment bulk sampling
XX400	Environmental and socioeconomic work (excluding permitting)
XX500	Geotechnical and siting studies, and planning
XX600	Agency reconnaissance, government and public relations, and permitting
XX700	Mining, including a test mine
XX800	Mineral processing and metallurgy sampling and testing (upstream)
XX900	Smelting/refining(downstream)

X1400	Financial analysis (cost estimates are within elements 0100 to 1300)
X1500	Tax studies and analysis
X1600	Planning, budgeting, project accounting, and reporting
X1700	Preparation of next step of project, of design basis report, or project closure or alternative action by company

changes to the activities listed, but the general logic and activity identifications should apply to most mineral projects to be evaluated. The more consistent the approach, the more accurate the comparison in choosing between the various mineral projects. Using this numbering system and applying time elements to each activity by number allow a schedule network to be built on the computer.

BREAKDOWN OF THE ENGINEERED, SYSTEMATIC, THREE-PHASED APPROACH

This section and Appendices 4.7A–D provide a detailed description of the activities and sequences that are recommended to properly perform a mineral property feasibility study, with the expectation that the property, if developed, will perform at the levels predicted by the feasibility study. In the appendices, some numbers in the sequence appear to be missing to allow for future additions to the WBS system.

Phase I: Preliminary Feasibility Study

Although the objective of each phase of every mineral property feasibility study should be to maximize the value of the property to the company by determining how to proceed with it, more specific to the preliminary feasibility study is to consider those logical mining and processing methods (and other project elements) in just enough detail such that one can

- Determine that they will work together to meet the company's objectives (which are usually financial); and
- Estimate the capital and operating cost, commensurate with the engineering that has been expended.

Depending on the country where the study is to be governed, the product must meet the standards of the U.S. Securities and Exchange Commission *Industry Guide 7* (SEC 2007); *The Australasian Code for Reporting of Exploration Results, Mineral Resources and Ore Reserves (The JORC Code)*, prepared by the Joint Ore Reserves Committee (AusIMM 2004); or Canada's National Instruments 43-101 and 43-101CP.

The preliminary study is based primarily on information supplied through exploration. The company management should tell the exploration group that its report must contain the following information with appropriate maps and cross sections:

- Property location and access
- Description of surface features
- Description of regional, local, and mineral-deposit geology
- Review of exploration activities
- Tabulation of geologic resource material
- Explanation of resource calculation method, including information on geostatistics applied
- Description of the company's land and water position
- Status of ownership and royalty conditions
- History of the property
- Rock quality designation (RQD) values, at the least, and any rock mass classification work that has been done
- Results of any special studies or examinations the exploration department has performed (metallurgical tests, geotechnical work, etc.)
- Report on any special problems or confrontations with the local populace
- Any other pertinent data such as attitude of local populace toward mining, special environmental problems, availability of water and hydrologic conditions in general, and infrastructure requirements

Ideally, a number of mining and processing alternatives will be examined as a screening process. Obviously these need not be in-depth studies, but most experienced mining engineers will quickly be able to determine what mining methods will be applicable and can then place costs on several alternatives for this application. Likewise, an experienced mineral processor can determine the candidate process flow sheets and can place costs on these alternatives.

At the same time, all the other elements of the project must be considered and studied in just enough detail to discover any fatal flaws or problems that need engineering mitigation. Certainly, environmental and socioeconomic issues need to be studied and scoped to the extent that any existing or expected problems will be detected. Then all of these items can be examined for future cost and work plans.

Costs and expenditure schedules will be based on industry-factored historical experience. Major capital costs can be based on telephone quotes from suppliers or canned commercial programs built for this type of application. Usually, no field work or metallurgical testing will be conducted unless a definite metallurgical problem is recognized with the resource and suspected to be a fatal flaw, in which case it should be studied.

Depending on the complexities of the project, approximately 5,000 to 30,000 worker-hours of work is needed to complete these activities during the preliminary study. This description is written for a company or group that is prepared to perform most of the evaluation activities with various contractors. Thus for every task that is to be contracted:

1. A scope of work must be developed;
2. The industry needs to be surveyed for potential contractors;

3. Contractors must be evaluated to ensure they are qualified and likely to perform as expected;
4. A request for bid proposal documents needs to be prepared and sent out;
5. Bid documents must be evaluated and the award made;
6. Negotiations with the winning bidder may be necessary if there have been variances to its bid package, and adjustment made; and finally
7. The contractor can be mobilized.

All of these take a considerable amount of effort. If the work is to be done by experienced in-house engineers on the project team or from that function of an organization, then the contracting procedure does not apply. However, such activities as writing the scope of work should still be carried out by the central project team to make sure that potential challenges/problems are fully identified and that potential impacts are considered for all the other parts of the project.

The results of this preliminary study will be adequate for comparative screening of mining and processing alternatives, while an economic analysis will determine whether to proceed with (or reject) the project. A primary objective of the study is to plan and estimate costs for a further predevelopment program if warranted. Approximately 4% to 8% of the project engineering will need to have been completed, in which case the probable error of cost estimates accuracy should be between 35% and 45%. If 10% to 12% of the total project hours have been completed in the study, the probable error should be between 30% and 35%, while contingencies of between 20% and 35% for capital costs will apply. An economic analysis will be performed, and the preliminary feasibility report will be fully documented. At this point, presentations to management will be made and, depending on the results of the economic analysis, approval to proceed to the next step of the project (or otherwise) follows.

Major Activities of the Preliminary Feasibility Study

A description of these preliminary study activities and tasks can be found in Appendix 4.7A. This generic list applies to all mineral properties but can be adapted with addition and deletions for a particular deposit. Remember, for any of these activities that need to be contracted, the seven contracting steps listed will consume a lot of time.

Phase II: Intermediate Feasibility Study

Based on results of the preliminary study showing that a project has the potential to achieve the desired company goals, the intermediate feasibility study should be initiated. The specific object for this study is significantly different than for the preliminary study. Now that it has been shown, by using at least one mining/processing system, that the mineral resource being examined has potential economic viability, the objective must now focus on methods to optimize each component mine/plant process, while at the same time taking an in-depth look at all of the project parameters briefly studied in the preliminary study.

At this time, accurate topography maps specific to the area must be generated, if not already available. Any shortcomings in the land and water status discovered in the preliminary study must be corrected at this point before investing any more money.

Mine design will be based on information from the early exploration (delineation) drilling program plus any additional exploration sampling done between the two phases. In some cases, bulk sampling may be required. Thus, if permits can be obtained, a test mine may be justified after this phase of the study. If further exploration drilling or trenching takes place during this phase, permits and contractor agreements must be prepared. Under the control of the project team, the sampling program must

- Prepare a sample flow chart,
- Prepare a chain-of-custody security procedure (if not already in place; designed to protect the integrity of the eventual sample analysis), and
- Procure and analyze the new samples.

The new geology and mineral information must be fed into the database and evaluated. After rebuilding and analyzing the new database and documenting the current reserves and resources, new reserve and resource maps can be constructed for mine planning.

Given the shape and character of the ore reserve identified to this point, the mine planning will begin. Only measured and indicated geologic resource material may be used for mine planning in the United States and Canada. Although those mining methods considered in the preliminary study may be reexamined, other methods should also be considered, since the ore body shape, size, character, and grade may have changed. The methods described in this text on mine planning and mining methods should be followed. But this time, after a rough screening of multiple mining methods, two or three of the most probable mining methods (or variations), which are considered safe and environmentally permissible and that will probably yield the lowest cost (or greatest recovery), should be carried through the study until an economic comparison can be made. Likewise, with the latest mineralogical data and mining methods, several mineral processing and waste disposal alternatives should be considered, and those that seem likely to yield the best economics should be carried through the study until a true economic comparison can be made between the methods.

Facilities siting and geotechnical investigations will need to be conducted. If competent personnel are not available within the company, contract preparation to cover the scope of work for the approximately 125 intermediate feasibility activities must be done. The same list of contracting activities must be completed that are shown in Appendix 4.7A for Phase I, the preliminary study, and time must be scheduled for all of this contracting effort. One must not underestimate the time it can take to perform these tasks: scopes of work, requests for proposals (RFPs), survey of industry contractors, obtaining a legal contract, allowing time for bids and evaluating the bids, and negotiating the contract details with the successful contractor.

This must be done for each contractor. It may take several months to get a contractor assessed and the details of their contract accepted. But with contractors on board, work can then begin with environmental baseline studies, impact assessments, and long lead time permit applications. Again, if competent personnel are not available within the company, contract preparation to cover the scope of work for these environmental activities must be done. Bidding lists must be prepared, RFPs issued, bid evaluation criteria written, and the bid evaluation administered. Finally, when negotiated details of the contract are completed, environmental contracts are awarded. Although the baseline studies take time, they should be completed by the time the intermediate feasibility study is

done, which will allow for this information to be submitted, along with the intermediate mining and process planning, to the permitting agencies.

Results of the intermediate study will be adequate for determining economic feasibility and defining additional predevelopment and/or metallurgical testing requirements. In many cases, the benefits and requirements for a test mine or bulk sampling will be fully recognized and defined at this point. In most cases, specific permitting will be required, and this will require time to receive such permits.

The cost estimates for the (two or three) alternatives developed during this phase should be based on detailed functional analysis of the mining and processing methods of each operation, on suppliers' written quotes, and on bench-scale metallurgical testing. By the end of the intermediate study, the engineering on the project should be between 12% and 15% completed. The probable error of cost estimates should be 15% to 20%, while contingencies of between 15% and 20% will apply. Economic analysis will be performed on the favorable sets of alternatives selected. Usually, no more than three sets of alternatives will be evaluated. When the intermediate feasibility report is fully documented, presentations to management will be made and, depending on the results of the economic analysis, approval to proceed to the next step of the project (or otherwise) will follow.

Major Activities of Intermediate Feasibility Study

A description of these intermediate study activities and tasks can be found in Appendix 4.7B. This generic list applies to all mineral properties but can be adapted with addition and deletions for a particular deposit. For any of these activities that need to be contracted, the seven contracting steps listed in the preliminary feasibility discussion apply and will consume a lot of time.

Need for a Test Mine

Many times the feasibility team will not be able to obtain enough ore quality and geotechnical information working with just exploration sampling. In these cases a test mine must be considered. The test mine may come after the intermediate feasibility study or during the final feasibility study. The advantages of a test mine are as follows.

- **From a mining perspective.** Verifies the expected ore continuity, thus eliminating disastrous surprises; accurately assesses the rock strength, allowing prudent planning and sizing of the commercial mine opening; verifies mining efficiency and productivity as it relates to drilling, blasting, and materials handling; determines from reliable water studies the nature of mine water inflows, thus allowing for adequate water-handling procedures to be installed before problems are encountered; better quantifies the mine ventilation friction factors and requirements; and confirms the character of the waste product and how it will be handled in the commercial operation.
- **From a metallurgical perspective.** Verifies and optimizes the metallurgical flow sheet with a pilot-plant process that is continuous lock cycle testing; determines what size and type of equipment will be optimal for the metallurgical recovery; determines what type and amount of reagents will lead to the best recoveries and concentrate grades; determines the required amount of water and how to achieve a water balance; provides a more accurate prediction of concentrate grade, moisture content, and impurities; and provides a much better assessment of the work index from a bulk sample than from small samples.
- **From an environmental perspective.** Demonstrates the ability to control the operation in such a manner that it will not harm the environment; allows the project team to completely study the waste characterization and determine any future problems; and, if water discharge is involved, allows the project team to study the difficulty of settling the discharged water and determine what is necessary to mitigate future problems and determine if zero discharge is possible.
- **From an engineering design perspective.** Improves the ability to make more accurate cost estimates, because of better knowledge of the abrasivity of the rock and of the ground/slope control of the stopes/pit walls, which could lower the cost estimate because less contingency may be needed; improves labor estimates because of a better understanding of the productivity of each unit operation; predicts a more accurate schedule, because of better understanding of the unit productivities; and lowers the overall risk of the project in every aspect.
- **From the perspective of expediting later mine development.** Shortens the overall schedule from the end of the feasibility study to the end of construction, because of early access to develop the commercial mine, and completely utilizes the openings as part of the commercial mine operation; because access to the underground opening already exists, some shafts may be able to be raise bored and then expanded by mechanical excavation rather than by the more expensive conventional shaft sinking methods; and finally, the test mine may be an ideal training facility prior to the commercial mine start-up.

Activities related to the test mine are found in Appendix 4.7C.

Phase III: Final Feasibility Study

The final feasibility study should be initiated when results from the intermediate study show that the project still has the potential to achieve the desired company goals. The objective, as in the first two phases, is still to determine the potential value of the property to its owners—either by determining the optimum method of developing it, by selling it, or by doing nothing further at the moment. However, more specific to the final study, the objective now becomes one of minor refinements to all of the details of the intermediate study that yielded results that met the company objectives. This is designed to optimize the return on the future investment. The final feasibility study will be prepared during the permitting time schedule for the project, since final project features must be reflected in the permits to accurately assess impacts and mitigation for the agencies, commentators, stakeholders, nongovernmental organizations (NGOs), and community. Assuming that this project still shows favorable results at the end of this phase of study, the design parameters set in the final feasibility study will feed into the design basis report, which guides the project into the design and construction phase, and finally into operations.

If test mining with bulk sampling and pilot-plant testing has not been completed, it now becomes part of the final feasibility study. Mine and process facilities will be further studied, and the best alternative developed in the intermediate study will be optimized. Using the latest exploration and

metallurgical test data, probably from the test mine bulk sample, the reserves will be updated and the metallurgical flow sheet will be optimized. Final environmental impacts will be determined following prescribed guidelines. Applications for construction and operating permits will usually be made early in this phase of study (subject to later modification). Mine and process operating cost estimates will again be made by performing a functional analysis. Capital cost will be refined by again soliciting written quotes from vendors. By the end of the final study, the engineering should be 18% to 25% completed. The probable error of cost estimates should be 10% to 15% of the total cost estimate, with a contingency of 10% for most engineered structures. Other less well-defined aspects of the project (e.g., mine development) should have contingencies of at least 15%. An economic analysis will be performed, with the final feasibility report fully documented. At this stage, presentations are made to management, and, depending on the results of the economic analysis, it will give approval to proceed to the design and construction phase of project development and for the associated budget.

Major Activities of Final Feasibility Study Plan and Budget

A description of these final feasibility activities and tasks can be found in Appendix 4.7D. This generic list applies to all mineral properties but can be adapted with addition and deletions for a particular deposit. For any of these activities that need to be contracted, the seven contracting steps listed in the preliminary feasibility discussion apply and will consume a lot of time.

Combining Classic Approach with Recommended Approach

Because there are good reasons (as outlined at the beginning of this chapter) to sometimes utilize the nonuniform classic conceptual/scoping study approach, if the decision is made to move the project to the next level of study, one should convert to the engineered, systematic three-phased approach. In this case, the conceptual/scoping study should be compared with the details of the engineered, systematic, phased preliminary study. Whereas in the classic scoping study only 2% of the engineering may have been done for the first phase, in the engineered, systematic preliminary study as much as 4% to 8% of the engineering would be completed. This means that if one is now going into the intermediate feasibility study in the engineered, systematic three-phased approach, the extra work to be done in the intermediate study must be planned so that by the end of the intermediate study, all of the reasonable functional alternatives of the operation should have been examined, the optimal method selected, and 12% to 15% of the engineering work completed before going into the final feasibility study.

Most mine management people believe that the final feasibility study is the final document of the feasibility process. Unfortunately, with this in hand, most management teams will head for the bank or a joint venture partner and on to a design contractor without fully documenting everything that went into the full feasibility study. This includes not only a description of the geologic reserves, mine and plant facilities, and hardware, along with the positive economic picture, but all of the company design and operating philosophy that is so important when the build-and-operate stage is reached. The plans on how to execute the project and how to operate the completed facility are equally as important to the design contractor, the banker, and the potential joint venture partner. If all important activities through to the final operation have not been examined and then documented, the project is not ready to move forward.

PROJECT DESIGN BASIS REPORT PREPARATION

With project approval, the course of action will either be to go directly into the project execution phase or possibly seek out a joint venture partner. In either case, the design basis report (DBR, sometimes called a design basis memorandum or design basis document) needs to be prepared. The approved project feasibility report will be presented in sufficient detail to produce a DBR, which is the document that will guide the project through the next step: designing the project based on the preceding studies.

Why a DBR Is Needed

The primary purpose of the DBR is to be able to convey to future design engineers a consolidated document in which all the needed information is contained in a condensed version. But it can also serve to inform others, such as financial organizations, construction personnel, or persons who may be interested in a joint venture. Although much of the information is also contained in the final feasibility study, this document is written more for the purpose of documenting (for management) that the project is indeed both feasible and economically viable. In contrast, the DBR is written to convey all of the technical information that will be needed by the architect/engineering (A/E) design organization, which has already been developed by the owner's project feasibility team. It contains all of the drawings prepared during the final feasibility study, plus any others required to convey the needed technical information to the A/E organization for the project, and will be used as a basis for the final bids by the various A/E organizations.

In the introduction, the writer should define the purpose and use of the DBR. At a minimum, the DBR serves several purposes. The DBR

- Defines the technical basis for project design and construction so that basic, detailed engineering downstream can proceed;
- Provides the basis for a coordinated review by the organizational entities involved—the future operations group, the engineering group, management, and the future A/E team;
- Provides documentation for the technical basis and facilities description from the final feasibility study cost estimates; and
- Conveys the company's construction and procurement philosophy to the future A/E team.

The DBR is usually written in several volumes (in the case of the following example, five volumes were produced). Rather than describing in specific detail what should be written under each section and subsection of each volume, a brief description is given here concerning the general content of that volume with a generic outline of items given in Appendix 4.7E.

Volume 1: Management Summary

The management summary, prepared by the project executive or project manager as applicable, summarizes the project objectives, the assumptions that were made, the work that has been completed, the economic analysis and associated risk,

and the recommendations of the project team. Other items that should be covered (if studied by the project team) include project funding and the business plan with market and competition analysis and strategies. Any outstanding major issue involving government agencies related to utilities, transportation, land, royalties, or potential project partnerships must also be mitigated. At the end of the summary are the conclusions and recommendations, with discussions on the reserves, the feasibility of the project, the market, the schedule of the design, construction and start-up as planned in the feasibility study, any preappropriation work contemplated, and needed funding. An example outline of the information that is contained in Volume 1, Management Summary, is shown in Appendix 4.7E.

Volume 2: Project Economics

Prepared by the project executive or project manager, project economics summarizes the capital and operating costs, project schedule, market forecasts, inflation projections (if constant dollar analysis was not used), and other factors that affect the total erected cost and project economics. Identified project risks and the measures needed to mitigate those risks should be documented. An example outline of the information that is contained in Volume 2, Project Economics, is shown in Appendix 4.7E.

Volume 3: Technical Narrative

Prepared by the project team, the technical narrative describes the technical basis for the project and lists the design considerations and constraints. This is the technical meat of the project. The narrative must convey to the future A/E contractor exactly what is to be built and exactly what the A/E constructor is to do and precisely how it will accomplish that. Nothing can be left out. For this reason, all of the drawings prepared during the final feasibility stage, plus whatever drawings are necessary to convey the message to the A/E organization, must be in the DBR. The better defined the project is in the DBR, the more accurate the cost will be to the bid estimates, and the fewer exceptions that will have to be negotiated. An example outline of Volume 3, Technical Narrative, is found in Appendix 4.7E.

Volume 4: Project Execution Plan

This document, prepared by the project team, defines the real and potential problems in the detailed engineering, procurement, and construction of the project. Furthermore, it goes on to describe the best plans to ensure that these problems are mitigated or at least minimized. The recommended contracting plans are spelled out, as are the plans for engineering and design, procurement, and construction. An example content outline of Volume 4, Project Execution Plan, is in Appendix 4.7E.

Volume 5: Operating Plan

Prepared by the company's operations department, the operating plan explains how to minimize the impact for identified potential problems in start-up and continuing operations. Although much of the company's operating philosophy should already have been placed into the design as presented in the final feasibility study, the writers of the operating plan should again emphasize the company's attitude toward mechanization and automation, and what they are willing to pay for it; and its policy on safety and environmental issues and maintenance and contracting. Such issues as labor recruitment and training will be planned, scheduled, and budgeted. Learning-curve estimates will be applied toward the production buildup, so the estimated production will be on schedule and project economics will be preserved. An example outline of Volume 5, Operating Plan, is found in Appendix 4.7E.

It is this DBR document that is used as the basis for the subsequent engineering design. Not only does it contain the technical data and information decided on by the company during the final feasibility study but also the project execution plan for contracting, building, and constructing the mines of the project. It also contains the operating plan, which will guide the engineers and builder to construct the mine/plant so the operating philosophy of the company can be quickly achieved and maintained.

Historic information on the activity duration that goes into the project schedule and the functions that will be performed in the engineering design and final constructed project is included in the next section. It often appears to laypeople that building mines and plants takes much too long and costs too much, but this is not the case. What is true is that the expectations based on most of the final feasibility studies are overoptimistic, and thus the project begins badly. Data from case histories are presented in the next section showing what should be expected.

FEASIBILITY AND PROJECT TIMING, AND SCHEDULE

The time it takes between the discovery of a resource that may be a potential ore body and when the ore body is brought into production can vary significantly. Obviously, with an extremely high-grade ore body, it may take significantly less time to identify enough ore to start mining. Likewise, if money can be made no matter how you mine it, then the company may not want to spend a lot of time optimizing the mining and milling methods (though this could and has proved to be a mistake in the past). On the other hand, it may take many years to define large, marginal mineral resources and to optimize every aspect of the study in order to turn the resource into a viable reserve.

Technological changes over time may also allow the property to be developed after many years of study. The other factor is the ever-changing environmental permitting, which can vary significantly: Although a small punch coal mine in Appalachia can take less than a year, the development of a world-class zinc/copper mineral resource in Wisconsin (United States) was stopped for 20-plus years and finally terminated, even though it can be demonstrated that the underground mine can be built and operated in a manner that would be environmentally acceptable anywhere else. Overall it usually takes from 2 to 6 years just to complete the mineral property feasibility evaluation study.

The overall time from find-to-mine is logically divided between the classical phases of mineral development:

- Preliminary exploration and discovery
- Land and water acquisition commitment
- Exploration
- Feasibility studies/environmental permitting
- Final engineering
- Development and construction
- Start-up to full production

All of these activities vary greatly in length. In this chapter, only the length of the feasibility studies and environmental permitting will be considered.

Table 4.7-3 Estimates for average duration of project evaluations

Project Evaluation Phase	Time Duration
Preliminary	7.5 months (156 working days)
Intermediate	2 years, 8 months (666 working days)
Final	2 years, 10 months (709 working days)
Total	6 years, 1.5 months (1,531 working days)

Nelson & Associates (Nelson 1979) conducted a study for the U.S. Bureau of Mines on the duration of these phases of mineral development for four mining projects in Wisconsin and Minnesota (United States). (Three were operating and one was being considered.) Because these states have strict systems of environmental permitting for new mine development, it is not surprising that the Nelson study found that permitting time for a metal mine in Wisconsin was, by hindsight, more than 100% optimistic. For example, the following information comes from Nelson's Summary of Time table:

- Environmental monitoring: 2.18 years
- Environmental impact report evaluation: 4.85 years
- State permits: 5.25 years
- Local permits: 3.25 years
- Environmental impact report preparation: 1.55 years
- Wisconsin Department of Natural Resources (WDNR) for the Wisconsin Environmental Protection Agency: 3.90 years
- Federal environmental impact statement (EIS): 3.05 years
- Master hearings: 1.16 years
- Other WDNR permits: 3.05 years

In reality, some of these activities can go on simultaneously or overlap. But even the most optimistic schedule to receive permits in Wisconsin for a metal mine was 10 to 12 years.

In addition, in the same report, Nelson also developed a time estimate, based on these four major projects, for feasibility studies as 8 years, which seems too long. However, this information came from four major projects done by four different major mining companies. Although it certainly can take 8 years to do a complete mineral property feasibility study for many projects, it is not necessarily true for all of them. Table 4.7-3 is taken from one mineral company's estimates of the average time expected to complete the feasibility/evaluation on 10 (small to large) projects.

However, this schedule overlaps all activities possible on maintaining a high level of engineering standards (the approximate 300 total activities listed previously, completed mostly by contractors). Depending on the size, grade, location, ownership of the project, and how much financing the owner needs, these times can change radically. The total worker-hours to complete a feasibility study from the conceptual study through the final feasibility study will vary from 50,000 worker-hours to more than 100,000 worker-hours. By the time the final feasibility study is finished, 18% to 25% of the total engineering for the project will have been completed.

In contrast to these long time estimates, Cusworth, (1993) presented the estimates for Australia as typical durations for feasibility studies:

- Scoping study: 7 to 9 months
- Prefeasibility study: 9 to 13 months
- Feasibility study: 12 to 17 months

Therefore, it could be concluded from Cusworth that all projects in Australia vary only from a total of 28 to 39 months. Unfortunately, no details are given as to what was actually covered during these periods. It would have to be assumed that much of the difference between the United States and Australia is the U.S. environmental agencies' red tape. But two other factors may play a significant role: (1) Probably more virgin deposits were being discovered in 1993 in Australia than in the United States, which might tend to be of a higher grade; and (2) Australians tend to turn everything over to contractors, which, with their larger staffs, can usually perform faster than their U.S. counterparts.

Scheduling of each project element must be done from the beginning. This is one of the important reasons to document in advance all of the activities of each feasibility level phase. Then estimated worker-hours of labor time must be assigned to each of these hundreds of project activities and subactivities. Setting up and maintaining the schedule of even a medium-sized project is a major task involving thousands of activities.

ORGANIZING THE PROJECT TEAM

There are many ways to organize a project team, depending on

- Phase of the feasibility study,
- Size and complexity of the project,
- Location of the project, and
- Size and experience levels within the parent company.

First, the talent that is needed either part-time or full-time on a project feasibility team must be considered. Certainly, the team needs people who understand and can perform project management, as well as costing and scheduling for the project. In addition, every technical discipline that has been considered in the evaluation must be populated. This includes the fields of geology, geostatistics, mining, metallurgy, environmental consideration, hydrology, geomechanics, civil infrastructure, and economic evaluation. But there must also be people who can provide and evaluate legal, land, water, public relations, socioeconomic, marketing, tax, and financial information. Depending on the size of the parent company, it must either build the organization within the company structure or depend on the consulting industry to supply the needed talent.

Taking the in-house approach, the company must form a project management and development organization whose staff will be assigned to the project management nucleus of each project. In addition, technical specialists are assigned from a technical support organization on an as-needed basis to perform the multitude of technical activities that will be required. By approaching the problem in this fashion, and using proper labor scheduling, many projects can be handled simultaneously. This approach works well on small- to medium-sized projects up through the intermediate feasibility phase of study; for large or mega-projects, it would probably only work in the preliminary phase.

Taking the consultant approach, the company should still form a project management organization to manage each project but then contract to either one large multidisciplined consultant organization or individual discipline consultants to perform the various technical tasks of each project. The consultant approach will not be discussed in detail, since the A/E consultant normally supplies all the organization's needs.

In-House Project Teams

Two basic management philosophies must be considered: functional matrix or line/staff organizations. This operating philosophy goes beyond the consideration of managing projects but is the means by which all supplied labor report to the company's various functional departments. There will be a considerable difference in how the project teams are made up, depending on whether the company operates as a line/staff organization, a functional/matrix organization, or a hybrid of the two.

It is difficult to generalize, but if the company is running several small- to medium-sized projects, which are in the preliminary or even the intermediate feasibility study phase, it is more cost-effective to organize a core group—consisting of the project manager and a project cost and schedules coordinator—and temporarily assign experts from the matrix technical organization rather than organize several line/staff organizations for each project. By allocating work in this manner, each discipline can usually handle several projects at one time with proper scheduling. It can usually work well through the intermediate level of feasibility, particularly if the projects are located in the same country as the home office mine evaluation and development group. However, when the project is overseas or if it is a large project, the amount of field work required during the intermediate and final studies mandates that it is usually best to move the dedicated project team to a location near the site.

At such time as the magnitude and importance of a project justifies it, a separate project team organization is established. This would normally occur at the end of either the preliminary or intermediate study phase when the cost, duration, level of staffing, or overall importance indicates that a separate project team should be created. At this point, the team would be transferred to a location close to the site of that project but still functioning under the project development group. It is also worth noting that in some countries there is little or no technical mineral engineering base on which to draw for a staff and one must be literally imported.

At the conclusion of the preliminary or intermediate study phase and when it is determined that a separate project organization should be established, an independent project team is organized and works through the local organization as determined by management and coordination with the affiliate or country manager. In such cases, the project may have a project executive who also serves on the local country management committee or staff.

ACKNOWLEDGMENTS

The author acknowledges the contributions of W.J. Bulick and G.D. Mittelstadt for the original work they completed in 1977 wherein they developed the detailed "Recommended Approach" for the three-phased feasibility study methodology described in this chapter.

APPENDIX 4.7A
PHASE I: PRELIMINARY FEASIBILITY STUDY COMPLETE ACTIVITY DEFINITIONS

Activity No. (from WBS) **Activity Title and Description**

10100 **Public Affairs**

- Do in-house determination of public affairs' perceived responsibility and identify company official to serve as spokesperson for the project.
- Inform state government officials if the mineral resource is a new major discovery, prior to official public announcement of the discovery. Then prepare and disseminate initial press release announcing discovery.
- Identify statewide media editors and set up proper liaison and method of briefings.
- Identify concerns of local, regional, and state population, and prepare proactive response demonstrating how each concern will be mitigated. As more data are received, update these proactive responses to the public.

10101 **Review Exploration Report**
Review report prepared at end of exploration phase. Report should contain information on
- Mineral deposit,
- Property location and access,
- Area surface features,
- Exploration activities completed and planned,
- Geology (regional, local, and deposit),
- Potential ore reserves,
- Company's land and water position,
- Property ownership and royalties,
- Property history,
- Special studies performed or environmental problems noted, and
- General data.

Review should include trip to project site to familiarize team members with site and area.

10102 **Prepare Preliminary Study Plan and Budget**
Prepare preliminary feasibility study schedule, with labor and cost budgets necessary to complete preliminary study. Prepare schedule to show activities and time for remainder of project phases:
- Intermediate and final studies
- Design, construct, and develop (through start of production)

10103 **Present Preliminary Study Plan and Budget to Management**
Present schedule, plan, and budget for review.

10104 **Obtain Approval of Preliminary Plan and Budget**
Obtain approval from appropriate levels of management to proceed with preliminary feasibility study outlined in schedule, plan, and budget.

10201 **Review Land and Water Status**
Review land ownership and water rights, control, royalty, and lease situation developed during exploration phase. Project team members should review land status with personnel in the company's land office or its land agent.

10301 **Assemble and Edit Drill-Hole Data**
Assemble drill-hole data pertaining to deposit. Audit data for correctness and completeness.

10302 **Check and Approve Preliminary Reserves**
Check and modify or approve preliminary reserves calculated by exploration group.

10303 **Document and Review Geology and Reserve Data**
Write report documenting drill-hole and reserve data. Report should contain appropriate tables, maps, sections, and written information concerning mineral inventory and reserve data, regional and local geology, and other pertinent information. Review assembled information with appropriate levels of management. Write report in style and format suitable as chapter in preliminary feasibility study report.

10304 **Prepare Intermediate Predevelopment Plan and Budget**
Develop scope of work, schedule, and budget for predevelopment drilling program for next phases of work.

10401 **Develop Environmental Work Specifications**
Define scope of work for an environmental overview of project and surrounding area.

10402 **Develop Environmental Overview**
Develop general environmental plan for protecting quality of water, land, ecology, cultural resources, and socioeconomics of project area during construction and operation. Determine costs, if applicable, to prevent or mitigate environmental damages and return area to near original condition at project end. Costs should have accuracy of +30%.

10403 **Document and Review Environmental Results**
Write report documenting environmental overview. Review results of study with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in preliminary feasibility report.

10501 **Develop Geotechnical Work Specifications**
Develop scope of work necessary for siting, soils mechanics, rock mechanics, and hydrology studies.

10502 **Perform Geotechnical Overview**
Examine drill cores or send cores for testing, if necessary, to determine unusual characteristics that may impact mining costs. Evaluate potential problems and associated costs. Perform field reconnaissance, with appropriate lab and field tests if necessary, to determine soils and surface hydrology conditions in and around potential mine, mill, tailings, and surface facility sites. Evaluate potential problems and associated costs.

10503 **Establish Tentative Siting Preferences**
Select tentative mine, mill, tailings disposal, and surface facilities sites based on preliminary evaluation of costs, soils mechanics, surface hydrology, and general environmental conditions. Costs should have accuracy of +30%.

10504 **Document and Review Geotechnical Results**
Write report documenting geotechnical and siting overview. Review results with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in preliminary feasibility study report.

10601 **Develop Permit Application Specifications**
Develop scope of work necessary to determine governmental agencies involved and permits required for every stage of project through design/construct and into operation.

10602 **Conduct Preliminary Permit and Agency Overview**
Conduct literature search and telephone conversations to determine permits required to develop, construct, and operate project. Determine local, state, and federal agencies involved. Evaluate the time and cost of permits and bonds needed. These costs should have an accuracy of ±30%.

10603 **Document and Review Permit and Agency Results**
Write report documenting results of permit and agency overview study. Review with appropriate levels of

management and other personnel. Write report in style and format suitable as chapter in preliminary feasibility study report.

10701 **Develop Mine Work Specifications**
Develop scope of work necessary for conducting mining evaluation studies.

10702 **Conduct Mining Literature Search**
Review available literature involving mining methods and schemes for deposits of similar nature. This activity could involve visiting similar operations to gather data pertaining to mining methods, equipment, personnel, and costs.

10703 **Identify Possible Mining Methods**
Through literature search, personal knowledge, mine visitations, and discussions with other people, identify technically feasible mining methods applicable to this type of deposit.

10704 **Develop Tentative Layout for Each Mining Method**
Lay out preliminary mine plan for each technically feasible mining method considered.

10705 **Evaluate Alternative Mining Methods**
Perform rough capital and operating cost calculations for each technically feasible method selected. Evaluate several production rates. Perform quick discounted cash-flow analysis and rank methods in order of economic preference. Eliminate alternatives with little or no chance of economic success. Determine production rates that will satisfy market conditions and give best economic rate of return.

10706 **Perform Mine Preliminary Functional Analysis**
Evaluate operational cycles and requirements for labor, equipment, and supply for each mining function and for each alternative selected in Activity 10705 based on mine engineer's experience. The functions include drilling, blasting, loading, hauling, scaling, bolting, ground control, hoisting, primary crushing (if underground), maintenance, supply/debris handling, pumping, and other support services. Prepare cost and operational cycles for each function.

10707 **Develop Mine Capital and Operating Cost Estimates**
Estimate capital requirements necessary to bring mine on stream. Estimate operating costs required to produce ore. Estimate costs for two to four mining methods and production rates selected for study. Costs should have accuracy of ±35% to 40% (depending on method of functional analysis and geologic definition). List costs in format for financial analysis.

10708 **Document and Review Mine Results**
Write report documenting mine study work performed. Review results with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in preliminary feasibility study report.

10801 **Develop Mill Work Specifications**
Develop scope of work necessary for conducting milling evaluation studies.

10802 **Determine Tentative Mill Process Requirements**
Use literature search, company personnel experience and discussions with others to determine feasible process methods. Determine processing requirements for each alternative. Activity may require input from bench tests performed during exploration phase or during preliminary study phase.

10803 **Prepare Mill Flow Sheet**
Prepare flow sheet for each process alternative. Flow sheet should contain sufficient detail to allow selection and sizing of equipment. Perform capital and operating cost calculations for each technically feasible method. Perform quick discounted cash-flow analysis and rank methods in order of economic importance. Eliminate alternatives with little or no chance of economic success.

10804 **Perform Preliminary Mill Functional Analysis**
Evaluate operational cycles and requirements for labor, equipment, and supply for each milling function and for each alternative selected in Activity 10803 based on the metallurgical engineer's experience. The functions include stockpiling/reclaiming, crushing, grinding, screening, concentrating, classifying, clarifying, tailings/waste disposal, concentrate handling at the mill site, maintenance, supply/debris handling, and other support services. Prepare cost and operational schedules for each.

10805 **Evaluate Custom Milling Alternatives**
Investigate opportunities for selling run-of-mine (ROM) material. Determine sales price and charges associated with selling ROM (if a reasonable alternative). Investigate opportunities for tolling ROM material. Determine custom mill capacity, timing, and costs. Costs should include capital and operating expenses for everything associated with tolling. These include transportation of product to custom mill, losses/deducts for processing, tolling charge, sampling methods, transportation of concentrate, and personnel requirements.

10806 **Develop Mill Capital and Operating Cost Estimates**
Determine capital and operating cost estimates for all milling operation alternatives and different production rates. Costs should have accuracy of ±30%. Put costs in format suitable for financial analysis.

10807 **Document and Review Mill Results**
Write report documenting mill study work performed. Review results with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in preliminary feasibility study report.

10901 **Develop Smelter/Refinery Work Specifications**
Determine general requirements for smelting and/or refining mill concentrates. Define and document the scope of work for the custom refining study.

10902 **Evaluate Custom Smelter/Refining Alternatives**
Do preliminary investigation of opportunities for custom smelting and/or refining project concentrate. Determine custom refining capacity, timing, and costs.

Costs should include capital and operating estimates for everything associated with custom refining. These include transportation of concentrate to refinery, transportation losses (where applicable), smelting/refining charge (consider deducts and/or credits), transportation of refined product, and personnel requirements. Costs should have accuracy of ±25%.

10903 **Document and Review Refinery Results**
Write report documenting refinery work performed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in preliminary feasibility study report.

11001 **Develop Surface Facilities Work Specifications**
Develop scope of work and schedule necessary for study of project surface facilities not connected with mine and mill studies.

11002 **Determine Tentative Surface Building Requirements**
Make preliminary estimate of surface buildings required for project operation. Include buildings that serve support function for mine and mill but not buildings directly related to mining and milling activities. Types of buildings include ambulance garage, administration/office, dry/changehouse, guardhouse, security fence, surface shops, and port facilities (if applicable). Include concentrate storage and loading facilities capital and operating costs at shipping docks. These can run into millions of dollars if you have to supply them.

Determine operating and maintenance personnel and equipment requirements (includes shop, office, and dry equipment).

11003 **Determine Tentative Surface Utilities Requirements**
Make preliminary estimate of utilities required for project construction, development, and operation. Study does not include power distribution within facilities included in mining and milling studies. Utilities include electric power (including internal switching and transformers), fuel for buildings and fuel storage for operating equipment, communications (radio, voice/data telephone system, and GPS), potable water, water for dust control, water and system for fire protection, sewage system, and garbage/trash/solid waste removal and disposal area and system.

Determine operating and maintenance personnel and equipment requirements.

11004 **Determine Tentative Surface Transportation Requirements**
Make preliminary estimate of transportation needs for moving equipment, supplies, material, and mine/mill product into and out of project area during project construction, development, and operation. Study should include alternative transportation method such as truck, rail, ship/barge (if feasible), and air haulage (if feasible), combinations of above, and personnel transportation.

Study should determine access road, personnel, and equipment requirements.

11005 **Determine General Surface Facilities Arrangement**
Make preliminary estimate of requirements for
- Internal road for surface facility, plant, and disposal area(s) (does not include haulage roads for open-pit mine but does include equipment for maintaining auxiliary roads);
- Parking areas;
- Construction laydown area(s); and
- Storage area(s).

Prepare preliminary plot plan showing arrangement of all surface facilities, including the listed items, water facilities, mine, mill, and tailings facilities. Determine maintenance material and supply requirements for these areas.

11006 **Determine Surface Mobile and Miscellaneous Equipment Requirements**
Make preliminary estimate of equipment requirements not covered under other activities. This includes equipment for ambulance(s); road and yard area maintenance; supervisor pickups/car(s); maintenance personnel pickups and trucks; loader(s)/backhoe(s); forklift(s); crane(s)/cherry picker(s); portable welder(s), compressor(s), generator(s), and light set(s); small rear-dump truck(s); and crawler tractor(s) with dozer. Determine operating and maintenance personnel and equipment requirements.

11007 **Develop Surface and Ancillary Facilities Capital and Operating Cost**
Determine capital requirements necessary to build surface and ancillary facilities. Determine operating costs associated with surface facilities, including personnel, supplies, office, and safety equipment. List the costs in spreadsheet format suitable for financial analysis. Costs should have accuracy of ±30%.

11008 **Document and Review Surface Facilities Results**
Write report documenting results of surface facilities studies. Review results with appropriate levels of management and other personnel. Write report in format and style suitable as chapter in preliminary feasibility study report.

11101 **Determine General Personnel Requirements**
Determine approximate administrative and management personnel requirements, and operating, maintenance, support, and supervisory personnel requirements developed in preceding activities. Split requirements into salaried exempt, salaried nonexempt, and hourly classifications. Develop labor buildup schedules for each classification.

11102 **Determine Approximate Administrative Costs**
Determine salaries and wages of personnel identified in Activity 11101. Determine payroll burden associated with salaries and wages. Determine cost, type, and quantity of office equipment and supplies required for all offices, including administration, mine, mill, maintenance, and others. Prepare costs in form suitable for financial analysis. Costs should have accuracy of ±20%. Include costs for relocation and salaried personnel.

11103 **Document and Review Organization and Administration Results**
Write report documenting administrative costs and personnel requirements. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in preliminary feasibility study report.

11201 **Assess Miscellaneous Labor-Related Cost Factors**
Assess impact and cost of factors affecting labor recruiting, hiring, and retention. Factors include incentive system, labor setting, recruiting, training, retention, performance, and cost. Factors may also include employee housing and company-supplied transportation. List costs in spread format suitable for financial analysis. Costs should have accuracy of ±20%.

11202 **Document and Review Labor-Related Results**
Write report documenting labor-related studies. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in preliminary feasibility study report.

11301 **Conduct Preliminary Market Studies**
Perform market studies to determine selling price of salable products and probable product sales potential. Estimate price ranges for life of project (in terms of constant dollar, not inflation). If changes in product sales potential are identified for the future, they should be included as sensitivities. Prepare expected sales of products in format suitable for financial analysis.

11302 **Document and Review Marketing Results**
Write report documenting marketing studies. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in preliminary feasibility study report.

11401 **Develop Tax Overview Specifications**
Develop scope of work and schedule necessary for conducting study of taxes applicable to project.

11402 **Conduct Tax Overview Study**
Make preliminary study of taxes applicable to project and their cost and impact on construction, development, and operation of project. Prepare tax rates in form suitable for financial analysis.

11403 **Document and Review Tax Study Results**
Write report documenting tax studies. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in preliminary feasibility study report.

11401 **Develop Preliminary Financial Analysis Criteria**
Develop criteria for performing preliminary financial analysis. Criteria should include overall project schedule (includes intermediate and final evaluation, design, construction, development, and startup); mine and product estimated production; capital and operating costs estimates; royalties; escalation factors (only if this is not a constant dollar analysis); corporate overhead allocation; working capital; property acquisition costs; mill recovery; depreciation methods; depletion allowance; tax rates; weighted contingency for unforeseen factors if not included on every capital cost item; capitalization factor; salvage values; working capital; sensitivity analysis; and project alternative comparisons.

11402 **Conduct Financial Analysis**
Conduct financial analysis for total project using Apex or other suitable computer program. Print results of economic analysis.

11403 **Conduct Financial Sensitivity Studies**
Evaluate risk sensitivity of project to key factors such as operating costs, capital costs, reserves, grade, production sales, mill recovery, royalties, taxes, and other items with high degree of uncertainty. Conduct sensitivity analysis using computer program that will perform Monte Carlo simulation, which will assess combined risk sensitivities. Print results of the sensitivity analysis.

11404 **Document and Review Financial Results**
Write report documenting financial analysis and sensitivities. Review results of work with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in preliminary feasibility study report.

11601 **Prepare Intermediate Study Plan and Budget**
Update intermediate feasibility study plan and schedule using formalized scheduling techniques. Update budget for intermediate study, including any additional exploration or sampling needed. Schedule and budget should conform to the activities outlined in Activity 10304 and used in financial analysis (11401).

11602 **Prepare Preliminary Report**
Prepare formal report detailing preliminary study work performed. Prepare report in style and format that is suitable for presentation to management, suitable for use by other project teams, and containing history and results of work performed.

11603 **Present Preliminary Report Plan and Budget to Management**
Present all data generated during preliminary study, plus plan and budget for intermediate study, to management for review. Present information in meeting(s) with hard copies of reports, schedules, and data. Distribute report at least 1 week prior to meeting to allow personnel time to read and review.

APPENDIX 4.7B
PHASE II: INTERMEDIATE FEASIBILITY STUDY COMPLETE ACTIVITY DEFINITIONS

Activity No. (from WBS) **Activity Title and Description**

20100 **Public Affairs**
- As soon as company management approves the intermediate feasibility study plan and budget, notify state government officials that the project will proceed to the next level of examination.
- Brief the media on the decision to proceed to the next level, making sure the media understand that the next level of decision making is many months away and that the final decision of whether or not to build a mine is probably years away.

- Set up in-house means to directly respond to questions from the public by disseminating information as it becomes available and presenting speeches at professional, civic, and labor organization meetings. This may also be done by mineral industry audiovisual presentations tied in with the local settings and issues.
- Conduct meetings to help determine the needs of the area, which will promote sustainable development and lead to a social license to operate.

20101 **Get Management Approval of Intermediate Study Plan and Budget**
Get approval from appropriate levels of management to proceed with intermediate feasibility study outlined in plan, schedule, and budget submitted to management for review at end of preliminary study.

20201 **Review Land and Water Status**
Review land and water ownership, control, royalty, and lease situation developed during exploration phase and updated during preliminary study (if any work done). Project team should review land status and water with personnel in company land office and other appropriate individuals with respect to site locations identified during preliminary study. All related water rights should be determined.

20202 **Develop Topographic Map Work Specifications**
Develop scope of work and schedule necessary for topographic mapping. Prepare request for proposal (RFP) to send to contractors capable of performing the work. RFP should include draft of proposed contract.

20205 **Prepare Topographic Maps**
Notify contractor to proceed with work required by contract. Obtain prepared maps and other data from contractor.

20206 **Negotiate Land and Water Acquisition Requirements**
The company land office should start negotiating options on land and water requirements identified in the preliminary study. Requirements should include alternatives, because generally the final mine, plant, tailings sites, and so forth are not yet identified at this stage of project evaluation. This probably means optioning some land not needed for final selected sites.

20207 **Update Land and Water Acquisition Requirements**
Land and water requirements should be updated as intermediate study progresses and project team learns more about requirements. This may allow land personnel to drop negotiations on certain pieces not needed for project. This updating will not normally select final land sites required for project development, construction, and operation.

20208 **Determine Land and Water Acquisition Costs**
Land personnel should determine approximate costs of buying and/or leasing land and acquiring water necessary to construct, develop, and operate project. Costs will become part of intermediate study financial analysis, so accuracy should be within ±15% to 20%. Put costs in format suitable for financial analysis.

20209 **Document and Review Land and Water Situation**
Write progress report documenting results and costs of land and water negotiations to date. Review results of negotiations with appropriate levels of management and other personnel. Prepare risk analysis and mitigations for land and water satisfactory procurement. Write report in style and format suitable as chapter in intermediate study feasibility report.

20301 **Develop Predevelopment Drilling Work Specifications**
Evaluate exploration report and data. Develop scope of work and schedule necessary to perform predevelopment drilling activities. This activity assumes no exploration drilling was performed during or after the preliminary study and additional drilling is required to bring the reserve accuracy to range to within ±15% to 20%.

20302 **Prepare Predevelopment Drilling Permit Applications**
Gather data required to prepare applications for permits to do predevelopment drilling field work. Prepare applications.

20303 **Procure Predevelopment Drilling Permits**
Submit completed applications for permit to appropriate governmental agencies. Wait for agencies to approve applications. Obtain approved permits.

20306 **Perform Predevelopment Exploration Drilling and Other Field/Lab Work**
Notify contractor(s) to proceed with work required by contract(s). Do other geologic field work as required. What is needed is sufficient drilling and field work to get reserve estimates within ±15%–20% accuracy range. Assay drill-hole samples and/or log drill holes and obtain rock quality designations (RQDs).

20307 **Prepare Test Drill Sample Flow Chart and Chain of Custody**
Prepare flow chart (listing) of drill cores required for various tests (e.g., metallurgy, rock mechanics, porosity, permeability, density, and moisture). Chart should identify size and amount of cores required, location of procured cores (area of deposit), purpose of cores, place cores sent for testing, types of tests, method of assay, number of duplicate tests, number of blind tests, number of tests on standards, and core storage instructions. Establish a mandatory chain-of-custody protocol with proper check points and sign-offs.

20308 **Develop Mineral Inventory Work Specifications**
Develop scope of work and schedule necessary to determine deposit mineral inventory. Determine data requirements for computerized and/or hand-calculated mineral inventory system. In addition to mineral and geologic data, RQD must be developed. Inform data gatherers of required data format.

20309 **Procure Other Drill Samples**
Other core samples are necessary for porosity, permeability, Cerchar abrasivity, density, and moisture

determinations. *Other* means samples needed for tests other than metallurgy and rock mechanics.

20310 **Analyze Other Drill Samples**
Send other core samples to appropriate lab or testing facility(ies). Analyze and test core samples for porosity, permeability, density, and moisture. Send test data to project team and other interested parties.

20311 **Assemble and Edit Drill-Hole Data**
Assemble drill-hole data pertaining to deposit. Edit data for correctness and completeness.

20312 **Build Drill-Hole Computer File**
Prepare mineral inventory data for entry in computer system. Build drill-hole files in computer. Types of data to include: identification; geologic parameters; RQD values for each interval of the mining horizon and 20 ft above and below; collar coordinates and elevation; assay values and intervals; hole depth, dip, and direction; and date hole completed.

20313 **Prepare Geologic Maps**
Prepare necessary drill-hole maps and cross sections, with computer and/or by hand, to help evaluate the mineral deposit.

20314 **Delineate Mineral Zones**
Identify and delineate mineralized zones. Delineate by computer from drill-hole files and/or by hand.

20315 **Compute Potential Mineral Reserves**
Build computer block model and compute mineral reserves with various cutoff grades, mining heights, waste thicknesses, and so forth. Calculate reserves by hand if computer block model is not developed. Prepare a risk analysis and mitigation plan for the mineral reserve tabulated.

20316 **Document and Review Mineral Inventory Results**
Write report documenting results of Phase I predevelopment program. Report should contain data on geology, field work, and reserves. Review results with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report.

20401 **Develop Environmental Work Specifications**
Develop scope of work and schedule necessary for environmental baseline studies, environmental impact analyses, and environmental control plans required for project analysis and costs. Work will serve as database for project permit applications.

20404 **Perform Air Quality Baseline Study**
Conduct literature search to determine amount and value of air quality and meteorological data available in project area(s). Establish project site monitoring stations to gather air quality, including radiological (if required) and meteorological baseline data. Gather data over required period of time.

20405 **Perform Water Quality Baseline Study**
Conduct literature search to determine amount and value of surface and groundwater quality data in project area(s). Gather and analyze samples of surface water in the area(s) over required period of time, generally on performing hydrology studies (Activity 20508).

20406 **Perform Ecological Baseline Study**
Conduct literature search to determine amount and value of ecological data available in project area(s). Gather and/or study samples of life forms (flora and fauna) in area(s) over required period of time.

20407 **Perform Socioeconomic Baseline Study**
Perform literature search to determine amount and quality of labor and housing available in general area. Conduct general area survey to verify and/or update statistics on amount and quality of labor and housing and other socioeconomic data. Study the sustained development options for the affected area. Consider the need for a social license to operate in the area affected.

20408 **Conduct Archeological Investigation**
Conduct project area search for cultural resources or items of historical significance. Concentrate search in areas of potential land disturbance caused by mine, plant, tailings, and surface facilities construction and development.

20409 **Assess Environmental Impacts**
Assess impact to baseline environment caused by construction, development, and operation of mine, plant, tailings disposal, and surface facilities.

20410 **Develop Air Quality Plan and Costs**
Develop plan, with one or more alternatives, to maintain air quality in and around project area. Evaluate effects caused by construction, development, and operation of mine, plant, tailings disposal, and surface facilities. Estimate capital and operating costs to implement the plans and put costs in format suitable for financial analysis. Cost accuracy should equal ±15%.

20411 **Develop Water Quality Plan and Costs**
Develop plan, with one or more alternatives, to maintain surface water quality in and around project area. Evaluate effects caused by construction, development, and operation of mine, plant, tailings disposal, and surface facilities. Estimate capital and operating costs to implement the plans and put costs in format suitable for financial analysis. Cost accuracy should equal ±15%.

20412 **Develop Ecological Plan and Costs**
Develop plan, with one or more alternatives, to maintain quality of ecology in and around project area. Evaluate effects caused by construction, development, and operation of mine, plant, tailings disposal, and surface facilities. Estimate capital and operating costs to implement the plans and put costs in format suitable for financial analysis. Cost accuracy should equal ±15%.

20413 **Develop Reclamation Plan and Costs**
Develop plan, with one or more alternatives, to reclaim land disturbed by effects of construction, development, and operation of mine, plant, tailings disposal, and surface facilities. Estimate capital and operating costs to implement the plan and put costs in format suitable for financial analysis. Cost accuracy should equal ±15%.

20414 **Develop Socioeconomic Plan and Costs**
Develop plan, with one or more alternatives, to estimate requirements for community development. Plan

may include requirements for employee housing; medical and dental facilities; schools; community utilities (power, water, sewer, etc.); community services; skills and occupational training other than for the operation; recreational activities; and potential sustained development infrastructure. Estimate capital and operating costs to implement the plans and put costs in format suitable for financial analysis. Cost accuracy should equal ±15%.

20415 **Document and Review Environmental/ Socioeconomic Study Results**
Write report documenting environmental and socioeconomic work performed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report. Contractors should submit report in draft form for project team review before finalizing. Prepare risk analysis and mitigation plan for environmental and socioeconomic concerns.

20501 **Develop Siting and Geotechnical Work Specifications**
Develop scope of work and schedule necessary for siting, rock mechanics, soils mechanics and foundation, and hydrology studies.

20504 **Prepare Hydrology Permit Applications**
Prepare necessary permit application(s) to perform hydrology studies of groundwater and surface water quantities and qualities. Permits are needed primarily to drill test wells.

20505 **Conduct Siting Studies**
Conduct studies to determine suitable locations of all surface facilities for the mine, plant, roads, tailings disposal, and surface facilities. Identify several sites.

20506 **Procure Hydrology Permits**
Submit permit application(s) to appropriate governmental agency(ies). Wait for permit approval. Get approved permit(s).

20507 **Prepare Soils Mechanics Permit Applications**
Prepare necessary permit application(s) to conduct soils and foundation investigations. Permit(s) are likely needed for test pits and test borings.

20508 **Conduct Hydrology Studies**
Conduct studies to collect groundwater quantity and quality data. This usually requires drilling and pump-testing wells to determine amount and quality of water expected during mining and amount and quality of water required for makeup. Conduct studies to determine surface water flow patterns and amounts to expect during possible maximum flood and 100-year-flood periods. Send study data to project team in report form. Contractor should submit report in draft form for review by project team before finalizing.

20509 **Procure Rock Mechanics Samples**
Procure drill-core samples to use for rock mechanics tests. Drilling is usually performed as part of predevelopment drilling program.

20510 **Procure Soils Mechanics Permits**
Submit permit application(s) to appropriate governmental agency(ies). Wait for permit approval. Get approved permit(s).

20511 **Procure Soils Mechanics Samples**
Procure soils samples to use for soils mechanics tests and foundation analyses. Procure samples in areas preferred for plant and surface facilities construction and tailings disposal. Samples usually consist of test borings and test pits.

20512 **Conduct Rock Mechanics Tests**
Ship rock mechanics samples to testing laboratory. Conduct appropriate tests to determine strength of rock. Analyze test results to determine size of openings and pillars in underground mine or pit slope angles (stability) in open-pit mine. Send test results in report form to project team. If rock appears to be applicable to mechanical excavation methods, send rock samples for Cerchar abrasivity tests. Develop rock mass rating designation and/or Barton's Q designation. Contractor should submit report in draft form for review by project team before finalizing.

20513 **Conduct Soils Mechanics Tests**
Ship soils mechanics samples to testing laboratory. Conduct appropriate tests to determine physical and chemical properties affecting building foundations and tailings disposal areas. For open-pit mines, tests are needed to determine slope stability. Conduct appropriate field tests to determine above-soils properties and water flow characteristics. Analyze test results. Field tests could include location of suitable construction materials. Send test results in report form to project team. Contractor should submit report in draft form for review by project team before finalizing.

20514 **Establish Siting Preferences**
Rank sites selected in Activity 20505 in order of preference. Consider factors such as relationship to existing facilities, capital and operating costs, environment, land position, topography, accessibility, capacity, surface water flow patterns, soils mechanics data, and relationship to mineral deposit. Perform ranking using matrix evaluation procedures.

20515 **Document and Review Siting and Geotechnical Results**
Write report documenting siting and geotechnical work performed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report. Contractor should submit report in draft form for review by project team before finalizing. Prepare a risk analysis and mitigation plan for the siting, geotechnical, and hydrological information used in the design.

20601 **Develop Agency Reconnaissance, Government, NGO, and Public Relations Work Specification**
Develop scope of work and schedule necessary for agency reconnaissance, government relations, nongovernmental organizations (NGOs), and public relations studies and/or work.

20604 **Conduct Agency and NGO Reconnaissance Literature Search**
Search literature to get overview of permits required by various government agencies, which may affect design, construction, development, or operation of project. Study area projects and identify active NGO groups in the area.

20605 **Identify Involved Government Agencies**
Conduct telephone conversation and personal visits to update data on government agencies having jurisdiction over design, construction, development, and operation of project. Determine all legal and political jurisdictions and all laws, regulations, and legislative codes at the federal, state, and local levels that are applicable to the process of mine/mill planning and operation. The following must also be identified:

- List all political jurisdictions in which the mining operation will exist.
- Obtain copies of all federal and state laws and codes relating to the state and country in which you want to construct a mining operation.
- Obtain a list of all mining permits required and a description of the regulatory processes involved in obtaining the permits.
- For properties within the United States, request determination from the district engineer of the U.S. Army Corps of Engineers (and other federal agencies if federal lands are involved) on its possible involvement and the necessity for a federal environmental impact statement (EIS) under the National Environmental Policy Act.
- If federal EIS is required, determine if state environmental impact report may be used as database or whether operative federal agency will require more, less, or other data than that collected for the state agency.
- Participate in any hearings on any federal statement or actions that occur independent of the state.
- Determine with the state environmental agency which state laws will be applied to the mine development under its jurisdiction. Obtain in writing the rationale for elimination of any potentially applicable laws.
- Inventory other state laws, permits, and permissions applicable to a mine in that state.
- Obtain copies of county zoning codes, sewerage codes, and information on which districts, special assessment districts, or other subjurisdictions of the county may be influenced by the mine.
- Determine each code and jurisdiction that may be encountered and the responsible local administrators. Obtain requirements to be fulfilled under each code.
- Obtain copies of all codes and rules applicable in the township or incorporated area, especially zoning and those related to utilities, waste disposal, and highways.

20606 **Determine Agency Regulations**
Conduct telephone conversations and personal visits to update data on government agency regulations affecting design, construction, development, and operation of project.

20607 **Determine Agency Permit Requirements**
Conduct telephone conversations and personal visits to update data on government agency permit requirements affecting design, construction, development, and operation of project.

20608 **Develop and Implement Government, NGO, and Public Relations Programs**
Develop program(s) to keep government, NGOs, and public informed of nature and status of project. Implement one or more of the programs.

20609 **Document and Review Agency, NGO Reconnaissance Results**
Write report documenting agency and NGO's reconnaissance work performed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report. Contractor should submit report in draft form for review by project team before finalizing.

20610 **Document and Review Government, NGO, and Public Relations Programs**
Write report documenting government and public relations programs developed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility report. Develop a risk analysis and mitigation plan for the government, NGO, and public relations programs.

20701 **Develop Mine Work Specifications**
Develop scope of work and schedule necessary for conducting mining evaluation studies.

20704 **Update Mining Literature Search**
Review company, contractor, and general available literature published about mining deposits of similar nature. Search should identify and benchmark mine data related to the mining method, unusual characteristics, types of equipment, potential problems, and so forth. Search may include visits to operating properties of similar nature.

20705 **Identify Possible Mining Methods**
Identify mining methods suitable for developing and producing deposits of this nature. Use combination of literature search and experience of company personnel and contractor personnel. List and define the potential methods. Consider range of production from the various methods.

20706 **Develop Tentative Layout for Each Mining Method**
Prepare tentative mine development and production layouts for each possible mining method identified. Prepare layouts with sufficient detail and accuracy to allow comparisons of capital and operating costs.

20707 **Evaluate Alternative Mining Methods**
Evaluate operational characteristics of each possible mining method. Perform comparative capital and operating cost analyses, using present worth techniques. Identify other factors influencing selection of preferred mining method(s) such as environment, safety, hydrology, recoveries, rock mechanics,

potential for mechanical excavation, dilution, and production limitations.

Rank alternatives in order of preference using matrix system and considering all listed factors and others, if applicable. Select two or three best methods for more detailed evaluations.

20708 **Refine Mine Layouts and Develop Mine Plans**
Prepare mine layouts for chosen alternatives in sufficient detail to allow development of mine plans. Five-year mine plan and life-of-mine plan will be based only on proven and probable reserves for all properties within the United States and Canada or where the ownership stock is listed in those two countries. Mine plans should have an accuracy of ±15% to 20%. Mine plans should include layouts and schedules for head frame, shaft, stations, preproduction development, underground service area development, production, various sizes of underground storage, and the cost benefit of each size and continuing production development.

20709 **Perform Mine Functional Analyses**
Calculate operational and development cycles, labor requirements, equipment requirements, and supply requirements for each mining function and for each alternative selected in 20707 based on mine industry experience in these mining methods. The functions include drilling, blasting, loading, hauling, scaling, bolting, ground control, mine backfill (if needed) hoisting, primary crushing (if underground), maintenance, supply/debris handling, pumping, and other supports services. For each function, develop personnel productivity learning curves and prepare cost and operational schedules for each.

20710 **Develop Mine Capital and Operating Cost Estimates**
Develop cost estimates for total mining operation and alternatives. Costs should have accuracy of ±15% to 20%. Because costs will become part of intermediate financial analysis, put in format suitable for financial analysis.

20711 **Document and Review Mine Results**
Write report documenting mine study work performed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report. Contractor should submit report in draft form for review by project team before finalizing. Prepare a risk analysis and mitigation plan on the proposed mining operation. At this point, try to locate and evaluate mining contractors and perform a cost comparison analysis.

20801 **Develop Mill Work Specifications**
Develop scope of work and schedule necessary for process, milling, waste rock storage, and tailings disposal studies.

20804 **Conduct Milling Literature Search**
Review company, contractor(s), and general available literature published concerning processing material of similar nature. Search should identify and benchmark some possible processing methods, types of equipment, potential problems, and so forth. Search may include visits to operating properties using processes of similar nature.

20805 **Procure Metallurgical Samples**
Procure drill-core samples to use for metallurgical testing. Drilling may be performed as part of predevelopment drilling program. Make sure that the samples represent the ore body. Large core samples for autogenous grinding test may be needed.

20806 **Conduct Metallurgical Tests**
Ship metallurgical samples to testing laboratory. Conduct appropriate tests to determine comminuting characteristics (work index); separation and concentration characteristics of all types of ores; reagent consumption; heads, tails, and concentrate analyses; process flow sheet; environmentally harmful gaseous, liquid, and solid products produced; complete waste characterization of all waste products; long-term leachability of metal ions from tailings; and areas of uncertainty. Send test results to project team in report form. Contractor should submit report in draft form for review by project team before finalizing.

20807 **Determine Mill Process Requirements**
Evaluate metallurgical testing results. Use test results, literature search, company experience, and contractor experience to select two or three best process variation methods. Determine processing requirements for each alternative.

20808 **Prepare Milling Flow Sheet**
Prepare flow sheet for each process alternative. Flow sheet should contain sufficient detail to allow selection and sizing of equipment and show material balance.

20809 **Perform Mill Functional Analyses**
Calculate the operational cycles and labor, equipment, and supply requirements for each milling function and for each process alternative selected in 20807 based on the various sizes of production from the mine and industry experience. The functions include stockpiling/reclaiming (size of storage), crushing, grinding, screening, concentrating including heap leaching (if applicable), classifying, clarifying, tailings disposal, concentrate handling, maintenance, supply/debris handling, and other support services. Prepare cost and operational schedules for each.

20810 **Investigate Custom Milling Alternatives**
Investigate opportunities for selling run-of-mine (ROM) material. Determine sale price and charges associated with selling ROM. Investigate opportunities for tolling mine-produced material. Determine custom mill capacity, timing, and costs. Costs should include capital and operating estimates for all associated tolling activities such as mill expansion costs to company (if any), transportation of product to custom mill, losses/deducts for processing, tolling charge, sampling methods, transportation of concentrate, and personnel requirements.

20811 **Determine General Mill Plant Arrangement**
Determine arrangement of mill facilities, including tailings, for each alternative. Prepare design basis and general arrangement drawings.

20812 **Develop Mill Capital and Operating Cost Estimate**
Develop cost estimates for total milling operation alternatives. Costs should have accuracy of ±15%. Because costs will become part of intermediate financial analysis, put costs in format suitable for financial analysis.

20813 **Document and Review Milling Results**
Write report documenting milling and metallurgical work performed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report. Contractor should submit report in draft form for project team review before finalizing. Prepare risk analysis and mitigation plan for the metallurgical processing.

20901 **Develop Refinery Work Specifications**
Develop scope of work and schedule necessary for custom smelting/refining studies.

20904 **Investigate Custom Smelting/Refining Alternatives**
Investigate opportunities for custom smelting and/or refining project concentrate. Determine custom refining capacity, timing, and costs. Costs should include capital and operating estimates for everything associated with custom refining such as transportation of concentrate to refinery, refining charge (consider deducts, penalties, and/or credits), transportation of refined product, and personnel requirements.

20905 **Document and Review Custom Smelting/Refining Results**
Write report documenting smelting/refinery work performed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report. Contractor should submit report in draft form for project team review before finalizing. Prepare a risk analysis and mitigation plan of the smelting/refining process.

21001 **Develop Surface Facilities Work Specifications**
Develop scope of work and schedule necessary for study of project surface facilities not connected with mine and mill studies.

21004 **Determine Surface Building Requirements**
Determine surface buildings required for project operation. Include buildings serving support function for mine and mill but not buildings directly related to mining and milling activities. Types of buildings include ambulance garage, fire-fighting facility, administration/office, dry/changehouse, guardhouse, and surface shops. Determine operating and maintenance personnel and equipment requirements (including shop, office, and dry equipment). Prepare design basis and general arrangement drawings. Develop capital and operating cost estimates with ±15% accuracy to include in intermediate financial analysis. Put costs in form suitable for financial analysis.

21005 **Determine Surface Utilities Requirements**
Determine utilities required for project construction, development, and operation. Study does not include power distribution inside mine and mill battery limits distribution within facilities included in mining and milling studies. Utilities include electric power; fuel for buildings and fuel storage for operating equipment; communications (radio, telephone, and computer networks required); potable water; fire protection; sewage system; and garbage, trash, and solid waste removal and disposal. Determine operating and maintenance personnel and equipment requirements. Develop applicable piping and instrumentation diagram/drawing (P&ID) and line drawings. Develop capital and operating cost estimates with ±15% accuracy to include in intermediate financial analysis. Put costs in form suitable for financial analysis.

21006 **Determine Surface Transportation Requirements**
Determine transportation needs for moving equipment, supplies, material, and mine/mill product into and out of project area during project construction, development, and operation. Study should evaluate alternative transportation methods such as truck haulage; rail haulage (both off-site and in-plant); ship/barge haulage and port facilities (if needed); air haulage (if feasible); and combinations of these methods.

Study should determine access road requirements and costs, capital and operating costs, personnel and equipment requirements, and other costs associated with each feasible transportation system. Develop capital and operating costs with ±15% accuracy to include in intermediate financial analysis and put costs in form suitable for financial analysis.

21007 **Determine Surface Mobile and Miscellaneous Equipment Requirements**
Determine the surface mobile and miscellaneous equipment requirements not covered under other activities. This includes equipment for emergency medical and safety; road and yard area maintenance; supervisor pickups and car(s); maintenance personnel pickups and trucks; loader(s)/backhoe(s); forklift(s); crane(s)/cherry picker(s); portable welder(s)/compressor(s)/generator(s); small rear-dump truck(s); and crawler tractor(s) with dozer. Determine operating and maintenance personnel and equipment requirements. Develop capital and operating cost estimates with ±15% accuracy to include in intermediate financial analysis. Put costs in form suitable for financial analysis.

21008 **Develop Water Management Plan and Costs**
Determine requirements for total project water management system. This will require evaluating one or more alternatives for mine, mill, tailings disposal, potable, fire protection and other water usage requirements; mine dewatering and pumping requirements; project water balance (identify all water sources and losses); makeup water requirements and source (if water short); water treatment, disposal, or evaporation system (if excess water); potable water system (include source, treatment, storage, and distribution); fire protection system (include source, treatment, storage, and distribution); and dust control water requirements. Determine operating and maintenance personnel and equipment requirements, including buildings or structures to house facilities. Develop P&ID. Develop capital and operating cost estimates with ±15% accuracy to include in intermediate

financial analysis. Put costs in form suitable for financial analysis.

21009 **Determine General Surface Facilities Arrangement**
Determine requirements for surface facility, plant, and disposal area(s) internal road (does not include haulage roads for open-pit mine); parking areas; construction lay-down area(s); and storage area(s) (including mine waste).

Prepare plot plans showing alternatives for arrangement of all surface facilities including listed items, water facilities, mine, mill, and tailings facilities. Rank alternatives in preference order using matrix system to evaluate factors such as facility spacing and location, environment, accessibility, utilization, capital cost of each alternative, and operating costs (if different and applicable).

Choose best alternative. Prepare design basis and general arrangement drawings. Show the capital costs of areas selected from the preceding matrix analysis. Determine operating and maintenance equipment and personnel requirements for areas identified in 21007, and maintenance material and supply requirements for areas listed in 21009.

21010 **Determine Warehouse Requirements**
Determine size of warehouse and storage yard facilities; amount of warehouse inventory; equipment (mobile and stationary) necessary to store warehoused items, load and unload supplies, and move supplies within confines of project area; and operating personnel requirements. Develop capital and operating costs with ±15% accuracy to include in intermediate financial analysis. Put costs in form suitable for financial analysis.

21011 **Develop Surface Facilities' Capital and Operating Cost Estimates**
Operating cost estimates should have accuracy of ±15%. Because costs will become part of intermediate financial analysis, put in format suitable for financial analysis.

21012 **Document and Review Surface Facilities Results**
Write report documenting surface facilities studies. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report. Contractor should submit report in draft form for review by project team before finalizing. Prepare risk analysis and mitigation plan for any and all surface facilities or utilities.

21101 **Determine General Personnel Requirements**
Determine administrative and management personnel requirements; and operating, maintenance, support, and supervisory personnel requirements developed in all the preceding project activities. Split requirements into salaried exempt, salaried nonexempt, and hourly classifications. Develop labor buildup schedules for each classification using results of learning curve analysis for each classification.

21102 **Prepare Organization Charts**
Prepare charts showing how each project alternative should be organized. Charts should show lines of authority and responsibility.

21103 **Determine Administrative Costs**
Determine salaries and wages of personnel identified in 21101; payroll burden associated with salaries and wages; and cost, type, and quantity of office equipment and supplies required for all offices including administration, mine, mill, maintenance, and others. Prepare costs in form suitable for financial analysis. Costs should have accuracy of ±15%.

21104 **Document and Review Organization and Administration Results**
Write report documenting administrative costs and personnel requirements. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report.

21201 **Develop Labor Plan**
Develop plan, with alternatives, for attracting and keeping productive, qualified personnel. Items to investigate include recruiting, training, absentee and turnover projections, commuting/fly in–fly out work force, community development, salaries/wages, fringe benefits/payroll burden, incentive system, and union/nonunion considerations.

21202 **Prepare Labor-Related Cost Estimates**
Identify personnel and equipment requirements for plans developed. Prepare capital and operating cost estimates associated with plans developed. Costs should have accuracy of ±15%. Put costs in format suitable for financial analysis.

21203 **Document and Review Labor-Related Results**
Write report documenting labor-related studies. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report. Prepare a risk analysis and mitigation plan for all administrative and labor-related issues.

21301 **Conduct Intermediate Market Studies**
Update market studies to determine product requirements, supply and demand forecast, selling price and marketing strategy of salable products, and position relative to competitors. Review metallurgical results of most recent testing against product sales specifications. Estimate price ranges for life of project. Prepare prices in format suitable for financial analysis.

21302 **Document and Review Market Study Results**
Write report documenting marketing studies listed in 21301. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report. Prepare a risk analysis and mitigation plan for all aspects of marketing the product.

21401 **Develop Intermediate Financial Analysis Criteria**
Develop criteria for performing intermediate financial analysis. Criteria include overall project schedule (includes final evaluation, design, construction, development, and start-up), capital and operating costs, royalties; escalation factors (though the analysis will probably be done in constant dollars), tax rates, working capital, property acquisition costs, mine and mill

recovery, revenues, depreciation methods and depletion allowance, allowance for unforeseen factors, capitalization factors, salvage values, corporate overhead allocation, sensitivity and risk analysis (see 21403), and project alternative comparisons.

21402 **Conduct Financial Analysis**
Conduct analysis for total project using a suitable computer program. Print results of economic analysis.

21403 **Conduct Financial Sensitivity Studies**
Evaluate sensitivity/risk of various key factors. Also, quantify the degree of risk and perform Monte Carlo risk analysis on the collective factors: operating costs, capital costs, reserves, grade, mill recovery, royalties, taxes, and other items with high degree of uncertainty. Print results of sensitivity/risk analysis.

21404 **Document and Review Financial Results**
Write report documenting financial analysis and sensitivities. Review results of work with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report. Prepare a risk analysis and mitigation plan for the techniques used in the financial analysis.

21501 **Develop Tax Study Specifications**
Develop scope of work and schedule necessary for conducting study of taxes applicable to project.

21502 **Conduct Intermediate Tax Studies**
Update tax studies to determine taxes applicable to project. Analyze taxes to understand how they affect construction, development, and operation of project. Prepare tax rates in format suitable for financial analysis.

21503 **Document and Review Tax Studies**
Write report documenting tax studies. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in intermediate feasibility study report. Prepare a risk analysis and mitigation plan related to the taxing of future property and production.

21601 **Prepare Final Study Plan and Budget**
Update final feasibility study plan and schedule using formalized scheduling techniques. Update budget for final feasibility study. Schedule and budget should conform to those used in financial analysis (Activity 21401).

21602 **Prepare Intermediate Report**
Prepare formal report detailing intermediate study work performed. Prepare report in style and format that
- Is suitable for presentation to management,
- Is suitable for use by other project teams,
- Contains history and results of work performed, and
- Has a composite table of all the risk factors analyzed in the report.

21603 **Present Intermediate Report, Plan, and Budget to Management**
Present all data generated during intermediate study, plus plan and budget for final study, to management for review. Present information in meeting(s) with hard copies of reports, schedules, and data. Distribute report at least 1 week prior to meeting to allow personnel time to read and review.

APPENDIX 4.7C ADDITIONAL TESTING ACTIVITIES (SUCH AS A TEST MINE OF BULK SAMPLE)

Activity No. (from WBS) Activity Title and Description

30301 **Perform Final Exploration Drilling and Other Field Work**
Continue work outlined under predevelopment drilling contracts (Activity 20306). Do other geologic field work as required. Final exploration means sufficient drilling and field work to get reserve estimates within ±10% accuracy range. Assay drill-hole samples and/or log drill holes.

30302 **Assemble and Edit Drill-Hole Data**
Assemble drill-hole data pertaining to deposit. Edit data for correctness and completeness. Types of data included: identification; geologic parameters; collar coordinates; assay values and intervals; hole depth, dip, and direction; and date hole completed.

30303 **Update Drill-Hole Computer File**
Prepare mineral inventory data for entry in computer system. Add to existing data to update drill-hole files in computer.

30310 **Prepare Geologic Maps**
Prepare necessary drill-hole maps and cross sections to help evaluate the mineral deposit. Prepare maps with computer and/or by hand.

30311 **Delineate Mineral Zones**
Identify and delineate mineralized zones by computer from drill-hole files and/or by hand.

30312 **Compute Potential Mineral Reserves**
Build computer block model and compute mineral reserves with various cutoff grades, mining heights, waste thicknesses, and so forth. Calculate reserves by hand if block model not developed.

30313 **Document and Review Mineral Inventory Results**
Write report documenting results of predevelopment program. Report should contain data on geology, field work, and reserves. Review results with appropriate levels of management and other personnel. Write study in style and format suitable as chapter in final feasibility study report.

30710 **Develop Test Mine Work Specifications**
Develop scope of work and schedule necessary for designing, constructing, developing, and operating test mine (assuming that test mine is needed). Prepare request for proposal (RFP) to send to contractors capable of performing the work. RFP should contain draft of proposed contract.

30711 **Determine Test Mine Permit Requirements**
Identify permits required to design, construct, develop, and operate test mine. Refer to work performed under Activity 20607. Recheck with government agencies for new or different requirements.

30712 **Plan Bulk Sampling Program**
Calculate amount of bulk sample required for pilot-plant testing. Evaluate geologic and reserve data to choose test mine bulk sampling areas representative of deposit. Interface bulk sampling plan with test mining plan, Activity 30713. Modify bulk sampling plan and areas based on realistic mining plan, time schedule, and budget. Select pilot plant to run bulk sample(s). Plan metallurgical tests required. Determine requirements for sample(s) handling and transportation and sampled material disposal.

30713 **Plan Test Mine Program**
Develop a mine plan to select layout and development necessary for the following: metallurgical bulk sampling program (underground [UG] and open pit [OP]); predevelopment drilling program (UG); test mining program; rock mechanics tests (UG and OP); pillar, drift, and stope size evaluations (UG); drilling and blasting or mechanical excavation tests (UG and OP); ground support tests (UG); slope-stability tests (OP); and materials handling tests (UG and OP). Design required test mine surface facilities, access system and development (surface mine stripping or underground mine station[s], and level[s]) needs. Develop schedule and budget for test mine activities. Prepare construction contractor bid package.

30714 **Prepare Test Mine Permit Applications**
Prepare permit application(s) necessary to perform test mining program.

30715 **Procure Test Mine Permits**
Submit permit application(s) to appropriate government agency(ies). Wait for permit approval(s). Obtain approved permit(s).

30716 **Management Approval of Test Mine**
Get approval from appropriate levels of management to proceed with test mining as outlined in budget and schedule developed under Activity 30713.

30717 **Locate, Evaluate, and Select Test Mine Contractor**
Identify contractors capable of performing the work. Send each contractor copy of bid package developed in 30713. Evaluate bids received, contractor's financial status (Dun & Bradstreet report if required) and other pertinent data. Select preferred contractor, preferably using matrix evaluation if low bid is not only selection criterion. Inform contractor(s) of its selection. Give notice to proceed. Revise, if necessary, scope of work and contract to reflect information contained in bids.

30718 **Prepare Test Mine Contract**
Write contract, with assistance from law office and controllers. Get necessary company approvals. Send contract to contractor for signature. Get approved contract from contractor and review for signature correctness. Some delay can occur if contractor wants to negotiate terms before approving.

30719 **Mobilize Test Mine Contractor**
Require time for contractor to arrive on-site and set up once notified to proceed.

30720 **Construct Test Mine Surface Facilities**
Build or erect surface facilities necessary for construction, development, and operation of test mine, including hoisting facilities, shaft collar, and headframe for an underground test mine.

30721 **Perform Test Mine Access and Level Development**
For underground test mine, sink shaft (or other method of access), excavate, and construct station(s) and perform necessary level development. For open-pit test mine, strip necessary overburden and waste material.

30722 **Perform Test Mining**
Conduct mining tests as outlined under Activity 30713.

30723 **Procure Test Mine Bulk Samples**
Procure test mine bulk sample(s) as planned under Activity 30712 in intermediate study. (In many cases, this activity and 30724 occur between the intermediate and final feasibility study.)

30724 **Perform Test Mine Predevelopment Work**
Perform test mine drilling and other geologic work as outlined under Activity 30713.

30725 **Update Potential Mineral Reserves**
Update mineral reserve calculations using drilling, assay, and geologic data gathered during test mining (Activity 30724).

30726 **Update Engineering Data**
Update all previously acquired engineering data with the data gathered during test mine operation.

APPENDIX 4.7D
PHASE III: FINAL FEASIBILITY STUDY COMPLETE ACTIVITY DEFINITIONS

Activity No. (from WBS) **Activity Title and Description**

30100 **Public Affairs**
As soon as the company management approves the final feasibility study plan and budget, notify state government officials that the project will proceed to the next level of examination. Brief the media on the decision to proceed to the final feasibility study, making sure to emphasize that the final decision of whether or not to build a mine is probably many months or even years away. Continue the dissemination of information as it becomes available and continue presenting speeches at local and state meetings. Set up local town meeting where stakeholders can question first-hand what will take place if a mine is built. Address their remaining concerns and the company's plans to mitigate their concerns.

30101 **Management Approval of Final Study Plan and Budget**
Get approval from appropriate levels of management to proceed with final feasibility study outlined in plan, schedule, and budget submitted to management for review at end of intermediate study (Activity 21603).

30201 **Review Land Status**
Review land ownership, control, royalty, and lease situation updated during intermediate study. Project

team should review land status with personnel in company's land office, and other appropriate individuals with respect to site locations identified during intermediate study.

30202 **Finalize Land Acquisitions and Costs**
Land personnel should determine final costs of buying and/or leasing land necessary to construct, develop, and operate project. Commitments for land are probably required at this time. Costs will become part of final study financial analysis so accuracy should be within ±10%. Put costs in format suitable for financial analysis.

30203 **Document and Review Land Situation**
Write report documenting results and costs of land negotiations. Review results of negotiations with appropriate levels of management and other personnel. Complete all land maps. Write report in style and format suitable as chapter in final feasibility study report.

30304 **Develop Core Drilling Work Specifications**
Develop scope of work and schedule necessary for core drilling program to obtain samples for the following tests: metallurgical (may not need if test mine program planned), rock mechanics (may not need if test mine program planned), Cerchar abrasivity, density, porosity, permeability, and miscellaneous. This program may be accomplished with regular predevelopment drilling program or as separate program.

30307 **Prepare Test Core Sample Flow Chart**
Prepare flow chart (listing) of drill cores required for various tests (e.g., metallurgy, rock mechanics, porosity, permeability, density, moisture). Chart should identify size and amount of cores required, from where cores procured (area of deposit), purpose of cores, where cores are sent for testing, types of test, and core storage instructions.

30308 **Conduct Core Drilling Program**
Perform the field core drilling program as planned and scheduled under Activity 30307.

30309 **Analyze Other Core Samples**
Send other core samples to appropriate lab or testing facility(ies). Analyze and test core samples for porosity, permeability, density, and moisture. Send test data to project team and other interested parties.

30401 **Develop Environmental Work Specifications**
Develop scope of work and schedule necessary for environmental impact analyses and environmental control plans required for project analysis and costs. Work will serve as base data for final feasibility costs and probable update data for permit applications. Prepare request for proposal (RFP) to send to contractors capable of performing the work. RFP should include draft of proposed contract.

30404 **Assess Environmental Impacts**
Reassess impact to baseline environment caused by construction, development, and operation of mine, plant, tailings disposal, and surface facilities. This should include input from the final feasibility study of mine, mill, tailings, and surface facilities.

30405 **Finalize Air Quality Plan and Costs**
Finalize chosen plan to maintain air quality in and around project area. Update effects caused by construction, development, and operation of mine, plant, tailings disposal, and surface facilities. Complete design basis drawings. Estimate capital and operating costs to implement the plans. Put costs in format suitable for financial analysis. Cost accuracy should equal +10%.

30406 **Finalize Water Quality Plan and Costs**
Finalize chosen plan to maintain surface water quality in and around project area. Update effects caused by construction, development, and operation of mine, plant, tailings disposal, and surface facilities. Estimate capital and operating costs to implement the plans. Complete design drawings. Put costs in format suitable for financial analysis. Cost accuracy should equal +10%.

30407 **Finalize Ecological Plan and Costs**
Finalize chosen plan to mitigate ecological disturbances caused by effects of construction, development, and operation of mine, plant, tailings disposal, and surface facilities. Estimate capital and operating costs to implement the plans. Put costs in format suitable for financial analysis. Cost accuracy should equal +10%.

30408 **Finalize Reclamation Plan and Costs**
Finalize chosen plan to reclaim land disturbed by effects of construction, development, and operation of mine, plant, tailings disposal, and surface facilities. Estimate capital and operating costs to implement the plans. Complete design basis drawings. Put costs in format suitable for financial analysis. Cost accuracy should equal +10%.

30409 **Finalize Socioeconomic Plan and Costs**
Finalize chosen plan to estimate requirements for community development. Plan should include requirements for the following: employee housing, medical and dental facilities, schools, community utilities, community services, and recreational activities. Estimate capital and operating costs to implement the plans. Put costs in format suitable for financial analysis. Cost accuracy should equal +10%.

30410 **Document and Review Environmental Study Results**
Write report documenting environmental work performed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility study report. Contractors should submit report in draft form for project team review before finalizing.

30501 **Develop Siting and Geotechnical Work Specifications**
Develop scope of work and schedule necessary to finalize siting, rock mechanics, soils mechanics and foundation, and hydrology studies. Prepare RFP to send to contractors capable of performing the work. RFP should contain draft of proposed contract.

30504 **Prepare Hydrology Permit Applications**
Prepare necessary permit applications to perform hydrology studies of groundwater and surface water

quantities and qualities. Permits are needed primarily to drill test wells.

30505 **Procure Hydrology Permits**
Submit permit application(s) to appropriate governmental agency(ies). Wait for permit approval. Get approved permit(s).

30506 **Conduct Hydrology Studies**
Conduct studies to finalize groundwater quantity and quality data. This usually requires drilling and pump testing wells to determine amount and quality of water expected during mining and amount and quality of water required for makeup. Conduct studies to determine surface water flow patterns and amounts to expect during possible maximum flood and 100-year-flood periods. Send study data to project team in report form. Contractor should submit report in draft form for review by project team before finalizing.

30507 **Prepare Soils Mechanics Permit Applications**
Prepare necessary permit application(s) to finalize soils and foundations investigations. Permit(s) probably necessary to dig test pits and do test borings.

30508 **Procure Soils Mechanics Permits**
Submit permit application(s) to appropriate governmental agency(ies). Wait for permit approval. Get approved permit(s).

30509 **Procure Soils Mechanics Samples**
Procure soils samples to finalize soils mechanics tests and foundation analyses. Procure samples in areas preferred for plant and surface facilities construction and tailings disposal. Samples usually consist of test borings and test pits. Samples will serve as basis for buildings, dams, shafts, and other foundation design specifications.

30510 **Conduct Soils Mechanics Tests**
Ship soils mechanics samples to testing laboratory. Conduct appropriate tests to finalize physical and chemical properties affecting building foundations, tailings disposal areas, and shaft collars. For open-pit mines, tests are needed to determine slope stability. Conduct appropriate field tests to determine above-soils properties and water flow characteristics. Analyze test results. Field tests could include location of suitable construction materials. Send test results in report form to project team. Contractor should submit report in draft form for review by project team before finalizing.

30511 **Procure Rock Mechanics Samples**
Procure drill-core samples to finalize rock mechanics properties. Drilling is part of core drilling program (Activity 30310).

30512 **Conduct Rock Mechanics Tests**
Ship rock mechanics samples to testing laboratory. Conduct appropriate tests to finalize strength of rock. Analyze test results to finalize size of openings and pillars in underground mine or pit slope angles (stability) in open-pit mine. If applicable, test for the application of mechanical excavation. Send test results in report form to project team. Contractor should submit report in draft form for review by project team before finalizing.

30513 **Finalize Siting Preferences**
Determine the final location of all surface facilities. This includes shaft and other mine facilities, mill and processing facilities, tailings facilities and pipelines, and surface ancillary facilities such as roads, buildings, power lines, gas lines, storage areas, waste disposal areas, parking areas, and construction lay-down areas. If an open-pit mine, this would include location of pit. Locate all sites within a few feet of their planned constructed location. Complete design basis drawings. Final facilities location selection should include factors such as the following: facility spacing and location, environment, accessibility, utilization, capital cost, and operating costs (if different and applicable).

30514 **Document and Review Siting and Geotechnical Results**
Write report documenting siting and geotechnical work performed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility study report. Contractor should submit report in draft form for review by project team before finalizing.

30601 **Develop Permit Application Work Specifications**
Develop scope of work and schedule necessary for preparation of permit applications. Prepare RFP to send to contractors capable of preparing permit applications. RFP should contain draft of proposed contract.

30604 **Prepare Permit Applications**
Procure necessary forms and formats for all permits required to construct and operate project. Complete all permit applications as required by local, state, and federal agencies. Submit applications to appropriate governmental agencies.

30605 **Procure Construction and Operating Permits**
Wait for various governmental agencies to approve permit applications. Get approved applications from agencies. This task could require some application rewriting or amending if one or more agencies need data not presented in original application.

30606 **Expand Government and Public Relations Programs**
Expand and update program(s) to keep government and public informed of nature and status of project.

30607 **Document and Review Government and Public Relations Programs**
Write report documenting status of government and public relations programs. Review results of programs with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility report.

30701 **Develop Mine Work Specifications**
Develop scope of work and schedule necessary for conducting final mine evaluation study. Prepare RFP to send to contractors capable of performing the work. RFP should contain draft of proposed contract.

30704 **Develop Final Mine Layout**
Prepare final mine development and production layouts. Prepare layouts with sufficient detail and accuracy to develop mine plans and allow estimating capital and operating costs, and development and operating schedules to accuracies of ±10% to 15%.

30705 **Develop Final Mine Plan**
Mine plans should, include layouts and schedules for headframe, shaft, stations, preproduction development, underground service area development, production, and continuing production development. Complete design basis drawings. Develop life-of-mine production plans as well as detailed 5-year mine production plans. Mine plans should have an accuracy of +15%.

30706 **Perform Mine Functional Analyses**
Calculate operational cycles, and labor, equipment, and supply requirements for each mining function. Refine the functions analysis made earlier to include drilling, blasting, loading, hauling, scaling, bolting, ground control, mine backfill (if needed), hoisting, primary crushing (if underground), maintenance, supply/debris handling, pumping, and other support services. For each function, develop personnel productivity learning curves and prepare cost and operational schedules for each.

Use personnel productivity learning curves developed in intermediate feasibility study for each function. Prepare cost and operational schedules for each.

30707 **Develop Mine Capital and Operating Cost Estimates**
Develop cost estimates for total mining operation. Costs should have accuracy of ±10% to 15% and will become part of final financial analysis. Put costs in format suitable for financial analysis.

30708 **Develop Mine Design Specifications**
Develop design specifications for competitive bidding of mine design, construction, and development work. Prepare bid packages. Design specifications for an underground mine should include systems for mine access, materials and personnel handling, ventilation, communications, electrical, mine dewatering, and fuel storage and handling; maintenance and warehousing facilities; explosives handling and storage facilities; crushing facilities; and sewage system.

Design specifications for an open-pit mine normally include communications system(s); sewage system; electrical system; mine dewatering system; fuel storage and handling system; oil, lubrication, and antifreeze system; and explosives handling and storage facilities.

30709 **Document and Review Mine Results**
Write report documenting mine study work performed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility study report. Contractor should submit report in draft form for review by project team before finalizing.

30721 **Perform Test Mine Access and Level Development (if not yet completed)**
For underground test mine, sink shaft (or other method of access), excavate and construct station(s), and perform necessary level development. For open-pit test mine, strip necessary overburden and waste material.

30722 **Perform Test Mining (if not yet completed)**
Conduct mining tests as outlined under Activity 30713 in intermediate study.

30723 **Procure Test Mine Bulk Samples (if not yet completed)**
Procure sample(s) as planned under Activity 30712 in intermediate study. (In many cases, this activity and 30724 occur between the intermediate and final feasibility study, in which case these activities would be omitted here.)

30724 **Perform Test Mine Predevelopment Work (if not yet completed)**
Perform test mine drilling and other geologic work as outlined under Activity 30713 in intermediate study.

30725 **Update Potential Mineral Reserves (if not yet completed)**
Update mineral reserve calculations using drilling, assay, and geologic data gathered during test mining (Activity 30724).

30726 **Document and Review Test Mine Results (if not yet completed)**
Write report documenting test mine work performed. Review results of test mining with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility study report.

30801 **Develop Mill Work Specifications**
Develop scope of work and schedule necessary for final process, milling, and tailings disposal studies. Prepare RFP to send to contractors capable of performing the work. RFP should contain draft of proposed contract.

30804 **Procure Metallurgical Samples**
Procure drill-core samples to use for metallurgical testing. Drilling is usually performed as part of predevelopment drilling program. This activity may be unnecessary if bulk sample is obtained from test mine.

30805 **Conduct Metallurgical Testing**
Ship metallurgical samples to testing laboratory or pilot mill, if bulk sample for test mine is used. Conduct appropriate tests to determine final metallurgical data and design specifications for comminuting characteristics; separation and concentration characteristics of reagent consumption; heads, tails, and concentrate analyses; process flow sheet; environmentally harmful gaseous, liquid, and solid products produced; and areas of uncertainty.

Send test results to project team in report form. Contractor should submit report in draft form for review by project team before finalizing.

30806 **Finalize Mill Process Requirements**
Evaluate metallurgical testing results. Use test results, literature search, company experience, and contractor experience to determine the best process method. This method, and other technical data gathered, will serve as basis for mill design.

30807 **Prepare Milling Flow Sheet**
Prepare flow sheet for chosen process. Flow sheet should contain sufficient detail to allow selection and sizing of equipment.

30808 **Perform Mill Functional Analyses**
Calculate the operational cycles, and labor, equipment, and supply requirements for each milling function and the process method used in Activity 30807. The functions include the following: stockpiling/reclaiming (size of storage), crushing, grinding, screening, concentrating including heap leaching (if applicable), classifying, clarifying, tailings disposal, concentrate handling, maintenance, supply/debris handling, and other support services. Prepare cost and operational schedules for each.

30809 **Develop Mill Design Specifications**
Develop specifications for competitive bidding of mill and tailings facilities design and construction. Prepare bid packages. Complete design basis drawings and basic engineering drawings.

30812 **Develop Mill Capital and Operating Cost Estimates**
Develop estimates for total milling operation. Costs should have accuracy of +10%. Costs will become part of final financial analysis. Put costs in format suitable for financial analysis.

30813 **Document and Review Milling Results**
Write report documenting milling and metallurgical work performed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility study report. Contractor should submit report in draft form for project team review before finalizing.

30901 **Develop Refinery Work Specifications**
Develop scope of work and schedule necessary for finalizing custom refining plans.

30902 **Finalize Custom Refining Contract**
Start finalizing contract terms with custom refinery(ies) suitable for processing mill concentrates. Finalize with custom refinery(ies) quantities of material for processing, timing, and costs. Costs need to include capital (if required) and operating estimates for everything associated with tolling such as transportation of concentrate to refinery, refining charge (consider deducts and/or credits), transportation of refined product, and personnel requirements. Costs should have accuracy of +10%.

30903 **Document and Review Refining Results**
Write report documenting refinery work performed. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility study report.

31001 **Develop Surface Facility Work Specifications**
Develop scope of work and schedule necessary for final study of project surface facilities not connected with mine and mill studies. Prepare RFP to send to contractors capable of performing the work. RFP should contain draft of proposed contract.

31004 **Finalize Surface Building Requirements**
Finalize surface buildings required for project operation. These include those serving support function for mine and mill but not buildings directly related to mining and milling activities. Types of buildings include ambulance garage, administration/office, dry/changehouse, guardhouse, and surface shops.

Finalize operating and maintenance personnel and equipment requirements (including shop equipment, office, and dry equipment). Complete design basis drawings. Develop capital and operating cost estimates with +10% accuracy to include in final financial analysis. Put costs in form suitable for financial analysis.

31005 **Finalize Surface Utilities Requirements**
Finalize utilities required for project construction, development, and operation. Study does not include power distribution inside mine and mill battery limits (distribution within facilities included in mining and milling studies). Utilities should include electric power; fuel for buildings and fuel storage for operating equipment; communications (radio and telephone); potable water; fire protection, sewage system, and garbage/trash/solid waste removal and disposal. Finalize operating and maintenance personnel and equipment requirements. Complete design basis drawings. Develop capital and operating cost estimates with +10% accuracy to include in final financial analysis. Put costs in form suitable for financial analysis.

31006 **Finalize Surface Transportation Requirements**
Finalize transportation method chosen in intermediate study for moving equipment, supplies, material, and mine/mill product into and out of project area during project construction, development, and operation. Methods evaluated include haulage by truck, rail, ship/barge (if feasible), and air (if feasible), or combinations of these.

Finalize access road requirements and costs, capital and operating costs, personnel and equipment requirements, and other costs associated with transportation system. Develop capital and operating costs with +10% accuracy to include in final financial analysis. Put costs in form suitable for financial analysis.

31007 **Finalize Surface Mobile and Miscellaneous Equipment Requirements**
Finalize requirements not covered under other activities. This includes equipment for medical emergencies, road and yard area maintenance, supervisor pickups/car(s), maintenance personnel pickups and trucks, loader(s)/backhoe(s), forklift(s), crane(s)/cherry picker(s), portable welder(s)/compressor(s)/generator(s), small rear-dump truck(s), and crawler tractor(s) with dozer. Finalize operating and maintenance personnel and equipment requirements. Develop capital and operating cost estimates with

+10% accuracy to include in final financial analysis. Put costs in form suitable for financial analysis.

31008 **Finalize Water Management Plan and Costs**
Finalize requirements for total project water management system. This includes the following: mine, mill, tailings disposal, potable, fire protection and other water usage requirements; mine dewatering and pumping requirements; project water balance (identify all water sources and losses); makeup water requirements and source (if water short); water treatment, disposal, or evaporation system (if excess water); potable water system (include source, treatment, storage, and distribution); fire protection system (include source, treatment, storage, and distribution). Finalize operating and maintenance personnel and equipment requirements, including buildings or structures to house the water-related facilities. Complete design basis drawings. Develop capital and operating cost estimates with +10% accuracy to include in final financial analysis. Put costs in form suitable for financial analysis.

31009 **Finalize General Surface Facilities Arrangement**
Finalize requirements for surface facility, plant, and disposal area(s); internal road (does not include haulage roads for open-pit mine); parking areas; construction lay-down area(s); and storage area(s).

Prepare plot plans showing final arrangement of all surface facilities, including items in list, water facilities, mine, mill, and tailings facilities. Finalize capital costs of these surface facilities. Determine operating and maintenance equipment and personnel requirements under preceding surface activities (31004 to 31009). Finalize maintenance material and supply requirements for areas identified in list. Complete design basis drawings.

31010 **Finalize Warehouse Requirements**
Finalize size of warehouse and storage yard facilities; amount of warehouse inventory; equipment (mobile and stationary) necessary to store warehoused items, load and unload supplies, and move supplies within confines of project area; and operating personnel requirements. Complete design basis drawings. Finalize capital and operating costs with +10% accuracy to include in final financial analysis. Put costs in form suitable for financial analysis.

31011 **Develop Surface Building Design Specifications**
Develop design specifications for competitive bidding of design and construction. Buildings are identified under Activity 31004. Prepare bid package(s).

31012 **Develop Surface Utility Design Specifications**
Develop design specifications for competitive bidding of design and construction. Utilities are identified under Activity 31005. Prepare bid package(s).

31013 **Develop Surface Transportation Design Specifications**
Develop design specifications for competitive bidding of design and construction. Facilities are identified under Activity 31006. Prepare bid package(s).

31014 **Develop Water Facilities Design Specifications**
Develop specifications for competitive bidding of design and construction. Facilities are identified under Activity 31008. Prepare bid package(s).

31015 **Develop Surface Facilities Capital and Operating Cost Estimates**
Assemble capital and operating cost estimates for surface facilities. Costs should have accuracy of +10%. As costs will become part of final financial analysis, put costs in format suitable for financial analysis.

31016 **Document and Review Surface Facilities Results**
Write report documenting surface facilities studies. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility study report. Contractor should submit report in draft form for review by project team before finalizing.

31017 **Develop Environmental Monitoring Plan (EMP) for Proposed Operation**
Now that all of the mine/plant facilities are defined, complete design basis drawings, specify the labor disciplines, the types and requirements of the monitoring program, the inspections to be required, and the method whereby corrective action and compliance will be achieved.

31018 **Define Cost of EMP**
All professional and staff personnel cost and their equipment must be included. Also include allowances for outside testing on a scheduled basis.

31019 **Amend All Permit Applications to Include Aspects of EMP That Pertain to Various Permits**
Return to the various permit applications and insert those actions and plans that the operating company will take to monitor and control all aspects of the operation to remain in compliance with various regulators' requirements.

31101 **Refine General Personnel Requirements**
Finalize administrative and management personnel requirements; and operating, maintenance, support, and supervisory personnel requirements developed in preceding activities. Split requirements into salaried exempt, salaried nonexempt, and hourly classifications. Finalize labor buildup schedules for each classification.

31102 **Update Organization Charts**
Finalize organization charts showing the project organization. Charts should show lines of authority and responsibility.

31103 **Define Administrative Costs**
Finalize salaries and wages of personnel identified in 31101; payroll burden associated with salaries and wages; and cost, type, and quantity of office equipment and supplies required for all offices including administration, mine, mill, and maintenance. Prepare costs in form suitable for financial analysis. Costs should have accuracy of +10%.

31104 **Document and Review Organization and Administration Results**
Write report documenting administrative costs and personnel requirements. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility study report.

31201 **Refine Labor Plan**
Finalize plan for attracting and keeping productive, qualified personnel. Plan should include items such as recruiting, training, absentee and turnover projections, commuting (including fly in–fly out), community development, salaries/wages, fringe benefits/payroll burden, incentive system, and union/nonunion considerations.

31202 **Refine Labor-Related Cost Estimates**
Finalize personnel and equipment requirements and capital and operating cost estimates for the plan developed. Costs should have accuracy of +10% and be in format suitable for financial analysis.

31203 **Document and Review Labor-Related Results**
Write report documenting labor-related studies. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility study report.

31301 **Conduct Final Market Study**
Update market studies to determine selling price of salable products. Check product specifications of final metallurgical test with required product specifications. Estimate price ranges for life of project and prepare prices in format suitable for financial analysis.

31302 **Document and Review Market Study Results**
Write report documenting marketing studies. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility study report.

31401 **Develop Financial Analysis Criteria**
Develop criteria for performing final financial analysis. Criteria should include overall project schedule (design, construction, development, and start-up), ore production and final production schedule, capital and operating costs, royalties, escalation factors, tax rates, working capital, property acquisition costs, mill recovery, depreciation methods, depletion allowance, allowance for unforeseen, capitalization factors, sensitivity and risk analysis (see 31403), salvage values, and corporate overhead allocation.

31402 **Conduct Financial Analysis**
Conduct financial analysis for total project using a suitable computer program. Print results of economic analysis.

31403 **Conduct Financial Sensitivity Studies**
Evaluate sensitivity/risk of various project key factors. Also, quantify the degree of risk and perform Monte Carlo risk analysis on the collective factors, including operating costs, capital costs, reserves, grade, mill recovery, royalties, taxes, and other items with high degree of uncertainty. Conduct sensitivity analysis using a suitable computer program. Print results of sensitivity analysis.

31404 **Document and Review Financial Results**
Write report documenting financial analysis and sensitivities. Review results of work with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility study report.

31501 **Develop Tax Study Work Specifications**
Develop scope of work and schedule necessary for finalizing study of taxes applicable to project.

31502 **Conduct Final Tax Study**
Update tax studies to finalize taxes applicable to project. Analyze taxes to understand how they affect construction, development, and operation of project. Prepare tax rates in format suitable for financial analysis.

31503 **Document and Review Tax Studies**
Write report documenting tax studies. Review results of studies with appropriate levels of management and other personnel. Write report in style and format suitable as chapter in final feasibility study report.

31601 **Prepare Design, Construction, and Development Schedule and Budget**
Update and expand plan and schedule using formalized scheduling techniques. Update budget for project design, construction, and development. Schedule and budget should conform to those used for final study financial analysis (Activity 31401).

31602 **Prepare Final Study Report**
Prepare the design basis memorandum documenting all of the technical parameters in a single document. Prepare formal report detailing final study work performed. Prepare report in style and format that is
- Suitable for presentation to management,
- Suitable for use by other project teams, and
- Containing history and results of work performed.

31603 **Present Report, Plan, and Budget to Management**
Present all data generated during final study, plus plan and budget for design, construction, and development phase to management for review. Present information in meeting(s) with hard copies of reports, schedules, and data. Distribute report at least 1 week prior to meeting to allow personnel to read and review.

APPENDIX 4.7E
OUTLINE OF DESIGN BASIS REPORT SECTIONS

VOLUME 1: MANAGEMENT SUMMARY

INTRODUCTION AND SUMMARY
Technical feasibility
- Ore deposit
- Facilities
- Viability

Economic feasibility
- Investment and capital cost
- Economic analysis
- Sensitivities

- Operating cost
- Sales price and operating profit
- Construction and life of mine schedule

Product market analysis
- Competitive situation
- Market development activities
- Execution plan
- Project execution responsibility

Division of project execution (if applicable)
- Line of reporting
- Planned method of contracting
- Construction plan
- Construction labor buildup

Business plan
- Objectives
- Demand for finished or refined product

Product market analysis
- Competitive situation
- Market development activities

Market strategy
Outstanding issues
- Country mining law and code
- Potential project partner (if being considered)
- Land purchase from the local government

Purchase of private land and rights-of-way
- Interface with country agencies
- Reestablishment of contractual basis
- Project mobilization
- Construction and operating permits
- Power supply agreements
- Concentrate transport rail agreement concentrator water supply agreement

CONCLUSIONS AND RECOMMENDATIONS
- Conclusions
- Reserves
- Feasibility
- Market
- Preappropriation work funding
- Recommendations

VOLUME 2: PROJECT ECONOMICS

FOREWORD
SECTION I: OVERVIEW
Project schedule
Capital cost estimate
Operating cost estimate
Marketing
Business climate and investment outlook
Economic analysis
Finance/funding
SECTION 2: SCHEDULE
Project schedule
Schedule basis and assumptions
SECTION 3: CAPITAL COST ESTIMATE
Capital cost estimate summary
Initial facilities
Deferred/replacement capital
Owner's costs
Facilities cost estimate basis
- Schedule basis
- Sources of cost information
- Escalation basis (if used)
- Direct materials basis
- Direct labor basis
- Construction indirect costs
- Contractor engineering cost basis
- Contractor's fee basis
- Project contingency cost basis

SECTION 4: OPERATING COST ESTIMATE
Summary
Operating cost estimate basis
- Production schedule
- Sources of cost information
- Escalation (if used)
- Operating labor
- Operating supplies
- Repair and maintenance material
- General and administrative cost
- Other costs
- Operating cost contingency

Projected first year operating costs
- Production factors
- Project timing
- Business factors

Position of this property in world seriatim of industry
- Comparison with other mine candidates for development
- Comparison with existing and potential mine producers

SECTION 5: MARKETING
Summary
Overview of the commodity market
Commodity demand
Commodity mine supply/demand balance
Commodity price
Market analysis
Commodity concentrate market
Commodity finished product market
By-product market
Marketing and business strategy
SECTION 6: BUSINESS CLIMATE AND INVESTMENT OUTLOOK
Summary
Political outlook
Economic outlook
Investment climate
Microeconomic outlook
SECTION 7: ECONOMIC ANALYSIS
Summary
Basis of analysis
- Capital costs
- Operating costs
- Working capital

Production data
- Revenue
- Escalation
- Tax

Economic results
Sensitivities
- Revenue and cost

SECTION 8: FINANCIAL STRATEGY
Financial strategy objectives
Financing plan

VOLUME 3: TECHNICAL NARRATIVE

(For subcategories in Volume 3 marked with an asterisk, there should be a summary, the technical design basis for that item, the design considerations and assumptions that were made for

that item, the technical system description of the components of that system within a subcategory, environmental control systems, and, finally, the equipment list for the subcategory. Although these items are not repeatedly listed under each subcategory, each must be documented.)

SECTION 1: OVERVIEW
Introduction
- Mine
- Primary crushing
- Concentrating/cleaning
- Waste disposal
- Offsites
- Waste dump leaching (if applicable)
- Leachate recovery plant (if applicable)
- Plans for future expansion (if applicable)

Design basis
- Production rates
- Start-up scheduled
- Production buildup schedule
- Objectives of each operational function in design

SECTION 2: MINE AND PRIMARY CRUSHING
General summary
Geology, exploration, resource, and reserve description
Mining*
- Mining plan

Layout of mining facilities
- Description and site conditions
- Design considerations
- Plot plan
- Type of building and construction

Civil works related to mining
- Summary
- Site investigations
- Site preparations
- Miscellaneous civil works

Primary crushing and storage facilities*
Maintenance facilities*
Auxiliary mine buildings*
Utilities
- Summary
- Water supply*
- Fire protection*
- Power*
- Compressed air*
- Fuel oil and lubrication handling facility*
- Communications*

Industrial wastewater collection, treatment, and disposal*
Other environmental control systems
Warehousing and supplies handling*
Discussion of pre-engineering trade-off studies
SECTION 3: ORE CONVEYANCE SYSTEM
(Whatever system is to be used must be fully described. Whether a mine hoisting shaft, a slope conveyor system, overland conveyor system, slurry pipeline, truck or rail system, etc., the design basis must be given.)*
SECTION 4: CONCENTRATOR OR PROCESS CLEANING
General summary (battery-limits)
Layout and civil considerations
- Location map
- Plot plan
- Site considerations

Course product storage*
Communitions circuit(s)*
Mineral extraction circuit(s)*
Thickening, filtering, and drying*
Chemical storage, preparation, and distributions*
Sampling and process control*
Utilities and yard facilities*
Yard and plant piping*
Maintenance facility for process plant*
Warehousing and handling of supplies of processing plant*
Auxiliary processing buildings *
Environmental control systems
Any product expansion plans*
SECTION 5: WASTE DISPOSAL AND WATER RECOVERY/TREATMENT
General summary (battery limits)
Waste system pipeline*
Waste disposal area description
- Summary
- Site selection
- Regional topography and geology

Local site geology
- Hydrology (groundwater)
- Meteorology
- Hydrology (surface water)
- Seismicity

Operation of waste disposal area
- Summary
- General features
- Description of proposed deposition system
- Completion plans
- Seepage mitigation plans
- Dust control plans

Waste dam construction
Summary future work
- Waste dam design basis (specify waste compaction if required)
- Waste dam details
- Stability analysis
- Construction materials specification and placement procedures
- Quality control plans
- Staged dam construction sequence
- Equipment list

Reclaim water system*
Seepage water recovery*
Waste utilities and services*
Waste pond area civil works and buildings*
Maintenance of waste facilities*
Other environmental control systems
SECTION 6: OFFSITES
General summary
- Facilities
- Product storage, transport, and shipping
- Freshwater supply
- Electric power supply
- Access roads
- Communications
- Fire protection
- Mine area drainage and waste treatment plant
- Solid waste collection and disposal plans
- Plant security
- Product transport, storage, and shipping*

- Water supply*
- Electrical power supply*
- Access roads*
- Communications system*
- Security facilities
- Mine area drainage treatment plant*
- Solid waste collection and disposal*

Other environmental control systems
SECTION 7: DUMP OR PAD LEACHING (if applicable)
Summary
Design basis
- Metallurgical process
- Operating schedule
- Projected tonnages and analysis
- Process flow sheet and mass balance

Leaching parameters
- Reagent requirements
- Environmental requirements

Design considerations
- Process design support documents
- Factors considered
- Environmental considerations

System description
General description
- Leach area preparation
- Pregnant leach solution collection
- Leach solution distribution
- Raffinate and pregnant leach
- Solution pumping

Emergency discharge handling
- Electrical system description
- Plant heating, ventilation, and air conditioning
- Control and instrumentation

Waste diversion system*
SECTION 8: DOWN STREAM EXTRACTION
(Any and all downstream extraction processes, such as SX/EW or metals smelting and refining must be fully described.)*

VOLUME 4: PROJECT EXECUTION PLAN

SECTION 1: INTRODUCTION
Objectives and purpose
- Clearly convey to company management how project will be executed.
- Clearly convey to future A/E and construction contractors how project will be executed.
- Provide organizational structure and divisional responsibility for project.
- Complete safe, operable mine/plant, on schedule, within budget.
- Complete mine/plant, meeting all country and government regulations.
- Identify major outstanding issues and action that must be addressed prior to execution.
- Define complete basis to enable project to mobilize and accelerate critical early activities to achieve earliest project completion.

Conclusions
SECTION 2: BACKGROUND
Project history
Project general description
- Mine
- Process plant
- Infrastructure/offsites
- Other facilities

Project milestones
Guidelines to use of country resources
SECTION 3: PROJECT ENVIRONMENT CONTROLS AND BUSINESS ENVIRONMENT
Concerns and interest of country government
- Environmental protection required and permits needed
- Water supply (construction)
- Water supply (operations)
- Waste disposal impoundments
- Roads, electrical power, and communication
- Concentrate transportation
- Mine
- Process plant

Land acquisition
Country taxes
Labor market
- General
- Market mechanism
- Subcontracting labor supply
- Direct hire

Employment requirements
Competition for resources during project period
Country economy
Resources of concern
Public relations
Company public relations plan
Project team public relations plan
Contractors and subcontractors public relations
SECTION 4: PROJECT EXECUTION ORGANIZATION
Overall project organization
Engineering, procurement, and construction coordination task force organization
Company project organization
Project executive's organization
Contractor(s) project organization expected
Deputy project director in home country
Deputy project director in country of project
Deputy project director of engineering
Deputy project director of procurement
Deputy project director of construction
Project control director
Finance director
Human resource director
Turnover and replacement organization
SECTION 5: SCHEDULES AND LABOR REQUIREMENTS
Schedules
- Mine engineering
- Mine procurement
- Mine construction
- Process plant engineering
- Process plant procurement
- Process plant construction
- Infrastructure/offsites engineering
- Infrastructure/offsites procurement
- Infrastructure/offsites construction

- Labor distribution to all areas in all phases
- SECTION 6: PROJECT ENGINEERING EXECUTION
- BASIS (assuming appropriation approval)
- Objectives
- Detailed work plan for contract engineering
  - Methodology execution
  - Division of work
  - Amount of work in the home country
  - Amount of work in the foreign project country (if applicable)
  - Engineering personnel orientation
  - Orientation meetings
  - Site orientation and description
  - Mine description
  - Process plant description
  - Infrastructure/off-site
  - Other facilities
  - Planned organization
  - Project basic documentation and references
  - Engineering documents
- Standards and criteria to be used
- Engineering quality control
- Quality assurance achievement expected
  - Purpose
  - Scope
  - Audit methodology expected
  - Contractor
  - Company
- SECTION 7: PROJECT PROCUREMENT EXECUTION
- BASIS
- Procurement organization, functions, and responsibilities
  - Scope and policy
  - Organization
  - Responsibilities and functions
- Procurement procedures and documentation
  - Procedures expected
  - Documentation expected
  - Country vendor survey information
- Available materials in country or nearest available
- Available fabrication facilities in country or nearest available
- Available subcontracting services in country or nearest available
- SECTION 8: PROJECT CONSTRUCTION EXECUTION
- BASIS
- Construction management
  - Project organization
  - Construction management procedures
  - Reporting
  - Construction expected
  - Construction management interfaces project management
- Preappropriation activities (as applicable)
- Labor
  - Craft supply plan
  - Logistics of labor source
  - Supervision required
  - Safety organization
  - Expatriate housing (if applicable)
- Construction equipment, tools and consumables in general
  - Major equipment
  - Procurement sources
- Transportation of equipment, tools and consumables
  - Maintenance program expected
  - Tools
  - Consumables
  - Fuel
  - Aggregate
  - Concrete
- Construction facilities

VOLUME 5: OPERATING PLAN

- SECTION 1: INTRODUCTION
- SECTION 2: OWNER
- Local organization
  - Location
  - Description of staff
  - Type of management
- Management committees (if applicable)
- Business interfaces
  - Transportation company
  - Utility companies
  - Adjoining property agreements
  - Operating consulting agencies (if applicable)
  - Government regulatory, licensing and permitting agencies
- SECTION 3: OPERATING DEPARTMENTS
- General
  - Operating schedule
  - Mine camp (if applicable)
  - Personnel transportation
    - Staff
    - Hourly
  - Food service (if applicable)
  - Medical facilities
- Functional department and interrelationships
  - Mining department
    - Mine operation
    - Geological/surveying
    - Mine engineering
    - Mine and field maintenance
    - Electrical
    - Primary communition
    - Other functional operating group specific to this property
  - Concentrator/cleaning plant department
    - Plant operation
    - Metallurgical/process engineering
    - Maintenance
    - Electrical
    - Process control and instrumentation
  - Central maintenance and fabrication department
  - Transportation department
- Other operating department specific to this property
- SECTION 4: RECRUITING
- Labor needs
  - Staff (by function)
  - Hourly (by function)
- Manning plan buildup estimate
  - Staff (by function)
  - Hourly (by function)
- Availability of personnel labor pool
  - Staff (by function)
  - Hourly (by function)
- SECTION 5: TRAINING
- Training objectives
  - Initial training
  - Ongoing training
- Management and professional development

- Training program
  - Job positions to be trained to match job descriptions
  - Training organizations
    - Use of outside institutions
    - Vendors training
    - Inside training
  - Initial training time estimated
- SECTION 6: START-UP
- Basis of start-up philosophy
  - Who will participate
  - Who will be in charge of start-up plan
  - Mining department's plan
  - Concentrator/process plant's plan
  - Transportation facilities' plan (if applicable)
- Organization for start-up
  - Mine
  - Concentrator/process plant
  - Transportation
- Start-up assistance
  - Operational staff
  - Architect/engineering contractor
  - Vendors and other consultants (if applicable)
  - Time and budget estimate for start-up
- SECTION 7: INFRASTRUCTURE AND SUPPORT SERVICES (any auxiliary operations that support the main production operations)
- Housing (if applicable)
- Food service (if applicable)
- Personnel transportation (if applicable)
- Power system
- Power generation
- Acquired power
- Water system
- Tailings/waste disposal system
- SECTION 8: MAINTENANCE
- Company philosophy and policies
- Maintenance control programs
  - Work control system
  - Preventive maintenance
  - Maintenance planning and scheduling
  - Maintenance management reports
  - Job priorities
  - Downtime analysis philosophy
  - Backlog reporting system
  - Numbering control system
  - Warehouse and inventory control system
- Other tasks
  - Maintenance work requirements
  - Collection and cataloging of equipment information
  - Develop equipment
  - Identification codes
  - Develop preventive maintenance schedules
  - Develop maintenance forms
  - Execute contracts for rebuild and repair components
- SECTION 9: ROAD MAINTENANCE
- Description of road system to be maintained
- Responsibilities for specific areas to be maintained
- SECTION 10: ENVIRONMENTAL
- Company policy and objectives
  - Present conditions by areas
  - Source of pollution by areas
  - Assessment of hazards from above sources
  - Objectives of monitoring program
- Monitoring program recommended responsibilities
  - Internal responsibilities
  - Consultant responsibilities
- SECTION 11: ADMINISTRATION AND SUPPORT SYSTEM
- Purchasing department
- Controllers department
  - Financial control
    - Registration and depreciation of property and materials
    - Accounting system
  - Financial reporting
  - Cost accounting and cost distribution
  - Capital and expense budgets
  - System development
- Marketing
  - Marketing philosophy of major products
  - Marketing philosophy of by-products
- SECTION 12: COMMUNICATIONS
- Company philosophy
- Organization
- Central database system
- Computer applications support
  - Ore resource management and information
  - Operation production modeling and automation
  - Personnel
  - Management
    - Capital/financial
    - Equipment
    - Communication systems
  - Mine systems support (including GPS)
    - Plant systems support
    - Office systems support
- SECTION 13: SAFETY
- Company philosophy
  - Organization
  - Training
  - Safety protective equipment policies
  - Fire protection
  - Mine fire protection
  - Plant fire protection
  - Other surface area protection
- Interrelationships between operations and safety/health and first-aid clinics
- SECTION 14: SECURITY
- Company philosophy (this section dependent on geographic and political location of operation)
- Organization required
  - Internal organization
  - Contracted organization
  - Function of organization
  - Areas of security concern
    - Mine
    - Plant
    - Transportation of product
    - Other surface facilities
- APPENDICES
- Organization charts
- Condensed job descriptions of all jobs
- Maintenance management control system

CHAPTER 4.8

Cost Estimating for Underground Mines

Scott A. Stebbins

INTRODUCTION

Estimating the costs of mining is often referred to as an art. Unfortunately, this definition turns many would-be evaluators away because of this understandable misconception. Cost estimating, as with any predictive process, requires an evaluator to envision and quantify future events—in other words it requires one to be creative. A better description is that estimating the costs of mining is a creative endeavor. Fortunately in mining, most of the values that an evaluator must predict either stem from measurable entities, such as the configuration of a deposit, or from well-understood and accepted engineering relationships. In actuality, mine cost estimating is a process of matching values obtained through simple engineering calculations with cost data, a process made easier in recent years thanks to readily available printed and electronic information databases.

Mine cost estimating is also referred to as an art because no widely accepted rigorous approach to the process exists. Unlike the process of estimating costs in the building construction industry, in mining, the process varies noticeably from one evaluation to the next, not only in approach but also in scope.

A complete mine cost estimate cannot be fully detailed in the few pages available here. The information presented in this chapter is primarily aimed at minimizing the intimidation felt by many geologists and engineers when they undertake a cost estimate. The basic premise is that anything can be estimated. And the approach detailed here is one in which more or less complete listings of labor, supply, and equipment requirements are based on information about the deposit and the proposed mine. These listings are then used in conjunction with documented salaries, wages, supply costs, and equipment prices to produce estimates of mine capital and operating expenditures. This method, most often referred to as an abbreviated itemized approach, is much easier than it might initially appear. Although there are several other methods available, including parametric equations, factoring, cost models, and scaling, itemized estimates have the advantage of providing thorough documentation of all of the assumptions and calculations on which the estimated costs are based. As a consequence, the results are much easier to evaluate and adjust, and for this reason, they are more useful. Because they rely on much of the same information required to do a proper job using any of the other methods, evaluators are often surprised to find that engineering-based, itemized estimates can be accomplished with some expedience.

Early in any mine cost estimate, long before the evaluator begins to worry about the cost of a scoop tram, the scope of the evaluation must be determined. To accomplish this, the purpose of the estimate must first be defined. If it will be used to select which one of several deposits should be retained for future exploration expenditures, then the estimate will be less thorough than one used to determine the economic feasibility of a proposed mine or one used to obtain funding for development. Coincidently, the level of information available with regard to deposit specifics also plays a part in determining the scope of the estimate. As the level of information increases, so do the scope of the estimate and the reliability of the results.

Accuracy is a measure of predicted (or measured) value versus actual value. It cannot really be quantified until well after the project is under way and the estimated costs can be compared with the actual expenditures. So, cost estimators instead work more in terms of reliability, which is a measure of the confidence in estimated costs. Reliability is determined by the level of effort involved in the evaluation and by the extent of the available deposit information. Simply, the more information that is available (specifically geologic and engineering information), the greater the reliability of the estimated costs. If an evaluator has a firm grasp on the deposit specifics and works diligently to estimate all the costs associated with development and production, then a highly reliable estimate should result.

Estimators determining the potential economic success of developing a mineral deposit must undertake an iterative process of design and evaluation. After settling on an initial target production rate, the process can be broken down into the following four steps:

1. Design the underground workings to the extent necessary for cost estimating.
2. Calculate equipment, labor, and supply cost parameters associated with both preproduction development and daily operations.

Scott A. Stebbins, President, Aventurine Mine Cost Engineering, Spokane, Washington, USA

3. Apply equipment costs, wages, salaries, and supply prices to the cost parameters to estimate associated mine capital and operating costs.
4. Compare estimated costs to the anticipated revenues under economic conditions pertinent to the project (using discounted cash-flow techniques) to determine project viability.

After the estimator evaluates the results, he or she will make adjustments to the design and the production rate as necessary and then repeat the process.

PRELIMINARY MINE DESIGN

The goal of the mine planner is to optimize economic returns from the deposit (or to otherwise achieve the corporate goals of the project's owners). The objectives of evaluators as they design a mine for the purpose of estimating costs is to determine the equipment, labor, and supply requirements both for preproduction development work and for daily operations. The extent to which the evaluator takes the design is important—the process is one of diminishing returns. Roughly speaking, 10% of the engineering required for a complete mine design probably provides the data necessary to estimate 90% of the costs. More detailed final engineering aspects of mine design (such as those needed to ensure adequate structural protection for the workers and sufficient ventilation of the underground workings) seldom have more than a minor impact on the overall mine costs.

At the initial stages of an estimate, the key element is distance. In the preliminary design, engineers need to establish the critical distances associated with access to the deposit, whether by shaft, adit, or ramp. Most of the costs associated with preproduction development are directly tied to the excavations required to access the deposit. The length (or depth) of these excavations, along with their placement, provide several cost parameters directly, such as those needed to determine preproduction consumption of pipe, wire, rail, and ventilation tubing. These distances also provide an indirect path to estimating preproduction consumption values for items such as explosives, drill bits, rock bolts, shotcrete, and timber. And finally, they impact many subsequent calculations that the evaluator must undertake to estimate the required sizes of pumps, ore haulers, hoists, and ventilation fans.

Engineers let the configuration of the deposit and the structural nature of the ore, footwall, and hanging wall dictate the stoping method used to recover the resource. Stoping method selection is discussed in great detail in other chapters of this book.

The underground development openings necessary to access and support the stopes are as important as the stoping method itself. Engineers rely on some basic calculations to estimate the lengths of the drifts, crosscuts, ramps, and raises associated with each stope. After they determine the amount of ore available in the stope, they use those lengths to approximate the daily advance rates needed to maintain the desired ore production rate. While it is true that the use of average rates can be quite misleading (particularly in the first 5 years of operation), for the purposes of estimating costs (in particular in estimating preliminary costs), the overall costs per ton will not change much through the process scheduling of these activities in detail. And while the timing of the costs will have some impact on project economics, the extent to which they are detailed vs. the overall impact on project economics refers back to the statement about diminishing returns in the first paragraph of this section.

In the process of determining stope development requirements, estimators rely on stope models in conjunction with the deposit dimensions. For example, the diagram in Figure 4.8A-1 (Appendix 4.8A) provides the basis of the stope design for the room-and-pillar method. From that basis, the evaluator can then move on to use relationships similar to Example 1 to establish the design parameters for the stope.

Example 1. Stope Design Parameters

1. **Stope length:** The maximum suggested stope length, L_{ms}, is estimated by

$$L_{ms} = [(S_o + S_{hw}) \div 1{,}732{,}000] + 5.4$$

where
S_o = ore strength (equal to the ore compressive strength, kPa, times the ore rock-quality designation, %)
S_{hw} = hanging wall strength (equal to the hanging wall compressive strength, kPa, times the hanging wall rock-quality designation, %)

If the actual deposit length, L_{ad}, is greater than the maximum stope length, then the suggested stope length, L_s, is as follows:

$$L_s = L_{ad} \div \text{rounded integer of } [W_{ad} \div (L_s \times 0.75)]$$

where
L_{ad} = projected deposit length (plan view) ÷ cos(deposit dip)

If the actual deposit length, L_{ad}, is less than maximum stope length, then the stope length, L_s, is equal to the actual deposit length, L_{ad}.

2. **Stope width:** The maximum suggested stope width, W_{ms}, is estimated by

$$W_{ms} = L_s$$

If the deposit width, W_d, is greater than the maximum stope width, W_{ms}, then the suggested stope width, W_s, is calculated as follows:

$$W_s = W_d \div \text{rounded integer of } [W_d \div (W_{ms} \div 0.75)]$$

If the deposit width, W_d, is less than the maximum stope width, W_{ms}, then the suggested stope width, W_s, is equal to the deposit width.

3. **Stope height:** The suggested (vertical) stope height, H_s, is estimated by

$$H_s = T_d \div \cos(D_d)$$

where
T_d = measured deposit thickness
D_d = deposit dip (degrees)

4. **Resource recovery:** The suggested resource recovery, R_r (%), is provided by:

$$R_r = [(S_o + S_{hw}) \div 1{,}055{,}865] + 48.857$$

5. **Pillar size:** The plan view area of the pillars, A_p, is estimated by

$$A_p = \{L_s \times W_s \times [1 - (R_r \div 100)]\} \div 25$$

6. **Pillar width:** The pillar width, W_p, is provided by

$$W_p = W_{pr} \times \sqrt{[A_p \div (W_{pr} \times L_{pr})]}$$

where
W_{pr} (pillar width ratio) = $W_s \div (W_s + L_s)$
L_{pr} (pillar length ratio) = $L_s \div (W_s + L_s)$

7. **Pillar length:** The pillar length, L_p, is provided by

$$L_p = L_{pr} \times \sqrt{[A_p \div (W_{pr} \times L_{pr})]}$$

8. **Face height:** If the stope height, H_s, is greater than 7.6 m, then the estimated face height, H_f, is provided by

$$H_f = H_s \div \text{rounded integer of } (H_s \div 7.6)$$

If the stope height, H_s, is less than 7.6 m, then the estimated face height, H_f, is equal to the stope height, H_s.

9. **Face width:** If $W_s - W_p$ is greater than 12.2 m, then the suggested face width, W_f, is estimated as follows:

$$W_f = (W_s - W_p) \div \text{rounded integer of } [(W_s - W_p) \div (12.2 \times 0.75)]$$

If $W_s - W_p$ is less than 12.2 m, then the suggested face width, W_f, is provided by

$$W_f = W_s - W_p$$

10. **Advance per round:** The suggested advance per round is provided by

$$0.952679 \times [(W_f \times H_f)^{0.371772}]$$

11. **Development requirements (advance per stope for room-and-pillar stopes in deposits that dip less than 25°):**
    - Haulage drifts
      - length = stope length
      - location = ore
    - Haulage crosscuts
      - length = stope width
      - location = ore

Evaluators apply relationships such as those shown in Example 1 to a multitude of deposit configurations to arrive at a stope design. By building similar relationships for any stoping method, they can determine the pertinent associate stope development requirements and, subsequently, the pertinent cost parameters.

Sketches (usually a three-view drawing) of the deposit access headings, stopes, and underground excavations (shops, pump stations, lunch stations, hoist rooms, etc.) provide much of the preliminary mine design information that an evaluator needs for a cost estimate. Only the lengths of the excavations are needed early in the analysis. Values determined by evaluators as they calculate the subsequent cost parameters provide the information necessary to define the cross-sectional areas of these openings.

COST PARAMETERS

Engineers find that the process of defining the parameters necessary for a cost estimate is a wonderful (perhaps only for an engineer) progression of simple mathematical calculations in which one value seems to always lead to, and interconnect with, the next. These calculations branch in ways that create many logical paths to a complete compilation of the needed cost-estimation parameters, but all paths do eventually lead to such a compilation. One generalized path is illustrated in this section. Be aware, however, that most of these procedures are interchangeable, and many paths exist. Also, it is not the intent here to work through a complete step-by-step estimate, because such an example would apply only to a finite number of deposit types. The intent is instead to provide insight into the process that estimators use and to remove some of the mystery that might create a hesitation to proceed. Successful estimators need to show a willingness to suggest values for as-of-yet unknown parameters. For example, if one is working at an operating mine, then it is possible to know all of the required parameters and to calculate, as opposed to estimate, the costs. But for undeveloped projects, it is not possible to know parameters such as the ore and waste powder factors and the amount of water that must be pumped on a daily or hourly basis.

Most (if not all) parameters required for a cost estimate fall into one of three categories in that they define labor, supply, or equipment requirements. These categories represent the items that cost money, that is, the items for which funds must be expended. Consequently, evaluators work in this phase of the estimate to specify the equipment, the supplies, and the work force necessary to mine the deposit. They find that the key to specifying these factors lies in the process of determining how much time (how many hours) it takes to perform the individual tasks of mining.

Operations in an underground mine are, for the most part, either cyclic or continuous in nature, and most are designed to transport materials such as ore, waste, air, water, workers, and supplies. Operations that do not transport materials (such as equipment repair or rock support installation) are typically in place solely to service operations that do.

The rate at which ore is produced provides evaluators a good place to start as they begin to define the cost parameter values. This rate is typically based on the desired life of the mine and the size of the resource.

Resource size is known (or it has at least been approximated, hence the evaluation) and estimators often begin with the following relationship, a variation of which is known as Taylor's rule, to approximate a possible project life:

$$\text{project life, yr} = 0.2 \times \sqrt[4]{\text{resource size, t}}$$

With values for the mine life and the resource known, estimators can then determinate the daily production rate as follows:

$$\text{production rate, t/d} = \text{resource, t} \div [\text{mine life, yr} \times \text{operating schedule, d/yr}]$$

Of course, many factors influence the rate of ore production (such as market conditions, deposit configuration, and profit maximization), so many evaluators use more sophisticated approaches to determine the initial production rate (Tatman 2001). As the evaluation of a project proceeds, however, the production rate

needs to be altered from one iteration to the next as the economic ramifications of each development scenario become clear.

After an initial production rate is determined, evaluators can use it in conjunction with the ore haul distances (gleaned from the mine design) to estimate the capacities of the machines used to collect ore in the stopes, transport it through crosscuts and drifts, and then finally haul it (through an adit, ramp, or shaft) to the surface. The heights and widths of these machines (rear-dump haulers, scoop trams, rail cars, conveyors, etc.) provide the basis for the cross sections of all the openings through which they must travel. Evaluators multiply the products of the heights, widths, and lengths of the openings by the density of the rock through which they pass to determine the amount (in metric tons) of rock that must be removed during their excavation. When they apply a powder factor (kilograms of explosive per metric ton blasted) to this amount, the result is the amount of explosives needed to liberate the rock. As stated earlier, evaluators find that as one design parameter is determined, its value usually provides the information needed to determine many more.

After they determine the size of the haulers, engineers can refer to manufacturer's literature (often available through their Web sites) to ascertain the speeds of those machines in relation to various haul conditions. And with those speeds, they can calculate how many hours the machines need to operate each day to meet production goals and, in turn, the required number of machines and operators. Evaluators rely on cycle-time calculations (Example 2) to supply the basis for most such values, and as such these calculations represent one of the more important concepts of any cost estimate. Cycle-time calculations are used whenever an estimator needs to determine the number of machines required to perform a cyclic operation.

Example 2. Cycle-Time Calculations

Consider a case where a 20-t capacity, articulated rear-dump truck hauls ore to the surface. Ore is placed in the truck by a 6.1-m^3-capacity remotely operated loader near the entrance of the stope. The truck hauls the ore 550 m along a nearly level drift, and then it hauls the ore 1,450 m up a 10% gradient to the surface. After reaching the surface, the truck travels another 200 m to the mill, where the ore is dumped into a crusher feed bin. (If the truck is not loaded to capacity, it is primarily because the capacity of the loader bucket in conjunction with the number of cycle either under- or overloads the truck.)

First, the speeds of the machine must be ascertained over each segment of the haul route. This information is gleaned from technical manuals supplied by equipment manufacturers. In this example, the approximate speeds over the following gradients are as follows.

1. Haul speeds:
   - Up a 10% gradient, loaded ≈ 6.4 km/h
   - Over a level gradient, loaded ≈ 16.1 km/h
   - Over a level gradient, empty ≈ 20.3 km/h
   - Down a 10% gradient, empty ≈ 15.8 km/h

   These values include an allowance for a rolling resistance equivalent to a 3% gradient.
2. Travel times:
   - Haul travel times are

   [550 m ÷ (16.1 km/h × 1,000 m/km)] × 60 min/h = 2.05 min
   [1,450 m ÷ (6.4 km/h × 1,000 m/km)] × 60 min/h = 13.59 min
   [200 m ÷ (16.1 km/h × 1,000 m/km)] × 60 min/h = 1.04 min
   - Return travel times are

   [550 m ÷ (20.3 km/h × 1,000 m/km)] × 60 min/h = 1.63 min
   [1,450 m ÷ (15.8 km/h × 1,000 m/km)] × 60 min/h = 5.51 min
   [200 m ÷ (20.3 km/h × 1,000 m/km)] × 60 min/h = 0.59 min
3. Total travel time:

   2.05 + 13.59 1.04 + 1.63 + 5.51 + 0.59 = 24.41 min

   Evaluators may wish to tune the above estimate further by considering delays attributable to altitude duration, acceleration, and deceleration. However, the effort spent should be proportionate to the purpose of the estimate and the reliability of the available information. Specifically, if acceleration and deceleration were to increase the overall cycle time by 30 seconds (or 2%) but the mill had not been firmly sited (which might change the overall haul distance by as much as 10%), then the effort spent fine-tuning the estimate would be futile because it would do nothing to increase the reliability of the results.

   In addition to travel, the truck's cycle also includes time spent in loading, in dumping the load, and in maneuvering into position for each of these tasks. In this example, one also needs to estimate the cycle time for the loader to figure the amount of time that the hauler spends in the loading portion of its cycle. For this example, it can be assumed that the weight capacity of the loader is 13.44 t and that, for any given load, the bucket is typically 85% full. It can also be assumed that the ore in its blasted condition weighs 2.85 t/m^3. If the round trip from the dump point to the active face and back takes the loader 2.40 min (1.40 min to haul and 1.00 min to return), the loader takes 0.80 min to collect a load of ore and 0.40 min to dump that load, and the truck spends 2.65 min maneuvering and dumping during each cycle, then the following series of calculations provides the time necessary to load the truck as well as the overall cycle times of both vehicles.

   Given a production rate of approximately 4,000 t/d, a shift length of 10 h and a production schedule of about two shifts per day, the following are calculated.
4. Loader volume capacity:

   6.1 m^3/load × 2.85 t/m^3 × 0.85 = 14.78 t/load

5. Loader weight capacity: Because the weight capacity of the loader is 13.44 t, the load is limited by weight.
6. Loader cycle time:
   - Collect load ≈ 0.80 min
   - Haul load ≈ 1.40 min
   - Dump load ≈ 0.40 min
   - Return time ≈ 1.0 min
   - Total cycle time ≈ 3.60 min
7. Truck load time:
   - 20 t ÷ 13.44 t/load = 1.49 loads or two cycles per truck
   - Two cycles per truck × 3.60 min/load = 7.20 min to load truck
8. Total truck cycle time:
   - Load = 7.20 min
   - Travel = 24.41 min
   - Maneuver and dump = 2.65 min
   - Total cycle time = 34.26 min
9. Daily truck productivity:
   - 2 shifts/d × 10 h/shift × 60 min/h = 1,200 min/d
   - (1,200 min/d ÷ 34.26 min/cycle) × 20 t/cycle ≈ 700 t/d

10. Truck requirements:

    4,000 t/d ÷ 700 t/truck = 5.71, or 6 trucks

11. Hourly truck productivity:

    (20 t/cycle ÷ 34.26 min/cycle) × 60 min/h ≈ 35 t/h

12. Daily truck use:

    4,000 t/d ÷ 35 t/h ≈ 114 h/d

Next, evaluators need to determine the work force required to operate the truck fleet. Typically, equipment operators work noticeably less than the total number of hours for which they are paid. After evaluators account for the time workers spend at lunch and on breaks (in addition to time they lose traveling to and from the working face), they find that, on average, about 83% of the operator's time is actually spent in productive activities (the actual value of course varies from one operation to the next). Consequently, the total amount of time for which workers must be paid to achieve the 4,000-t/d production rate is as follows:

114 h/d ÷ 0.83 = 137 h

Because each shift is 10 hours long, the number of truck drivers is determined by

137 h ÷ 10 h/shift = 13.7 or 14 workers

Estimators now need to reexamine the number of trucks that they initially selected. In this case, it is apparent that, after accounting for worker efficiency, more trucks will be needed, that is

14 workers ÷ 2 shifts/d = 7 trucks

Therefore, in examining the trucks as they operate over the designed haul profiles, evaluators approximate values for several key cost parameters. The number of trucks, the number of operators, daily truck use (hours per day), and the number of hours that the drivers must work all become clear. Because the two latter values differ and because each is used to determine a different cost, evaluators also find that each must be estimated separately.

Maintenance-labor requirements can be estimated either as a factor of the number of operating units or, in some cases, as a factor of the number of operators. Supervision and technical staffs can then be determined from the sum of the results.

If evaluators determine the hourly work force properly, they have gone a long way toward ensuring an acceptable level of reliability. Wages often account for more than half the total operating cost, so if the work-force estimate is solid, the cost estimate is probably more than halfway complete. Conversely, the cost of operating underground mining machinery typically represents a far less significant portion of the total underground operating cost. But because the size and configuration of the work force is closely tied to the equipment requirements (and because the equipment purchase costs can be significant), evaluators should strive to properly determine those requirements. The results have a direct impact on the reliability of estimated costs.

Costs parameters for other cyclic operations (drilling, mucking, loading, hauling, hoisting, etc.) can be ascertained in a manner similar to that used in the truck example above. As is evident, cycle-time calculations are not difficult. Evaluators find the task of locating the rates (or speeds) at which machines operate (drill penetration rates, mucker transport speeds, hoist velocities, etc.) much more troublesome, but even this information is often readily available. The most common sources include literature from manufacturers, references such as this handbook, information databases such as *Mining Cost Service* (InfoMine USA 2009b), or statistical compilations such as those contained in the *Mining Source Book* (Scales 2009). Exclusive of these, speeds or rates of advance are very often easy to estimate through observation. And with the machine speed and a bit of imagination, any evaluator can provide a perfectly reasonable estimate of the cost parameters associated with almost every cyclic operation. It may also be useful to maintain a database of advance rates and machine productivity for different situations.

Machines that facilitate a continuous movement of materials (ore, waste, air, water, workers, etc.) are considered noncyclical, and the associated cost parameters can be estimated accordingly. Conveyors, generators, pumps, and ventilation fans fall into this category. In Example 3, a method that can be used to approximate the parameters associated with draining the mine and pumping the water to the surface is presented. This example illustrates the estimation process as it applies to continuous-flow operations.

Example 3. Continuous-Flow Calculations

Consider a case where a mine produces water at a rate of 400 L/min. Common engineering references indicate that a flow rate of roughly 1.0 m/s represents a reasonable value for the velocity of liquid pumped through a conduit. With this information, the following series of calculations provides an estimate of several of the required cost estimation parameters.

1. Pipe diameter:
   - The volume of water that flows through a meter of pipe each second is approximately

     (400 L/min ÷ 60 s/min) ÷ 1 m/s = 6.66 L/m

     6.66 L/m × 0.001 m^3/L = 0.0066 m^3/m

   - The diameter of pipe that enables the desired flow rate is approximately

     cross-sectional area of a pipe = ($\pi \times d^2$) ÷ 4

     $[(0.0066\ m^3 \times 4) \div \pi]^{0.5}$ = 0.092 m or 9.2 cm

   Therefore, the shaft must be fitted with a 9.2-cm inside-diameter pipe to remove water from the mine.

   Although no longer accepted, units of horsepower (hp) provide a useful visualization to cost estimators. The definition of the term (1.0 hp = 33,000 ft·lb/s) incorporates three primary contributors to costs: weight, distance, and time.

   To state that relationship in words, if the weight of the material, the distance that it must be moved, and the speed at which it is moved are all known, then the energy required for the task can be roughly estimated, as can the size of the motor and the subsequent costs. The more accepted unit of watts correctly incorporates mass into the equation, but to provide insight into the estimation

process, the following relationship can be used to approximate power requirements for the drainage problem illustrated earlier.

2. Pump horsepower:
   - The volume of water in the pipe at any one point of time is approximately

     $250\ \text{m} \times 3.281\ \text{ft/m} \times \{[\pi \times (9.2\ \text{cm} \times 0.03281\ \text{ft/cm})^2] \div 4\} = 58.70\ \text{ft}^3$

   - The velocity of the water is approximately

     $1.0\ \text{m/s} \times 3.281\ \text{ft/m} = 3.281\ \text{ft/s}$

   - The weight of the water in the pipe is approximately

     $58.70\ \text{ft}^3 \times 62.4\ \text{lb/ ft}^3 = 3{,}663\ \text{lb}$

   - Therefore, the horsepower required to move the water up the shaft is approximately

     $(3.281\ \text{ft/s} \times 3{,}663\ \text{lb}) \div 550\ \text{ft·lb/s} \approx 22\ \text{hp}$

     $22\ \text{hp} \times 0.7457\ \text{kW/hp} = 16.4\ \text{kW}$

For cost-estimating purposes, evaluators can use this value to approximate the size of a pump and the power required to move the water. However, it is important that evaluators differentiate between actually specifying the equipment—as an engineer would do in the advanced stages of a mine design—and approximating representative parameters. There is, of course, more to selecting a pump and determining the required power than has been illustrated. And pipes come in a limited range of standard diameters. But evaluators must keep in mind the purpose of the estimate and the reliability of the available information.

Well-established equipment selection procedures for items such as pumps are available elsewhere in handbooks such as this, and their use is, of course, encouraged whenever appropriate. But estimators can rely on the basic principles just presented, or variations of those principals, to approximate the cost parameters associated with almost any underground continuous-flow system, whether it is pumping water, conveying ore, blowing ventilation air, or transporting backfill. Each moves a specific weight over a specific distance at a specific speed. The basic premise of the approach presented here is that anything can be estimated. In the early stages of a deposit evaluation, specific requirements for tasks such as draining the mine are sketchy at best, so the evaluator must keep in mind that additional complication does not necessarily lead to additional reliability.

But that is not to say that cost-estimating approaches, such as the one shown in the previous example, are unreliable. For comparison purposes, the actual power required to transport water up a shaft is typically determined by using relationships similar to the following:

$$\text{power} = \text{pressure} \times \text{volume}$$

$$\text{pressure} = \text{fluid density} \times \text{gravity} \times \text{height}$$

Most importantly, the calculations must account for pump and motor efficiency, which is most often in the range of 65% and 75%.

3. Pump horsepower:
   - Flow rate ≈ 400 L/min ≈ 6.667 L/s
   - Pumping height ≈ 250 m
   - Pressure = $1{,}000\ \text{kg/m}^3 \times 9.81\ \text{m/s}^2 \times 250\ \text{m} = 2{,}452.5\ \text{kPa}$
   - Power = 2,452.5 kPa × 6.667 L/s = 16,350 W or 16.35 kW
   - 16.35 kW ÷ 0.7457 kW/hp = 22 hp
   - If the pump efficiency is 68%, then the pump power requirement is approximately 16.35 kW ÷ 0.68 efficiency = 24.4 kW.

In comparing the two relationships and the associated results, evaluators can see that the primary difference is in the pump efficiency value, which of course should be the case unless the head loss due to friction is excessive.

The previous series of calculations provides the size of the drain pump and the diameter of the associated pipe, which are both needed to determine the associated costs. This series also represents a process that estimators can use to determine the cost parameters associated with almost any continuous-flow operation. Of course, the equipment use value (in terms of hours per day) for continuous-flow systems is usually apparent because these types of systems either operate for the entire shift or the entire day.

Evaluators often find it difficult to determine mine ventilation requirements and the associated cost parameters. To determine these parameters, evaluators must have an understanding of both the energy required to move air through the mine and the volume of air that must be moved. Typically, the nature (length, perimeter, and roughness) of the openings that provide access to the deposit are examined along with the same qualities of the stopes to approximate the energy required to deliver air to the underground workings. Flow rates are based on the number of workers, the amount of air required to dilute diesel fumes, and any volume losses through rock structures or abandoned workings. The energy and volume values, when considered along with the natural ventilation properties of the designed workings, are then used to approximate the size and horsepower requirements for the fans, or in other words, the parameters needed to estimate costs.

Ventilation calculations are really beyond the scope of most early-stage feasibility studies. However, they must be considered in a cost estimate because they can represent the one item that can profoundly change the size (or number) of the deposit access openings. If ventilation horsepower requirements are excessive (for instance, if large volumes of air must be pushed through a very limited number of small openings), then operating costs increase dramatically, and either the size of the openings should be enlarged or there need to be more openings. Total ventilation requirements can be estimated quite reliably using curves based on the annual tonnage mined and whether or not the mine is fully diesel mechanized.

After most of the equipment and associated labor parameters have been approximated, evaluators need to begin to determine supply consumption. Evaluators may notice that the equipment operating parameters provide the basis for consumption rates of several supplies, such as diesel fuel, electricity, repair parts, lubricants, and tires. However, it is critical to note that the more popular cost services, such as *Mine and Mill Equipment Operating Costs Estimator's Guide* (InfoMine USA

2009a) and the *Cost Reference Guide* (EquipmentWatch 2009) include these as equipment operating costs. Evaluators are cautioned not to include these values twice in their estimates.

When engineers define supply cost parameters, they find that the explosives consumption rate is a good place to start. For estimating purposes, the amount of explosives consumed is reflected in the powder factor. At operating mines, powder factors are determined through trial and experience and are dynamic. Because such information does not exist for a proposed operation, a historic value from a mine that relies on a similar stoping method to recover comparable rock provides a reasonable starting point. Powder factors at operating mines can be found in case studies contained in handbooks such as this or in statistical compilations such as the *Mining Source Book* (Scales 2009). In addition to the explosives consumed in the stopes, estimators also need to consider that explosives are consumed in each development heading and that powder factors will vary from one to the next in relation to the face area, the configuration of the opening, and the rock characteristics. Powder factors for blasts in the development headings are typically higher than those for the production blasts in the stopes.

Estimators can use the explosives consumption rate (typically reported in terms of kilograms of explosive per metric ton blasted) in conjunction with the density of the explosive, the diameter of the blastholes, and a hole-loading factor to approximate the drilling requirements (in terms of meters drilled per day). They can then divide that value by a drill penetration rate to arrive at drill use (in terms of hours per day) and, subsequently, the minimum required number of drills and drillers. Estimators can also use drilling requirements to approximate the number of blasting caps and the lengths of fuse consumed each day. And when viewed in relation to drill bit and steel wear rates, the daily drilling requirements can also provide the consumption rates for these supplies.

Consumption rates for many of the supplies needed at a mine are directly tied to the advance rates of the development openings in which they are placed. The following are obviously used up at a rate that mimics the rates of advance of the associated development openings (both prior to and during production): compressed air pipe, freshwater pipe, drainage pipe, electrical cable, ventilation tubing, and rail. Rock bolt, timber, shotcrete, and rock bolt matt requirements also vary in proportion to the advance rates of the development openings.

Evaluators quickly notice that the tasks of estimating the consumption rates for supplies and the daily use requirements for the mining machinery are not difficult. They do, however, often find it difficult to fully understand and incorporate all of the implications of the differing specifications for all these supplies and machines (tapered vs. rope-threaded drill rods, ANFO vs. emulsion explosives, friction-set vs. resin-set rock bolts, hydraulic vs. pneumatic drifters, etc.). Although a full knowledge of all of these implications is not necessary for a reliable estimate, engineers who fully understand them will most certainly have increased confidence in their results.

COST ESTIMATES

After an evaluator has established all of the cost parameters, the estimation process is one of simple calculations and tabulations. Because most costs, both capital and operating, are tied to average daily equipment use, supply consumption, wages, or salaries, estimators from this point forward need only identify the most reliable source of cost information, apply the costs to the previously derived parameters, and then tabulate the results. This process is well demonstrated in the cost models found in Appendices 4.8A through 4.8C. (Daily equipment use varies greatly according to the mine development schedule, so the estimate must be based on "snapshots" of the schedule at representative times; that is, this snapshot is the goal.)

Evaluators calculate equipment operating costs by multiplying use (in terms of hours per day) by the hourly operating costs for the machine, which they typically glean from sources that include the *Mine and Mill Equipment Operating Cost Estimator's Guide* (InfoMine USA 2009a) and the *Cost Reference Guide* (EquipmentWatch 2009). Costs from these sources are categorized as to repair parts and labor, fuel, electricity, lubricants, tires, and ground-engaging components (bucket teeth, tracks, etc.). Those preproduction development costs associated with machine use are really just summations of equipment operating costs over the period of time needed to excavate the development openings. When the mine is in production, daily equipment use varies according to the mine development schedule, so estimates should be based on a representative "snapshot" (or series of snapshots).

Labor costs are determined in a similar manner. To arrive at daily labor costs, estimators need only multiply the number of workers assigned to any one discipline by the number of hours worked per shift and then multiply the result by the associated hourly wage (factored for burden). Wages from mines found throughout North America can be found in labor surveys published by InfoMine USA. The factors shown in Table 4.8-1, when applied to average wages for the United States, are sometimes used to roughly estimate wages in other parts of the world.

These factors are based on mandated minimum wages in the respective countries, and as a consequence, they provide only a rough guideline and should be used with some caution. As an evaluation progresses, estimators should attempt to gather actual salary and wage data for the region in which the project is located. A case can be made that that labor efficiency is proportional to wage rates, so that more people are required to achieve the same result in lower-wage environments. Consequently, lower wage rates rarely result in proportionally lower operating costs. Wages must be factored for the additional expenses incurred by the employer for each employee.

These expenses, commonly referred to as burden, include contributions to Social Security taxes, worker's compensation and unemployment insurance, retirement plans, and medical benefit packages. Additionally, evaluators must factor either the wages or the work force to account for the expenses associated with vacation and sick leave, shift differential allowances, and overtime pay. Publications available from InfoMine USA contain extensive details of the costs of these benefits at more than 300 active operations. Estimators calculate costs for salaried workers in a manner similar to those that they use for hourly workers, and the sources for salaries are the same as those for wages.

Finally, evaluators calculate supply costs by multiplying daily consumption rates by the prices of the consumables. These are typically gleaned from individual vendors or from *Mining Cost Service* (InfoMine USA 2009b). As with those associated with equipment operation and labor, the expenses associated with supply consumption contribute both to preproduction development and to operating costs. Estimators need to tally the costs of items such as pipe, rail, ventilation tubing, electric cable, rock bolts, and shotcrete for each development

Table 4.8-1 Adjustments for wages worldwide

Country	Percentage of Average U.S. Wage
Australia	141.1
Brazil	29.4
Cambodia	13.9
Chile	30.3
Croatia	55.5
Czech Republic	55.2
Ecuador	41.3
Indonesia	8.1
New Zealand	131.6
Peru	34.8
Russia	14.4
South Africa	22.8
Sri Lanka	12.1
Thailand	18.7
Venezuela	36.7
Zambia	9.4

opening, both before and during production, along with expenses of drill bits, explosives, caps, and fuses.

Up to this point, costs have been estimated in terms of dollars per day. The utility of this approach now becomes apparent. Operating costs are most often reported in terms of dollars per ton of ore, and capital costs are typically reported as annual expenditures. To report operating costs in the appropriate terms, evaluators need only divide the sum of the daily operating costs by the total amount of ore mined each day. For capital costs, evaluators can simply multiply the daily costs for a specific task by the number of days it takes to complete that task (for instance, the number of days needed to complete an adit) or, if the task takes more than a year to complete, by the number of days spent on the task each year.

Operating costs typically include a miscellaneous allowance for expenses too small or too numerous to list separately, or for expenses associated with unscheduled and unanticipated tasks. Evaluators sometimes account for such uncertainties by always faulting to the generous side when they calculate each cost estimation parameter. However, it is preferable to include and list the allowance as one separate value so that those who rely on the estimate can judge its impact for themselves.

Capital costs should include a contingency fund. As opposed to the function of the miscellaneous allowance that was included with the operating costs, the contingency fund is an actual expense that represents an account set aside for any additional, unforeseen costs associated with unanticipated geologic circumstances or engineering conditions. The contingency fund is not in place to cover inadequacies in the cost estimate or failings in the mine design, but the amount of the fund is typically proportional to the amount of engineering that has gone into the project. The money is almost always spent.

Evaluators also need to account for several other expenses in the capital-cost tabulation. These include costs associated with efforts expended on project feasibility, engineering, planning, construction management, administration, accounting, and legal services. For lack of better information, estimators commonly factor values for these from the overall (equipment purchase plus preproduction development) capital cost. A variety of sources report an equivalent variety of factor values, but some of the more commonly used factors include the following:

- Feasibility, engineering, and planning: approximately 4% to 8%
- Construction supervision and project management: approximately 8% to 10%
- Administration, accounting, permitting, and legal services: approximately 8% to 14%

As an alternative, evaluators can base these values on estimates of the time spent on each in conjunction with the salaries of the suitable personnel because most of the expenses are attributable to their work (along with the associated office overhead). However, many of these preproduction tasks are often outsourced, and if such is the case, the associated expenses should be adjusted accordingly.

To permit a mine, engineers are typically required to submit the results of much of the work that they undertake during the feasibility, engineering, and planning process to the appropriate permitting agencies. Estimators are cautioned not to include these expenses twice in their evaluations, once as part of the feasibility, engineering, and planning cost and again as part of the permitting cost.

ECONOMIC EVALUATION

To determine the economic viability of a proposed mine, evaluators must compare estimated costs to anticipated revenues under the economic conditions linked to the project (taxes, royalties, financing, etc.). As mentioned previously, costs are categorized as either capital or operating so that they may receive the appropriate treatment in an after-tax analysis. Operating costs are those that can be directly expensed against revenues as they accrue and include funds that an organization spends operating the equipment, purchasing supplies, and paying wages and salaries. Capital costs are those that cannot be fully expensed in the year incurred and include items such as the following:

- Exploration
- Property acquisition
- Engineering and construction management
- Mine and mill equipment purchase
- Infrastructure
- Preproduction development
- Buildings
- Contingency fund
- Working capital
- Postproduction reclamation

Estimators categorize operating costs in several ways. Production-oriented evaluators are typically most comfortable with results that reflect costs in terms of dollars per unit of development (e.g., dollars per meter of drift) or dollars per unit of production (e.g., dollars per metric ton mined). Because operators primarily write checks to the supply vendors, the equipment manufacturers, or the workers (wages and salaries), many evaluators prefer to see costs broken down accordingly. The choice is really just a matter of preference tempered with intended use. Because most early-stage economic evaluations intend only to estimate overall operating costs, the breakdown is not critical, only the results.

The process of an after-tax discounted-cash-flow economic evaluation is beyond the scope of this discussion. Reliable results are based on many factors in addition to the

estimated costs. Project revenues, for instance, are not simply the product of the commodity price, the production rate, and the resource grade. The recovered grade, for instance, must be factored for losses and dilution at the mine, and for concentration inefficiencies at the mill. Charges that the operator must pay for smelting and refining must be considered, as must penalties for deleterious minerals. Federal and state income taxes, as well as sales, property, and severance taxes, reduce anticipated revenues. And if operators rely on external financing to back their project or if royalties must be paid to partners, property owners, or other entities, then project economics are further diminished.

In closing, one should keep the estimate in perspective. There is no way to exactly predict the costs of a proposed mine, and all evaluators know that their estimate will ultimately be proven wrong. However, evaluators must do their best to minimize the extent to which their estimated values differ from the actual project costs.

UNDERGROUND MINE COST MODELS

Appendices 4.8A through 4.8C present three cost models that evaluators can use to make preliminary, order-of-magnitude estimates for projects for which there is limited deposit information. These models are based on theoretical engineering parameters and do not represent any specific mine. They include the following techniques: room-and-pillar mining, block-cave mining, and mechanized cut-and-fill mining.

Engineers do not rely on models to make significant economic decisions. A cost model, no matter how carefully the estimator prepares it, is only a representation of a hypothetical set of resource parameters and cannot be expected to represent costs for a specific deposit with the degree of reliability necessary for investment. Models can, however, be quite useful as comparative tools, and evaluators often rely on them to establish cutoff grades for preliminary reserve estimates.

The figures in the appendices are idealized sketches of the stope layouts for each model.

Model Construction

The models presented in Appendices 4.8A through 4.8C were developed by evaluating sets of hypothetical resource parameters using standard engineering-based cost-estimating techniques (such as those described in the preceding paragraphs) to approximate capital and operating costs for underground mine designs based on specific deposit parameters. Some of the selected salary, wage, and supply costs on which the program relies are listed in Tables 4.8-2 through 4.8-4. These are the most recent values from *Mining Cost Service* (InfoMine USA 2009b).

Cost estimates for the modeled projects list all of the labor, material, supply, and equipment operating expenses accrued at the mine site, including those associated with supervision, administration, and on-site project management. Also listed are the costs of purchasing and, if necessary, installing all of the necessary machinery, as well as those associated with preproduction development work and constructing the surface facilities. Costs not included in the estimates are as follows:

- Exploration
- Off-site roads, power lines, or railroads
- Taxes (except sales tax)
- Depreciation
- Off-site product transport

Table 4.8-2 Annual salaries for professionals (2009 dollars)

	Annual Salary, US$	
Job Title	**Small Mines**	**Large Mines**
Mine manager	93,300	153,000
Superintendent	72,000	104,700
Foreman	62,000	71,500
Engineer	75,500	83,100
Geologist	62,500	71,000
Shift boss	54,000	66,000
Technician	40,000	50,000
Accountant	52,000	60,800
Purchasing agent	60,000	64,800
Personnel manager	68,000	99,900
Secretary	30,000	36,200
Clerk	32,000	35,800

- Town site construction and operation
- Incentive bonus premiums
- Sales expenses
- Interest expense

Each modeled mine includes at least two routes of access to the deposit. For mine models that produce less than 4,000 t/d through a single shaft, a secondary access raise provides emergency egress and completes the ventilation circuit.

In the models, ore and waste rock densities are 0.367 and 0.401 m^3/t, respectively. Ore swells to 155% of its in-place volume on excavation, and waste swells to 145% of its in-place volume. Rock-quality designations and compressive strengths vary from one model to the next. Values for several methods from a variety of mines are listed in Table 4.8-5.

Preproduction development work blocks out enough ore to initiate operations at the design production rate. And the level of production development work is designed to maintain that rate throughout the life of the mine. All shop, office, worker changehouse, warehouse, and mine plant buildings are constructed on the surface. Working capital allows for 2 months of project operation, and a sales tax rate of 6.75% is applied to all equipment and nonfuel supply purchases. Capital costs do not include the expenditures associated with outside contractors, infrastructure, home office overhead, insurance, or project startup (except working capital). Costs are in late 2008 and early 2009 dollars.

Unit Costs

Wages and salaries used in the models represent U.S. national averages as reported in *U.S. Metal and Industrial Mineral Mine Salaries, Wages and Benefits, 2009 Survey Results* (Salzer 2009). In keeping with the results of that survey, lower wages and salaries are used for the smaller mines, and higher wages and salaries are used for larger mines. In the models, the cutoff point between small and large mines is set at 100 employees. Equipment and supply prices are, for the most part, taken from *Mining Cost Service* (InfoMine USA 2009b).

In the models, the salaries shown in Table 4.8-2 are adjusted upward to account for a 38.0% burden rate at the small mines and a 44.0% burden rate at the larger mines. Hourly wages used in the cost models are shown in Table 4.8-3. The wages shown in Table 4.8-3 are adjusted upward to account for a 38.0% burden rate at the small mines and a 44.0% burden rate at the larger mines. Supply prices used in the models are shown in Table 4.8-4.

APPENDIX 4.8A
COST MODELS FOR ROOM-AND-PILLAR MINING

These models represent mines on flat-lying bedded deposits that are 2.5, 5.0, or 10 m thick, respectively, with extensive areal dimensions. Access is by two shafts that are 281, 581, or 781 m deep and a secondary access/vent raise. Ore is collected at the face using front-end loaders and loaded into articulated rear-dump trucks for transport to a shaft. Stoping follows a conventional room-and-pillar pattern, with drilling accomplished using horizontal drill jumbos. A diagram of the development requirements for room-and-pillar mining is shown in Figure 4.8A-1, and cost models are shown in Table 4.8A-1.

APPENDIX 4.8B
COST MODELS FOR BLOCK-CAVE MINING

These models represent mines on large, bulk deposits, roughly 450, 525, and 600 m to a side. Access is through three to five shafts that are 430, 530, or 630 m deep and by secondary access/ventilation raises. Ore is collected using slushers, and haulage from the stopes is by diesel locomotive. Stope development includes driving drifts (haulage, slusher, and undercut) and raises (stope draw, orepass, and boundary weakening). Caving is initiated by blasting on the undercut level. A diagram of the development requirements for block-cave mining is shown in Figure 4.8B-1, and cost models are shown in Table 4.8B-1.

APPENDIX 4.8C
COST MODELS FOR MECHANIZED CUT-AND-FILL MINING

These models represent mines on steeply dipping veins, 3.5, 4.0, or 4.5 m wide, respectively, and 500, 1,400, or 1,900 m along the strike. Access is via a shaft that is 524, 719, or 863 m deep. Haulage to the shaft is by scoop tram. Stoping includes drilling and blasting with jumbos, ore collection and haulage from the stopes by scoop tram, and sand filling. A secondary access/vent raise extends to the surface. A diagram of the development requirements for mechanized cut-and-fill mining is shown in Figure 4.8C-1, and cost models are shown in Table 4.8C-1.

CHAPTER 4.9

Cost Estimating for Surface Mines

Scott A. Stebbins and Jennifer B. Leinart

INTRODUCTION

It is obvious that costs vary from one mine to the next. So, although it is of interest to know the costs associated with surface mines in general terms, it is also important to understand how to estimate the costs of a proposed operation in a way that considers the unique development and operational parameters, and subsequently costs, of each deposit. Although focusing primarily on how to estimate costs, this chapter also includes general operating expenses for typical surface mine configurations.

There are probably as many ways to estimate mining costs as there are cost estimators. Because of the lack of a standardized approach, evaluators are left to estimate costs as best they can, so almost everyone uses a slightly different method. A standardized method that suits every situation would be extremely difficult to develop, given that each proposed mine is unique and conditions can be so variable. Although no such approach exists, many well-documented methods are available. For example, there are the tried-and-true, broad-brush approaches, one of which is the parametric method, where costs are derived from general algorithms (or curves) of the following form:

$$\text{cost} = x(\text{parameter})^y$$

The parameter in these algorithms can be almost anything, but most often it is the production rate. The x and y values are derived through statistical evaluations of known or estimated cost data. The U.S. Bureau of Mines Cost Estimating System, also known as CES (USBM 1987), can be considered a parametric approach, as can methods developed by O'Hara (1980) and Mular (1982).

Another example of a broad-brush method is the factored approach. Usually with this technique, one primary cost (such as the cost of the purchased equipment) is subjected to a series of factors to estimate all the other pertinent costs of the project (Vilbrandt and Dryden 1959). This method has fallen out of general use because it is, in light of subsequent approaches, considered too general.

Evaluators also commonly rely on a comparative approach. With this method, estimators examine costs at similar projects and make adjustments, often through the use of scaling factors (Schumacher and Stebbins 1995), to account for differences in operating parameters. This may be the most comforting of the broad-brush approaches, but it can also be the most misleading. Conditions simply vary too much from one project to the next to rely too heavily on comparative costs. If conditions were the same at every deposit, then assigning costs from a past or similar project would be acceptable, and the approach would be widely used. But it is the differences in the operating parameters from one project to the next that dictate the differences in costs, so these must be fully considered.

Cost models are a form of the comparative approach. These consist of a compilation of cost estimates along with the parameters on which those estimates are based. Evaluators find the example from within the compilation that most closely resembles their project, and they then use the costs associated with the example as an indication of the costs at their project. Example cost models for typical surface mine configurations can be found in Appendix 4.9A.

Significant effort went into the derivation of the specific variations of the aforementioned methods, and each represents an invaluable source of useful, reliable information. In particular, the CES curves (USBM 1987) enable evaluators to estimate costs for a multitude of mining and mineral processing activities for which no other source exists. But, arguably, the concern with each of these approaches is the lack of transparent detail. Evaluators are left to wonder if results truly represent their project. Even though broad-brush methods are often used because much of the information needed for more detailed analyses is difficult to obtain, evaluators still continually strive for more verifiable, and hence reliable, results.

In the past, the broad-brush approaches also maintained their popularity in part because more detailed analyses were time-consuming. Over the past 20 years, however, things have changed. Most evaluators now use a more detailed, engineering-based approach to estimating costs at almost every stage of

Scott A. Stebbins, President, Aventurine Mine Cost Engineering, Spokane, Washington, USA
Jennifer B. Leinart, CostMine Division Manager, InfoMine USA, Spokane Valley, Washington, USA

project evaluation. Two events have led to this eventuality: The first was the development, publication, and distribution of *Mining Cost Service* (InfoMine USA 2009b), along with an increase in the availability of information similar to that contained in *Mining Cost Service* through the Internet. This annually updated document is a comprehensive compilation of current mine and mineral processing cost information. The second event was an improvement in spreadsheet and application-based calculation modeling capabilities, which enabled evaluators to handle the significant increase in the amount of work associated with engineering-based estimates in a timely manner. Evaluators now conduct engineering-based estimates in time frames previously achievable only when they used the broad-brush approaches.

ENGINEERING-BASED, ITEMIZED COST ESTIMATING

The method detailed in the next few paragraphs is best described as an engineering-based, abbreviated, itemized approach. It consists of three major steps, along with a highly variable number of minor steps.

In the first step, estimators design a mine to the maximum extent possible given the available information. For a deposit that can be mined using surface techniques, even a general pit outline, an overall depth, and a delineation of the routes to the processing plant and the waste stockpiles provide a great deal of information pertinent to the cost estimate.

In the next step, evaluators estimate or calculate all the parameters associated with the things that cost money: the workers, the equipment fleet, and the consumable supplies. This step is where an estimator expends the most effort, although the first design step previously outlined is the most important in achieving reliable results.

The final step is the simplest, thanks to publications such as *Mining Cost Service*. Evaluators need only apply known unit costs for labor, equipment operation, and supplies to the projected and calculated development and operating parameters to arrive at estimates of the operating costs (in addition to estimates of many of the preproduction development costs). They then need to apply equipment purchase prices along with the costs of some common mine facilities to the previously determined parameters to arrive at the primary components of a capital cost estimate.

The advantages of the engineering-based, itemized approach are many. It can be applied at almost any stage of a project evaluation, from the initial phases when information is scarce to the final stages when almost all pertinent resource and project characteristics have been established. It is reliable in that it concerns itself almost exclusively with parameters specific to one deposit. It lends itself well to computerization because so much of the work involves simple calculations (albeit a lot of them) that are easily encoded on a spreadsheet or a Windows-based application. It is easily adjusted and updated as more information becomes available. As such, the reliability of the estimate increases as the information base expands. And when the evaluation stage is complete, the final computerized product is (in essence) a dynamic cost model that engineers can use to examine operational alternatives throughout the life of the mine.

Traditionally, and logically, evaluators have kept the level of detail in their cost estimates comparable with the amount of information available for the deposit. Unfortunately, it is sometimes tempting to reduce the level of detail in an effort to reduce the amount of time spent on the estimate. Ignoring detail by procedures such as averaging site parameters or combining cost components can reduce the representativeness of the estimate. For instance, if haul distances and gradients for individual haul segments can be gleaned from maps and plans, the cycle time associated with the haul may be significantly different than the cycle time for a more convenient but less reliable overall distance and average gradient (over the entire distance). Example 4 (presented later in this chapter) helps to illustrate this point.

Just as significantly, combined cost values, such as those presented for equipment operation in various publications, can also lead to estimates that are not fully representative. If such costs are broken down into individual components, (i.e., fuel, lubricants, repair parts, tires, and wear parts), then each component can be adjusted individually to suit conditions. For instance, in a situation where a mobile loader is used to collect extremely abrasive rock, the evaluator might adjust the tire and wear part consumption rates upward. If these components were not treated separately, the evaluator might simply adjust the entire composited operating cost upward. The significance of avoiding such an approach is this: If you increase the tire consumption rate by 100% (i.e., multiply the tire operating cost by 2) and the tire cost is initially 10% of the overall operating cost, then the impact on the overall machine operating cost is minimal, as would be any error in the evaluator's assumption of the increase. And, because equipment operating costs may only represent 25% of the overall operating cost, the impact of any error would be even less. In essence, a 100% error in a cost component that comprises only 2.5% of the overall cost is much less significant than a similar error in a cost component that comprises 25% of the overall cost.

GETTING STARTED

Often, where to start is the question. It is sometimes a difficult question to answer when an estimator is trying to figure out how much a deposit will cost to mine. However, when evaluators begin the process of approximating the costs of a mining project, they soon notice a synergy. As one parameter is determined, the value of another is often defined. For instance, as the number of trucks needed to haul the ore is determined, the number of drivers required to operate the trucks and the number of mechanics needed to maintain them are also determined. An evaluator can then use those values to begin the process of estimating the sizes of the shop, the parking lot, the living quarters (if needed), and the workers' changehouse.

A few things must always be known to estimate the costs of a surface mine. The first four things to look for are a target production rate, a stripping ratio, the ore and waste haul profiles, and an estimated powder factor. Just those four items provide a good start.

The target production rate is most often based primarily on the overall size of the resource, although the assets of the operator play a secondary role. In very general terms (from a strictly economic perspective), the more revenues that the project generates early in its life, the better. To that end, operators in a perfect world prefer to maximize the production rate and initiate operations as soon as possible. On the other hand, operators often rely on revenues from the project to fund further development and expansion and thereby minimize early expenditures and the associated economic risks. For the purposes of early-stage feasibility analyses, estimators often aim for somewhere in the middle. A variation of Taylor's rule (Hoskins 1977) provides a reasonable value and is expressed as follows:

$$\text{capacity, t/yr} = (\text{metric tons resource}^{0.75}) \div 70$$

In comparison to production rates at active mines, results from this equation (which was in use as far back as the 1970s) are now conservative. Operators now try to drive economic conditions in their favor by taking advantage of economies of scale. Doing so also shortens the duration of their projects. As an added economic benefit, revenues (and hopefully profits) are maximized as early as possible in the project. A current and more representative equation that works in a manner similar to the variation of Taylor's rule just mentioned is as follows:

$$\text{capacity, t/yr} = (\text{metric tons resource}^{0.69}) \div 20.12$$

For the other items, a sketch or two can be of great help. A plan view of a proposed pit, the surrounding terrain, and the location of the mill and waste dump sites along with a few cross sections through the pit and along the main haul routes furnish the information needed to roughly estimate the stripping ratio and to define the haul-route profiles.

DRILL AND BLAST

To estimate the costs of drilling and blasting, engineers can glean a great deal of information from just a powder factor. Such a factor (which is most often reported in terms of kilograms of explosive per metric ton blasted) of course differs from one project to the next and is typically determined through experimentation, observation, and adjustment over time at an active operation. Consequently, the value will not be known ahead of time. But reported powder factor values are plentiful in books such as this handbook, in case studies contained in periodicals, and in publications such as the *Mining Source Book* (Scales 2009).

A powder factor from a mine in rock similar to that of a proposed project should supply an initial value that is within reason. From this one value, engineers can of course estimate the cost of explosives in terms of dollars per metric ton of ore. But in addition, they can also estimate how much (in terms of meters) to drill each day, which in turn provides the number of blastholes that must be drilled each day, and that value in turn furnishes the number of caps and boosters consumed each day.

With the daily drilling requirements in hand, estimators can approximate values for daily drill use (in terms of hours per day), drill bit and steel consumption, and (with all this previous information) they can proceed to gauge the required number of drillers and blasters. All of this is a lot to derive from just a powder factor and it is important to remember that for an early-stage cost estimate, precise values are not necessary (nor can they be expected). Reasonable, representative values are required, but highly precise values are simply not obtainable at the early stages of a cost estimate unless the information needed for such precision exists.

To illustrate the process, Example 1 works from a powder factor to estimate consumption rates (and subsequently costs) for explosives, caps, detonation cord, and drill bits and steel. From there, estimated values are further used to suggest drill use (in terms of hours per day) as well as labor requirements.

Example 1

Consider the case where the following have been determined:

- Production rate = 5,000 t/d
- Stripping ratio = 2.5:1 t waste to t ore
- Ore powder factor = 0.305 kg/t ore
- Waste powder factor = 0.331 kg/t waste
- Explosive (ANFO) specific gravity = 0.80
- Hole diameter = 15.24 cm
- Bench height = 12.20 m
- Subdrilling = 1.43 m
- Stemming = 4.27 m
- Drill bit penetration rate = 1.10 m/min
- Drill bit consumption = 2,500 m/bit
- Worker efficiency = 83%
- Drill relocation and setup = 2 min/hole

Based on this information, the following can be calculated.

1. Explosive consumption:

   Ore: 5,000 t/day $\times$ 0.305 kg/t ore = 1,525 kg/d

   Waste: 5,000 t ore/d $\times$ 2.5 t waste/t ore $\times$ 0.331 kg/t waste = 4,138 kg/d

   total = 1,525 kg/d (ore) + 4,138 kg/d (waste) = 5,663 kg/d

2. Daily drill-hole volume:

   5,663 kg/d $\times$ (0.80 $\times$ 1,000 kg/m^3)) = 7.08 m^3/d

   unit volume of blasthole = [π $\times$ (15.24 cm $\times$ 100 cm/m)^2] $\times$ 4 = 0.01824 m^3 per meter of depth

3. Daily drilling requirements:

   total drilling (explosives only) = 7.08 cm^3/d $\div$ 0.01824 m^3/m drilled = 388 m/d

   hole loading factor = ((12.20 m + 1.43 m) – 4.27 m) $\div$ (12.20 m + 1.43 m) = 0.687

   total drilling requirement = 388 m $\div$ 0.687 = 565 m/d

   holes drilled each day = 565 m $\div$ (12.20 m + 1.43 m) $\approx$ 42 holes

4. Drill use:

   daily drill use = (565 m $\div$ 1.1 m/min) $\div$ 60 min/h $\approx$ 8.56 h/d

5. Worker requirements for drilling:

   daily drilling = 8.56 h/d + ((2 min $\times$ 42 holes) $\div$ 60 min/h) = 9.96 h/d

   worker requirement = 9.96 h/d $\div$ 0.83 (worker efficiency) = 12.0 h/d

6. Worker requirements for blasting:

   blasthole loading = (4 min/hole $\times$ 42 holes) $\div$ 60 min/h = 2.80 h/d

This example points out the one real difficulty of engineering-based itemized cost estimates—values for several parameters are not always readily apparent or available. Powder factors, drill penetration rates, drill bit consumption rates, and bench heights have yet to be determined in the early stages of project evaluation, and subdrilling depths and stemming requirements have yet to be calculated. In the engineering-based itemized approach, evaluators determine most such parameters using one of two processes: statistical analysis of reported data or calculations based on established engineering relationships.

In Example 1, various mine operating information sources are searched to compile a series of data points. As mentioned earlier, these sources include case studies printed in periodicals, data in publications such as the *Mining Source Book* (Scales 2009), and compilations in handbooks such as this. For example, if engineers need to estimate a powder factor, they might first collect and compile as many reported values as possible. At the same time, they would identify a parameter related to the powder factor and gather associated, representative data points. Powder factors are often listed along with a rock type, for instance, and rock types can be roughly related to compressive strengths (discussed in other chapters of this handbook). With these two data strings (powder factors and rock compressive strengths), evaluators can develop an empirical relationship that they can then use to estimate a powder factor based on the rock type (as represented by an estimate of the compressive strength of the rock). Typically, such a relationship must be derived through geometric regression of the data. One such compilation (based on information primarily from the *Mining Source Book* and this handbook) provided the following algorithm:

$$\text{powder factor, kg/t} = 0.0240 \times (\text{compressive strength, MPa})^{0.4935}$$

Geometric regression analysis is outside the scope of this discussion but is detailed in most statistical analysis textbooks.

For a specific deposit, values for the compressive strength of the rock become clearer as more information becomes available and actual testing begins, but the value gained through the regression should provide a reasonable basis for early estimates. And, while for illustrative purposes in this chapter, the powder factor is related to rock strength, it may be more closely tied to other factors such as the production rate, explosive type, or rock quality. When a relationship such as this has been derived, it can be used to estimate values at other properties.

Evaluators also rely on standard, established engineering relationships to determine some of the project cost parameters. In Example 1, for instance, if the bench height is 15 m, an engineer can rely on well-established blasting design algorithms (Olofsson 1997) to determine subdrilling and stemming requirements as shown in Example 2.

Example 2

1. Maximum blasting burden:

   $\text{maximum burden} = 1.36 \times (L_b^{0.5}) \times R_1$

   where

   L_b = charge concentration ~ 14.5 kg/m (Olofsson 1997)

   R_1 = correction for vertical drilling ~ 0.95 (Olofsson 1997)

   $\text{maximum burden} = 1.36 \times (14.5^{0.5}) \times 0.95 = 4.92 \text{ m}$

2. Subdrilling:

   $\text{subdrilling} = 0.3 \times 4.92 \text{ m (maximum burden)} = 1.48 \text{ m}$

3. Error in drilling:

   $\text{error in drilling} = [152 \text{ mm (blasthole diameter)} \div 1{,}000] + (0.03 \times (15 \text{ m} + 1.48 \text{ m})) = 0.65 \text{ m}$

4. Adjusted burden:

   $\text{burden} = 4.92 \text{ m (maximum burden)} - 0.65 \text{ m} = 4.27 \text{ m}$

5. Stemming:

   stemming = 4.27 m (equivalent to burden)

Although Example 2 relies on algorithms from Olofsson (1997), there are several such sources for drilling and blasting engineering calculations, and each may be more or less detailed in its approach. It is only important that, in the early stages of an evaluation, estimators arrive at reasonable, reliable numbers.

As is evident, both of these values (stemming and subdrilling depths) are needed to provide a reasonable estimate of daily drilling requirements (in terms of meters drilled). When an evaluator analyzes these values in conjunction with the bench height, the result is the number of holes that must be drilled each day and, subsequently, the number of caps and boosters consumed on a daily basis.

EXCAVATE AND HAUL

Estimators find that most of the expense of any surface mine is attributable to excavating the rock, loading it into some sort of conveyance, hauling it somewhere (either a mineral processing plant or a stockpile), and then dumping it. Consequently, a representative estimate hinges on the reliability of the excavating and hauling costs.

As with the cost estimates of all the other surface-mining tasks, the basis for the costs of excavating and hauling begins with the design. It is crucial to know the routes over which the ore and waste will be hauled. The more that is known about these routes, the more reliable the estimates will be. Distances and gradients are the key components. And while average gradients over total haul distances can be used, much more reliable results are achieved if the routes are split into segments at each significant change in gradient. The importance of carefully defining the distances and gradients of each segment increases with the stripping ratio. Evaluators find that large projects with high stripping ratios can become, in essence, waste bound, in that the space needed to stack and store waste is at a premium. At such deposits, operating costs are more sensitive to waste haul distances and gradients than to any other factor.

To estimate excavating and hauling costs, evaluators must first determine cycle times for both the excavators and the haul trucks. Evaluators use these cycle times in conjunction with respective machine capacities to gauge the size of the required fleet and to eventually estimate operating costs and purchase prices. If the purpose of an evaluation is to estimate the average costs of production for the project, then the haul profiles should be defined at a point halfway through production. In other words, they should be based on the pit profile at that point in time when about half the resource has been extracted. When engineers structure the cost-estimating process on a spreadsheet or through a Windows application (or any number of other computerized approaches), it is entirely possible for them to estimate the costs associated with haul profiles from any bench, in fact from any point on any bench, in the pit. This is, of course, pertinent when an evaluator is optimizing a resource with software that asks for production costs from various benches as part of the optimization process.

Cycle times for excavators are, for the most part, fixed and related to machine size. Wheel loaders are the exception

in that they are sometimes called on to travel a short distance from the active face to the loading point. Most tracked excavators simply pivot after they collect a load of broken rock to transfer that load to the truck. Truck cycle times are more complicated. Although some of the time components are fixed (spot, load, dump, and turn), travel times typically represent the largest component of a truck's cycle. It is also the component that typically has the greatest impact in distinguishing costs at one project from those at another.

Engineers attempt to achieve the following goals as they design the excavator and hauler segments of their mine plan:

- Three to six loader cycles should completely fill the truck bed.
- Loader bucket capacities should be selected so that, whatever the number of cycles, the truck is full or close to full after loading is complete. For instance, a 7.0-m^3 bucket could be used to fill a 21.0-m^3-capacity truck, but it would be inefficient if used to fill a 17.0-m^3-capacity truck. Two loads would not fill the 17.0-m^3-capacity truck completely, but three loads would overfill it.
- The number of trucks and the number of loaders should be determined to minimize both the amount of time that any loader must wait for a truck and the amount of time that any truck must wait in a queue to be loaded.

To meet these goals, engineers rely on a multistep process. First, they estimate the loader cycle time and use it in conjunction with the loader's bucket capacity to determine the number needed to meet production goals. This first step is straightforward and proceeds as shown in the following example.

Example 3

Estimate daily excavator and truck use for the following situation:

- Shift length ≈ 8 h
- Production schedule ≈ 2 shifts/d
- Waste production capacity ≈ 18,000 t/d
- Front-end-loader bucket capacity (volume) ≈ 11.5 m^3
- Front-end-loader bucket capacity (weight) ≈ 21.7 t
- Average bucket fill factor ≈ 90%
- Material weight ≈ 2,400 kg/m^3
- Material swell ≈ 55%
- Cycle time
  - Load ≈ 12 s
  - Lift and swing time ≈ 12 s
  - Dump time ≈ 8 s
  - Return and lower time ≈ 10 s
- Rolling resistance ≈ 3%
- Haul profile
  - *Segment 1:* From working face across pit floor, 200 m at 0% gradient
  - *Segment 2:* From pit floor to pit entrance, 1,200 m at 12% gradient
  - *Segment 3:* From pit entrance to waste stockpile, 1,600 m at –6% gradient
  - *Segment 4:* From base of stockpile to top of stockpile floor, 800 m at 12% gradient
  - *Segment 5:* From top of stockpile across to dump point, 200 m at 0% gradient
- Operator efficiency ≈ 83%

1. Bucket load:

   2,400 kg/m^3 ÷ [1 + (55% swell ÷ 100)] = 1,550 kg/m^3

   [11.5 m^3 × 1,550 kg/m^3 × 0.90 (fill factor)] ÷ 1,000 kg/t = 16.0 t

2. Total cycle requirement:

   18,000 t/d ÷ 16.0 t/cycle = 1,125 cycles/d

   [1,125 cycles/d × (12 s + 12 s + 8 s + 10 s)] ÷ 60 s/min = 787.5 min/d

3. Loader operators:

   [787.5 min/d ÷ 0.83 (efficiency)] ÷ 60 min/h = 15.8 h/d

   15.8 h/d ÷ 8 h/shift ≈ 2 operators

Next, an average truck cycle time is determined (see Example 4). Evaluators base both haul and return times (travel times) on the length of the haul and the average gradient over that length. Gradient is defined as the change in elevation divided by the length over which that change takes place. A downhill gradient is typically reported as a negative value, and an uphill gradient is reported as a positive value.

Engineers typically obtain the speeds of the trucks over these haul distances through rimpull/speed/gradeability curves and retarder curves, which are specific for each vehicle. Examples of these curves can be found in the *Caterpillar Performance Handbook* (Caterpillar 2009). Travel speeds (with the vehicle either loaded or empty) for down-gradient segments can be gleaned from the retarder curves, and travel speeds for up-gradient segments (loaded or empty) are taken from the rimpull/speed/gradeability curves.

On examination, it is apparent that the data in these curves can also be subjected to geometric regression analyses to provide relationships that estimators can then use to approximate speeds based on the specific gradients. These relationships do not provide precise results, but they are more than adequate for early-stage cost-estimating purposes. Estimators typically ignore increases in travel times due to acceleration or deceleration over haul lengths of any significance. Over very short hauls, these need to be considered.

Evaluators also need to adjust the travel gradients for rolling resistance. Because of the flexibility inherent in roadbeds and the weight on the tires, trucks always "sink" into the road surface just a little as they travel along. One way to visualize rolling resistance is to view it as the gradient that the tire must continually overcome to drive out of the slight depression that it creates in the roadbed because of the weight that it carries.

Example 4

Consider the following situation:

- Bed capacity (volume) ≈ 60 m^3
- Bed capacity (weight) ≈ 90 t
- Material weight ≈ 2,400 kg/m^3
- Material swell ≈ 55%
- Turn and spot time ≈ 15 s
- Dump time ≈ 8 s
- Return and lower time ≈ 12 s

First, the time to load the truck is estimated from the previous example.

1. Load time:

   60 m^3 bed capacity ÷ [11.5 m^3 bucket capacity × 0.85 (fill factor)] ≈ 6 cycles to load

   [6 cycles × (12 s + 12 s + 8 s + 10 s)] ÷ 60 s/min ≈ 4.20 min/truck

2. Travel time—fully loaded:

   Segment 1: 0% gradient resistance + 3% rolling resistance = 3% total resistance

   [(400 m ÷ 1,000 km/m) ÷ 43 km/h] × 60 min/h = 0.54 min

   Segment 2: 12% gradient resistance + 3% rolling resistance = 15% total resistance

   [(1,200 m ÷ 1,000 km/m) ÷ 9 km/h] × 60 min/h = 8.00 min

   Segment 3: –6% gradient resistance + 3% rolling resistance = –3% total resistance

   [(1,600 m ÷ 1,000 km/m) ÷ 64 km/h] × 60 min/h = 1.50 min

   Segment 4: 12% gradient resistance + 3% rolling resistance = 15% total resistance

   [(800 m ÷ 1,000 km/m) ÷ 9 km/h] ÷ 60 min/h = 5.33 min

   Segment 5: 0% gradient resistance + 3% rolling resistance = 3% total resistance

   [(400 m ÷ 1,000 km/m) ÷ 43 km/h] × 60 min/h = 0.54 min

   total haul time loaded = 15.37 min

3. Turn and dump time = 1.20 min.
4. Travel time—return empty:

   Segment 5: 0% gradient resistance + 3% rolling resistance = 3% total resistance

   [(400 m ÷ 1,000 km/m) ÷ 63 km/h] × 60 min/h = 0.38 min

   Segment 4: –12% gradient resistance + 3% rolling resistance = 9% total resistance

   [(800 m ÷ 1,000 km/m) ÷ 32 km/h] × 60 min/h = 1.50 min

   Segment 3: 6% gradient resistance + 3% rolling resistance = 9% total resistance

   [(1,600 m ÷ 1,000 km/m) ÷ 32 km/h] × 60 min/h = 3.00 min

   Segment 2: –12% gradient resistance + 3% rolling resistance = 9% total resistance

   [(1,200 m ÷ 1,000 km/m) ÷ 32 km/h] × 60 min/h = 2.25 min

   Segment 1: 0% gradient resistance + 3% rolling resistance = 3% total resistance

   [(400 m ÷ 1,000 km/m) ÷ 63 km/h] × 60 min/h = 0.38 min

   total haul time for return = 7.51 min

5. Turn and spot to load = 0.80 min
6. Total cycle time:
   - Load = 4.20 min
   - Travel loaded = 15.37 min
   - Turn and dump = 1.20 min
   - Return time = 7.51 min
   - Turn and spot to load = 0.80 min
   - Total cycle time = 29.08 min
7. Required number of trucks:

   6 cycles/truck × 11.5 m^3/cycle × 0.9 (fill factor) × 1,550 kg/ m^3 = 96,225 kg/load

   18,000 t/d ÷ (96,225 kg/load ÷ 1,000 kg/t) = 187.1 loads/d

   187.1 loads/d × 29.08 min/load = 5,440.9 min/d

   5,440.9 min/d ÷ (2 shifts/d × 8 h/shift × 60 min/h) ≈ 6 trucks

8. Time spent in queue:

   29.08 min/cycle ÷ 6 trucks = 4.85 min available to load truck

   Because 4.85 minutes > 4.20 min/load, then

   time the loader spends waiting for a truck = 4.85 min – 4.20 min = 0.65 min

   Had the time that the loader spent waiting for a truck been negative (i.e., trucks have to wait for the loader), it would have been necessary to increase the size of the loader.
9. Truck drivers:

   5,440.9 min/d ÷ 0.83 (efficiency) ÷ 60 min/h = 109.3 h/d

   109.3 h/d ÷ 8 h/shift ≈ 14 operators

Because of the efficiency of the truck drivers, it is apparent in these estimates that at least one (and probably two) utility operators will be needed to drive the trucks while the regular drivers take their breaks. And if this estimate is to represent the costs at a point in time halfway through the project, then more trucks may be needed later in the project as the pit deepens and haul distances increase. The six trucks indicated at this point are operating close to their maximum capacity.

If, instead of estimating the travel times over each haul segment, evaluators had calculated an average haul gradient over the entire haul distance, the results would have been noticeably different because the average gradient is about 5.0%. The significantly slower segment where the gradients are 12% would not have the same impact on the analysis and the haul-cycle time would be reduced by more than 1.5 minutes. This is one example where a high level of detail, even at a very early stage of an analysis when information is scarce, has a significant impact on the reliability of the results.

Most of the machine specifications stated in the excavator and truck examples were taken from the *Caterpillar Performance Handbook* (Caterpillar 2009). Machine specifications are very often available from equipment manufacturers. Similar information can also be found in *Mining Cost Service* (InfoMine 2009b).

ANCILLARY SYSTEMS

To produce a complete cost estimate, much work remains for the evaluator even after the drilling, blasting, excavating, and hauling costs have been determined. However, these previously determined costs (along with the parameters derived during the estimation process) do provide a basis for estimates of the remaining costs.

To begin with, the costs associated with many of the machines typically found at any surface mine have yet to be estimated. For most such projects, costs for bulldozers, graders, dust suppressant tankers, equipment-maintenance trucks, pumps, lighting plants, personnel movers, and, in some cases, generators, crushers, and conveyors, may all need to be estimated and included.

For each of these machine types, the determining factors that provide the basis for the estimated costs are (as with the drills, excavators, and haulers) the capacity of the machine and how many hours it must operate each day. Consequently, the techniques that evaluators rely on to estimate the capacity and daily use parameters for each are similar to those they use to gauge the same parameters for the drills, excavators, and haulers.

For instance, at almost every surface mine, a fleet of bulldozers manages blasted rock at the working faces and dumped waste rock at the stockpiles (in addition to performing a host of other tasks). The process that estimators use to determine the number and operating requirements of these machines is rarely as straightforward as the process that they use to determine the excavator and loader needs, but it is still based on a very similar approach.

At all but the smallest operations, bulldozers work continuously at each dump site. They also often work at each active face, moving scattered, broken rock to the excavator. The size requirements for these machines are based on the amount of material that they handle each shift and the distance that the material must be moved. Specifically, each blade load carries with it a volume that will be moved over a distance at a speed typically specified in the manufacturer's documentation. With these three parameters (speed, distance, and capacity), an engineer can approximate productivity through the following general relationship:

$$\text{productivity, t/h} = (\text{volume, m}^3 \times \text{density, t/m}^3 \times \text{velocity, m/h}) \div \text{distance, m}$$

And with that, the engineer can estimate daily use as follows:

$$\text{daily use, h/d} = \text{production rate, t/d} \div \text{productivity, t/h}$$

When hourly costs (available from the sources mentioned earlier) are applied to the daily use (hours per day) values, the results report in terms of dollars per day. To arrive at a final value in terms of dollars per metric ton of ore, evaluators need only to divide the dollars per day value by the metric tons of ore mined each day.

Evaluators can use a similar process to arrive at daily use values for the graders and dust suppressant tankers. For instance, consider a road built from friable material in a wet environment that would need to be graded twice daily. If the length and width of the road are known, then an estimator can use the following general relationship to approximate the amount of time spent grading the road each day:

$$\text{productivity, m}^2\text{/h} = \text{velocity, m/h} \times \text{blade width, m}$$

And with this, the evaluator can estimate daily use (in terms of hours per day) as follows:

$$\text{daily use, h/d} = \text{grading requirements, m}^2\text{/d} \div \text{productivity, m}^2\text{/h}$$

As previously demonstrated, when hourly costs are applied to the daily use values, the results report in terms of dollars per day and subsequently in dollars per metric ton of ore.

CAPITAL AND OPERATING COSTS

For the purpose of project evaluation, costs are typically categorized as either *operating* or *capital* (as opposed to *fixed* or *variable*) so that they can be subjected to after-tax, discounted cash-flow analyses. In short, operating costs are those that can be fully expensed in the year incurred. The expenses of the consumables (including those associated with equipment operation), wages, and salaries are typically all considered operating costs and are most often estimated either in terms of dollars per metric ton of ore or dollars per year. Capital costs are those that cannot be fully expensed in the year incurred and include items such as the following:

- Mine and mill equipment purchase
- Development
- Engineering and construction management
- Infrastructure
- Working capital
- Postproduction reclamation
- Preproduction stripping
- Property acquisition
- Exploration
- Buildings
- Contingency fund

Although this chapter deals primarily with costs and cost estimation, it is worth mentioning that from an after-tax economic-viability standpoint, it is best to minimize the preproduction capital expenses and incur them as close to start-up as possible. Because of the time value of money, capital expenses accrued later in the operation have a lesser impact on the overall project net present value. So, during the preliminary mine-design process, evaluators find that it is worth the effort to structure the project in a way that expedites production.

COST COMPONENTS

While expenses at a mine can be categorized as either *capital costs* or *operating costs*, both are comprised almost entirely of labor, supply, and equipment components. Whether building a processing plant, constructing a tailings impoundment, or mining an ore deposit, evaluators find that most of the money spent on the project goes to either the workers (laborers, skilled tradesmen, equipment operators, supervisors, technicians, managers, etc.), the supply vendors (to purchase wood, drill bits, concrete, steel, explosives, tires, diesel, etc.), or to equipment manufacturers (to purchase machines or buy parts).

LABOR

Wages and salaries, and the "burdens" associated with each, very often represent the largest expenditures at any mineral-development project. In fact, wages, benefits, mandated employment taxes, and bonuses can sometimes account for

more than half of the total operating costs. Depending on the size of the mine, labor costs can account for anywhere from 15% to 60% of the total operating costs. These costs can escalate if the mine is situated in a remote area without a local source of skilled labor.

Wages also tend to be one of the more variable components of an evaluation. Project location has a significant impact, and evaluators are urged to examine wages on a regional level to properly account for the associated expenses in their evaluation. Wages and salaries for miners in several countries are tracked and reported in publications such as *U.S. Metal and Industrial Mineral Mine Salaries, Wages and Benefits: 2009 Survey Results* (Salzer 2009).

Base wages are "loaded" with mandated employment taxes, including Social Security, Medicare, unemployment taxes, and workers' compensation taxes. Other items add to the burden factor, such as shift differentials; overtime; medical, dental, and vision benefits; retirement plans; short- and long-term disability insurance; life insurance; accidental death and dismemberment insurance; sick leave; vacation and holiday pay; and other benefits. To retain employees, companies often use creative benefits such as paid tuition, transportation to remote mine sites, attendance bonuses, safety bonuses, family and individual assistance plans, and paid fitness-club memberships.

Many mines pay their production miners a bonus based on meeting development or production goals. These bonus systems are sometimes modified to include safety, ground conditions, and other factors. Safety violations can reduce or even eliminate a production bonus. Other criteria sometimes used to calculate bonuses are individual performance, safety performance, commodity price, profit, recovery, ore grade, production, and cost savings to calculate bonuses.

SUPPLIES

Supply prices are less volatile than wages and salaries, but they still vary from one region to the next and from one vendor to another. While it is always preferable to obtain local prices from established vendors, it is often impractical to do so during the early stages of project evaluation. *Mining Cost Service* (InfoMine 2009b) provides an extensive array of supply costs that are reliable for early-stage feasibility work.

In the evaluation process, some supply costs are commonly reported as equipment-operating costs because their consumption rates are directly tied to machine use. Diesel fuel, gasoline, electricity, tires, and lubricants all fall into this category. And, as demonstrated earlier, many of the project's labor requirements and subsequent costs are also directly dictated by daily machine use. In addition to individual equipment-operator requirements, mechanic, electrician, machinist, and equipment-maintenance worker requirements also vary in proportion to machine use.

EquipmentWatch's *Cost Reference Guide* (EquipmentWatch 2009), InfoMine USA's *Mine and Mill Equipment Costs: An Estimator's Guide* (InfoMine USA 2009a), and equipment manufacturer publications such as Caterpillar's *Caterpillar Performance Handbook* (Caterpillar 2009) provide invaluable equipment operating parameter and cost information. As such, they also serve as indirect guides to mechanic requirements and equipment-related supply consumption rates (fuel, electricity, tires, and lubricants). Some recent prices for supplies commonly consumed at surface mines are listed in Table 4.9-1.

Table 4.9-1 Supply prices (2009 dollars)

Item	Price per Unit, US$
Ammonium nitrate fuel oil (ANFO)	1.06/kg
Extra-gelatin dynamite	4.50/kg
Primers (0.45 kg)	4.58 each
Blasting caps (nonelectric, 6-m lead)	3.15 each
Detonation cord (25 grain)	0.063/m
Detonation cord (40 grain)	0.073/m
Rotary drill bits (17.15 cm)	2,746 each
Rotary drill pipe	81.58/m
Percussion drill bits (4.45 cm)	58.80 each
Percussion drill steel	78.63/m
Dust suppressant	0.82/L
Diesel fuel	0.720/L
Lubricants	2.171/L
Cement	112.36/t
Tailings pipe (20.3-cm abrasion-resistant steel)	56.98/m
Water return pipe (10.2-cm polyvinyl chloride)	15.88/m
Synthetic liner (36-mil Hypalon)	11.04/m^2
Geotextile	4.16/m^2
Soil stabilizer	3.20/L

EQUIPMENT

As with the supply prices, equipment purchase prices are typically obtained from vendors. However, in the early stages of an evaluation, it is even more difficult to obtain these values than it is the supply costs because the necessary machines can only be specified in the most general terms. InfoMine USA's *Mining Cost Service* (InfoMine 2009b) and *Mine and Mill Equipment Costs: An Estimator's Guide* (InfoMine USA 2009a) also contain extensive purchase price lists for machines commonly used at surface mines. For early-stage feasibility work, equipment prices are usually based on list prices as suggested by the manufacturers, with no discounts assumed and no options added.

Early in the evaluation process, most evaluators specify new machines for all production-related project requirements, and purchase prices reflect this. If anticipated use is minimal, estimators may specify previously owned (used) machines for some of the secondary support equipment, such as water tankers and road graders. If previously owned machines are relied on for production work, the equipment productivity and availability (and the associated operating costs) should be adjusted accordingly in anticipation of increased maintenance and repair requirements.

COST MODELS

When evaluators have limited deposit information, they can use mine models for order-of-magnitude estimates. In addition, models can be used to provide insight into the nature of mining costs in general. The impact of changes in operating parameters can be easily understood when presented in a format that compares costs associated with one configuration directly to those associated with another.

Appendix 4.9A presents three cost models that evaluators can use to make preliminary estimates for projects. The cost models include surface mines of 1,000, 10,000, and 80,000 t/d.

Each cost model compares stripping ratios of 1:1, 2:1, 4:1, and 8:1 (waste to ore). In these cost models, note the

Table 4.9-2 Hourly wages for personnel (2009 dollars)

Worker	Hourly Wage, US$
Driller	22.20
Blaster	22.36
Excavator operator	22.80
Truck driver	19.97
Heavy equipment operator	21.98
Utility operator	18.17
Mechanic	22.53
Electrician	23.90
Maintenance worker	18.20
Laborer	17.30

Source: Salzer 2009.

Table 4.9-3 Annual salaries for professionals (2009 dollars)

Job Title	Annual Salary, US$
Mine manager	147,600
Superintendent	92,600
Foreman	71,700
Engineer	79,500
Geologist	73,000
Technician	48,700
Accountant	64,600
Purchasing agent	63,100
Personnel manager	89,800
Secretary	35,700
Clerk	39,700

Source: Salzer 2009.

unexpected changes dictated by increases in stripping ratios at the larger operations, and also note the ratio of labor costs to equipment operating costs as production rates increase.

These models are theoretical and are not representative of any existing mine. Note the pit and haul parameters, which provide the basis for each design. These should be one of the key points of comparison if the models are to be used to provide estimates for any proposed operation. Costs associated with each model account for all pertinent labor, material, supply, and equipment operating expenses accrued at the mine site. Costs for supervision, administration, and on-site project management are all included. Expenses associated with preproduction development, equipment purchase and installation, and building and facility construction are also included. In these models, costs for the following operations and facilities are considered:

- Ore and waste drilling, blasting, and excavation
- Ore haul from the active face to the mill site
- Overburden and waste haul from the active face to the dumpsite
- Constructing and operating the facilities required for equipment maintenance and repair, electricity and fuel distribution, drainage, explosives storage, and sanitation
- Constructing a mine office, a warehouse, and a worker changehouse plus all associated site work

The mines in the cost models are located in areas of moderate relief with warm summers and temperate winters. Wages and salaries used in the cost models are from *U.S. Metal and Industrial Mineral Mine Salaries, Wages and Benefits: 2009 Survey Results* (Salzer 2009).

Representative hourly wages used in the models are listed in Table 4.9-2. In the models, the above wages are adjusted upward to account for a 39.0% burden rate. Salaries for professionals that were used in the models are shown in Table 4.9-3, and in the models, the salaries are adjusted upward to account for a 39.0% burden rate. Models were constructed with Sherpa Cost Estimating Software for Surface Mines (Stebbins 2009).

APPENDIX 4.9A

The following tables present cost models for a surface mine producing ore at waste-to-ore strip ratios of 1:1, 2:1, 4:1, and 8:1.

Table 4.9A-1 Surface mines: 1,000 metric tons of ore per day

	Stripping Ratio, Waste/Ore			
Cost Parameters	**1:1**	**2:1**	**4:1**	**8:1**
Ore production, t/d	1,000	1,000	1,000	1,000
Waste production, t/d	1,000	2,000	4,000	8,000
Total resource, million t	3.12	3.12	3.12	3.12
Final pit dimension				
Pit depth, m	84	97	115	141
Pit floor length, m	154	177	210	256
Pit floor width, m	77	88	105	128
Final pit wall slope, degrees	50	50	50	50
Haul profile—ore				
Face to pit ramp				
Distance, m	87	91	98	110
Gradient, %	0.0	0.0	0.0	0.0
Ramp entrance to pit exit				
Distance, m	414	564	770	1,031
Gradient, %	12.0	12.0	12.0	12.0
Pit exit to mill				
Distance, m	342	394	468	571
Gradient, %	2.0	2.0	2.0	2.0
Haul profile—waste				
Face to pit ramp				
Distance, m	117	130	150	180
Gradient, %	0.0	0.0	0.0	0.0
Ramp entrance to pit exit				
Distance, m	112	173	251	343
Gradient, %	12.0	12.0	12.0	12.0
Pit exit to waste stockpile				
Distance, m	171	197	234	286
Gradient, %	2.0	2.0	2.0	2.0
Stockpile base to surface				
Distance, m	213	269	339	427
Gradient, %	12.0	12.0	12.0	12.0
Across stockpile to dump				
Distance, m	109	137	172	217
Gradient, %	0.0	0.0	0.0	0.0
Hours per shift	8	8	8	8
Shifts per day	2	2	2	2
Days per year	312	312	312	312
Bench height—ore, m	3.66	3.66	3.66	3.66
Bench height—waste, m	4.88	4.88	4.88	4.88
Powder factor—ore, kg/t	0.35	0.35	0.35	0.35
Powder factor—waste, kg/t	0.31	0.31	0.31	0.31
Development				
Preproduction stripping, t	30,000	60,000	120,000	240,000
Haul road construction, m	1,565	1,955	2,483	3,165
Equipment, number and size				
Hydraulic shovels, m^3	1 each 2.3	1 each 2.3	1 each 2.3	1 each 2.3
Front-end loaders, m^3	1 each 2.3	1 each 2.3	1 each 3.8	1 each 12.2
Rear-dump trucks, t	4 each 32.0	5 each 32.0	4 each 41.0	6 each 54.0
Percussion drills, cm	2 each 6.35	3 each 6.35	4 each 6.35	6 each 6.35
Bulldozers, kW	2 each 60	3 each 60	4 each 60	3 each 110
Graders, kW	1 each 105	1 each 105	1 each 115	1 each 115

PART 5

Management and Administration

CHAPTER 5.1

Mine Economics, Management, and Law

Michael G. Nelson

INTRODUCTION

Finding an ore deposit and putting it into production as a mine requires the execution of many complex tasks, such as exploration and evaluation, planning, development, production, processing, and reclamation. Also required is a team of technical experts with skills in many areas—drilling, mapping, modeling, equipment selection, explosives and blasting, ground control, ventilation, power systems, waste disposal, and so forth. Much of the content of this handbook is devoted to these types of tasks and skills, almost all of which are specifically technical, based on various disciplines of science and engineering.

However, the technical aspects of mine development and production are not sufficient by themselves. Even when all the science and engineering are done correctly, there are other key components to a successful project. Capital and start-up funds are required; the mine must make a profit; day-to-day operations must be efficiently managed; and operations must be in conformance with all local and national laws, which may in some cases change unexpectedly.

This chapter deals with mine economics, management, and law, and specifically with aspects of those three topics that directly influence the ability of a company to find a mineral deposit, develop a mine, and operate the mine profitably. The disciplines and practices of mine economics, mine management, and mining law are largely devoted to controlling risk and maximizing returns from the exploitation of mineral deposits. Those risks and returns accrue to investors, mining company shareholders, governments, and residents of the area around the mine.

Every investment carries risks, and successful investors are adept at assessing and accommodating those risks. Management and control of the risks associated with mining investments require special methods, because the assets in a mining investment are more difficult to quantify than those in many other investments. Furthermore, some investors have a perception that mining investments can deliver high rates of return. The term *gold mine* is frequently used in a colloquial sense to describe an unusually good investment.

Unfortunately, under the right combination of these circumstances, large investments can be made and lost in mining ventures that are valued incorrectly or unscrupulously. A good historic example is the case of the Emma mine, which was located near Salt Lake City, Utah (United States) and whose history is described in detail by Jackson (1955). The original Emma claims were staked in 1864 by two prospectors, Chisholm and Woodman, who were described as "rough in manners and character."

As was common in that time and place, the original owners tried to work the prospect but were compelled to bring in partners to finance the venture. The ownership rapidly became unclear, but by 1868, ore was being shipped to Great Britain for reduction. At this point, two skilled promoters entered the scene. General George Baxter, former president of the New York Central Railroad, and Trenor W. Park, former receiver for the famous Mariposa estate in California, succeeded in gaining control of the mine.

By 1870, London capitalists had overcome the shock of their earlier, disastrous losses in the quartz-gold ventures of California, and registration of British companies intending to invest in American mining ventures boomed. Baxter and Park enlisted the assistance of a notable group, including Professor Silliman of Yale University, who prepared a favorable report; William Morris Stewart, U.S. senator from Nevada; and Major General Robert C. Schenck, the U.S. minister to the Court of St. James. This group was assisted in its efforts by one Baron Grant, a promoter who, in return for providing introductions to British financiers, would receive 10% nominal capital of any new company. A prospectus for the Emma Silver Mining Company was issued in 1871, offering £1,000,000 in shares at £20 per share. In addition to Schenck, Stewart, Baxter, and Park, the company's board included three members of Parliament. Professor Silliman's report was taken at face value, and no independent evaluation was made. The shares were soon selling at £3 to £4 above the offering price.

At first, the mine was highly productive, yielding daily a hundred tons of ore containing 5.7 to 20.10 kg (200 to 700 oz) of silver per ton, and within a few months $1,500,000 in ore had been mined (Rickard 1932). However, there was considerable skepticism in the United States. The *Engineering and Mining Journal* commented, "We do not see in the prospectus

Michael G. Nelson, Department Chair, Mining Engineering, College of Mines & Earth Sciences, University of Utah, Salt Lake City, Utah, USA

of the company any justification for these high figures, except a historical one. The mine appears to be valued at five million dollars because it has produced some two million already, and no positive proof is offered as to the amount of ore actually known to be in reserve—at least, none that we have seen" (Anon. 1871).

At the end of 1872, the company director "made the astounding discovery that their stock of available ore was exhausted, everything in sight worth taking had been extracted without any new ore bodies having been discovered" (Jackson 1955). In the annual report issued on March 1, 1873, the directors expressed their "regret and disappointment" that the balance sheet was much less favorable than they had until recently anticipated. The shareholders were incensed, the mine in Utah was closed, and most of the work force dismissed. The share price dropped rapidly from £23 to one-tenth that amount.

By this time, Schenck had resigned from the board of directors, but as the lawsuits proliferated, back and forth across the Atlantic, the U.S. House of Representatives appointed a special committee to investigate his connection with the Emma mine promotion. Months of testimony resulted in 879 pages of proceedings and the finding that Schenck's conduct had been "ill-advised, unfortunate, and incompatible with the duties of his official position" (Jackson 1955).

Until 1892, exploration continued, companies were formed and dissolved, and sporadic but generally unprofitable production at the Emma mine continued. In 1894, the directors of the company that held the original Emma claims voted to devote their remaining small capital to the investigation of West Australian gold properties.

Unfortunately, even today, some of the errors made by investors in the Emma mine have not disappeared. Stock is issued and investment decisions are made on the basis of a single "expert" report, without seeking independent verification. Investors are impressed by the political, social, or economic standing of company officers and promoters, and fail to determine whether any of those individuals have the training and experience needed to operate a mining company. Past production is all too often taken as demonstrable evidence that reserves are still in the ground.

MINE ECONOMICS

This section addresses four topics related to the basic premises of the profitable exploitation of a mineral deposit:

1. Evaluation of mineral properties
2. Mineral property feasibility studies
3. Cost and cost estimation methods
4. Investment analysis

Financing of mining projects is addressed here but is discussed more thoroughly elsewhere in this handbook.

Mineral Property Evaluation

The deposit must be characterized adequately and with the required degree of certainty. The extent of the deposit must be defined, usually in terms of the amount of ore present. The quality or tenor of the deposit must also be defined, usually expressed for metal deposits as grade: the fraction of metal present, in milligrams per ton for precious metals, or as a percentage for base metals. For coal, quality is characterized by the impurities present, specifically sulfur and ash; the heating value; and (for metallurgical coal) the coking qualities. For industrial minerals, user requirements are often specific in terms of impurities and other properties, and standard expressions for quality are less common.

In all cases, the entire makeup of the deposit must be considered. The presence of certain impurities may render valueless an otherwise attractive deposit. For example, a limestone deposit that contains too much silica may not be suitable for the manufacture of cement. In other cases, the presence of an otherwise valuable constituent may lead to complications in the ore processing. For example, a gold–silver ore that has too high a silver content may require more expensive methods for recovery of the precious metals from the leach solution. Thus the characterization of a deposit must be carried out by a diverse team, whose members thoroughly understand geology, mining, mineral processing, metallurgy, and chemistry.

Besides characterizing the quality of the deposit, the evaluation will also include an analysis of the legal status of the mineral holdings. This will include determination of who owns the mineral or mining rights, who owns or controls the surface rights, who controls access to the property, and who owns the required water rights. The legal definitions of these rights vary widely among countries and even among states or provinces within some countries.

In many cases, the evaluation or characterization of a deposit will include a preliminary assessment of the feasibility of mining that deposit. That assessment will focus particularly on any characteristics of the deposit (and its locality) that may be problematic. Examples include deposits

- In particularly remote locations;
- Where permitting may be difficult;
- Where local opposition may be extreme;
- Where water, fuel, or electric power are expensive or unavailable in sufficient quantities; or
- Where the political climate is unstable.

These preliminary assessments are often called audits—environmental, regulatory, social and cultural, and so forth—and are described extensively in the literature.

Inaccurate or incomplete characterization of a mineral deposit can have serious consequences. Such inaccuracies may or may not be intentional, but once the numbers are in print, the tendency to use them for raising money may be difficult to resist. Errors in reserve estimation, intentional or not, continue to occur. Though such cases rarely become the subject of congressional hearings, as the Emma mine did, they do have serious consequences.

The requirements for accurate characterization of deposits are given in various national standards, as described in detail by Bourassa et al. (2003). These standards have been adopted by stock exchanges, government agencies, and professional societies to ensure uniformity and accuracy in reports describing mineral deposits.

In 1988, at the request of members of the Society of Mining Engineers (later changed to the Society for Mining, Metallurgy, and Exploration, or SME), the president of SME formed Working Party No. 79, Ore Reserve Definition. Its mission was to develop guidelines for the public reporting of exploration information, resources, and reserves. In 1989, the *Australasian Code for Reporting of Identified Mineral Resources and Ore Reserves* (the JORC Code) was published and was immediately incorporated into the Australian Stock Exchange listing rules. In 1991, SME's guidelines were first published, and the Institution of Mining and Metallurgy in the United Kingdom revised its standards for reporting of mineral

resources and reserves (SME 2007). The U.S. guide and U.K. revisions were both based on the 1989 JORC Code.

In the collapse of the Bre-X project in Indonesia (Danielson and Whyte 1997), private and institutional investors suffered huge losses when it was revealed that exploration results had been incorrectly reported. After that, international standards took on increasing importance (Cawood 2004). *The SME Guide for Reporting Exploration Information, Mineral Resources, and Mineral Reserves* was updated in 1999 when the reporting of mineral resources and reserves was required to be made by a "competent person," as defined therein (SME 2007). The *SME Guide* was then recommended for use by SME members. However, the U.S. Securities and Exchange Commission (SEC) did not recognize "resources," as defined in the *SME Guide* and other documents, in its evaluation of proposed mining projects (Kral 2003). When SME became a recognized overseas professional organization, it instituted its registered member category in 2006. Those who qualify can obtain this membership upgrade through SME. Applicants must first meet strict educational and professional standards and undergo a vetting process by the Society's Admissions Committee (Gleason 2007).

In an effort to resolve the differences between the *SME Guide* and the SEC rules and regulations for 2007, a revised version of the *SME Guide* was issued, which included improved definition of the term *mineral resources* and its subdivisions (measured, indicated, and inferred mineral resources), and clarification of the technical, economic, legal, and permitting requirements that must be satisfied before a reserve can be declared. A section was added defining the commodity prices that can be used for reserve estimation and reporting, and how price sensitivity should be measured during periods of low prices. Documentation requirements were clarified, including the requirement for a Mineral Reserves Declaration Report. The role of the competent person was reemphasized. However, the position of the SEC with respect to public reporting remains that stated in *Industry Guide 7* as interpreted by SEC staff (SEC 2007). Consequently, at any given time, some key aspects of the *2007 SME Guide* may be inconsistent with SEC requirements. The SME document, *The Guide for Reporting Exploration Results, Mineral Resources, and Mineral Reserves* (SME 2007) is available at the SME Web site.

When a big financial scandal like that of Bre-X is exposed, the details of the how the property was incorrectly valued are closely scrutinized. In contrast, companies and individuals are understandably reluctant to publicly discuss projects that were undertaken in good faith but fail nonetheless (SME 1998). Thus, it is difficult to assess the role of incorrect property valuations in those failures. Guarnera (1997) sums up the effect of geological risk in recent projects as follows: "No single feature has caused so many mining projects to fail as have reserves not being what were originally estimated by the mining company. A few examples of projects which have had notable reserve problems are:…Hayden Hill…Cove-McCoy…[and] Grouse Creek."

A brief discussion of these projects is instructive.

The McCoy property in Nevada (United States) was acquired in 1986, and the nearby Cove prospect was discovered in 1987. By 1988, the owner reported proven and probable mineable reserves at Cove of 65.3 t (metric tons) of gold and 3 kt of silver, with drill-indicated possible mineralization of 83.9 t of gold and 4.5 kt of silver (Emmons and Coyle 1988). In 1990, the owner reported that proven and probable gold reserves at Cove were cut by 11% to 4.6 million troy oz, and estimates of other mineralization at depth had dropped from 4.5 million oz of gold to about 900,000. The error was attributed to downhole contamination of cuttings in reverse circulation drilling (Gooding 1990). In 1993, Amax Gold reported a US$64.1 million write-down of the carrying value of Hayden Hill (*Globe and Mail* 1993). In 1996, the owner incurred a $30 million expense to stabilize the pit wall (*Globe and Mail* 1997). By 1998, production had been scaled back (Bagnell 1998), and by the middle of 2002, no production from Cove-McCoy was reported (*National Post Canada* 2002).

In 1992, the Grouse Creek mine in Idaho (United States) was permitted, with initial annual production expected at 3.1 t/a of gold and 12.4 t/a of silver, changing later to 2.2 t/a of gold and 77.8 t/a of silver (Anon. 1992). By 1995, the owner announced it was writing down its entire $US95-million investment in the mine because it had encountered significant shortfalls in both grade and tonnage of the ore being mined (*Globe and Mail* 1995).

Completion of permitting for the Hayden Hill project in California (United States) was announced by Haddon (1992). In 1993, the owner reported a US$64.1-million write-down of the carrying value of Hayden Hill (*Globe and Mail* 1993). Schwab et al. (1994) assert that some of the tonnage and grade shortfall that was experienced at Hayden Hill may have resulted from an absence of adequate drilling, obscured by variogram analysis that supposedly showed the grade variations within the range of low variance over distances which, on close inspection of the geology, could not be supported.

Finally, it is important to remember that reserve risk is not always a function of resource risk. Modifying factors in the various standards are meant to account for the conditions that should be considered when converting a mineral resource to an ore reserve.

Mineral Property Feasibility Studies

A feasibility study of a mining project is an appraisal of the commercial viability of that project, which accounts for engineering, economic, permitting, and environmental variables. Like mineral property evaluations, feasibility studies require the dedicated participation of a diverse group of skilled professionals. In addition to an understanding of geology, mining, mineral processing, metallurgy, and chemistry, the feasibility study team must also comprehend cost estimation, construction and project management, civil engineering, electrical engineering, permitting and other legal requirements, economics, and finance.

To control costs and to cater to the progressive increase in geological confidence and understanding of the modifying factors, feasibility studies are usually conducted in stages. If a study at the first stage produces favorable results, indicating the property may be exploited profitably, a more detailed (and costly) study will be conducted, resulting in an increased certainty of the project economics. Some mining companies have internal experts who conduct feasibility studies, while others rely on engineering firms or consultants to fulfill this function. In all cases, feasibility studies are conducted to defined standards, stating the requirements for a study at a given level of certainty. Although these standards vary somewhat, in all cases the notion is the same: increasing the detail increases the certainty but costs more money. For example, Vancas (2003)

Table 5.1-1 Criteria for feasibility studies

Type of Study	Completion of Engineering Documents*, %	Probable Error, %
Rough order-of-magnitude	2	±35–45
Preliminary (conceptual or scoping)	5	±25–35
Budget appropriation (prefeasibility)	15	±15–25
Project control (feasibility)	27	±10–20
Definitive	40	±5–15

Source: Adapted from Vancas 2003.
*Drawings, specifications, procedures, etc.

describes the scheme used by Bateman Engineering for defining types of feasibility studies, as shown in Table 5.1-1.

Although not specified in the scheme of Table 5.1-1, the steps needed for permitting and reclamation should also be considered, and are often included, in the various stages of a feasibility study.

It is important to remember that any feasibility study is only as good as the information used to prepare it. Although this may seem obvious, many errors can lead to inaccuracies in a study. Gypton (2002) reviewed 60 projects and found only 15 came in under budget. Of the 45 over budget, 35 were more than 15% over. Of all the projects, 25 were within the ±15% criteria. Similarly, Bertisen and Davis (2007) reviewed 63 mining and smelting projects completed over four decades and found that as-built capital costs averaged 25% higher than estimates at the bankable feasibility study stage. About half of the projects had as-built capital costs outside the expected ±15% of the feasibility study capital cost estimate, and cost overruns of 100% or more occurred in roughly 1 of 13 projects.

What could lead to such errors? Vancas (2003) gives a list of project pitfalls:

- Being forced into unrealistic deadlines
- Not defining the scope of the project clearly at the beginning of the project
- Allowing changes of the scope without documenting them or determining their impact to the schedule, resources, and project budget
- Getting senior management's attention too late for them to help
- Inability to say "no" (even when obvious that what is being requested is impossible)
- Not establishing communication channels from the beginning of the project
- Not establishing a control mechanism to track and monitor the project
- Deserting control mechanisms when the project starts getting into management by crisis
- Continually reorganizing the project team
- Committing to arbitrary dates with no real basis for setting those dates
- Building up staff too quickly when work is not ready and/or disbanding support staff too quickly
- Not having a person in charge of the project with responsibility, accountability, and authority
- Not freezing the specifications and other baseline definitions

To this list could be added the too-common errors of confusing precision with accuracy and not understanding the inherent risks associated with mineral resources, particularly at the inferred resource category. Bertisen and Davis (2007) asserted that the persistence of bias is intentional, driven by a scarcity of project financing and the need to inflate the project economics in a bid to secure financing.

Danilkewich et al. (2002) provide guidelines for the project owner in preparing for a feasibility study. They suggest the owner be responsible for preparing a complete scope of work, a full delineation of assumptions and constraints, a well-defined execution plan, and a comprehensive bid checklist.

Feasibility studies are an indispensable tool in the decision-making process that leads up to the development of a mineral deposit. However, their preparation and interpretation must be carefully managed to ensure satisfactory results. Northcote (2007) provides an excellent discussion of how to minimize functional risks during a project evaluation and summarizes it thus:

> To reduce project failures, the foundations need to be properly laid. This starts with the stakeholders understanding the project life cycle versus the value of the impact of change and having a quality project evaluation report.
>
> A competent project evaluation manager needs to be appointed who will select appropriately skilled and managed study groups to assist in identifying the opportunities and the risks. Setting up of the study at the outset so that all participants know the systems, schedules and objectives is crucial to a focused and on timely outcome. Once the project evaluation has commenced, retention or access to key people will reduce revisiting concepts and strategies that more than likely have been addressed in the evaluation process. This can reduce cost and schedule impacts.
>
> Project evaluation management is challenged in keeping study groups focused and addressing the risk issues in a timely manner. Regular scheduled meetings, competently chaired, generate synergies that keep the study groups focused. Special review meetings are to be scheduled throughout the project where peer reviewers are invited to test the other's findings.
>
> Before a commitment can be made by the stakeholders, in addition to the usual documentation covering the mining, technical, budget estimates, construction schedule and market aspects, there needs to be a design criteria and a project execution plan.
>
> Short cuts during project evaluation will result in a weak foundation and increase the risk of project failure.

Cost Estimation

Cost estimation is a part of every feasibility study. A mineral deposit should not be considered for development unless the estimated annual operating profit after taxes and other costs is sufficient to recover, with interest, the cost of developing the mine and of closing and reclaiming it. Such considerations should also include sufficient income to provide for mine closure and final reclamation costs. This is often neglected, and poor performance at closure can lead to bad public relations, denial of future permits, and even bankruptcy.

As a project progresses through the types of feasibility study previously described, the cost estimates are successively

Table 5.1-2 Specifications for capital cost estimates in feasibility studies

Category	Conceptual or Scoping Study	Prefeasibility Study	Feasibility Study
Basis, to include the following areas: civil/structural, architectural, piping/HVAC, electrical, instrumentation, construction labor, construction labor productivity, material volumes/amounts, material/equipment, pricing, infrastructure	Order-of-magnitude, based on historic data or factoring	Estimated from historic factors or percentages and vendor quotes based on material volumes	Detailed from engineering at 15% to 25% complete, estimated material take-off quantities, and multiple vendor quotations
Contractors	Included in unit cost or as a percentage of total cost	Percentage of direct cost by area for contractors; historic for subcontractors	Written quotes from contractor and subcontractors
Engineering, procurement, and construction (management) (EPC(M))	Percentage of estimated construction cost	Percentage of detailed construction cost	Calculated estimate from EPC(M) firm
Pricing	FOB mine site, including taxes and duties	FOB mine site, including taxes and duties	FOB mine site, including all taxes and duties
Owner's costs	Historic estimate	Estimate from experience, factored from similar project	Estimate prepared from detailed zero-based budget
Environmental compliance	Factored from historic estimate	Estimate from experience, factored from similar project	Estimate prepared from detailed zero-based budget for design engineering and specific permit requirements
Escalation	Not considered	Based on company's current budget percentage	Based by cost area with risk
Working capital	Factored from historic estimate	Estimate from experience, factored from similar project(s)	Estimate prepared from detailed zero-based budget
Accuracy	±50%	±25%	±15%
Contingency	25%	15%	10% (actual to be determined based on risk analysis)

Table 5.1-3 Specifications for operating cost estimates in feasibility studies

Category	Conceptual or Scoping Study	Prefeasibility Study	Feasibility Study
Basis	Order-of-magnitude estimate	Quantified estimates with some factoring	Describes the basis of the estimate; detailed from zero-based budget; minimal factoring
Operating quantities	General	Estimates with some factoring	Detailed estimates
Unit costs	Based on historic data or factoring	Estimates for labor, power, and consumables; some factoring	Letter quotes from vendors; minimal factoring
Accuracy	±35%	±25%	±15%
Contingency	25%	15%	10% (actual to be determined based on risk analysis)

Courtesy of M.A. Holden.

refined and made more accurate. At higher levels of certainty, more detailed drawings and more directly quoted prices for major equipment are required. One approach defines three types of feasibility study: conceptual or scoping, prefeasibility, and feasibility. Tables 5.1-2 and 5.1-3 show the specifications for the capital and operating cost estimates, respectively, in each type of study.

The correct completion of a cost estimate requires consistency, attention to detail, and good sources of cost information. Many equipment suppliers have proprietary software for estimating capital and operating costs, which may often be used at no cost by prospective customers. For example, Caterpillar equipment costs can be determined directly from the company's Build and Quote Web site (Caterpillar 2010). In addition, regularly updated cost data are available by subscription at the *CostMine* Web site, maintained by InfoMine (2010). Inaccurate cost estimates will result in cost overruns and may result in the expenditure of large amounts of capital funds on a project later found to be unprofitable, or conversely, the rejection of a project that would have resulted in significant profits.

Investment Analysis

An investment analysis may be carried out as part of a feasibility study or as a separate effort. In any case, the purpose of the analysis is to determine whether or not development of the project will provide sufficient economic returns to justify the required initial and ongoing investment required. The analysis must consider the cost of the capital funds employed and the risk involved in the project.

For any development project, investment of the required funds must be justified to the funding source. When a company considers investing its own funds in a project, that alternative will be compared with other available investment opportunities. Those may include other new projects, improvements to existing facilities or equipment, or additional exploration for new prospects. If funding is to be sought from outside investors, those investors will make the same sort of comparisons.

Several criteria may be used for analysis of investments. Some are relatively easy to calculate, such as the accounting rate of return and the payback or payout period. Other criteria are calculated using discounted cash-flow methods, which are more complex. These include present value, future value, annual value, net present value (NPV), benefit–cost ratio, and internal rate of return (IRR).

NPV is the most commonly used, single criterion for comparing investments, but some analysts also use the IRR. There is some controversy over the use of these two criteria. Torries (1998) states that "both NPV and IRR have valid uses as merit measures for practical application of investment evaluation methods [and] IRR has no greater number of faults than does NPV, even when multiple root problems are included," whereas Hajdasinski (2000) believes that "the IRR is a conceptually flawed and operationally dysfunctional project evaluation criterion."

Discounted cash-flow (DCF) methods require detailed and extensive calculations, and executing them by hand requires considerable skill and patience. The development of personal computers has made DCF analysis much easier. Commonly available programs, such as Microsoft Excel, include built-in functions for many of the parameters associated with DCF analysis, and more sophisticated programs are readily available. Unfortunately, the relative ease with which DCF analysis may now be conducted has not altered the fact that the results of such an analysis are only as good as the input data. In some cases, when a complex analysis is done by computer, it is tempting to simply assume that the results are valid without rigorously reviewing the input data and assumptions.

Other drawbacks to DCF methods are summarized by Clevenger (1998) and Lawrence (2000). For example, it is difficult to estimate some of the key parameters, such as future cash flows and discount rates, and the practice of subtracting the cash flows of one project from those of another that is mutually exclusive (before discounting) can produce incorrect results. In addition, DCF measures do not directly recognize the value of future opportunities, unless the uncertainty regarding the execution of those opportunities is estimated and included in the analysis. Finally, small changes in the discount rate used can dramatically change the results of the analysis. Regarding this last point, Lawrence notes that "whilst it is preferable for valuations by DCF/NPV modeling techniques to give as much detail as possible in the derivation of the technical basis of the inputs used and the Discount Rate selected, it is more important for it to contain a table or graph showing the impact on the valuation of a change of 1% in the Discount Rate, from say zero to 15% per year (in real terms). This allows the reader to truly test the reasonableness of the valuation by estimating a value based on other Discount Rates."

Statistical simulation methods are often used to more accurately quantify the range of error associated with cost estimates and investment analyses. These methods are discussed in subsequent chapters in this handbook.

MINE MANAGEMENT

The topics of leadership, employee relations, and training, discussed in subsequent chapters of the handbook, are all important components of mine management, which will be discussed in general here.

Engineers are often skeptical of management experts. An anonymous cynic defined a manager as "someone who can always tell you what you've done wrong, but never tell you what to do next." Nonetheless, the operation of a single mine or a mining company requires the expert and careful management of dozens, if not hundreds, of functions and tasks.

Historic Approaches

The scope of topics included under the heading "Mine Management" has grown considerably as the industry has progressed and adapted to changing conditions. Early handbooks were often directed specifically to the country in which they were published and addressed practical matters such as mine organization; business and technical management; accounting principles; cost-keeping; mine records; wage schemes; contract work; bonus, cooperative, and leasing systems; methods of paying wages; accident compensation; pensions and benefit funds; labor relations; arbitration and conciliation boards; changehouses; mine communities; miners' dwellings; potable water supply systems; sanitation and diseases encountered in mining; and worker health and safety.

Contemporary Management Values

It is interesting to compare the historic topics with those in the public statement of the Rio Tinto Group, a large, multinational mining company. Rio Tinto first published *The Way We Work—Our Global Code of Business Conduct* in 2003; it was last updated in 2009 and is available in print and on the Internet (Rio Tinto 2009). Although it is intended to provide the company's employees with guidance on how to conduct themselves at work and when representing Rio Tinto, the document by implication describes Rio Tinto's management approach to corporate responsibility, sustainability, and integrity. All employees are strongly encouraged to report any violations of law and are provided with the means to do so. Strong commitment is expressed for important values:

- Incident- and injury-free workplaces
- Protection of health and well-being
- Excellence in environmental performance and product stewardship
- Respect for the rights and dignity of Rio Tinto's employees and those of its business partners
- Respect for human rights consistent with the Universal Declaration of Human Rights
- Strong relationships with communities and indigenous peoples
- Avoidance of conflicts of interest
- Prohibition of bribes and corruption, in all forms
- High ethical standards in dealing with governments
- Accurate and consistent communication with the media and investors
- Maximum transparency consistent with good governance and commercial confidentiality

Clearly, the preceding list does not include all the issues managed by Rio Tinto and its employees. Rather, the company must deal with issues covered in the historic handbooks plus those described in *The Way We Work*. That second set of issues may be thought of as *higher values*, which must now be rationally and consistently managed by all mining companies. Management of higher values is important first because it is simply the ethically and morally correct thing to do. Second, because mining companies continue in business by public consent, when values like those expressed in *The Way We Work* are not upheld, a company loses credibility and may eventually lose its license to operate in a given location.

The International Organization for Standardization (ISO) has prepared standards for environmental management, ISO 14001, and quality management, ISO 9001 (ISO 2010). Full discussion of the management of these values is beyond the scope of this chapter. However, some brief examples are instructive.

Labor Relations Management

Companies that manage higher values have an approach to labor relations that is significantly different from the historic norm. Zanolli (1972) notes that the United Mine Workers of America has been "involved in widely publicized and bitter battles with the coal industry employers in collective bargaining…[and]…has even battled with the government and in 1947 had the experience of collectively bargaining with the Government when the coal mines were taken over by the Federal Government." This adversarial relationship of miners' unions with employers and governments was common in many countries until the 1980s. The author recalls being told in 1987, by a West Virginia mine superintendent, "Anything I can do to get rid of a union miner is good. Every union miner is just a problem." Contrast this with a statement made by Leigh Clifford, then-CEO of Rio Tinto, in 2007: "Do you remember how anarchic labour relations nearly throttled WA's [Western Australia's] iron ore industry in the 1970s and drove our chief customer to encourage supply from Brazil? Today, work practices in our mines are more rational and everyone—employees, customers, companies and governments, is better off as a result" (Clifford 2007). Progressive mine managers recognize that their employees constitute a resource equal in value to their ore reserves and treat them accordingly.

Safety Risk Management

The concepts of risk management appeared in the 1970s (Field 2003) and were first applied in the petrochemical, nuclear, military, and aerospace industries. This proactive approach to improving risks, as opposed to a reactive "fix it when it breaks" mentality, was in most cases triggered by a major public disaster such as the Flixborough (England) chemical plant disaster in 1974, the Three Mile Island (Pennsylvania, United States) nuclear plant event in 1979, the *Piper Alpha* offshore oil platform disaster in the North Sea in 1988, and others (Joy and Griffiths 2007).

The management approach to a given issue can be either proactive or reactive. Proactive change involves actively attempting to make alterations to the work place and its practices. Companies that take a proactive approach to change are often trying to avoid a potential future threat or to capitalize on a potential future opportunity. Reactive change occurs when an organization makes changes in its practices after a threat or opportunity has already occurred (Reference for Business 2010). Risk management methods enable the systematic application of a proactive approach.

For many years, the management of safety in the mining industry was reactive. Breslin (2010) notes that "most of the Federal safety and health legislation has followed major mining disasters that received significant public attention." In some cases, a reactive response still occurs. As recently as 2006, three mine disasters in the United States (with a total of 19 fatalities) resulted in the passage by the U.S. Congress of the Mine Improvement and New Emergency Response (MINER) Act. Popovich (2010) observed that, since 2006, U.S. coal companies have spent almost $800 million on new mine safety technology and equipment, much of which was required for compliance with the MINER Act. Unfortunately, although reactive management can control many conditions, it cannot control them all. In addition, behavior control, whether individual or corporate, is achieved more successfully by proactive methods.

Risk management has been applied in many areas of the mining industry. As early as 1974, Matthews (1974) recognized that "most of the contractual problems related to underground construction are associated with risk and its management. Unless all of the ramifications of this subject are understood, it will be difficult to employ contracting practices best suited to the needs of a particular project. It is hoped that a detailed study of the nature of risk will assist in this understanding." Hebblewhite (2009) describes the use of risk management techniques for the control of geotechnical hazards in Australian mines. Assessment of risks, including political risk (Gavelan and Dessureault 2004), is also a standard part of almost all mineral property evaluations and project feasibility studies.

The application of risk management techniques to mine safety has been notably successful. The Australian mining industry initially identified the use of risk-based management techniques during the 1980s. Using research studies performed by the coal sector, which evaluated techniques used in the nuclear industries of various northern hemisphere countries, the industry identified the scope of applying a risk-based approach to mining. Primarily because mining has many uncertainties and a large number of variables, a clear-cut answer cannot always be defined for every situation. The value of risk management became clear in the mid-1990s, shortly after the 1994 Moura coal mine explosion in Australia, in which 11 miners died (Hopkins 2000). As a result, the mining industry began using risk analysis methods to mitigate certain key hazards.

By 1997, regulatory bodies in Australia began to require safety management plans for principal hazards. Western Australia passed the Mines Safety and Inspection Act (Western Australia 1994), and in New South Wales, the chief inspector of coal mines published a risk management handbook (NSWDPI 1997). Queensland issued standards the next year (QDME 1998; QMC 1999). These regulations require mines to perform major hazard risk assessments on a regular basis to address the possibility of unwanted events such as spontaneous combustion, gas outbursts, explosions, air blasts, inundations, and roof falls.

A comparison of fatality rates (number of fatal injuries per million hours worked) for underground mining from 2004 to 2006 indicates that the risk management approach to mine safety is having a marked effect (Table 5.1-4).

In 2001, the Minerals Council of Australia initiated a national project to promulgate a good practice guideline for risk assessment in the minerals industry. The Minerals Industry Safety and Health Centre (MISHC) at the University of Queensland was commissioned to draft guidelines, working closely with a representative cross section of the industry, which included seven large mining companies and nine government agencies. The resulting document, National Industry Safety and Health Risk Assessment Guideline, Version No. 7 (Joy and Griffiths 2007), is an exhaustive discussion of risk management as applied to mine safety. It includes descriptions

Table 5.1-4 Underground mine fatality rates 2004–2006, United States and Australia

Country and Commodity	Average Fatality Rate (fatal injuries per million hours worked)
U.S. coal	0.25
U.S. metal/nonmetal	0.14
Australia coal	0.04
Australia metalliferous	0.07

Source: Adapted from Iannacchione et al. 2007.

of methods and procedures, examples of forms, worksheets, reports, and other valuable resources. MISHC provides an on-line resource of information on mining industry risk management through its Minerals Industry Risk Management Gateway (MIRMgate 2010).

The use of risk management methods to manage mine safety has spread rapidly. Safety standards and practices in Great Britain, which apply to all industries and workplaces, are described in *A Guide to Health and Safety Regulation in Great Britain* (HSE 2009). They were developed in 1992 and are quite similar to those in Australia. Many large mining companies, including Alpha Natural Resources, Anglo American, Barrick Gold, BHP Billiton, Newmont Mining, Rio Tinto, and others, have embraced an approach to safety, health, and environmental quality that uses the principles of risk management.

MINING LAW

Mining law traditionally refers to the body of law governing access to mineral deposits, the right to mine those deposits, and the taxes or royalties assessed on the products of mining. In the last half century, many other laws that affect mining operations have been enacted. Those laws vary considerably from one country to another, and even within countries, but it is useful to consider them in six general (if somewhat overlapping) categories:

1. Access to the land
2. Right to mine
3. Taxes, leasing fees, and royalties
4. Employment, work conditions, and compensation
5. Environmental protection
6. Cultural and social issues

Access to the Land

These laws will govern which lands may be accessed for exploration and mining. Restrictions may be placed to protect forests, parks, and cultural resources. Regulations may specify access or leasing fees for exploration or mining. Companies may be required to attain more than one access right. For example, in some jurisdictions, the surface and mineral estates may be severed; that is, a company or individual may own surface and mineral rights but may be denied vehicular access to its property through a national park or other protected area. In other jurisdictions, such as Great Britain and South Africa, the state owns all minerals. The concept of state ownership of minerals leads to a system of mineral leases, or concessions, which requires some effort to understand. The distinction between real property and chattel, or personal property, is significant with respect to the distinctions between ownership of a mineral reserve in place and the mineral product after it has been mined or the wastes that are stored on the mine property after beneficiation.

Right to Mine

Unless the lands containing a mineral deposit are purchased in fee simple, the right to mine begins with permission from the property owner to enter the property. If this right is granted by means of a lease, then the lessor may require evidence that a social license to mine can be obtained.

In most jurisdictions, the right to mine requires one or more permits from government agencies. In some cases, the mining permit may be secured with relative ease, but mining cannot begin until several environmental and other permits are also in place. In some jurisdictions, the permitting process may seem opaque and difficult, especially to outsiders.

The right to mine may be forfeited if a company violates any of the laws to which it is subject. In some cases, this forfeiture may be a direct result of government actions; in other cases, it may be the *de facto* result of large fines or other penalties. In the worst case, a national government may confiscate or nationalize the property, mining claims, equipment, and all other assets of a mining company.

Taxes, Leasing Fees, and Royalties

Taxes and fees paid by a mining operation can be complicated. In many cases, a mining operation may be taxed by several entities. For example, a mine in the United States may include lands where ownership is divided among the federal and state governments and private holders. That mine could well be required to pay leasing or claim fees to the federal and state governments, corporate income taxes to the federal and state governments, severance taxes or royalties to the state government, real property taxes to the county government, and royalties to the private landholder. Some government agencies require the payment of lease fees and royalties in advance, and this may significantly increase the capital investment required to place a property in operation. During the feasibility analysis, it is important to consider the likely tax and royalty liabilities for a project.

When taxes, fees, and royalties are set by government agencies, they may be subject to change at short notice. In some countries, laws may be changed with little or no regard for existing contracts and agreements, and these changes can suddenly and drastically alter the economic viability of a project. For example, although *ex post facto* protection is taken for granted in the United States and many other countries, this is not the case everywhere, and the local situation should always be carefully investigated.

Employment, Work Conditions, and Compensation

Laws may specify wage rates and required benefits packages in a given location; limit work hours; determine the conditions for operation of labor unions; or specify the makeup of the work force in terms of ethnic or gender diversity, percentage of local or native residents to be employed, and so forth. Other laws may include provisions to protect the safety and health of workers, including required personal protective equipment, safe working conditions, safety requirements for equipment and machinery, and compensation for workers injured or made ill by working conditions.

Environmental Protection

Detailed discussion of environmental assessments, environmental impacts, and other environmental issues may be found in Part 16 of this handbook. This chapter discusses only general considerations.

Environmental laws cover many areas. They usually govern the use and contamination of surface and groundwater, the discharge and storage of solid waste (including dust, waste rock, and tailings) or domestic waste (garbage), the disposal of radioactive and other hazardous materials, and the control of gaseous emissions from equipment and processes. In most locations these laws also cover the protection of endangered and/or protected species or ecosystems (including parks, forests, rivers, and lakes) and the protection of *viewsheds* (including the night sky). Entities protected under environmental laws may be widely distributed in space and time—for example, a caribou herd or a salmon fishery.

It is important for mining companies and mining engineers to be aware of some of the land-use planning concepts under which lands may be designated under a certain usage category and thus rendered unsuitable for mining. Unsuitability may be afforded to areas with natural hazards, renewable resources, fragile ecosystems, historic sites, and for which reclamation is technically or fiscally not feasible. This land-use concept is also called *legal sterilization of lands*. Mine designers who are unaware of the designation concept and its application in environmental protection laws may find their pet projects stalled when they least expect it.

Environmental laws usually govern the restoration or reclamation of sites and features disturbed or altered by mining activities. Reclamation requirements may be specific and detailed, and extend far into the future, representing a liability that is difficult to quantify. Many government agencies require the posting of a bond to guarantee compliance with reclamation requirements. In some circumstances (when risk cannot be adequately quantified), bonding companies are unwilling to issue a bond. In such cases, the mining company is required to post the full amount required. In the worst case (usually for a smaller company), this will effectively halt the project; in the best case, it will increase the upfront capital cost of the project.

Cultural and Social Issues

Laws relating to cultural and social issues may require protection of archaeological or historic heritage sites, protection of cultural heritage sites, and control of traffic from material haulage or employee travel. They may also regulate the construction of employee housing; specify the steps to be taken when local residents are relocated to accommodate mining operations; and prescribe compensation for property, water, subsidence, and access rights. Some local jurisdictions may require or request a mining company to make investment in local infrastructure as part of a mine development program.

Cultural and social issues are difficult to quantify, and laws regarding them can be subject to widely varying interpretations. Organizations opposed to a mining project often use these issues as the basis for objecting to the project, even after the required permits have been issued.

Mining Law in a Global Business Climate

It is often said that "gold is where you find it." Mining companies have historically operated in diverse global locations, and that is still the case. Companies must be prepared to conduct exploration, development, and production almost anywhere in the world. Although the technical requirements for these activities will differ in various locations, much greater differences will be found in the legal, political, and cultural requirements. Thus, it is important for a company to have employees who are well trained and experienced in the laws and practices of each country in which the company operates.

Almost all companies now state clearly their intention to operate in full compliance with all applicable laws and regulations. In almost all cases, mining companies are also committed to operating in compliance with the highest and best environmental standards, often those of the ISO or a similar organization, even if the local laws are less stringent.

Mining companies must be fully aware of all laws that apply to their operations. This will, of course, include local laws, but laws of the company's home country may also apply. For example, the U.S. Foreign Corrupt Practices Act of 1977 sets forth standards for accounting transparency and prohibits bribery of foreign officials (U.S. Department of Justice 2004). It applies to any U.S. or foreign corporation that has a class of securities registered or that is required to file reports under the Securities Exchange Act of 1934; to any individual who is a citizen, national, or resident of the United States; and to any corporation and other business entity organized under the laws of the United States or having its principal place of business in the United States.

Estimating Legal and Political Risk

The preceding discussion of mining law has alluded to instances when changes in political regime or local laws and regulations can seriously affect the viability of a development project or mining operation. The assessment and quantification of legal and political risk is one of the biggest challenges for a mining company, which must rely on its experience, internal expertise, and the advice of qualified consultants.

An annual survey of mineral development potential is conducted by the Fraser Institute of Vancouver, British Columbia, Canada (McMahon and Cervantes 2009). In 2008, 658 mining and exploration professionals responded to the survey, which calculates the policy potential index and the current mineral potential index. The policy potential index measures the effects on mineral exploration of government policies, including uncertainty over the administration, interpretation, and enforcement of existing regulations; environmental regulations; regulatory duplication and inconsistencies; taxation; native land claims and protected areas; infrastructure; socioeconomic agreements; political stability; labor issues; geological database; and security.

The current mineral potential index is based on whether or not a jurisdiction's mineral potential under the current policy environment encourages or discourages exploration. There is considerable overlap with the policy potential index, probably because good policy will encourage exploration, which in turn will increase the known mineral potential.

These indices provide a useful assessment of the risks associated with mineral exploration in the areas included in the survey: 7 states in Australia, 12 provinces in Canada, 14 states in the United States, and in 34 other countries. The Fraser Institute survey also includes comments made by respondents, which provide valuable insights based on their experiences. Because some of these comments illustrate how the legal and regulatory climate in a country can affect exploration projects, they are reproduced here to emphasize those effects. Because this handbook will be a reference for many years, and because political conditions in many locations can change unexpectedly, the names of countries and political leaders are not given.

> In [location A], title and laws mean nothing. The law is what [the government] says it is at any given time—and [the government] is an amorphous political party. After spending $10 million on exploration in [location A] we were stonewalled by [the government] for four years as a means to deny us the final production permit.
>
> —Exploration company, company president

> [Location B] is actively seeking independence and looking towards minerals and petroleum to fund the country.
>
> —Exploration company, manager

> In [location C], the landowners status is entrenched in law; therefore, tenure is secure, with the…government responsible for allocating royalties to their citizens. The government can choose to participate in a mining venture but, they purchase their position at fair market value and, only BEFORE, the project becomes revenue producing, operating mine.
>
> —Producer company with less than US$50 million revenue, corporate secretary

> In [location D], if you build it, [the president] will steal it. [Location E] is a close second for similar reasons along with tribal claims.
>
> —Producer company, company vice-president

> [Location F] introduces without discussion [and] unilaterally a royalty on an industry weeks away from opening a diamond mine after capital expenditure of $1 billion.
>
> —Exploration company, company president

CHAPTER 5.2

Economic Principles for Decision Making

Ian Runge

Mining used to be a business primarily focused on the technical aspects of getting valuable ore out of the ground and extracting the minerals in a metallurgically efficient way. Without denying the importance of these skills, a narrow focus on technical issues is no longer sufficient to guarantee success, even in rich ore bodies. Skill in economics is an essential partner to technical skill in every step of the mining process. The economic way of thinking starts before the first drill hole is put in the ground and includes not just the most economic way of mining but also the most economic method of assessing mining projects. Economics directs mining strategy and takes into account changes in worldwide demand for mineral products.

This chapter introduces the economic approach to decision making and focuses on how individuals engaged in mining enterprises make decisions using sound economic principles. While the better decisions and the more successful enterprises are adopted and copied by others, the less-successful enterprises fail or are taken over, and outdated practices disappear. Thus the structure of the industry evolves. This chapter presents these economically based decisions in three parts.

The first section, "Mining Economics and Strategy," looks at the industry from a strategic perspective—the broad trends in the mining world and the way that much of the world is interconnected—and highlights and challenges some common misconceptions of mining economics. For long-term success, practitioners must at least be cognizant of these broader influences.

The second section, "Costs," follows a narrower approach. Fortunately, most economic assessments in mines do not require a broad understanding of the whole financial world but can achieve reliable answers focused on what is happening in the company, the mine site, or just one part of the mine. This section focuses on costs and how the understanding of costs is critical for decision making—from day-to-day choices at the mine face to long-term life-of-mine planning.

The third section, "Time Value of Money," examines one of the most important aspects of assessment in all but the simplest of mines: understanding what is happening in the mine over an extended period of time. Investing in new, bigger machinery at the start can reduce costs and provides benefits over the rest of the mine life. Mining the richest ore first can increase profits and reduce debt but can also impact mine life. Understanding these issues requires economic tools to assess the time value of money.

MINING ECONOMICS AND STRATEGY

Most approaches to economics assume that one person or one company's actions do not affect the whole market. This assumption is usually quite reasonable, because even the biggest mining companies usually only account for a small proportion of world production. A single extra ton of copper produced at one mine will not change the world price of copper. Yet the world is interconnected, and the results for one participant in such an interconnected marketplace often depend on the choices (strategies) of all the other participants. Perhaps that extra ton of copper will not affect the world price, but if the changed economic forces that allow this mine to expand production also apply to its competitors, then maybe they too will expand their production. If everyone expands production, then perhaps the world price will change.

For many decisions in operating mines, the standard (non-strategic) approach of ignoring what competitors are doing and using conventional economic models is quite appropriate. If an electric rope shovel is more economical than a diesel-powered hydraulic excavator in a mine, this choice is unlikely to be wrong even when the outside world changes quite substantially, or even if other mines elsewhere in the world favor a different choice.

Nevertheless, there are many areas of mining and mining-specific applications where the use of conventional models must be used cautiously. One such area is in the understanding of risk and return. With financial investments (in the stock market, for example), low-risk, lower-return opportunities form part of a continuous spectrum to higher-risk and higher-return opportunities. In this style of market, the choice of a higher (expected) return opportunity is synonymous with greater uncertainty and higher risk. With individual mine investment, this risk/return trade-off is not so clear-cut. The uniqueness of each ore body and the idiosyncratic risk attached to each project means that higher returns are not necessarily synonymous with higher risk. This creates opportunities for operators who understand the characteristics of the ore body, and who

Ian Runge, Founder, Runge Ltd., Brisbane, Queensland, Australia

understand the risks associated with mining it, to potentially make higher-than-normal returns without exposing the company to any higher risk. It also inhibits some decision making when projects are evaluated using conventional models that are founded on efficient market risk/return characteristics.

Strategic considerations are also important because of high sunk costs in mining—a characteristic of mining that is less important in most other industries. If a company has high sunk costs but low cash costs and the market price declines quite substantially, the company is unlikely to go out of business or even to reduce production. With lower prices, cash flow is still likely to be positive, and even though the company might be reporting losses (from an accounting perspective), reducing production will result in even larger losses.

This raises two important strategic issues. If potential *competitors* have knowledge of a company's capital structure, acting rationally, they might be deterred from entering the same market, knowing that the company will not easily be put out of business. With less competition, the company may be able to gain a price premium. However, this comparative advantage can also work against the company if *customers* also know about the company's capital structure. If they believe the company will continue producing so long as price exceeds the company's cash cost, the company is vulnerable to exploitation. What should the company's strategy be? Can the company assume that its customers and competitors will act rationally? One must ask if one's own corporate structure promotes or inhibits rational choices for one's actions?

Conventional but incorrect economic thinking pervades many other areas of mining, often in critical areas such as reserve definitions and the change in costs as reserves are depleted. With few exceptions, mines commence at the shallowest and/or highest-grade sections of the ore body and progress to parts that are less economically attractive. Moreover, new discoveries are generally deeper and lower grade than existing mines. This suggests that the cost of mining and, with it, the price of mineral commodities must rise over time. Thus, for example, renewable sources of energy (solar, wind) are commonly seen as the inevitable successors to today's coal, oil, and uranium supplies.

Yet even this intuitively obvious trend hasn't proven correct over the last century, and economics provides much of the explanation. For example, Baumol and Blackman (1993) describe work by themselves and others demonstrating that "the real cost (price) of extraction for a sample of thirteen minerals had declined for all but two between 1870 and 1956" and that "the price of fifteen resources for the period 1900 to 1986 until the 'energy crises' of the 1970 [showed] negligible upward trend in the real (inflation-adjusted) prices." Practitioners who have spent a long time in the industry know this well.

The extraordinary growth in living standards since the industrial revolution has driven the demand for minerals, but the same technological developments that have underpinned this growth have also expanded the effective stocks of natural resources at a rate faster than their rate of exploitation. There is no guarantee that this historical trend will prevail in the future, but a long-term strategy that simply adopts the common view rather than one founded on the economics of supply and demand risks incorrect choices and over- or underinvestment.

COSTS

To most people the concept of *cost* is subject to no ambiguity. It is the amount of money one has to take out of their billfold, purse, or bank account to buy something. Day-to-day transactions seldom require any further discernment, because purchasing a small item on its own does not evidently preclude the purchase of anything else later on. For larger expenditures, the real cost is more evident. An overseas vacation might mean delaying the purchase of a new car for another year; in deciding to spend the money on the vacation, one must be comfortable with the idea of driving the old car for longer. The decision—the *real* cost of the vacation and the one that influences choice—is based on the imagined loss of enjoyment and utility from driving around in the new car that much sooner.

In economics, the cost of anything is the highest-valued opportunity necessarily forsaken. This chapter looks at cost from this economic perspective. Unlike accounting costs, which are historical, the economic view of costs is a forward-looking one. Costs in this sense inform decision making, choosing between the imagined value a person will enjoy from following one path and the value of an alternative path. The tools described in this chapter and in the following economics chapters are aimed at understanding this value in order to help make these decisions. This chapter introduces the concepts of marginal, average, variable, fixed, and sunk costs. It illustrates why the marginal cost calculation is such a vital one in pit optimization and in determining the scale of investments and why certain costs are excluded or included in cash-flow calculations.

Types of Costs

To make sensible business decisions, every business needs to know its costs to produce its products. Of the variety of ways to measure costs, some cost concepts are more appropriate for certain problems than others. This section explores these different cost concepts and some subtleties in understanding them.

Every business incurs costs that do not vary with output and costs that do. A *fixed cost* is an expense that does not vary with the level of output—for example, an annual payment to maintain a mining lease (assuming the payments are independent of production). The portion of a fixed cost that is not recoverable is a *sunk cost*. Sunk costs should not affect subsequent decisions and are excluded in preparing a cash flow of a mining property

Example 1. You have spent $15 million evaluating a mining property over a long period of time, and the project looks (almost) viable. Your accounting policy requires you to allocate the $15 million across the proven reserves, but when this cost is included, the project fails to meet your required investment return. Should the exploration costs be included or excluded?

Solution. The exploration costs should not enter into the decision to proceed or not. If you proceed with the project, your accountants will report a loss on the project (because they will write off the cost of exploration and assign it to the project), but if you *do not* proceed, your accountants will *still* report a loss. The $15 million is common to all alternatives because it has already been expended and is unrecoverable.

Are these costs truly unrecoverable? The exploration costs in this example may have already been spent, but they do not automatically become sunk costs. You might not be able to recover your whole $15 million of expenditure, for example, but the property might be salable for $10 million. Only $5 million of the original $15 million is a sunk cost, and $10 million is a *recoverable cost*.

How does one treat the cost of what is already owned, such as the exploration property in the preceding example or one's existing equipment? Such choices are common in operating mines, particularly when underutilized equipment is owned and can potentially be used in new, though less-than-ideal ways. In these cases, the company must use the economic cost to help make the decision, defined by the value of the opportunity that is forsaken. The choice is between *using* the equipment and doing *without* the equipment, and each alternative has various money costs and benefits. In the finance literature, these true economic costs are referred to as *opportunity costs*.

Example 2. You have some older equipment that cannot be used for overburden removal, and you propose to use it for reclamation. You already own it, so there is no purchase price and no cash flow. If you do not use it for reclamation, you could sell it for $1 million. Should the $1 million be included in the cash-flow analysis and in the decision to use it for reclamation?

Solution. Yes. The alternative case has its costs, plus a revenue of $1 million (minus taxes) from the sale of the equipment, so this potential revenue is lost in the first case.

Lost revenues (from the alternate scenarios) are called opportunity costs because, by accepting the project, other opportunities for using the assets are foregone. These true economic costs should be used regardless of the value that the accounting system places on the asset in question.

Variable costs change with the level of output. Typically, as output increases, so does the need for labor, fuel, electricity, and materials, so variable costs depend on the wages and prices that a firm must pay for these inputs. Although variable costs are commonly called *operating costs*, in the day-to-day decisions one cannot assume a one-to-one correspondence between what an accountant calls an operating cost and what is truly a variable cost. Whether a cost is a fixed or a variable cost depends on the time frame of the decision. For yearly budgeting, labor costs are a variable cost, because labor requirements can usually be increased or decreased in line with yearly production requirements. But on a day-to-day basis, most labor costs are fixed. If a truck driver has reported to work and there is no truck available, then this labor cost cannot be avoided.

Thus, even if the production manager (making day-to-day decisions) and the planning engineer (making life-of-mine decisions) both have the same objective—to maximize company profit—the way they make their choices might be quite different. For a production manager, almost all costs are fixed on a day-to-day basis, so from that perspective the lowest cost per ton is achieved when the production is at a maximum. Thus the normal and entirely rational objective for a production manager is to forget about costs and just maximize production. From the perspective of a long-range planning engineer, few costs are fixed. There is scope to buy and sell equipment, change equipment mix, and change the extraction sequence. Decisions must be made not only on production requirements but also on optimization of costs, both capital and operating.

Any new mining development also includes costs that the decision maker does *not* take into account. For example, following commencement of a new mine, the increased traffic might require higher costs of local road maintenance. Dust and noise pollution might impose costs on people quite removed from the project. This style of cost is termed an *externality*. Externalities can be both positive and negative. A supermarket valued at $0.5 million before a mine commences might be valued at $1 million after the mine starts due to the increased business it enjoys from mine personnel. Externalities are changes in value incurred by others outside of the company that are not explicitly taken into account in any decision within the company.

There is a risk that economic assessments which do not take into account significant externalities might lead to incorrect choices. Many large firms already extend their assessments to include externalities on social responsibility grounds even if no legislated requirement has mandated this.

Marginal Costs

In economics, few concepts are more important than the concept of marginal cost.

The marginal cost is the change in total cost. The counterpart to marginal cost is marginal revenue. Marginal revenue is the change in total revenue.

One can consider almost any production process, which will involve some fixed and some variable costs. As production expands, the fixed costs are unchanged, so the average per-unit cost of production attributable to this component declines. If this were the only trend, then the highest production case would be the lowest overall cost of production. However, few production processes work this way. The fixed parts of the process can only service a limited range of variable parts. As production expands for the same fixed components, the efficiency of the system declines. Each increment of production incurs a little more variable costs than the previous increment.

For example, a loader/truck system is the archetypal system in mining. The haul road establishment costs, loader capital costs, and most of the loader operating costs are the fixed components, and the trucks are the variable component. When only one truck is paired to the loader, the average cost of production is high because the fixed costs of owning and operating the loader are spread over a relatively small production. The loader spends a lot of time idle while the one truck is hauling the material to be dumped. When two trucks are allocated, production will increase—but not quite to double the previous amount, because there will be queuing at the start of the shift. The only extra costs are for the extra truck. As additional trucks are added, production will increase further but by a declining amount as the increasing numbers of trucks interfere with each other.

Figure 5.2-1 shows the idealized situation for this style of production process using sample production and production cost numbers for illustration.

The average cost of production is initially high at low levels of production, and each increment of production has a low but increasing marginal cost. If the marginal cost is less than the average cost, the average cost declines with increases in production. The production rate that yields the lowest average unit cost of production occurs where the marginal cost curve crosses the average cost curve (30 units of production in Figure 5.2-1).

Although the lowest average unit cost of production is certainly a desirable objective, usually the objective is to maximize profits (or minimize losses). If the selling price is $2.33, for example, production can be expanded to 40 units and the additional production still yields a return higher than the marginal cost. Indeed, this is the rule: Expand production until the marginal cost equates to the (marginal) revenue. If in

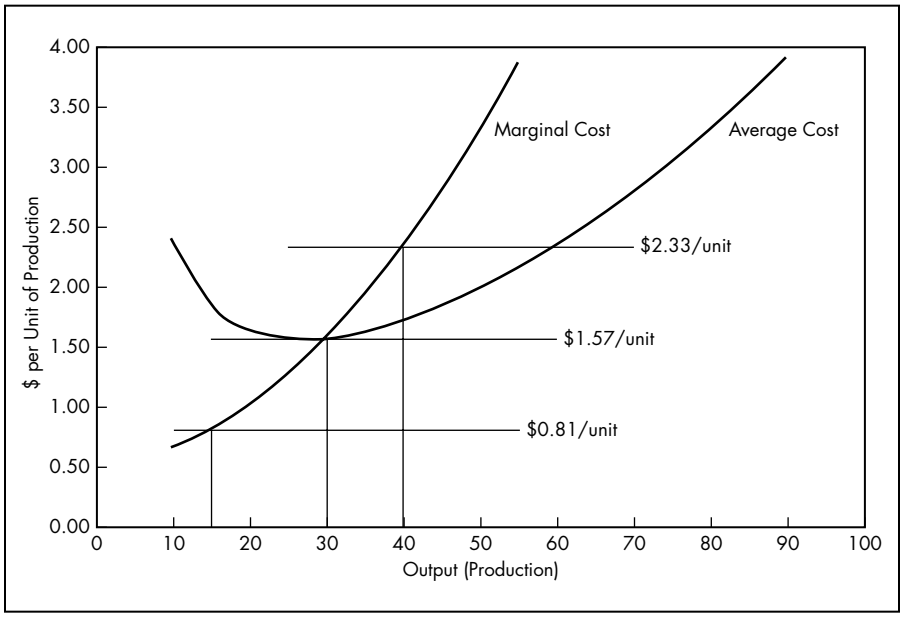

Figure 5.2-1 Average and marginal cost curves

this pricing scenario the production was expanded to 60 units, with an *average* cost of $2.33/unit, then the mine would still be profitable. However the production from the first 40 units would be subsidizing the last 20 units of production. Profits cannot be improved by increases in production rate where the marginal cost exceeds the marginal revenue.

A similar situation occurs for mines in a loss-making situation. In Figure 5.2-1, if the selling price is $0.81/unit, for example, the mine cannot avoid losses at any output level. But the losses are minimized at the point where the marginal cost equates to the selling price (about 15 units of production), not at the lowest point on the average cost curve (30 units of production).

For some simpler assessments (selecting loader/truck fleets, for example), reliable computer simulation packages are available. For most assessments, however, the compilation of a graph similar to Figure 5.2-1 is a lengthy process. The marginal cost curve normally cannot be calculated directly, because as the production expands, the process employed to undertake it frequently changes. If this example involved a loader/truck fleet, for example, the size of loader and truck selected might be quite different for an output of 60 units of production compared to an output of 20 units. Thus, a desired production rate of 60 units requires design of a system appropriate to this rate and its attendant costs, whereas a desired production rate of 30 units requires a system design appropriate to this lower rate—presumably using smaller equipment. The marginal cost is the change in total cost—calculated by multiplying the average cost at the higher production rate by this output and subtracting the equivalent total cost at the lower production rate.

In this example, the selling price was assumed to be independent of production. For many mineral commodities such as gold and silver, this is an appropriate assumption because gold and silver are readily transportable and freely traded on world markets, and the production from any one mine—even the biggest mines—is small compared to the size of the world market. But for many other commodities, price is dependent on production because the cost of transport to supply into larger and more distant markets reduces the mine gate price. Most industrial minerals are in this category, as well as bulk commodities such as coal. How then can the optimum output be determined?

In these cases (where price cannot be assumed constant), the same logic and the same rule applies: Select an output level where the marginal cost equates to the (marginal) revenue. In this case the marginal revenue is not a constant; it too must be calculated. Example 3 illustrates how the marginal revenue calculation can be addressed.

Example 3. Consider a mine currently producing 8 Mt (million metric tons) of coal per year under a mix of spot sales and contracts to a variety of regional customers. At any one time customers are all paying slightly different prices for the same coal, but in due course prices become more widely known and these influences reduce. Long-term contracts have price variation clauses that adjust to market conditions. The average selling price for the existing output is $10/t. You can expand production by 1 Mt/yr at an operating cost (for this extra coal) of $6/t with only a small amount of capital. Repaying this extra capital, you can still make your required return on investment at a selling price of only $9/t. You believe you can find additional customers who will purchase the extra 1 Mt/yr at $9/t. Should you proceed?

Solution. This seems to be a clear-cut case. If the selling price exceeds the marginal cost, profits increase with each increase in production. The risk is that, lacking any ability to keep prices secret (never a good strategy, in any case) for any length of time or to differentiate the new coal from the old coal, *all* of the output from the mine will be priced downward. Your customers themselves have incentives to do this. For instance, what is to stop your new customer from selling some of your new coal to one of your old customers (at perhaps $9.50/t), with both of them being better off?

In this example, prices are not independent of production. Selling some coal below average price makes it harder to

maintain the price of your existing supply. Perhaps you only risk downward price revision by 5%, but this reduced price applies to all of your output, if not immediately, then certainly in the near future. The marginal revenue is the change in total revenue, and this is not the same as the proposed $9/t selling price that the new customer is initially prepared to pay. Expansion is only viable to the point where marginal cost equates to marginal revenue. Table 5.2-1 shows this calculation.

The additional output has an effective selling price (marginal revenue) of just $5.50/t—a price at which the expanded production is not viable because it is less than the marginal cost of $9/t. Of course, real-life cases always have additional complexities that are not included in this example, but the principle applies. The change in total cost and total revenue should be applied to the change in production, and this result should guide the decision of whether or not to proceed, not the narrowly defined costs and revenues associated just with the extra production.

The confusion between average, incremental, and marginal payoffs can work the other way, too. Most managers naturally hesitate to throw good money after bad, but if an existing project is already making a loss, this may be irrelevant in the decision regarding incremental expenditure on it. Sometimes an existing project is yielding poor returns because of a bottleneck in the production chain, and small incremental investments to remove such bottlenecks can yield large marginal returns.

Whenever optimization is the objective, marginal costs should be the focus.

Procedures aimed at pit optimization (in open-pit mines) and cutoff grade calculations (in all types of mines) apply this identical principle. Starting from an initial ore body, they examine extensions to the ore body in all dimensions to ascertain whether the marginal revenues from the extension exceed the marginal cost of extracting the additional ore and waste. The optimum limit of mining is where, at the margins, the return equates to the cost.

TIME VALUE OF MONEY

Money tomorrow is not as valuable as money today. Given the choice of having the same amount of money in the future or right now, everyone would prefer to have it now. Money received in the future has some risk that it might not materialize, but even if there was no such risk, it is still worth more if it is available for use now. If it is available now, the things that one might conceivably do with the money are as broad as possible. If it is not available until some time in the future, then the opportunity set is limited to a smaller subset of this first set. Maximum freedom to choose is always worth something—particularly in more uncertain environments. Therefore, money to be received in the future must include a premium if it is to be considered equivalent to money in hand today. Future cash flows (money) must be discounted in order to compare with present cash flows.

Almost every economic decision in mining involves cash flows (spending money, receiving money) occurring at different points of time. Consequently, economic evaluations must incorporate a way for equating these money values at some constant point in time (usually, now). For simple calculations, future values are derived by taking current values and multiplying by the interest rate (compounded). Or, equivalently, future values (anticipated cash flows) are turned into the equivalent present value by discounting—that is, dividing by the compounded interest rate.

Table 5.2-1 Marginal revenue calculation

Production Scenario	Total Production, Mt/yr	Estimated Average Selling Price per t	Total Annual Revenue, millions
Current mine	8	$10.00	$80.0
After expansion	9	$9.50	$85.5
Extra output	1	$5.50 Unit marginal revenue	$5.5 Marginal revenue

For meaningful calculations of mining investment propositions, a complete tabulation is normally prepared for all of the cash flows through each year of the project's life. The aggregate cash flow (the sum of the expected positive and negative cash flows) in each year is calculated first, and this value is turned into a present value via the applied discount rate. To account for uncertainty and other factors, the discount rate is usually greater than the long-term interest rate.

Valuation at Constant Point in Time

The first series of time-value calculations apply simple formulas to bring anticipated cash flows to an equivalent time reference basis for calculation. Simple calculations are grouped into two categories:

1. How to turn a future value into the equivalent present value and vice versa, and
2. How to turn a regular series of equal values occurring over several years into an equivalent single amount in the present and vice versa.

The two functions used to relate present values to future values and vice versa are

1. Compound amount function (future value), and
2. Present value function.

The future value is determined by the following formula:

$$FV = PV \times (1 + i)\, n$$

where

FV = future value
PV = present value
i = interest rate (in the time period)
n = number of time periods (years)
$(1 + i)^n$ = compound factor

Example 4. Your company has to pay a reclamation bond to the government for each hectare (ha) of disturbed land. The funds are held in trust, earning interest at 6% compounded annually until reclamation is complete, whereupon they are returned. If you disturb 40 ha of land this year and the bond is $50,000/ha, how much do you expect to get back when reclamation is completed in 3 years' time?

Solution.

Present value: $50,000 × 40
(of money paid out now) = $2.0 million

Compound factor: $(1 + 0.06)^3$
= 1.191

Therefore,
Future value: $2,382,000

The present value function is used to move a future value estimate back to the present and is the inverse of the future value function:

$$PV = \frac{FV}{(1+i)^n}$$

where

$$\frac{1}{(1+i)^n} = \text{present value function}$$

Example 5. You have received bids from two manufacturers for purchase of a new dragline. The first bid (A) is competitive but from a company that requires payment in full on placement of order. The second bid (B) is for a higher price, but no payment is required until the machine starts digging in 3 years. Which is the preferred option?

Dragline A bid price (payment today):	$30,000,000
Dragline B bid price (payment 3 years' time):	$40,000,000
Required return on capital (discount rate):	15%
Time *n*:	3 years

Solution.

Present value (of purchasing Dragline B 3 years into future)	$40,000,000
	× 0.6575
	$26,300,000

Dragline B has a lower cost than Dragline A in present value terms.

Functions are also used to relate a regular series of equal values occurring over several years into an equivalent single amount. The most useful of these is the capital recovery function. Used to spread a present value amount evenly over a period of *n* years, it produces a series of equal values occurring at the end of each year for the time period specified.

$$\text{capital recovery factor} = \frac{i}{1 - \frac{1}{(1+i)^n}} = \frac{i(1+i)^n}{(1+i)^n - 1}$$

Example 6. The expected life of a rope shovel is 16 years, after which time the mine will close and the salvage value will be effectively zero. What is the annual owning cost, including allowance for return on your capital invested in the rope shovel? If the shovel works 6,000 hours per year, what is the hourly cost?

Required return on capital (discount rate):	15%
Cost of rope shovel:	$7,000,000
Time (*n*):	16 years

Solution.

Capital recovery factor:	$0.15/[1 - (1/1.15)^{16}]$
	$= 0.15/[1 - 0.1069]$
	$= 0.1679$
Equivalent annual cost of shovel over 16 years	$= \$7{,}000{,}000 \times 0.1679$
	$= \$1{,}175{,}300$/yr
Therefore, hourly cost	$= \$1{,}175{,}300/6{,}000$
	= $195.88 per hour

Almost all scientific or engineering calculators and spreadsheets now include functions capable of undertaking these calculations directly.

Discounted Cash-Flow Analysis

Although all of the functions discussed in the previous section are important in determining values for activities occurring over time, their usefulness is limited because they do not take taxation effects into account and need regular cash flows. Since almost all real-life cases involve taxation, and operating costs and revenues vary over time, an alternative evaluation method must be used. The method universally used for almost all mining and other business evaluations is the discounted cash flow (DCF) technique. (This technique is only briefly introduced for a simple case; however, Chapter 2.4 in the handbook addresses this technique from a broader perspective.) In *Mining Economics and Strategy* (Runge 1998), comprehensive examples of the DCF technique are set out for a wide range of mining applications.

A big difference exists between corporate finance (i.e., costing, economics, and capital investment decisions) and financial accounting, which stresses incomes and earnings. While accounting procedures document what has happened, mining economics aims at informed decisions on what to do. For accounting purposes, all expenditures are normally apportioned over the period that the expenditure translates into useful work. For planning and operating a business, there is no apportionment—allowance has to be made when the expense actually occurs.

Example 7. Consider the purchase of a dozer for $600,000 paid for today. The entire $600,000 is an immediate cash outflow. An amount of $600,000 has to be available at the time the dozer is delivered—before it has done any useful work. However, assuming straight-line depreciation over the 6-year life of the dozer, only $100,000 is considered an accounting expense in each year. Current earnings (reported profits) for this year are reduced only by $100,000. The remaining $500,000 is expensed (counted as an operating cost) over the following 5 years.

To run the business, what is important is cash flow, not accounting profit. In Example 7, the company supplying the dozer requires the full purchase price to be paid now, not just the amount of depreciation that the accountant attributes to this year's cost of production. Furthermore, capital expenditures always occur before any production, whereas accounting conventions only assign their costs (and revenues) during or after production has taken place.

The objective of a cash-flow analysis is to simulate all of the anticipated cash flows over the project's life (and express them in present value terms) to help make a decision to proceed or not. The most obvious cash flows are

- Revenues from sale of the products,
- Expenses incurred in producing the products, and
- Capital expenditures necessary to bring about production.

Capital expenditures are tabulated in the cash flow in the year prior to their use. The plant or equipment must be operational before any production takes place (the start of the

Table 5.2-2 Sample discounted cash flow

	Year*					
	0	1	2	3	4	5
1. Production, oz	—	32,000	50,000	50,000	50,000	45,000
2. Operating revenue at $500/oz	—	$16,000	$25,000	$25,000	$25,000	$22,500
3. Operating expenses	—	$10,598	$17,762	$19,339	$21,073	$20,882
4. Operating profit (2 – 3)	—	$4,402	$7,238	$5,661	$3,927	$1,618
5. Capital expenditure	$15,000	—	—	—	—	—
6. Tax depreciation this year at 27.5% (declining balance)	—	$4,125	$2,991	$2,168	$1,572	$1,140
7. End-of-year written-down value for tax purposes	—	$10,875	$7,884	$5,716	$4,144	$3,005
8. Salvage value (= 7)	—	—	—	—	—	$3,005
9. Taxable profit (4 – 6)	—	$277	$4,247	$3,493	$2,355	$478
10. Income tax payable at 35% tax rate	—	$97	$1,486	$1,223	$824	$167
11. After-tax profit (9 – 10)	—	$180	$2,760	$2,270	$1,531	$311
12. Net cash flow (4 – 5 + 8 – 10)	($15,000)	$4,305	$5,751	$4,439	$3,103	$4,455
13. Discount factor (at 15% ROI†)	1.0000	0.8696	0.7561	0.6575	0.5718	0.4972
14. Discounted cash flow (12 × 13)	($15,000)	$3,744	$4,349	$2,919	$1,774	$2,215
15. Net present value	$0	—	—	—	—	—

*All annual cash flows are in thousands, rounded to nearest thousand.
†ROI = return on investment.

period). With the end-of-year convention, capital expenditures are therefore placed at the end of the preceding year.

Cash-flow tabulations should normally commence with production tabulated on the top or near to the top of the table, because almost all of the revenue and many of the operating expenses are related to production. Revenues (the primary cash inflow) are also tabulated at the top of the table.

To obtain the operating profit, operating costs are subtracted from the operating revenues. All operating expenses are included in a cash-flow calculation, even if some of the costs pertain to production in following years. This differs from the way operating costs are treated for accounting purposes, where expenses that pertain to production in succeeding time periods (e.g., advance stripping) are apportioned to the period in which they directly relate to production.

A sample discounted cash-flow tabulation for a mining project is set out in Table 5.2-2. In this tabulation, a hypothetical gold mine with a 5-year life produces up to 50,000 oz/yr and expects to sell all of the output at $500/oz. The main background data needed for this tabulation (or any discounted cash-flow tabulation) are set out in Table 5.2-3.

In Table 5.2-3 the data has been deliberately chosen for illustrative purposes so that the selling price of $500/oz yields a net present value of zero at a discount rate of 15%. This discount rate is just a guideline and is usually determined by senior company finance personnel weighing the relative risks and the cost of capital between this project and any alternative projects that the company might otherwise choose to apply its resources to. Thus, in this example, if the gold price exceeded $500/oz, the internal rate of return would exceed this (opportunity) cost of capital, and the project could proceed.

Table 5.2-3 Base data for discounted cash-flow calculation

Item	Value
Initial capital cost	$15,000,000
Life of project	5 years
Salvage value at end of life	At written-down value
Production per year	Varies
Selling price	$500/oz
Annual operating expenses	As shown
Depreciation rate for tax purposes (declining balance)	27.5%
Tax rate	35%
Discount rate	15%

Although the format for cash-flow tabulations in real-life applications—even for large projects—is similar to Table 5.2-2, even simple assessments include many more elements than shown. Elements commonly built into the DCF tabulation include exchange rate factors, expected escalation and de-escalation of cost and revenue components (inflation adjustments), and finance charges.

CHAPTER 5.3

Management, Employee Relations, and Training

G. Aubrey Lee

INTRODUCTION

Demands for resources that must be accessed by mining are increasing exponentially. Energy demands in emerging industrialized nations such as China and India are putting a strain on the availability of coal and other resources throughout the world. In some areas, labor shortages are a tremendous hindrance to mining operations and are driving up prices of coal and metals because a stable, trained work force cannot be sustained.

As a result, recruiting, developing, and retaining a skilled work force must be incorporated into every mining organization's strategic planning process. At the same time, maintaining effective employee relations is becoming increasingly complex in today's globalized mining operations and must also be approached strategically. Components of these strategies must include

- Providing at all levels of the organization's effective leadership that recognizes maintaining good labor relations as essential to mining operations;
- Viewing training, employee development, and organizational learning as an integral aspect of company strategy, not merely a cost that adds no value;
- Managing employees' work/life balance, giving particular attention to shift work and other working conditions;
- Understanding that safety, like productivity and quality, can be managed to effectively protect the safety and health of miners working in potentially hazardous conditions;
- Managing contract workers who have become a critical component of the mining labor force;
- Effectively managing both union and nonunion mining work forces, as well as the legal, ethical, and practical implications confronting each scenario; and
- Understanding cultural differences and adapting management styles and practices to effectively manage the issue which may be foreign/counter to the manager's own culture.

The approach to managing each of these components will, of course, vary widely throughout the world. Culture, regulatory environments, and union versus nonunion status will all impact upon the way employee relations and training are managed and conducted. As a result, much of this chapter will be general in nature. Readers will need to assess what is written in light of their own specific circumstances and adjust their practices accordingly.

Another point to be emphasized that impacts the approach to this chapter is that many mining organizations are multinational and thus have managers working outside of their home country. Insights are offered about ways to approach employees from cultures whose norms and behaviors differ drastically from those of the "foreign" manager. Failure to understand how to manage cross-culturally is recognized as a frequent source of underperformance or even failure for expatriate managers and engineers. Sometimes this will be as critical as deficiencies in "hard" or technical skills. Thus, training and orientation in this area is essential.

Leadership is often described as achieving the goals of the organization through the efforts of others. This means that, although the primary responsibility is achieving the organization's goals, the only way to do that is by providing effective leadership for the employees.

FIRST PRIORITY FOR MINING LEADERS—HEALTH AND SAFETY

Mining has historically been difficult and sometimes dangerous work, although technology and safer work practices have improved working conditions in recent decades. Safety is a larger issue than ever before, however. The protection of the health and safety of miners is essential and should never be considered only in light of public opinion. In other words, workers must be protected because it is the right thing to do.

Managers in the mining industry must strive to manage health and safety issues in the same manner, regardless of the country in which they are doing business. Being lax in nations that have less stringent safety and health regulations is unfair to employees and can damage a company's reputation worldwide. Shareholders, the media, activist groups, unions, and governmental agencies now closely watch the safety, health, and environmental performance of multinationals and have

G. Aubrey Lee, Senior Consultant, SESCO Management Consultants, Bristol, Tennessee, USA

the capacity to take actions that can severely damage a company's ability to operate.

Although the top management and/or corporate boards (or governments) of mining organizations set policy, operating supervisors and managers on the front line have ultimate control over working conditions. They are responsible for promoting safe working practices by effectively training and managing miners and working conditions in the operations under their control.

BASIC PRINCIPLES OF MANAGEMENT

One key to successful management is to follow a consistent pattern of interaction with one's team. Effectively handling difficult situations while increasing the performance of the work group can make the difference between success and mediocre performance, particularly in a mining environment. Following are five key principles for successful leadership:

1. **Lead by example.** In most cultures, "do as I say, not as I do" will not be effective. Supervisors or managers with poor work ethics or sloppy or unsafe work practices tend to engender the same type of performance among their co-workers.
2. **Maintain self-esteem.** Berating employees in front of their peers, discounting their suggestions or complaints, and projecting a superior, "know-it-all" attitude will result in demotivated individuals who will never live up to their potential. In some cultures, such tactics can result in the total demoralization of the person. Mining leaders must do all they can to make employees feel they are valued and not just a means to an end. Employees need to understand that their job, regardless of where it stands on the company's organizational chart, is vital to the success of the mining operation where they are employed.
3. **Establish and maintain constructive relationships.** Adversarial relationships on the job are counterproductive and can even be dangerous to health and safety, particularly in mining operations. Mining operations supervisors and managers can influence employees' opinions about their jobs and the company more than any other group. Even in union environments with entrenched negative attitudes toward management, making a conscious effort to avoid conflict and engender positive interaction is critical.
4. **Always focus on the situation, the problem, or behavior—not the person.** People make mistakes. Except in situations where a person is intentionally trying to sabotage the organization, most poor performance is unintentional. Most employees do not consciously set out to do a bad job. This is not to say that some sort of corrective or disciplinary action should not be taken based on policy and past practice. Either way, the supervisor should address the issue, not the person, and make every effort to reinstruct, remind, or do whatever is needed to prevent a reoccurrence of the problem. Berating the person while offering little help to encourage better behavior or performance going forward is counterproductive and should be avoided. Furthermore, people are part of a system in any mining operation, that is, a system made up of other miners, equipment, tools, processes, procedures, and so forth. Supervisors and managers must recognize that if a system exists where employees have difficulty performing properly, perhaps the system is the root cause of the issue, not the miners. Often modifying a procedure, repairing equipment, or reconfiguring staffing will improve performance.
5. **Take initiative to make things better.** "Continuous improvement" is sometimes an overused expression, but it is still valid in any industry, particularly when supervisors and managers on the front line of a mining operation have opportunity to spot those seemingly little things that can make a big difference in quality, productivity, or safety. Miners under direction of a supervisor may have an even better perspective to see potential improvement. Much can be gained from soliciting and paying close attention to suggestions from employees. In addition to improving the operation, morale will be boosted if employees see that their ideas are heard and, where possible, implemented.

Good management, founded on the principles outlined above, must be supported by good habits. The characteristics seen in Figure 5.3-1, if integrated into the manager's behavior, can lead to more productive, profitable, and safer mining operations. As stated previously, cultural differences can arise when management practices are proposed that are more or less Anglo-American. However, many of the suggestions given will have universal application. Cultural differences are addressed more fully later in this chapter, with particular reference to assisting multinational managers who are working outside of their native culture.

MANAGING UNION OPERATIONS

Union membership is identified by the United Nations as a universally recognized right, as stated in Article 23, subsection 4, of the United Nations Universal Declaration of Human Rights (UNGA 1948). The same subsection acknowledges the right to *not* join unions. This ambiguity and the friction such a position creates are nothing new to the mining industry, where companies and unions have experienced difficult times in the past. Bloody and costly strikes, work stoppages, and other issues are still a possibility for many mining companies. Nevertheless, as has been proven by mining companies throughout the world with various unions, it is possible to manage in a way that creates favorable financial returns for the company while offering good compensation and working conditions to unionized miners (SESCO 1979).

Managers and supervisors should be aware that transnational union strategies have been globally invigorated by the consolidation of existing trade union organizations in the mining, chemical, and energy sectors. This resulted in the formation of the International Federation of Chemical, Energy, Mine and General Workers' Unions (ICEM) in 1996. The union's strategy is to consolidate local union activity with the entire global network of union members and outside resources. Experts say that this is an example of the coming trend of transnational union relations, resulting in unions forming alliances with human rights, environmental, and other activist groups to pressure transnational companies to agree on codes of conduct regarding alleged violations in areas such as civil rights, employment law, safety, and environment. The international media have also been mobilized to report on such alleged violations as a result of more concerted and high-profile global union activities. What does all this mean for mining supervisors and managers? Front-line mining leaders must understand that their role is

1. **Communicates Effectively**
   - Shares information with employees about job performance, about the company, and about how to do the job
   - Is a good listener; listens without interrupting or disagreeing
   - Asks for opinions and encourages employees to take initiative
2. **Provides Clear Performance Expectations**
   - Communicates both positive and negative feedback to employees
   - Addresses problems when they arise; does not wait for review time; addresses individual problems in private
   - Evaluates on performance, not personality
   - Communicates about "getting the job done" in meetings
   - Lets employees know that they are expected to seek solutions to their problems
   - Gets employees' buy-in on performance expectations by explaining the "whys" of the situation when appropriate
3. **Develops Employee Relationships**
   - Has genuine concern for employees—is not superficial or patronizing
   - Builds relationships and respects employees' individuality
   - Is caring about employees' personal lives without prying or invading privacy
   - Does not have "favorites"
4. **Does Not Micromanage**
   - Is careful not to overcontrol the employees
   - Delegates fairly
   - Gives employees a chance to grow
   - Keeps in touch about progress—asks the right questions
   - Responds enthusiastically to ideas and suggestions
   - Praises employees
   - Helps employees learn from their mistakes
5. **Has a Sense of Humor**
   - Admits mistakes
   - Remains consistently upbeat
   - Sets an example in professionalism, work ethic, integrity, tone, and morals
6. **Provides Consistent Direction**
   - Does not keep changing agendas
   - Sets priorities
   - Has a clear and consistent direction for the departmental operation and shares it regularly with employees
7. **Looks for Ways to Learn from Others**
   - Is open to change
   - Strives to present logic and thought, yet remains conscious of the fact that it requires people to accomplish goals
   - Recognizes that success primarily depends on employees

Figure 5.3-1 Characteristics of an effective manager

critical in addressing the mounting resources that organized labor is amassing to organize miners. Although there are no silver bullets to ensure good labor relations, leadership that promotes fair and consistent treatment of workers and safe working conditions goes a long way in avoiding issues with organized labor, including costly strikes, labor slowdowns, and the negative publicity such events can create.

The same skills required to effectively manage people in nonunion operations can be employed in union mines. However, all actions taken on behalf of or against employees must be within the tenets of the union contract. All who have ever managed union employees understand that there are stringent contracts that are inflexible, and there are those that permit managers some latitude. Labor laws that govern how contracts are written vary widely from nation to nation and can even fluctuate depending on the political party or group that is in power at the time. The relative strength or weakness of company and union leadership in a given situation also greatly influences how union miners can be managed. In nations that do not feature state-sponsored labor unions, many companies make a concerted effort to maintain a nonunion status because of the inefficiencies sometimes encountered in managing within the confines of a union contract.

Managers employing union miners must, of course, make every effort to avoid strikes, work stoppages, or slowdowns. Such events can be precipitated by any number of issues, including financial disagreements, disputes over working conditions, and the treatment of workers by management. Many labor relations experts contend that the last factor, particularly how people on the front line are managed, is a critical factor that can be positively impacted by training managers to practice effective employee relations skills. The following section includes some practical guidelines for managing a union work force and begins with a brief overview of labor law.

Managing Union Employees to Avoid Legal Issues

Although the following is based primarily on Anglo-American labor laws, some of the requirements will apply to the laws of other nations. Because labor relations are complex and location specific, expert counsel should always be sought when managing unionized employees, particularly in times of labor–management conflict.

- **Good-faith bargaining.** The labor laws of most Anglo-American countries and some other nations require employers and labor unions to bargain in "good faith." What constitutes good faith on the part of the employer

or the union is difficult to define and is constantly being interpreted based on the facts at hand. However, the basic requirement of good-faith bargaining is that both the employer and the union must negotiate with the view of trying to reach an agreement. The bargaining obligation is not satisfied by merely going through the motions without seeking to adjust differences. Should there be a dispute on the part of either party as to whether "good faith" is being exercised, it is up to the courts or whichever governmental agency regulates union–employer relations to determine the "totality of conduct" by looking at all relevant facts of the issues within the case at hand. There are numerous factors to consider, but, as mentioned previously, the determining factor will be the perceptions of both the union and the company as to whether the other side is trying to reach an agreement or is simply stalling or complicating the process.

- **Mandatory bargaining issues.** Some terms and conditions of employees must be on the bargaining table. Again, these vary from nation to nation, but wages, compensation for nonworked time, certain nonwage benefits, working conditions, management rights, and union management or leadership rights generally must be subject to negotiation.
- **Nonmandatory bargaining issues.** Certain subjects are nonmandatory and include the definition of the bargaining unit; conditions affecting supervisors; performance bonds; clauses that are illegal, such as harassment or discrimination, based on the laws and regulations of the nation; and right-to-work laws as may exist in certain nations, states, or provinces. Management should seek the appropriate legal counsel when determining what is mandatory and what is not, to avoid unnecessary conflict in the bargaining process, since this will vary widely and is, of course, subject to interpretation.

Management Actions During Contract Negotiations or Organizing Attempts

The behavior of management and supervisory personnel is critical during contract negotiations or during union organizing drives. Again, from an Anglo-American perspective, there are certain statements or actions that management cannot say or do lest they fall foul of the labor laws governing their country or province. Such prohibitions, as identified by SESCO Management Consultants (1979), include the following:

- **Bargaining individually with employees.** Because unions are organized collectives of people, management cannot bargain individually with employees on matters—even minor ones—pertaining to wages, benefits, or working conditions.
- **Threats, interrogations, promises, and spying (TIPS).** Management cannot threaten to close, move, or reduce operations to avoid being unionized, or coerce employees to accept part of a contract that is perceived as favorable to management and unfavorable to union workers. On an individual basis, management cannot threaten to discharge employees for engaging in union activity. Interrogating employees about their involvement or the involvement of other union activities could also result in the violation of labor laws. Spying on union activities to see who is supporting the union or attending union functions is also prohibited. Promising a pay increase or benefit improvement if employees do not join the union or if they support contract provisions that are unfavorable to the company, in the case of contract negotiations, is also illegal, as is making false statements about the positions of unions.

The TIPS model is an easy and effective way to remember what managers and supervisors can and cannot do during a union organizing campaign or contract renewal period. Remembering this simple acronym can save managers and supervisors much grief and legal problems when dealing with union employees in potentially volatile and confrontational times.

Behaviors Management Must Avoid:

Threaten employees
Interrogate employees
Promise employees
Spy on employees

What Management Can Do

The key to making comments to employees during organizational attempts or contract renewals is simple: Tell the truth. Managers can talk to employees about the company's position in negotiations or the status of the negotiation process as long as their comments are factual and accurate and do not threaten to reduce or promise improvements in pay, benefits, or working conditions.

Managers are free to impartially enforce rules in ways that are fair and consistent with past practices (and within the confines of the contract, if the company is unionized). In other words, management can continue to manage the business as long as union supporters or union employees are not singled out for harsh treatment. Most importantly, management can tell employees that the mine plans to keep operating to serve its customers during labor negotiations or strikes.

GLOBAL MANAGEMENT

Managing internationally outside of one's country of origin is complex and difficult. Most managers are trained in their home country and therefore adopt a management style based on their own culture. Since multinational ownership is prevalent in the mining industry and most companies rely on expatriate managers in various levels of mining operations, understanding how to adapt to different cultures is essential.

Management, according to Hofstede (2001), is primarily an invention of the West and, as such, carries the baggage of Western culture that often flies in the face of practices that are considered acceptable in other countries. The following discussion identifies four management competencies—leading, decision making, controlling, and motivating—and offers suggestions regarding the issues Western management style creates and how that style might be modified and adapted to fit a different cultural context. These are presented through Hofstede's framework of national value systems: power distance, individualism (as opposed to collectivism), masculinity, uncertainty avoidance, and long-term/short-term orientation. These five dimensions were found to exert strong influence on the relationships between employees and the acceptability of management behavior (Hofstede 2001).

1. **Small versus large power distance** describes the extent to which the less powerful members of institutions and

organizations expect and accept that power is distributed unequally. Small power distance (e.g., Austria, Israel, Denmark, and New Zealand) expect and accept power relations that are more consultative or democratic. People relate to one another more as equals regardless of formal positions. Examples of countries that value high power distance are Malaysia, the Philippines, and Panama. This means inequality is readily accepted and leaders are in fact expected to exert strong influence. Participative management styles that seek input from subordinates may not be effective and can be viewed as weakness on the part of managers.

2. **Individualism versus collectivism** refers to the extent to which people are expected to stand up for themselves and to choose their own affiliations, or alternatively to act predominantly as a member of a lifelong group or organization. Latin American cultures rank among the most collectivist in this category, including Guatemala and Ecuador, as well as China and certain other Eastern cultures. Western cultures, as seen in the United States, Great Britain, and Australia, are some of the most individualistic.
3. **Masculinity versus femininity** refers to the value placed on traditionally male or female values (as understood in most Western cultures). So-called "masculine" cultures value competitiveness, assertiveness, ambition, and the accumulation of wealth and material possessions, whereas feminine cultures place more value on relationships and quality of life. Because of taboos about sexuality in many cultures, particularly masculine ones, and because of the obvious gender generalizations implied by Hofstede's terminology, this dimension is often renamed by users of Hofstede's work as, for example, "quantity of life versus quality of life." Societies with strong masculine values are Japan, Austria, Mexico, the United States, and West Germany. China and Indonesia are also moderately high in masculine values. Countries with feminine values are Sweden, Norway, Denmark, and France. It is helpful to understand that both men and women tend to adhere to the dominant value in masculine and feminine cultures.
4. **Uncertainty avoidance** reflects the extent to which members of a society attempt to cope with anxiety by minimizing uncertainty. Cultures high in uncertainty avoidance prefer rules (e.g., about religion and food) and structured circumstances, and employees tend to remain longer with their present employer. Mediterranean cultures, Latin America, and Japan rank the highest in this category. Countries with low uncertainty avoidance values include Singapore and Jamaica.
5. **Long- versus short-term orientation** describes a society's "time horizon," or the importance attached to the future versus the past and present. In long-term-oriented societies, values include persistence (perseverance), ordering relationships by status, practicing thrift, and having a sense of shame. In short-term-oriented societies, values include normative statements, personal steadiness and stability, protecting one's face, respect for tradition, and reciprocation of greetings, favors, and gifts. China, Japan, and the Asian countries rank especially high in long-term orientation, with Western nations ranking rather low (or short-term), and many of the less developed nations rank very low.

Table 5.3-1 Cultural dimension comparisons among nations*

Country	Power Distance	Uncertainty Avoidance	Individualism	Masculinity
Australia	7	7	2	5
Costa Rica	8(tie)	2(tie)	10	9
France	3	2(tie)	4	7
West Germany	8(tie)	5	5	3
India	2	9	6	6
Japan	5	1	7	1
Mexico	1	4	8	2
Sweden	10	10	3	10
Thailand	4	6	9	8
United States	6	8	1	4

Source: Hofstede 2001, with permission from Geert Hofstede BV.
*1 = highest; 10 = lowest.

All of these cultural factors were found to exert strong influence on the relationships between employees and the acceptability of management behavior (Hofstede 2001). In addition, concepts of time, characterized by Trompeanaars and Hampden-Turner (1998) as *sequential* versus *synchronous*, can affect U.S. and Far Eastern business relationships and can have a strong impact on mining operations in particular.

It is important to note that these cultural differences describe averages or tendencies and not characteristics of individuals. A Japanese person, for example, can have a very low uncertainty avoidance compared to a Filipino, even though their national cultures point strongly in a different direction. Consequently, a country's scores should not be interpreted as deterministic. Table 5.3-1 provides other examples of cultural dimension comparisons.

Flexing Competencies to Avoid Cultural Conflicts

Conflicts relating to cultural differences often arise from the management responsibilities of leading, decision making, motivating, and controlling. The following are examples of the nature of certain conflicts and what might be done to eliminate or at least mitigate them.

Leading

Collectivist societies prefer tight social networks in which individuals care for one another; they desire organizations that are sensitive to the members' interests (Hofstede 2001). In societies high in collectivism (Asia, Middle East, Latin America), "warm" personal approaches are critical. In China specifically, all relationships are personal. This often frustrates Western managers who must, in their opinion, spend an inordinate amount of time developing relationships with officials in Chinese businesses before meaningful business discussions can begin. Time spent visiting with workers and discussing morale and health is also often viewed as unnecessary by Western managers but is essential to Chinese and other Eastern employee groups. Correcting mistakes or poor performance must be handled delicately. Extreme care must be used when criticizing in these societies. Loss of self-respect brings dishonor to workers and their families. Trompeanaars and Hampden-Turner (1998) described a frank discussion between a Dutch doctor and Chinese subordinate that resulted in the subordinate's suicide. This is a prime example of how "saving face" is extremely important in collectivist culture.

Perhaps the strongest impact of collectivist culture that often impedes and can even ruin American business relationships in China is *guanxi*. The most direct translation of the term is "relationship," but the concept is much more complex. It describes an intricate relationship built over time through the exchange of favors and social exchanges. It effectively creates an unspoken obligation that can even be banked. It could be likened to a currency that, to many Westerners, can be foreign and burdensome. However, it is deeply imbedded in the culture, and a failure to understand or a failure to participate can break deals (Xin and Pearce 1996).

Decision Making

Power distance reflects the tendency of people to accept inequality between individuals, organizations, and institutions (Hofstede 2001). In the United States, with low power distance, middle managers do not hesitate to take recommendations to the chief executive officer (CEO). In contrast, South Asian CEOs make the decisions and then provide detailed instructions to subordinates, reflecting high power distance (Javidand and Dasmalchian 2003). Participative management does not work in high-power-distance contexts, so top managers must be decisive. In Mexico, for example, participatory management is apt to be misunderstood. Managers are expected to be powerful in issuing orders.

At the other extreme, Arab and African leaders, exemplifying low power distance, often use a consultative approach in decision making, almost to a fault (Schuler et al. 1996). Uncertainty avoidance also impacts decision-making behavior. Germany ranks high in uncertainty avoidance compared to Singapore or to their European neighbor Denmark. Germans plan carefully, and this is reflected in their society, which is heavily dependent on rules and laws. The stereotypical German trend for excellence in engineering reflects the extreme desire to be precise and to avoid a poor design that could create risk. Americans with entrepreneurial tendencies often conflict with Germans who want no part in ventures that are not a sure thing (Baum et al. 2006.)

Motivating

Motivation techniques must fit culture. Intrinsic factors such as recognition, challenge, and work itself feature poorly in high-power-distance societies. Workers may see this as manipulative and thus not be motivated. In the United States, however, and in the United Kingdom, intrinsic motivation can work. Tangible reward must be offered, but appropriately (Huang and Van de Vliert 2003). From the collectivist perspective, tangible individual motivational techniques can be counterproductive (Persaud 2003). Groups are motivated in Japan and other collectivist societies as opposed to individuals. Although individual rewards for exemplary performance may not work in this situation, a group reward offered to everyone in the work group will most likely be successful (Caudron 1995).

Time also comes into play in motivating employees. The Western concept of sequential time describes time as linear like an arrow, as opposed to time being synchronous, recurrent, and cyclical in nature in Asian cultures. This often exasperates American and other Western managers who tend to operate on a schedule with the concept that "time is money" and "we must get this project done and get on to the next," which is an essential mindset to the mining industry.

Controlling

In the United States, termination for poor work performance or behavior that is against company policy is acceptable. However, some cultures avoid employee terminations for poor performance if at all possible (Nisbett 2003). When asked what to do about a 15-year employee with poor performance for a year, who previously had had outstanding performance, managers in the West vary considerably from those in the East in terms of their response. For example, 75% of Americans and Canadians, countries high in individualism, said to terminate; only 30% of Singaporean and Korean managers said to terminate, reflecting collectivist values.

Employee termination is also reflective of cultures high in masculinity. Feminine tendencies lean more in the direction of compassion, caring, and working with problem employees, as opposed to termination (Nisbett 2003). Managers in foreign countries often try to manage the wrong actions. In Hong Kong, an American Sears manager told employees to report to work on time, not late. They did, but left on time instead of working late hours, as they had been doing. This is another example of sequential versus synchronous time. Time to the Hong Kong workers was cyclical; start time did not matter. They would be there, as long as they are needed. However, tardiness and the linear time of the West was all the American manager understood. He would have gotten more productivity if tardiness had been tolerated.

The previous scenarios mostly describe Western managers working in foreign cultures. Managing multicultural work forces means that managers may encounter various dimensions of national cultures in the same work group. For example, in areas with highly diverse populations, managers may have to be sensitive concurrently, which is a challenge. As a result of this dynamic, managers sometimes create team leaders from each nationality in order to address concurrent multicultural issues, with particular emphasis given to language differences.

Ethnocentrism

One of the most damaging cultural issues multinational managers must avoid is an attitude called ethnocentrism. This means that people tend to regard their own culture as superior and downgrade the culture and practices of those from different cultures. American managers, for example, are often accused of ethnocentrism when they assume American business practices are best and degrade local customs and practices. Failing to learn about the language, history, religion, social practices, and legal/political structures will damage credibility, particularly if expatriate managers project a superior, ethnocentric attitude. Such behavior can cause managers to fail and create issues that may result in irreparable harm to a company's ability to manage and operate effectively.

Modifying to Management Competencies

Unless strategies to effectively change local cultures can be implemented, which is difficult and should not be taken lightly (Hofstede 2001), managers must be trained to manage outside their home culture. Trompeanaars and Hampden-Turner (1998) note that before behaviors and management styles can be modified, values must be reconciled. Western managers must understand that behaviors are rooted in deeply held values that may conflict with their training, which is rooted in Western management practices. The previous scenarios

illustrate concrete, visible conflicts; each is rooted in values, not merely superficial behavior patterns that can be easily modified. As a result, competencies must be enhanced with cross-cultural style flexing, based on a deep understanding of the values that dominate the other culture. This could be accomplished by the following:

- Proper selection of those intended for international assignments. Intensive interviews and selection devices must be employed to avoid sending those with latent prejudices that might later come forward and result in conflict.
- Deep immersion in the new culture prior to assignment and an understanding of the values and history of the country's culture. Hofstede's (2001) dimensions offer one approach to identifying cultural issues that managers must be prepared to address. Working through case studies similar to the examples described earlier can help the manager to develop cross-cultural competence.
- Assignment of a culture coach, preferably a bilingual member of the new culture, to work with the expatriate manager. It's important, however, that this individual not become a de facto manager simply by having proximity to the "boss."
- Having proper mechanisms in place to provide feedback about the manager's performance.
- Taking measures to ensure that the managers assigned to lead in another culture are ready for culture shock, separation from home (and possibly family) along with the different foods, language, beliefs, and all the components of culture that will confront them on a personal level. If the family is to be relocated with a manager, extensive efforts must be made to ensure they are prepared for the new culture and environment. All too often an international assignment fails, not because of the employee, but because the family was not adequately prepared for the drastic lifestyle changes required for living in a foreign country.

RECRUITMENT AND RETENTION

A shortage of qualified miners in all types of positions is a critical issue in many countries and regions of the world. During the last decades, as mining declined, the work force was not replaced. Now, economic growth in China, India, and other nations has driven demand for metals and coal. The coal mining industry's current boom cycle has created greater demand and higher prices, but many companies are unable to meet demands because of the severe labor shortage. People currently employed in mining are retiring, and there is a lack of younger people to fill the vacancies. In Canada, it is estimated that between 60,000 and 90,000 mining jobs will open up in the nation during the next decade with not enough applicants to fill them (CIM 2009). The Minerals Council of Australia estimates that by 2015, Australia alone would need 70,000 employees on top of the 120,000 it has now to keep up with demand (MCA 2008). In the United States, layoffs, outmigration, and an aging work force in the Appalachian region have created a shortage of experienced miners. Labor officials put that deficit at more than 6,000 miners in West Virginia and Kentucky alone—the second and third highest coal-producing states. Wyoming, the nation's top coal-producing state, faces similar problems (BLS 2008).

Effective employee relations and leadership skills go a long way to enhancing employee recruitment and retention. However, managers must also undertake specific employee recruitment and retention strategies in order to keep many mining operations fully staffed with competent employees. Recruitment and retention must thus be considered a key organizational objective. Such strategies might include the following:

- Develop retention plans (e.g., employee-friendly hours of work and rosters) to increase the attractiveness of the industry. Long hours and difficult shifts with hours that do not match lifestyles can create recruitment and retention issues, particularly for employees with families. Although cultures and employee preferences vary, a concentrated effort should be made to evaluate shifts to find a schedule that is preferable to employees and yet still meets the company's production needs.
- Upskill the workers remaining in the industry to cover skills obsolescence. If employees who are leaving take essential skills with them, often the only choice is to train those left behind in the skills being lost. This can have several positive effects. First, it can provide a more flexible work force, since employees who are able to do multiple, high-skilled jobs can cover for absences or provide extra help when needed. It can also motivate workers who prefer to do a variety of jobs, thus enhancing retention.
- Increase the emphasis on multitasking among existing employees. As with upskilling, having cross-trained employees, even in lower-skilled positions, increases work-force flexibility and can improve worker satisfaction. It can also, in some circumstances, reduce the number of miners needed in certain types of mining operations. Usually pay incentives are offered to employees who are cross-trained, but extra payroll expense is usually worth the additional skills and the flexibility it provides.
- Have recruitment strategies that encourage young people to enter the industry. Since the past economic slump, some mine operators have stopped recruiting and now older miners are retiring in large numbers. Special emphasis needs to be placed on targeting young people and pointing out the pay benefits and other advantages the mining industry can offer, particularly during times when employment in other industries may be shrinking. An important consideration here is that younger generations are motivated in different ways than older generations. Generally they do not expect to work for the same company all their lives, so "company loyalty" may be lacking. They are often motivated by the latest technology. Personal time is a priority, and excessive overtime requirements may cause them to seek employment elsewhere. They might also need more direction and feedback and expect working relationships that are less formal.
- Introduce paid training or subsidized training in or out of work time. All training offered in today's highly competitive work environment should be offered on paid time. Except in rare situations, new or present employees will not look favorably on unpaid training and might in fact be driven to seek employment elsewhere. The exception to this is when the company is paying tuition for college courses, which may or may not be undertaken during working hours.
- Develop partnerships with education. Partnering with colleges, universities, technical school, and other educational institutions is now being successfully practiced throughout the industry. Subsidizing training programs that are

tailored to the company's specific needs can attract young people who want to make sure they have a job after completing their degree or technical training program.
- Provide compulsory training commensurate with industry competencies, particularly for training required by law. It's necessary to ensure that employees have the basic skills needed for the job to which they are assigned. This may seem obvious, but often basic skill training is neglected, particularly when experienced employees are hired from other companies, as it is often assumed they have certain required skills and knowledge. This may be an incorrect assumption that can be both costly and dangerous. Training varies widely from company to company; just because a miner has performed the same or a similar job at another company does not mean the miner meets the standards for the new job. All newly hired experienced miners must be assessed and trained in areas where they are deficient. Legally required training, including safety and emergency procedures, must *never* be neglected and should always be undertaken for new hires or employees assigned to new positions with different safety requirements.
- Treat contractors as company employees for training purposes. Contractors are an increasingly important fillip to the company's own work force and provide essential human resources to fill various types of positions. Mining operators must ensure that contactors are trained to the same level as employees on the company's payroll, particularly in safety and operating policies and procedures that are specific to the mining operation.
- Multicultural and bilingual training may be necessary. Different cultures approach training and education differently. Nothing can frustrate workers and their supervisors more than being unable to effectively perform their assigned jobs after being trained. This can lead to poor work performance and can cause employees either to be terminated or to leave through frustration. It is imperative that managers be sensitive to cultural and language difficulties that can impede effective training so that they can make the necessary adjustments.

TRAINING AND EMPLOYEE DEVELOPMENT

Training and developing employees and managers is more critical than ever in today's mining industry. Competent workers who can work effectively and safely provide the company with a competitive advantage. In regions where employee recruitment and retention is an issue, having a comprehensive training program can help retain employees by giving them the opportunity to stay current with new procedures and technology. Additionally, prospective employees are more attracted to companies that have a training program that can make them competent miners in a planned, systematic manner.

Training Needs Assessment

No company can afford training that does not contribute to the productivity, quality, or safety of its mining operations. Training needs assessments are an excellent tool to identify programs that are needed and that will contribute to both long- and short-term objectives for the company. Following are some of the benefits of conducting a training needs assessment:

- After completion, the assessment can be used as a tool to evaluate the direction and purpose of training and how training decisions link to performance.
- This tool can help managers and employees complete individual training plans to ensure that employee development is in line with company-wide training efforts.
- The process can give an objective, businesslike basis for decisions when providing employees with the justification for training decisions is difficult.
- Because the mining industry is experiencing many changes in its work environment, it is important to assess the impact of these changes on performance and determine what skills and tools are needed to meet new challenges.
- It has become vitally important for the industry to ensure that training dollars are spent on specific skill needs that will positively impact performance.
- A training needs assessment is the first step in determining whether training is the appropriate response to a performance problem.

When the assessment is completed, a master training plan can be developed with the following elements: The training mission is the purpose or reason for doing the training. Training goals are developed next. They are driven by the mission statement. They are the specific objectives for conducting training in an organization. Once the training mission and training goals are developed, a training strategy is needed. The strategy articulates how to implement the mission and accomplish the goals. The training strategy is followed by a training plan. The training plan outlines the types of training that will be included in the process of meeting the strategy, the mission, and the goals. An implementation plan will help coordinate the timing and resources needed for the training.

Learning Organizations

Advancements in mining technology and a globalized mining industry require that employees at all levels of an organization become lifelong learners to ensure that their skills and knowledge do not become obsolete. Mining engineers, after graduating from college, must immediately begin to acquire new industry- or company-specific skills and knowledge in order to be productive. Senior engineers must also constantly learn to avoid becoming outdated. As a result, lifelong learning has to be deliberate, relevant, planned, and continuous. Organizational learning involves individual learning, and those who make the shift from traditional organization thinking to learning organizations develop the ability to think critically and creatively, which is easier said than done.

Senge (1990) describes five disciplines required for a learning organization:

1. **Personal mastery.** This applies to individual learning; organizations cannot learn until their members begin to learn. Personal mastery has two components: first, to define what one is trying to achieve (a goal), and second, to obtain a true measure of how close one is to that goal. This is critical to mining organizations that have a number of new employees. Knowing how competent an employee is at the job assigned is critical to safe and productive mining.
2. **Mental models.** A mental model is one's way of looking at the world. It determines how a person thinks and acts. A simple example of a mental model comes from Senge's description of arm wrestling (1990). In traditional arm wrestling, the goal is for participants to attempt to force the arm of the competitor to the table as many times as

possible, with each participant attempting to be the one who "flips" rather than be the one who is "flipped." This is a flawed mental model. If each participant could simply stop resisting and take it in turn to flip or be flipped as many times as possible, both could win. In other words, the "theory in use" of arm wrestling is flawed; with cooperation rather than competition, both arm-wrestlers come out ahead. Argyris (1990) suggests that in organizations, this can manifest itself as the desire to

- Remain in unilateral control;
- Maximize winning and minimize losing;
- Suppress negative feelings; and
- Be as rational as possible, by which people mean defining clear objectives and evaluating their behavior in terms of whether or not they have achieved them.

3. **Teams.** A workplace team is "a number of persons, usually reporting to a common superior and having some face-to-face interaction, who have some degree of interdependence in carrying out tasks for the purpose of achieving organizational goals" (French and Bell 1995). Successful teams usually exhibit the following characteristics:

   - A clear, elevating goal
   - A results-driven structure
   - Competent team members
   - Unified commitment
   - A collaborative climate
   - Standards of excellence
   - External support and recognition
   - Principled leadership (Larson and LaFasto 1989, as cited in French and Bell 1995)

   Teams contribute to organizational learning by fostering cooperative behaviors, improving communication, becoming better able to perform work tasks together, and building strong relationships. Creative solutions are developed through the synergy of individuals working together for a common goal. Learning takes place that would otherwise not have happened through individual efforts. (It is important to note here that the use of teams in certain cultures must be handled with care, taking into consideration existing cultural norms such as power distance. For example, cultures high in power distance *expect* leaders to tell subordinates what to do, and the notion of participating in any sort of joint decision-making process is totally alien.)
4. **Shared vision.** The shared vision of an organization must be built on the individual visions of its members. What this means for the leader in the learning organization is that the organizational vision must not be created solely by the leader; rather, the vision must be created through interaction with the individuals in the organization. This is particularly difficult in large organizations that may prefer to operate in a top-down fashion with executives and/or boards of directors creating the vision for the mining company. Effectively communicating the vision in a logical, meaningful fashion, however, and permitting various locations to adopt their own version of the corporate vision can be very effective.
5. **Systems thinking.** In order to understand the source of and the solutions to modern problems, linear and mechanistic thinking must give way to nonlinear and organic thinking, more commonly referred to as systems thinking—a way of thinking where the primacy of the whole is acknowledged. The defining characteristic of a system is that it cannot be understood as a function of its isolated components. First, the behavior of the system does not depend on what each part is doing but on how each part is interacting with the rest. Second, to understand a system, one must understand how it fits into the larger system of which it is a part. Third, and most important, the "parts" need not be taken as primary. In fact, how the parts are defined is fundamentally a matter of perspective and purpose; it is not intrinsic in the nature of the "real thing" being examined (Koffman and Senge 1993).

   On a practical level, systems thinking is perhaps more critical in mining than in most industries where maintaining a balance between safety and productivity is paramount. The interaction of people, equipment, and natural resources—often in potentially hazardous environments—can have disastrous unintended consequences if not fully understood from a systems perspective by all employees. Organizations that understand how systems thinking can improve individual learning by inducing people to focus on the whole system are able to gain a competitive advantage.

Global Transfer of Knowledge

In an age when multinational organizations dominate many sectors of the mining industry, it is essential to develop organizations that foster an environment conducive to learning and are able to effectively share actionable, practical knowledge among far-flung operations all over the world. Most mining engineers are aware of practices that are successful in other parts of the world, or at a nearby mining operation within their own company, that could be an asset to their existing operation. Having the ability to effectively share a new process or technological advancement developed in, for example, North America with mining operations in Asia can provide a tremendous competitive advantage.

Knowledge Management

The transfer of knowledge from one part of the organization to another is easier said than done. It is an aspect of knowledge management that seeks to organize, codify, create, capture, and distribute knowledge to ensure its availability for other users. It is more than just a communication process. If it were merely a question of communication, then a memorandum, an e-mail, or a meeting would accomplish the knowledge transfer. Knowledge transfer is more complex because (1) knowledge resides in organizational members, tools, tasks, and their subnetworks (Argote et al. 2000), and (2) much knowledge in mining organizations is often tacit, localized, and hard to articulate (Nonaka and Takeuchi 1995). Obstacles to organizational learning include the following:

- **Organizational culture.** A culture that is control-oriented and formal can inhibit learning. For knowledge to be shared effectively, employees at all levels of the organization must be free to communicate formally and informally.
- **Organizational structure.** Hierarchical structures, as opposed to those with fewer layers, can impede knowledge transfer much in the same way that formal cultures can. If information must be shared only formally, learning can be impeded. Often, informal

communication can lead to serendipitous learning, which is more beneficial than learning shared through formal means. "Organic" organization structures not hampered by rigid chains of command are better at facilitating knowledge transfer.

- **Trust.** Organizations that lack trust have difficulty in effectively sharing knowledge. Lack of trust is often based on fear and insecurity, which tends to make people hoard information, even in the same company; there is an unjustified acceptance that "knowledge is power."
- **Personal interaction.** Although various electronic media, including teleconferencing, e-mail, and the Internet, have made the transfer of large amounts of information easy and virtually instantaneous, no medium is better at facilitating learning than personal interaction between employees. Organizations that encourage extensive face-to-face interaction will always fare better in knowledge transfer than those that do not.
- **Being intentional.** Starting from the top, organizations must be intentional about learning and the transfer of knowledge. In mining, the day-to-day business of making a profit can often overshadow efforts to constantly learn, improve, and share information. Leaders must make sure that time and resources are available to learn, as well as to capture and share what has been learned with other parts of the organization.

Learning from the Outside

One of the greatest sources of new knowledge can come from outside the organization. Suppliers, vendors, and contractors can be a great source of information and learning opportunities. Often, efforts to keep trade secrets or unique processes from falling into the hands of competitors can backfire and cause organizations to lose opportunities to learn from, as well as teach, outside organizations that are essential to the company's success. Toyota is renowned for developing relationships that are mutually beneficial and result in tremendous cost savings and productivity improvements for itself and outside organizations. Rather than keep outside contractors at arm's length, Toyota strives to develop close, long-term working relationships and engage in mutual problem solving. They do not focus on price and detailed formal contracts as much as Ford, GM, or Chrysler, but rather on relationships grounded in trust that are beneficial to all partners. Such relationships result in tremendous costs savings and other improvements.

Alliances, partnerships, joint ventures, government partnerships and other forms of inter-organizational relationships are also tremendous sources of learning. They provide opportunities for knowledge sharing that mining companies must capitalize on to maintain a global competitive advantage. As in the case with contractor and supplier relationships, intentional efforts to develop ties based on mutual, long-term benefits, as opposed to short-term profits or cost savings, can create a competitive advantage for all parties.

Scope of Training

Each new miner should be provided thorough training in the areas discussed below. Safety and health training should never be viewed as a task to simply complete, regardless of the degree to which miners appear to understand what they are supposed to have learned. During the first week on the job, new miners should be assigned to a well-trained mentor, who will work closely with them to ensure that they are performing their tasks in a safe manner. Adequate time, effort, and resources should be devoted to the following subjects before a new miner begins work at the mine.

New Miner Training

An example of a training outline recommended for a new-miner training program is shown in Figure 5.3-2. This example is modeled on a U.S. program and as such is designed to meet the safety regulations of that nation. New-miner training must always begin with the safety and health training required by the regulatory agency that governs the locale where the miner will be working; most importantly, it must address the safety requirements specific to the new miner's job.

Initially new-miner training should include the following:

- Introduction to the work environments—information specific to the location(s) where the new miner will be working. Because training required by regulations will never cover the exact particulars of any miner's work environment, it is vital that this section of the training be extensively covered.
- General hazard observation—instruction on the recognition and avoidance of electrical hazards and other hazards present at the mine, such as traffic patterns and control, mobile equipment, and loose or unstable ground conditions.
- Emergency procedures—a review of the emergency medical procedures and the escape and emergency evacuation plans in effect at the mine, as well as instruction on fire warning signals and firefighting procedures.
- Health and safety—instruction on the health and safety aspects of the tasks to be assigned, including the safe work practices associated with such tasks, the physical and health hazards of chemicals, and the mandatory health and safety standards pertinent to such tasks.
- Legal rights—instruction on the statutory rights of miners and their representatives under the prevailing labor laws of the location. (Some nations may require that union representatives be present at such meetings or require that specific notice be given to representatives before training occurs. Managers must therefore be clear on what local laws require.)
- Line of authority—a review and description of the line of authority of supervisors and miners' representatives and the responsibilities of such supervisors and miners' representatives. Depending on the nature of prevailing labor laws, it is important that these lines be clearly established to avoid potential communication issues and/or the violation of miners' rights.
- Hazard reporting procedures—an introduction to the company rules and procedures associated with reporting hazards. Once again, these must be location and task specific. In all cases, the most critical health and safety information that all new employees need to know is that which is unique to their job and location.

Immediately after new miners begin work, they should be provided with training in the following subjects (as well as others that may be required by local regulations), if these subjects have not been taught earlier:

- Self-rescue devices—instruction and demonstration on the use, care, and maintenance of self-rescue and respiratory devices, if used at the mine.

Title: Blaster (blaster's helper)

Tasks: Responsible for safe blasting operations or assisting experienced contract blaster in proper loading procedures, shot guarding, and postblast examinations.

Materials needed: Company policy and operational procedures; location-specific regulations; company energy guide; loading poles; blasting equipment for type of initiation system used; information sheet for hazardous materials as applicable.

What instructor will do: Review company operating policy and rules; review material safety data sheet; demonstrate proper use of equipment; demonstrate proper preloading procedures; demonstrate borehole inspection prior to loading; demonstrate emergency procedures; demonstrate safe loading and handling procedures; demonstrate proper hookup and initiation procedures; demonstrate proper shot-guarding procedures; demonstrate proper warning signals; demonstrate postblast examination; review regulations for blasting; explain inherent job hazards; observe and give guidance to student during simulation and operation.

What student will do: Read company policy, company energy guide, and information sheet for hazardous materials; observe and listen to demonstrations and reviews; understand the proper use and care of equipment; simulate all steps of safe blasting—procedures for preblast operations, loading and handling explosives, firing of blast, and postblast procedures; simulate proper housekeeping procedures, as well as any other deemed necessary by instructor.

Evaluation procedures: Student will give correct response to questions and will successfully demonstrate knowledge of care and use of blasting equipment, safe handling and loading of explosives, hand and audible warning signals, emergency procedures, shot guarding, and any other demonstration deemed necessary by instructor. The student will be observed by an experienced blaster and supervised during light production; any retraining needed will be accomplished until the student can operate without significant error through three error-free cycles.

Title(s) of personnel conducting training: Experienced blaster, supervisor/foreman

Figure 5.3-2 Example outline of training procedures for new-miner training program

- First aid—a review of first-aid methods.
- Other health and safety training—any remaining training on any other subjects that promote occupational health and safety for miners at the mine.

Newly Hired Experienced Miner Training

Newly hired experienced miners should be provided essentially the same training as new miners. One of the biggest mistakes managers make when hiring employees from another mining company is assuming they have been properly trained. The issue here is that some have acquired bad habits, particularly if they have come from a culture that did not stress or enforce safe work habits or good work ethics. All course topics covered under "New Miner Training" should be reviewed with experienced miners.

Annual Refresher Training

Following is a list of topics that should be readdressed with all miners. This list is not exhaustive, and, as previously described, local regulations or mine conditions or processes should be carefully considered to ensure that no training requirement is overlooked.

- Mandatory safety and health standards—mandatory health and safety standards for assigned tasks, including information about the physical and health hazards of chemicals in the miner's work area, the protective measures a miner can take against such hazards, and the contents of the mine's hazardous chemicals awareness program.
- Transportation and communication—specific information about transportation controls, as well as communication systems, with particular reference to anything that may have changed since the miners were last trained.
- Fire and emergency evacuation—escape and emergency evacuation plans, fire prevention, warnings, and fire fighting.
- First aid—first aid methods and location of first aid stations and equipment.
- Ground conditions—ground conditions and control and other critical issues, since such conditions often change.
- Traffic patterns—traffic patterns and controls going to and from the mine site.
- Highwall practices—working in highwall areas.
- Water hazards—water hazards, pits, and spoil banks.
- Illumination—procedures for ensuring that areas are properly illuminated for night work.
- Electrical hazards—hazards directly and indirectly related to electrical equipment, wiring, and controls.
- Accident prevention—prevention of accidents, giving particular attention to the processes or pieces of equipment that are associated with most injuries (and fatalities).
- Health—personal health awareness with specific reference to the avoidance/prevention of health issues associated with the miners' environment.
- Explosives—awareness of safe work practices when explosives are in use, with primary focus on those not in blasting positions or others who will receive detailed, job-specific instruction about blasting.
- Respiratory devices—proper selection and use of respirators for certain positions and annual fit testing.
- Maintenance and repair—proper procedures for reporting damaged or malfunctioning equipment, with particular reference to issues that may cause unsafe working conditions.

- The use of hand tools and other equipment—instruction on the use of hand tools or other equipment not previously covered.
- Hazard communication—familiarization with the specific chemicals in use in the workplace, and how to read and follow the safety procedures in the case of accidental exposure from contact, inhalation, or ingestion.
- Other—additional job- or site-specific instruction not covered in any of the programs previously mentioned.

Training the Trainer

Although trainers must have some knowledge about mining operations, having the necessary skills to conduct a good training program is critical. Obviously, good trainers can make or break any training program. Regarding on-the-job training (OJT), many mining operations managers make the mistake of assuming the best miners make the best trainers, or "mentors" as they are sometimes called. Mentors or trainers should always be trained in basic training skills. Mechanisms must be in place to monitor the quality and effectiveness of OJT and to make sure that trainers are thorough, that they always emphasize safe work habits, and that they do not encourage new employees to shortcut processes or procedures. In some cases, experienced miners have, over time, learned how to simplify steps in a job, sometimes at the expense of safe work practices. Assigning a skilled trainer to periodically observe and assess OJT is a good investment. Training employees properly from the start is much more cost-effective than retraining, particularly if mistakes resulting in property damage or injuries have triggered the retraining needs.

Methods of Training

Various methods of training are available today. Each has strengths and limitations and should be evaluated based on needs, audience, and subject matter. Methods available include the following:

- Self-instruction, which may involve a workbook, DVD series, computer-based training, or an audiotape series.
- Mentoring, which usually involves assigning an experienced employee to work with and "coach" an inexperienced worker. It is "hands-on" training and permits the person to learn on the job a task that's been assigned. It can enable a transfer of tacit knowledge that could not be accomplished through other methods.
- OJT, or hands-on training, conducted in the actual work situation. This may or may not be done in conjunction with the mentoring process previously described. The advantage of this method is that, because the person learns by doing, the training is very practical. The disadvantage is that, if permitted to observe and train only on the assigned position, the person may not know how the job fits into the rest of the mining operation. It is therefore critical to provide employees with an overview of the entire mining process at this particular location.
- Seminars presented in formal training settings and covering a wide range of topics. These generally address material relevant to management, engineering, and other staff, although some seminars are appropriate for mining operations employees. It is important to carefully evaluate the subject matter, prior to delivery of a seminar, to make sure it is pertinent relative to the training needs assessment.
- Distance learning, which may include Web-based seminars, on-line degree programs, and teleconferences. These alternatives can afford some of the same benefits as formal or off-site seminars and avoid the time and expense of travel.
- Work-site visitation, which involves permitting individuals at all levels of the organization to visit other mining operations to observe and learn. This allows visitors to personally observe the operation, interact with those working in the process, ask questions, and/or hear presentations. This is an extremely effective method for sharing knowledge as well as for developing relationships. It is particularly helpful in the transfer of tacit knowledge that cannot be codified and stored.

Training, Motivation, and Retention

Behavior modeling first appeared as a method of instruction in the 1970s. It is based on the work of psychologist Albert Bandura. He concluded that people learn best by imitating the behavior of others (modeling), and then receiving an immediate, observable reward. B.F. Skinner expanded this into reinforcement theory. He observed that positive consequences produce positive results, and negative consequences produce negative results. The concept has been adopted by many corporations today and is the theory behind a great deal of current training material (Zemke 1978). Behavior modeling is based on the principle that if a person observes a task being done correctly, and then is given an explanation as to why it is being done that way, this knowledge and practice will be transferred and will transfer to the workplace more effectively. Employees will know not only how to do it but also why it must be done in a particular way.

Behavior modeling works in the following way: The trainer performs the task while the participant observes, and then explains to the person what has been done and why it was done that way. Then the trainer asks the employee to perform the task and explain how to do it and why. The trainer gives feedback as to the employee's performance. This process may be repeated several times until the employee has the skill. The method is highly effective in mining operations where training is done under the direction of a mentor or in an OJT setting (Figure 5.3-3).

Four tools are helpful in supporting behavior modeling: coaching, positive reinforcement, counseling, and feedback. Models for each of these tools appear in Figures 5.3-4 through 5.3-7 respectively.

Training Evaluation and Record Keeping

Evaluation and record keeping are essential to an effective training process. Records must be maintained for topics required by law. Records are also essential for knowing who is qualified to perform what jobs so that the company can avoid placing untrained, unqualified employees in certain positions. Evidence as to how well training has been conducted and retained by those being trained can be obtained through written or oral feedback. Either way, the results should be documented for future reference.

Simulation Training

Simulation permits training to be conducted in a realistic setting without the safety risks and property damage that are associated with OJT in an underground or a surface mining

Step 1	Explain the skill	The trainer explains how to do the job and why it is done this way.
Step 2	Show how to do it	The trainer shows how to do the job.
Step 3	Have employee show how to do it	The trainer asks the employee to demonstrate how to do the job.
Step 4	Have employee explain the skill	The employee explains how the job was done and why it was done that way.

Figure 5.3-3 Steps in behavior modeling

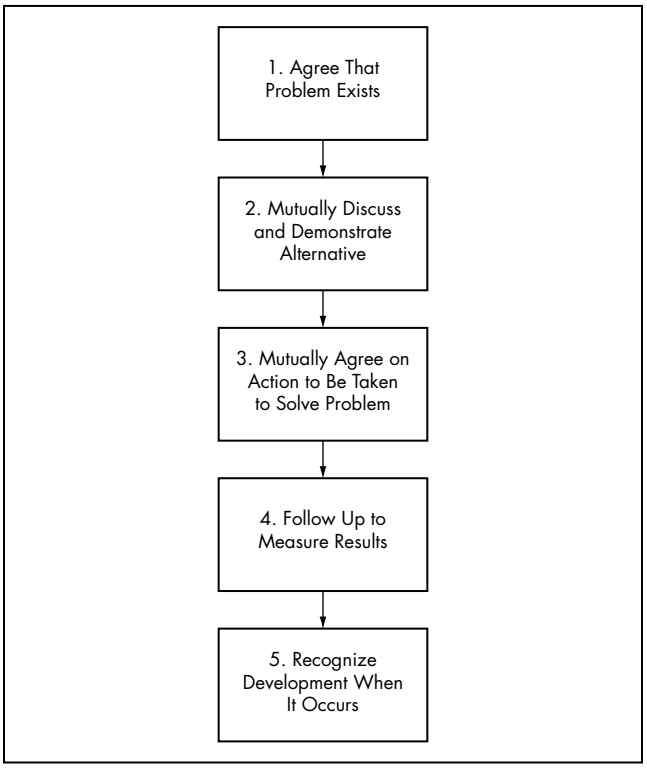

Figure 5.3-4 Steps to coaching technique

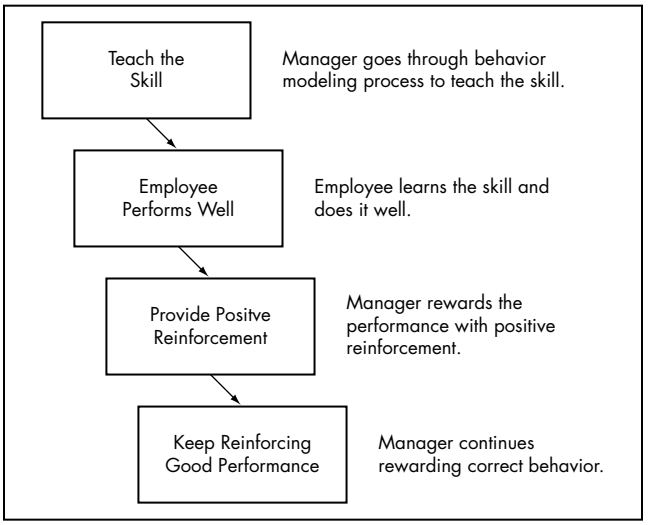

Figure 5.3-5 Positive reinforcement as a support to behavior modeling

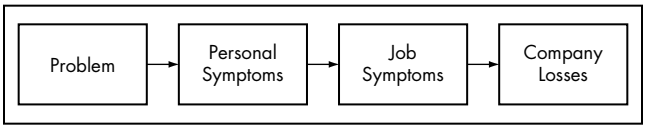

Figure 5.3-6 Counseling as an essential element in supporting new skills learned and maintaining productivity

1. Give frequent feedback	Do it all of the time.
2. Remark about the behavior	Let the person know when behavior is correct.
3. Reflect the feelings of the worker	Be sensitive to problems with the new skill.
4. Check perceptions	Ask how the person feels about the progress being made.
5. Give timely feedback	Provide feedback when the situation occurs. Do not wait several days.

Figure 5.3-7 Feedback as a means of reinforcing training

environment. In addition, simulators can be an asset to concept and capability development, to system design refinement and validation, and to process and systems modeling. Mining managers are therefore encouraged to evaluate the use of simulators and consider using them when practical and available.

SUMMARY AND CONCLUSIONS

The management of mining operations has become increasingly more complex in the last decade because of the rapidly growing global demand for mined resources. The need to maintain effective employee relations in far-flung global mining operations requires special leadership skills in order to effectively recruit, train, and motivate employees, particularly in light of today's mining labor shortages.

Mining leaders need to understand that efforts to maintain good employee relations must be ongoing and incorporated into the organization's strategic plan. Efforts should be tailored to fit the culture of the employees, and managers should understand that leadership styles and approaches must sometimes be adapted and modified to be effective in global operations.

A well-trained work force and a commitment to organizational learning can be a tremendous competitive advantage that must be nurtured and encouraged in today's world of rapidly changing mining technologies. Leaders must be innovative in seeking ways to develop, capture, and disseminate knowledge throughout the organization.

CHAPTER 5.4

A Global Perspective on Mining Legislation

Diana Dalton

The laws relating to the exploration for and mining of minerals, although often different in approach from one country to the next, do have similarities. The purpose of this chapter is to advise the reader of what approaches may be found in the international context and what they mean for the practitioner.

No mining law can be read in isolation. Many other laws impact mining operations and can affect the way a mining law is implemented administratively. In developed countries, the law has progressed over the last three centuries, changing in approach as new issues, technologies, and practices have evolved. In this environment, good practice exists, and change is addressed in the normal course of events by highly trained experts. However, in developing countries, such experience is usually lacking.

This uncertainty in dealing with sophisticated mining entities and expertise can be frustrating for companies but is understandable. It is important to recognize this and be willing to take time to transparently explain what is required. It is also important to understand the social, economic, and political environment in the country where mining operations are to occur.

COMMON LAW AND CIVIL LAW

Two systems of law exist in various forms: common law and civil law. Most of the world's large mining companies are headquartered in countries that practice common law but often run operations in countries that practice civil law. It is important to know what type of legal system applies in the country where the applicant is planning to work in order to understand the laws and regulatory system.

Common law is generally called English or British law and is the system one finds in British Commonwealth countries as well as the United States. A common law system is based primarily on custom (before there were written laws). Although much of common law has been codified, these customary laws continue to be applied by the courts. For instance, the United Kingdom does not have a written constitution but has a series of laws, agreements, and judicial decisions that set out the fundamental rights of citizens. Most other common law countries have written constitutions and statutes that encompass these common law principles and legal approaches. In a common law system, although the statutes are a primary source of the law, judicial interpretation and *stare decisis* (precedent) in case law co-exist as important elements of legal interpretation. In civil law systems, judges may look to other legal decisions but are not bound by them.

A *civil law* system is based on statutory law made by a legislature with regulatory powers given to the executive. Treaties, orders, decrees, and other such documents are also a part of the written law. Everything is written, and judges apply the law; they do not interpret it. Civil law is the system found in South America, Europe (except for the United Kingdom and those parts of Africa that are not part of the Commonwealth), and Asia. The civil code systems are French (Napoleonic), German, Scandinavian, Portuguese and Brazilian, Dutch, and Chinese. Each has a different approach to lawmaking. Although Brazil has transitioned to a German type of civil law, Quebec and Louisiana have French civil code systems (except for criminal law which is national codified law). Both Scotland and South Africa employ a mixture of civil law and common law. Japan, South Korea, and Taiwan are based on the German civil law system.

The difference in the two legal systems is important to understand, especially when it comes to disputes regarding agreements, which will be discussed later in this chapter.

WHAT IS A MINING LAW?

The words *mining law* and *mining code* are often used. They can be one and the same thing or totally different. Mining code most often refers to all the laws, regulations and guidelines, and agreements pertaining to exploitation of minerals. Thus the term encapsulates all the relevant legal documents that oversee that activity.

Mining law stems from property law. It is similar to land laws in which an owner of a property leases it to another who uses it for his or her purposes in return for payment for that use. So a mining law should determine

- Who owns the mineral resources;
- Who issues leases;
- How the rights will be allocated and what terms and conditions apply to those rights;
- How the resource is to be treated;

Diana Dalton, Lawyer and Independent Consultant in Mining Law, Halifax, Nova Scotia, Canada

- How the land from which those minerals are extracted is to be treated;
- Who pays what and to whom; and
- Whom the law applies to, whether the public, private investors, domestic companies, or foreign organizations.

OWNERSHIP OF MINERALS

In most civil and common law countries, the ownership of minerals is vested in the state. In unitary countries this would mean the national government. In federal countries, such as Canada and Australia, the constitutions have vested the provinces and states with natural resource jurisdiction.

The two major countries where this is not the case are the United States and the United Kingdom, where minerals form part of the land and thus are owned by whomever holds title to the land in which they exist. However, in the United Kingdom, there have been significant changes from private ownership. In 1946, coal was nationalized, and in 1994, all private rights disappeared and ownership was vested in the Coal Authority. Oil and gas are also vested in the state, while precious metals such as gold and silver are owned by the Crown. To mine these precious metals, it is necessary to obtain the right to mine from the Crown Estates Commission. However, all other nonenergy minerals are privately owned (though some are owned by the Crown or a department of government, just to complicate matters), and thus there is no national licensing system. To exploit these minerals requires regional planning approval.

Other than these two countries, either the constitution or a mining law will outline who owns the minerals and by what authority the law is administered. It sounds simple: the state owns the minerals and has jurisdiction to license the exploration and exploitation of all minerals. However, while the state may own the minerals, in many countries, it does not own the land in which those minerals exist. This is problematic, because one must deal with the private landowner in order to have use of the land.

LAND ISSUES

Most mining laws will address a number of land-related issues:

- What areas are reserved or can be declared to be reserved, such as national parks and nature reserves? These reserved lands may be permanent or temporary and are not usually declared pursuant to a mining law. Other legislation affecting land may determine when and how land is reserved for certain uses and who has the power to make these decisions.
- What is the process by which the applicant must get permission from the landowner to enter and/or use the land? Some laws are silent on this, but usually some section gives a right of entry and sets out how the applicant must deal with local landowners. This could be in the mining law but normally is in land-use laws, especially if there is a customary land title, as there is in most countries where tribal ownership is the way land is held. It is important to check these laws to determine the process for gaining entry to customary land.

In many developing countries, especially those with tribal ownership, there is no title registration system, thus making the determination of land ownership much more difficult. In developed countries, a land registration system has already been established, making it easy to determine the titleholder.

In other countries, such as Canada or Australia, large tracts of land are owned by the government (Crown land). Many countries have laws that allow the government to expropriate privately owned land according to a formula that ensures fairness to the landowner. This is used only in cases where the mining license applicant has not been able to reach a deal with the landowner and the discussions have been protracted and difficult. In Canada and Australia, it is also necessary to establish whether the lands are under a treaty agreement.

Because every country deals with land in a different way, no one model can be put forward as the norm. Numerous laws deal with land, such as forestry, agriculture, water, air, health, safety, transport, public security, zoning, parks, and reserves. All of these will impact land access and use.

The issue of entry and the use of customary land is a difficult one for mining companies everywhere as it is not a topic usually covered in the mining law. One country that has addressed this issue is Papua New Guinea. The Mining Act 1992 (established by Parliament of Papua New Guinea) sets out the principle of compensation, which is defined as "all loss or damage suffered or foreseen to be suffered by them [landowners] from exploration or mineral" operations. It also sets out what compensation is payable and in what circumstances. The act allows compensation for

- Damage to the natural surface,
- Severance of land from other land owned by the landholder,
- Loss or restriction of rights-of-way or easements,
- Loss or damage to improvements,
- Loss of earnings in land under cultivation,
- Disruption of agricultural activities, and
- Social disruption (usually meant to include the necessity of moving people from the area).

The act clearly states that no compensation is payable for allowing entry, for the value of any mineral on the land, or for rents or royalty assessed regarding the mining of minerals. It also states that any dispute over customary land is heard under the Land Disputes Settlement Act. In addition, because trees are an important resource for customary landholders, the value of trees is set by the Valuer-General under other legislation. (The Valuer-General is a public servant appointed by the minister under the Valuation Act, 1967, a law relating to the valuation of property.) In many countries these principles are not contained in legislation so these matters remain to be negotiated with the private or customary landowners. Despite the attempt by Papua New Guinea to address the issue, a mining company must determine land boundaries in tribal and clan-owned areas—a long and difficult process because there is no land registry system.

Land entry and access are complicated issues. They are time-consuming and often difficult, especially in customary land-owned areas. Therefore, before planning to start exploration or mining operations in such a country, it is important to solve any land and ownership interests to ensure that land access is available for both the mining and land-use activities connected with mining.

CONTENTS OF MINING LAW

A mining law is essentially a property law. It is important to understand how to get a legal right to explore for or mine the minerals—normally, a license or lease; how it is retained; and

what rights and responsibilities are part of the license. In some laws, the word *license* is used, while in others it is *lease*. For purposes of this chapter, license is used.

Most mining laws do not deal with the financial aspects of mining, such as taxation, although some laws may have a section dealing with royalties and so forth. Those provisions are usually defined by the tax laws (see "Financial" section later in this chapter).

Definition of *Mineral*

The definition of a mineral is different in most laws. For instance, in many countries one will see separate laws for coal (India) and precious minerals (Australia, Botswana), geothermal water, spring water, construction minerals, and alluvials. As such, the definition in the mining act may vary, making it necessary to determine which law establishes rights for the particular mineral of interest.

Who Can Apply

The law should state who can apply for mineral rights. In many laws, only local citizens have rights regarding alluvial or nonmechanized mining of minerals. Differences with regard to construction, industrial, and radioactive minerals also exist. Usually foreign companies can apply for rights, but it is necessary to register a local company at some stage under the company law of that jurisdiction.

Anyone who obtains a license is subject to certain rights established in the law:

- The right to enter the land (subject to access provisions)
- The right to explore for or mine the land
- The right to construct facilities and use water (subject to water laws)
- The right to ownership of minerals that are mined

This latter provision may not be specifically stated in the law, and, if it is not, there should be a condition in the mining license that transfers the ownership of the mined minerals from the state to the titleholder. This is necessary to ensure that the mining company has the right to market the extracted minerals.

Security of Tenure

One of the key elements of a law is security of tenure (or title). This allows the holder of the license to have the exclusive right to explore and mine minerals in the license area. In most laws, a license gives the exclusive right to explore (or mine) minerals in the area covered by the license, ensuring that no one else has access to that particular area. However, this right will not be given for a reconnaissance license, which is generally available for anyone at any time and is nonexclusive. It allows for access to an area for initial inspection, aerial surveys, and so forth but gives no right to proceed to exploration.

In many countries, an exploration license gives the exclusive right to explore within the area comprising the license for all minerals. In other jurisdictions, a license will only be given for a mineral or group of minerals specified in the license. This means that within the area of the license, two or more licensees could be exploring for different minerals—that is, exclusivity of the mineral but not the land area. The result of such an approach can lead to difficulties with other explorers when land access becomes an issue or if each finds the same or a different mineral in the same area, both of which are capable of being developed.

Security of tenure and continuity of such title are necessary. In most legislation, provisions give an explorer the right to a mining license (provided certain conditions are met) and the right to exploit any mineral that is found that can be economically mined. It is important to ensure that the company that has taken the risk and spent large sums of exploration dollars is able to proceed to the mining license.

Licenses

In most countries, there is a two-license system: exploration and mining. However, some countries have a claim system (e.g., all Canadian provinces and Namibia), which can replace the exploration license or be for smaller areas while an exploration license is granted for a larger area. Exploration licenses are usually granted for short periods: 1 to 2 years with renewals up to a specified total. Other laws have short terms, which are renewable for an indefinite period.

In many countries, it is mandatory to relinquish a specific percentage of the land (usually 50%) on each renewal. This mechanism is used by governments to ensure that licensees concentrate on the most prospective land in their license areas. In addition, it ensures that more land is available to new players who can apply for licenses over relinquished areas. The theory is that the more land being explored, the greater the possibility of finding an economically viable resource, which is in the interest of both the licensee and the government. Other conditions for exploration are minimum work programs and expenditures that must be carried out during the license term. Failure to comply means the loss of the license, unless an amendment is obtained.

A mining license usually runs for a specific period that allows for long-term mining activity. Many laws will specify a term (e.g., 25 years) with longer-term renewals. Others put no term on the license but allow for mining until abandonment or the resource is depleted in accordance with the mine plan.

Many countries have a license that allows a licensee to retain an exploration area for a specified period of time (usually 5 years) for a number of reasons, including the deposit cannot be developed at current market prices, the technology is not currently available, or the resources are required to sustain future operations of an existing or proposed mine. Each year, reports must be submitted demonstrating whether the circumstances have changed so mining can commence.

As stated previously, in most countries mineral resources are owned by the state. This allows governments to require reports be made to the government with regard to the work conducted, resources found, and geoscientific data (including cores and interpretations, etc.) collected. Submission of these reports is required, and failure to file may well result in the cancellation of the license. This information is then usually available for new explorers once a license terminates. Such information is also available to those who apply to explore areas that have become available due to relinquishments by another company.

Registration

Because mining laws deal with property, they include a system of registration for mining titles, which is overseen by an official, usually called a registrar. The registrar accepts applications for mining titles and registers the granting of those titles. The title is not valid unless it is registered, much the same as a deed for a home. During the term of a title, any legal matter that is undertaken, such as a transfer of title, joint

venture, mortgage, or other encumbrance on that license, must be registered in order to make any such document operative for the purposes of that title. Transfers of title usually require approval of a minister or another designated official before they can be registered. In many jurisdictions, agreements between joint venturers or partners also need to be registered.

One issue that arises has to do with multiple exploration applications for the same land. In some laws, it will be stated that the first application made to the registrar is the one that will be considered. If that application is found to be in good form with all the information required, it will be approved and other applications will not be considered. This is called a *first-in-time* provision and is considered important by the investment community. If two or more applications arrive at the same time, the law or regulations will outline how the registrar decides which application is considered first.

In other jurisdictions, multiple applications are considered on the basis of the work programs and expenditures. In other words, all applications are reviewed and a recommendation is made to the minister or official granting the license as to which program is most acceptable. This system is appropriate when the administration is open; however, the absence of such transparency is often problematic.

Cancellation, Termination, Suspension, and Surrender

Most mining laws have provisions that deal with the circumstances of cancellation, termination, suspension, and surrender of mining titles. All of these have different meanings and require different processes in order to be effected.

Cancellation is the termination of a mining title and is triggered by the government when the licensee does not conform in a material way to the terms and conditions of a license or is in contravention of the law. The government must usually follow a process in order to cancel a title. In common law systems, administrative law requires that a licensee be given adequate time to remedy the situation before a cancellation is made, and most laws will outline a process. If such is not the case, then an agreement should be made between the government and the licensee to address the issue.

The law should clearly specify the conditions under which cancellation occurs. This is particularly important for companies that require financing by banks or other lending institutions. Lenders use the mining title as a security for lending, and, because titles have a specified term, they will want to ensure that cancellation is a remedy in only the most serious of situations. Most lenders will insist on an agreement if no provisions are available in the mining law.

Termination is often referred to as the end of the title's term when the resource is depleted in the case of the mining license or when exploration is at an end. At this stage, abandonment works become operative, and such procedures are usually spelled out in the law or regulations. However, in some countries, provisions for site reclamation and facilities abandonment are covered by other laws, such as environmental, industrial, or land laws. For each project, such provisions are usually part of the environmental and/or mine plan and clearly outline the specifics for that project. These provisions could also be part of an agreement between the government and investor.

Suspension can be initiated by either the licensee or the government and is for a limited period of time. If done by the government, it is usually because of issues that arise if the licensee is not in compliance with the conditions of the license. In many instances, suspension is because of safety or health issues at an operation. An inspector often has the power to order a suspension of operations until safety issues are addressed.

If initiated by a company, suspension is usually due to market conditions, equipment failures, resource problems, force majeure, or other issues that require operations to cease for a period of time. Most laws will state that the licensee must inform the government and continue to report on any change in these conditions. The law should address both of these instances.

Surrender is the relinquishment of an area or license and is usually initiated by the licensee. Mandatory relinquishment of exploration land is a type of surrender.

Rentals and Fees

Some countries impose land rentals on the areas covered by licenses. These are usually set at a certain cost per hectare and may rise as land is relinquished. It is a mechanism used by governments to ensure that exploration proceeds on a timely basis. Rentals and fees for applications and other administrative procedures are usually published in regulations or guidelines.

Powers of Officials

It is always prudent to determine who is responsible for the administration of the mining law, and this determination will normally establish to whom applications must be sent, who grants such titles, and who administers those titles during the license term. It is extremely important to review inspection powers, because inspectors usually have the power to suspend operations and give orders to compel rectification of issues. In more developed countries, these inspection powers are seriously enforced, whereas in developing countries, enforcement can be more problematic.

Small-Scale Mining

In most developed countries, small-scale mining is treated similarly to large-scale and is implemented under the same law. In developing countries, small-scale, alluvial, and gemstone mining are more problematic because much of the small-scale mining is illegal. Despite provisions in mining laws to license such activities, the legal systems have not been able to address these activities due to the lack of enforcement and other social issues, such as poverty.

Alluvial mining is often addressed in the same law as larger-scale mining. A number of countries issue a small-scale license that is available only to its citizens, is of a shorter term, and can cover the same land as an exploration or large-scale mining license. Gemstone mining is treated similarly. Quarries are often managed under the mining law that applies to all mining activities, but some jurisdictions have a separate quarry law (for instance, the Aggregate Resources Act of Ontario, Canada), while some mining laws give a landowner the right to mine construction minerals on its own land without a license.

What is important to know is whether foreigners can mine on a small-scale basis and what minerals can be mined. It is also important to understand that these small-scale activities may well take place on larger areas that are already the subject of an exploration or mining license.

The presence of illegal mining poses real problems for a serious investor. Many governments are not equipped to deal

with these activities. Environmental degradation, as well as corrupt practices and criminal activity, are inherently connected to these illegal small-scale operations. For years many governments have tried through legislative means to address this illegal activity, yet it continues to be a serious problem. For governments it represents a loss of revenue, whereas for investors it can create an environment in which proper mining practices are absent and consequently the potential risks are much higher.

STATE PARTICIPATION

Many developing countries take a participating interest in mining projects. There are as many different approaches to this issue as there are countries. Because of pressures from international development agencies, most countries have what is termed a *participating interest*. This means that the country, at a point usually outlined in an agreement or the law, will buy into the project (up to a certain percentage) as a partner. The cost to the government would be the same as if a new joint venture partner were buying in—that is, past costs are paid for up to the time the participating interest is operative.

Some countries have what is termed a *carried interest*. This is extremely unpopular with industry as the company must *carry* the government and absorb its costs. Rather than buying in, the country gets a percentage of the project and does not contribute to any funds upfront. In most instances, the carry is for the exploration period through to feasibility. At the development stage, the country would commence paying its share.

Laws usually state the amount of participating interest. An agreement, similar to a joint venture agreement but which also includes financing provisions, outlines the details of how that interest will operate. The country usually takes its participation through a state-owned mining company or a holding company with which the agreement will be made.

AGREEMENTS

In general, agreements in common-law countries tend to be more detailed because of the focus on specific language. This is because law courts may have interpreted the meaning of certain words, and thus one must be careful as to how terms are stated. In countries that practice the civil code, this is not as much of a consideration. It is important to seek the advice of local counsel before commencing agreement negotiations, as they are aware of the various nuances and differences in the specific system of law.

The law should state who has the right to enter into the agreement on the part of the country. Usually other laws (or the constitution) establish who has power to make an agreement on behalf of the country, and there may be constitutional prerequisites. In some countries, agreements, once negotiated, are put before the parliament for final approval before they are signed. Companies usually have board directives as to who can sign agreements on their behalf. The most important thing to remember is that an agreement cannot change the law; only the legislature can do so. Therefore, it is extremely important to have the company legal counsel, as well as local counsel, involved in the process of negotiations.

It is now a practice in many places to sign letters of intent or memoranda of understanding that outline the broad issues on which the parties concur. These are not legally enforceable and are merely used to establish the general principle on which the parties will subsequently base a written agreement. Agreements are often necessary because investors want certainty in politically risky countries, especially to secure financing from lenders who want to ensure a predictable environment for the operation. They also provide for clarification of issues that may be unclear in the law or address issues that are not part of the law. Socioeconomic benefits accruing to local populations are also important consideration for governments, and the agreement will often address obligations on these issues.

Agreements can supplement or implement law. Most often investment or development agreements with a country are supplemental to legislation. In order words, they address issues that are either unclear or absent in the law. Because there are as many agreements as there are countries, it is impossible to outline what a standard agreement might entail. In general, however, such agreements address the following:

- Clarification of mineral rights, if there are no legal specifics on things such as duration of rights, relinquishments, selling or transferring, clarification of cancellation or suspension of right, and work obligations.
- Rights to sell and market minerals, as well as export them.
- Obligations of both parties. These should be agreed upon, especially with regard to who will build the infrastructure (roads, transmission lines, buildings, etc.) to support mining operations, the terms for employment and training for nationals, local procurement obligations, and reporting. This may include safety and health obligations and/or environmental provisions if no law addresses these matters. These can also cover what will happen to facilities and equipment on abandonment and could deal with reclamation issues in the absence of legislation.
- Fiscal and financial provisions: royalty and process of payment, exemptions, stability (ensuring that taxation will remain stable over the life of a mining operation), foreign exchange arrangements, repatriation of proceeds, debt–equity ratios, management fee charges, and so forth.
- Legal provisions, including force majeure, dispute settlement (arbitration) process, and expropriation of an operation. Many countries have arbitration acts, which are used to settle disputes. However, in developing countries, this is often not the case, and so provisions in the agreement usually appoint an international tribunal to hear the arbitration. Agencies most commonly used for arbitrations are the United Nations Commission on International Trade Law, the International Centre for Settlement of Investment Disputes, or the International Chamber of Commerce.

These agreements may or may not include state participation. In most instances, a separate agreement for such participation is necessary because the state's interest will be held by a state-owned company or holding company, which is legally separate from the government.

HEALTH AND SAFETY

In most developing countries, the same strict culture of safety or good health in the workplace found in developed countries does not normally exist. Therefore, it is incumbent on foreign companies working in these countries to teach and instill that culture in the workplace.

Most mining laws address the inspection powers required to enforce proper safety and health practices at mine sites but do not necessarily provide the detailed provisions a company

must follow. In fact, these provisions can usually be found in regulations made under the mining law, in separate mine safety laws, or in generally applicable occupational health and safety (OHS) laws. In addition, environmental, water, and/or health laws have provisions with respect to clean air and water, and requirements for the use of chemicals and toxic substances. Regulations addressing the conditions of premises as well as provisions for safety clothing, gear and equipment, safe work practices, hazard assessment, food storage and preparation, health hazards, disease, radiation, and noise can normally be found in a variety of these laws. There will also be provisions for accident investigations and reporting, health outbreaks, and other issues that may arise.

Many OHS laws allow for a mine safety plan to be submitted and approved by the authorized department or agency that oversees mining activities. The licensee would have to ensure that its plan sets standards that meet or are better than those in the various laws addressing OHS. Senior managers are obligated to implement and maintain safety programs in the workplace and could be legally liable if any accidents do occur. They must provide a continuously compliant safe and healthy environment.

ENVIRONMENT

Because mining affects air, land, and water, numerous laws and regulations address these three areas that exist outside mining law. Many countries have clean air and water laws that apply to exploration and mining operations. Environmental standards for toxic substances and chemicals can also exist in health laws, as noted previously. It is important that all these laws and regulations be made a part of any exploration or mining work plan.

Environment laws per se usually address the need for pre-assessment of the areas where operations will take place (baseline studies and impact assessment), resulting in an environmental plan that addresses the impacts on land, water, and air. This plan may be subject to a public review process, which involves local populations affected by the operations. These can be controversial (e.g., tailings and reclamation issues that are of paramount importance with respect to safety and health and the need to minimize an operation's physical impacts). The environmental plan will usually be approved by another ministry, separate from the mines department, so it will require coordination to ensure that the environmental approvals do not cause a delay in the project. It is often wise to employ an agent knowledgeable in local practices, as it is notoriously difficult to deal with multiple layers of bureaucracy, even in the most developed countries.

Mining laws or agreements may address abandonment procedures, such as what can be removed and the time lines for plant and equipment removal. These may be required at the outset of a project or may be developed toward the end of mine life. If the law does not address this subject, it would be wise to ensure that the agreement has provisions that clarify this in detail so the costs of abandonment can be adequately forecast and there is certainty as to what will remain after mine life. For example, if a company has built and maintained a road to a mine site, it should be considered whether the government will take over the responsibility of this road after the mine is gone. Local populations may use such a road during the exploration period or mine life, and, if so, the government may agree to assist in maintenance costs.

In general, a reclamation plan is required at the beginning of an exploration program or a mining operation to ensure that reclamation proceeds on land that is no longer required. These plans are usually mandated by environmental laws but can also be required as part of the application for a mining right. How the reclamation is paid for over the life of the mine is also found in environmental and/or tax laws.

Penalties are still the usual way in which countries deal with breaches of environmental standards—that is, the polluter pays. However, tradable or marketable permits are available in some countries for certain chemical compounds, such as carbon and sulfur dioxide, and this practice will become more widespread as climate change provisions are implemented around the world.

A proper approach to environmental matters impacts a company's international reputation, so it is important to take this seriously.

FINANCIAL

Taxation of minerals is a complex issue. It must be recognized that the mining industry is extractive and nonrenewable by nature, and at the same time a mining tax must take account of the huge risk that is connected to extraction and is not found in other industries. The risks—geology, market price, large capital investment connected with production, and the fact that it is a single-purpose industry—mean that it is a unique investment. In addition, extractive industries are subject to the effects of supply and demand; therefore, the project economics are always at risk because of world market prices.

Another unique feature is that it is necessary to find an economically viable deposit. The exploration part of the mining scenario is extremely high risk; it is estimated that only 1 in 10,000 exploration projects result in the discovery of an economically viable, exploitable resource. Companies may spend millions of dollars before finding a mineable deposit. Development requires large capital outlays before production can commence. Because it is so different from any other industrial enterprise, tax laws generally have special provisions to address these unique factors.

In order to attract and retain the industry, governments know they must be competitive with other mining jurisdictions. In addition, a stable fiscal regime is an attractive part of the investment portfolio. Many countries have enacted a number of special tax treatments, which are usually found in the tax laws.

Accelerated Depreciation

Most income tax laws allow for the depreciation of assets for all industries. In mining, accelerated rates are allowed because of the huge capital investment that is incurred before production. This accelerated depreciation usually applies to all tangible assets that have a useful life of more than 1 year and include structures, mine equipment, and mine processing plants as well as roads, schools, housing, power lines, and so forth, built to service the mine. The rate of this accelerated depreciation varies from country to country.

Amortization

This has wide variances in tax laws; some countries allow reconnaissance and exploration expenses to be amortized if development results from those activities. Others allow amortization on a declining basis on all tangible assets under

generally acceptable accounting principles as well as all survey, exploration, feasibility, and development expenses. Other approaches allow research and development costs either to be expensed in the year they are paid or to be amortized over a period of years.

Loss Carryforward

Most income tax laws allow extractive industries to carry their losses forward against income in subsequent years. These allowances vary from country to country.

Dividend Withholding Tax

This is applicable to any shareholder who receives dividends as a result of his or her investment in a project. The tax can vary according to whether the recipient is a foreigner or a resident of the country and from 5% to 10%. It is generally seen as a deterrent to mining investment.

Import/Export Duties

Because mining projects are capital intensive and most imports are for heavy equipment and machinery, it is usual to allow relief from duties on items required specifically for mining during the early stages of construction, development, and production while profitability is low or even nonexistent. After the mine is constructed and operating, these special provisions may no longer be applied, except for specific mine plant replacement or mine expansion activities. Mining operations seldom have customs duties relief on anything that is readily available in the country and which is of the same quality and standard.

Export duties should not be incurred on ore or product, except in the case of gemstones, in which an export price is often the only way governments receive revenue.

Reclamation

Because it is now standard in most countries to require mining companies to reclaim disturbed lands, it is necessary for governments to define how the costs of reclamation will be dealt with in their tax regimes. Many jurisdictions now require trusts to be set up, into which the companies contribute on a regular basis. As these trusts build up, they are used to pay reclamation costs both during the life of the mine and at its closure.

Although different countries use different mechanisms, there is often an allowance for contributions for reclamation. In trust situations, it is generally acceptable that the company can deduct contributions in the year they are made. Most often, funds received from the trust are considered income for tax purposes in the year they are taken. Some jurisdictions also tax the interest earned at the usual corporate tax rate, which results in double taxation in many instances and is considered unfair by many mining companies.

Other mechanisms, such as performance bonds, are also used to address reclamation. The cost of these bonds may or may not be deductible.

Royalty

The royalty on the mined resource is applied in different ways in different countries. It can be based on production, net smelter return, or sales. The royalty on production may give certainty to the government, with respect to royalty return on a project, especially when there is a downturn in prices. However, such a royalty is not simple to determine, because it is difficult for the government to monitor the actual production of the mined product and to differentiate between what is product and what is waste.

For these reasons, many governments usually base their royalty on an ad valorem basis—that is, sales price using arm's-length contracts. Bills of sale and invoices are easily audited by the government, and, therefore, a royalty based on this approach is easier to collect. A royalty based upon sales price means the government revenue will fluctuate according to the market. For companies, the sales price basis for royalty allows them to address price fluctuations and maintain economic viability.

Royalty payments may also be allowed as deductions for tax calculations.

Allowable Expenses

The corporate income tax law should also define the exemptions allowed against the payable income tax:

- **Capital cost:** The buildings, machinery, and plant required for extraction and processing; assets providing services to the mine or community (where a substantial proportion of employees of the mine reside at the mine); loading facilities; equipment; mining vehicles; and so forth.
- **Exploration expenses:** The full amount of all exploration and predevelopment costs.
- **Development expenses:** Acquisition, surface development, pre- and postproduction underground development.
- **Operating costs:** The costs incurred during normal operations, excluding depreciation, noncash costs, and financing charges.

Auditing Capacity

Governments are always concerned that they receive fair income from the mining resource. It is therefore necessary to address transfer pricing issues, which are extremely complicated. Many countries have special auditors who verify all expenses claimed by companies to ensure that they are reasonable and necessary. Usually, income tax legislation defines arm's-length transactions and has provisions for the power to audit and disallow expenditures that are not considered valid.

CONCLUSION

The mining law of a country is merely a small part of what must be addressed in order to obtain a license to explore or mine. Other laws impact heavily on the operations and must be followed if the activities are to be approved. Even administrative practices, which implement the provisions of a law, can affect whether approvals will be timely. It is wise to employ a local agent and legal counsel to assist in dealing with the processes and procedures that must be followed to commence mining activities. Contact with a local chamber of mines can also be extremely helpful.

When entering a new country, a company will be judged on the reputation it builds, not just on its reputation elsewhere. Following the rules, providing information throughout the process, working with local populations, and running safe and healthy operations are paramount to establishing a viable mining operation and maintaining a positive reputation.

PART 6

Mining Method Selection

CHAPTER 6.1

Evaluation of Mining Methods and Systems

Michael G. Nelson

INTRODUCTION

The relative merits of surface and underground mining are widely discussed and frequently debated. Some deposits can be mined entirely with surface methods, while others can only be worked underground. With all other conditions equal, surface mining is normally regarded as preferable, because of lower development costs, quicker start-up time, and lower accident rates generally associated with surface mining.

When choosing between surface and underground methods, some of the factors that must be considered include

- Size, shape, and depth of the deposit;
- Geologic structure and geomechanical conditions;
- Productivities and machinery capacities;
- Availability of experienced work force;
- Capital requirements and operating costs;
- Ore recoveries and revenues;
- Safety and injuries;
- Environmental impacts, during and after mining;
- Reclamation and restoration requirements and costs; and
- Societal and cultural expectations.

Some deposits may reasonably be mined entirely by surface methods. In general, such deposits are close to the surface and have a relatively uniform geology. Similarly, some deposits can only be mined economically by underground methods. These deposits are usually deeper, with geological and mineralogical characteristics that require more selective ore extraction. Finally, other deposits are best mined initially as open pits, with production shifting to an underground method as deeper portions of the ore body are extracted. An example of each type of deposit follows.

In suitable deposits, surface mining is more productive, more economic, and safer for workers. However, changes in environmental regulations and societal expectations may lead to fewer large open-pit mines, particularly if operators are required to backfill open pits and recontour waste dumps. These conditions may result in the development of small, high-grade deposits by very shallow open pits or in the development of high-grade underground mines in place of large open-pit mines. Where applicable, large, low-grade deposits may be mined by in-situ methods (Hitzman 2005). In some cases, especially in built-up areas, it has become almost impossible to obtain permits for new surface mines. This is the case for producers of crushed stone and dimension stone in large metropolitan areas in many developed countries. For this reason, several underground quarries have recently begun operating in the United States, and many more are in the planning stages.

Table 6.1-1 Major equipment in use at the North Antelope Rochelle coal mine

Description	No. in Use	Description	No. in Use	Description	No. in Use

Draglines	3	Water trucks	9	Mining shovels	14
Loaders	3	Drills	9	Dozers	27
Backhoes	6	Wheel dozers	13	Haul trucks	73

SURFACE AND UNDERGROUND MINE EXAMPLES

In some cases, the choice of surface or underground is obvious. One such example is the North Antelope Rochelle mine in Wyoming, United States, owned by Peabody Energy.

The North Antelope Rochelle mine shipped 88.7 Mt of compliance coal in 2008 and has produced more than 1,000 Mt since the mine began in 1983. It is the largest coal mining operation in the United States. Remaining coal reserves dedicated to the mine cover nearly 8,800 hectares with about 1,200 Mt of recoverable coal. The coal seam ranges from 18 to 25 m thick and lies from 15 to 105 m below the surface.

The complex employs a large fleet of big equipment, listed in Table 6.1-1. The three draglines have bucket capacities of 84, 76.5, and 65 m^3, respectively. The key to success is high volume and low unit costs.

Similarly, in the case of the Henderson mine, underground mining by panel caving was the most logical choice. The Henderson mine, located in Colorado, United States, is owned by Freeport-McMoran Copper and Gold, Inc. A cross section of the Henderson ore body is shown in Figure 6.1-1. Although

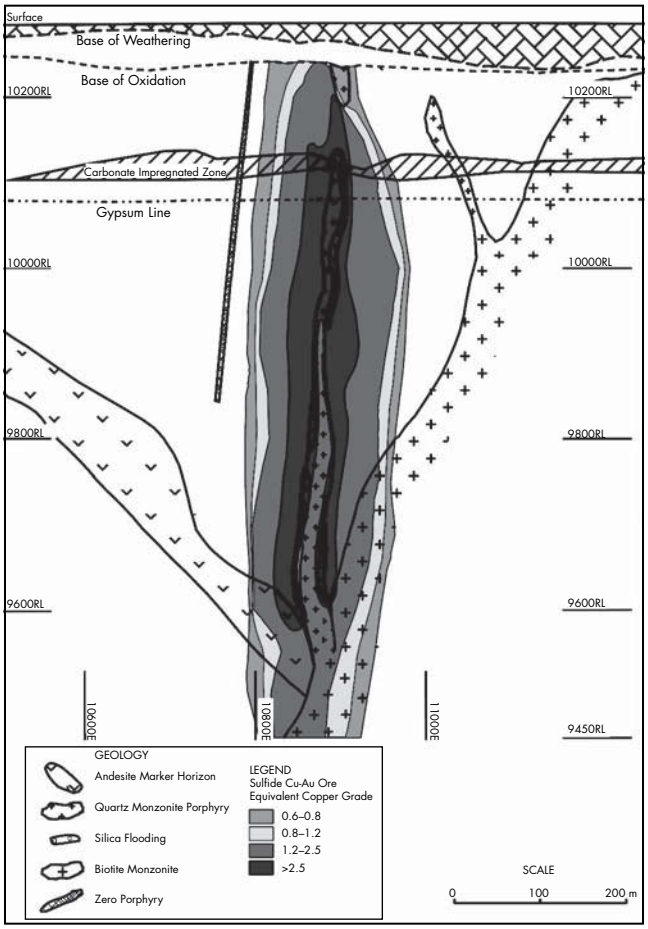
Source: Rech 2001.

Figure 6.1-2 Cross section of the Henderson mine

the ore body is relatively large, it is also quite deep—about 1,040 m below the top of Red Mountain. Development of an open-pit mine would have required removal of a large amount of overburden before the ore body was exposed. This would have required construction of roads, power lines, and other infrastructure to the top of Red Mountain, at 3,751 m above sea level. Thus development would have been extremely expensive, with no initial production to support development costs. The Henderson mine was developed as shown in Figure 6.1-2.

Finally, the Northparkes mine in Queensland, Australia, provides an example of a mine that began as an open pit and is now an underground operation. As shown in Figure 6.1-3, the Northparkes ore body is a narrow porphyry, 200–300 m across and about 900 m in height.



Beginning in the late 1970s, Northparkes was mined with two open pits, each about 150 m deep. Because the ore body has such a small cross section, the stripping ratio increased rapidly, and in 1993 development was begun for underground mining by block caving, as shown in Figure 6.1-4.

With these examples in mind, it is worthwhile to consider some specific differences between surface and underground mining.

PRODUCTION

Much more material is produced by surface than by underground mining. This is shown in Table 6.1-2, which gives recent data for the United States. It is apparent from Table 6.1-3 that sand, gravel, and stone products represent more than 90% of the material produced in surface mines each year.

The fraction of mined material produced by underground methods in the United States has decreased in recent years, as shown in Table 6.1-3. This results from the decrease in the fraction of coal produced underground; the fractions for metal and nonmetal minerals vary over the period.

Source: House et al. 2001.

Figure 6.1-3 Northparkes ore body

MINE SIZE

In terms of daily production tonnage, surface mines are almost always larger than underground mines producing the same commodity. This is partially true because open-pit mines must mine much more waste rock (and therefore have much more dilution of the in-situ mineral), whereas many of the underground methods can mine the same mineral much more selectively, with less dilution and therefore fewer metric tons.

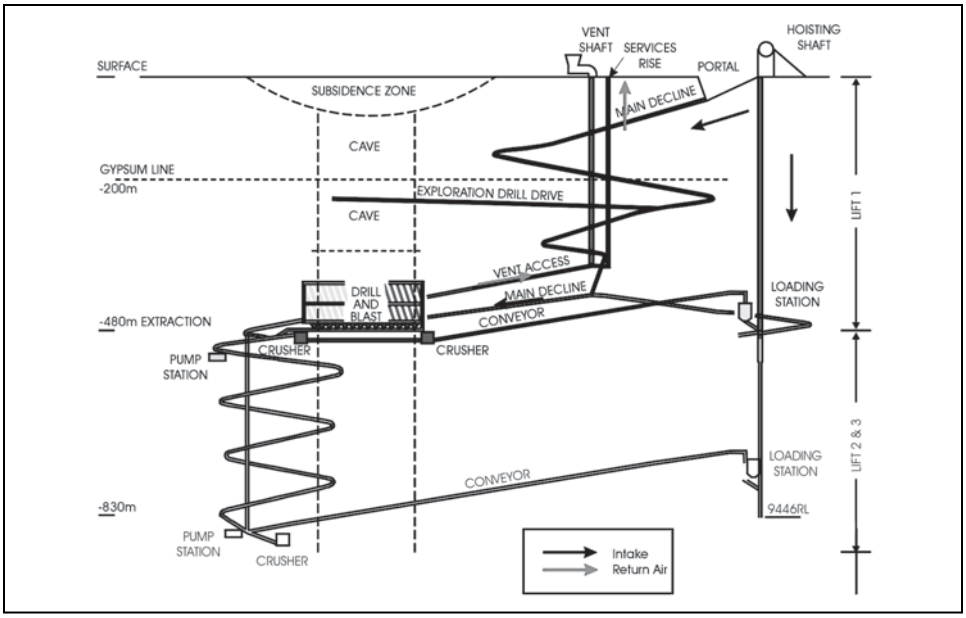


Table 6.1-4 shows approximate daily production rates for selected large surface mines; Table 6.1-5 shows similar data for large underground mines. These tables show the predominance of surface methods for large, high-tonnage operations worldwide. (Tables 6.1-4 and 6.1-5 are not intended to be complete but are included to provide an indication of the respective numbers and sizes of larger surface and underground operations.)

PRODUCTIVITY

When productivity is measured in metric tons mined per worker-hour, surface mines are almost always more productive. Table 6.1-6 shows data for coal mining in the United States. During 2006 and 2007, productivity in surface mines was more than three times that in underground mines. However, when choosing a mining method, it is important to go beyond a simple consideration of metric tons per worker-hour. For example, in a gold deposit, it may be more meaningful to examine grams or ounces of gold produced per worker-hour. In many gold mining districts, comparing the productivity of the surface mines and underground mines in this way shows much more comparable results.

SAFETY

The mining industry throughout the world continues to reduce the incidence of accidents and fatalities. The underground mining environment is recognized as being more hazardous than the surface. Table 6.1-7 shows the incidence rates per 200,000

hours for all accidents in the United States during the years 2003–2007; Table 6.1-8 shows the incidence rates for fatal injuries. These rates are higher in all cases for underground mining, and notably higher for underground coal mining.

DEVELOPMENT

Development for surface mining of coal and other bedded minerals involves the removing of cover layers of soil and rock to expose the coal. Surface mining is used when the coal seam is relatively close to the surface, usually within 60 m. The time between overburden removal and the mining of the product mineral should be as short as possible to optimize overall cash flow. However, for larger deposits covered by large amounts of overburden and waste, the amount of pre-stripping will also be large, leading to high preproduction development costs. The time required for pre-stripping can range from 2 to 6 years. Thus, interest costs during development will be high and will represent a significant portion of the pre-mining capital requirement before mining can start. When an ore body is steeply dipping and at or near the surface, open-pit mining can start with a small amount of stripping. However, as mining of such a deposit progresses, increasing amounts of waste rock must be removed. This must often be done many years before mining of the corresponding amount of ore at deeper levels can take place. Thus, the ultimate pit limits must be projected early in the mine planning process, and the investment cost for waste rock removal in advance of mining must be included in the economic evaluation. Waste rock stripping should be delayed as long as possible to avoid high interest cost for all the money spent in waste stripping activities. The increasing cost of stripping at greater depths is one of the major factors in deciding when to transition from surface to underground mining of a given deposit.

In an underground mine, a significant amount of infrastructure must be installed before mining begins. This will include shafts, hoists, ventilation fans, underground shops, travel ways for workers and machinery, ore storage bins, underground crushers, and so forth. This requires detailed long-range planning from the very beginning so that the requirements of future workings at deeper levels can be accommodated. A large capital investment is often necessary before production can start.

Underground mining methods require a more careful design and planning process, because it is difficult to make changes in a design after the infrastructure has been installed and the equipment purchased. This condition is often exacerbated when variables such as ore grade, mine water make, and ground control conditions change or are different than expected. It is very important that the underground mine design and the machinery capacities are properly chosen from the beginning. For all of these reasons, it is often prudent to develop a small test mine to accurately determine many of the unknown mine characteristics. A test mine and a properly conducted feasibility study will minimize these risks.

The development of a large underground mine can take as many as 5 to 10 years. Interest costs during development will therefore be high and may comprise 30% to 40% of the premining capital requirement before mining can start.

COST COMPARISONS

Estimates of capital and operating costs for surface and underground mines of various sizes and configurations are compiled regularly and in considerable detail by InfoMine, Inc. Those estimates are provided to customers as the *Mining Cost Service* and can be purchased in printed or electronic form, or accessed on-line. The cost estimates do not include permitting, environmental analysis, reclamation, or closure costs. Figures 6.1-5 and 6.1-6 summarize the cost estimates for surface mines.

The *Mining Cost Service* also provides estimates of capital and operating costs for underground mining. The data are more extensive, with estimates for eight mining methods, and shaft and adit access for each. Figures 6.1-7 and 6.1-8 summarize selected data.

While surface mining methods are relatively simple and uniformly applied, there are many underground mining methods, and application of any given method will vary from mine to mine. Thus it is much more difficult to accurately summarize costs for underground mining methods. Nonetheless, Figures 6.1-5 through 6.1-8 show the following trends:

- For small mines, capital and operating costs per metric ton of ore produced are lower for surface methods. Of course, dilution and ore grade must also be considered in a full economic analysis. For large tonnage production, capital and operating costs may be higher for surface

mines, depending on stripping ratio. In these cases, a dual feasibility study must be performed comparing the open-pit option to the best underground mining option.

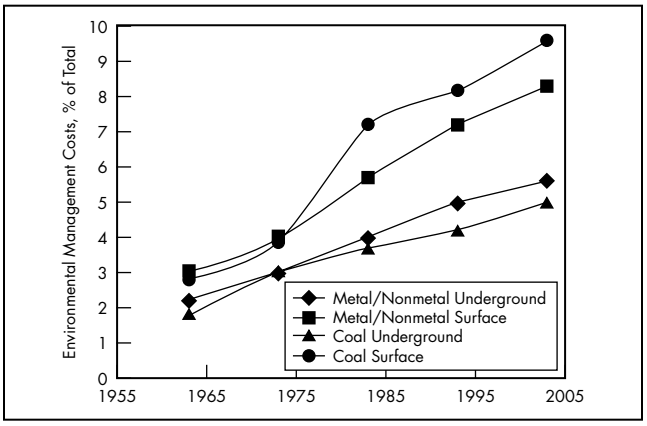
- In all cases, capital costs increase and operating costs decrease with increasing production tonnage.

ENVIRONMENTAL AND CLOSURE REQUIREMENTS

Surface mines create a much larger footprint than underground mines. In the United States, surface coal mines are required to backfill mine excavations, and recontour and revegetate waste piles. This is not the case for metal, but there are strong indications that the situation is changing. Indeed, in most countries, society no longer looks favorably on large, abandoned excavations, and the mandated costs of reclamation and closure for large surface mines are likely to increase. A permit for construction of a new surface mine or expansion of an existing surface mine cannot be obtained in some areas. In these cases, underground mining should be examined.

Costs of environmental compliance, reclamation, and closure are seldom published. However in 1999, Mudder and Harvey reported that closure costs for U.S. surface mines ranged from US$1,236 to US$3,707 per disturbed hectare, with coal mine costs on the higher end of the range at US$2,471 to US$3,707 per hectare. Costs for metal mine sites were lower, yet they were much higher in cases where extensive water management and acid rock encapsulation were required. In 1996, Homestake Mining Company reported average company-wide reclamation costs of US$3,361 per hectare. Between 1980 and 1992, 136 abandoned coal mine sites in Pennsylvania were reclaimed, at a cost of about US$2,348 per hectare (Bogovich 1992).

In 2004, Wilson and Dyhr estimated environmental and closure costs as a percentage of total operating costs for medium-sized mines with on-site processing and tailings disposal. Those estimates are summarized in Figure 6.1-9, where the higher costs associated with surface mining are clearly shown.



SELECTION OF A MINING METHOD

Based on this brief introduction, it may appear that surface mining is preferable to underground methods, particularly in regard to productivity and worker safety. However, as has been pointed out, selection of the best mining method for any deposit requires analysis of many factors besides the simple productivity in metric tons of ore per worker-hour.

The following subsections discuss in detail the procedures for selecting a mining method and include factors that influence the choice between surface and underground mining.

Location of the Deposit

In some cases, a mineral deposit may be located in a place where a large surface mine is simply unacceptable. The case of stone and other construction materials, already mentioned briefly, is an excellent example. These materials have a relatively low value and are used in large quantities, so it is important that they be mined as close as possible to the locations where they will be used. Those places are almost always heavily built-up areas. For example, the amount of concrete used in

Source: Data from Wilson and Dyhr 2004.

Figure 6.1-9 Environmental costs as percentage of total operating costs

Manhattan every 18 months—3.33 million m^3—is about the same amount as was used in the construction of the Hoover Dam on the border between Arizona and Nevada in the United States (Owen 2003). In such areas it is difficult, if not impossible, to expand an existing stone quarry, let alone open a new one, and the production of stone increasingly comes from underground quarries.

Of course, underground mining methods can also have adverse effects when operated under built-up areas. Surface subsidence and mine water release must both be monitored and controlled. Other factors also enter into choosing the location for a mineral deposit, including processing requirements, political and social conditions, and work-force availability, which are discussed in the following sections. Another factor, environmental and permitting requirements, is not discussed in this chapter.

Geology of the Deposit

Three aspects of a deposit's geology relate to the choice of surface or underground mining: the intrinsic value or grade, the morphology, and the structure.

A material with a higher intrinsic value will support a more expensive mining method. For example, Jim Walter Resources mines high-quality metallurgical coal at its Blue Creek mine in Alabama (United States) under very difficult conditions that include spontaneous combustion, deep cover (450 to 730 m), and high methane levels (Howell et al. 1991). A lower-quality coal would not support the high costs of mining in this geological setting. Similarly, an unusual narrow-vein gold deposit, where the gold occurs in very high-grade but sporadic pockets, supports a labor-intensive underground mining method (Original Sixteen to One Mine 2009). In general, deposits with lower intrinsic value or grade are more amenable to surface mining methods when other conditions permit.

Deposit morphology, including shape, extent, and depth, is also important. The economics of most surface mining methods (and some underground methods) are based on high production volume and low unit costs, and use of equipment that has high capital costs. These require large deposits with relatively uniform grade and few irregularities in shape or extent. Deposits that meet these criteria can often be mined profitably, even when the ore grade or product value is relatively low. Good examples of such surface mines are large coal mines in northeastern Wyoming, as described previously; the large porphyry copper mines, such as Bingham Canyon in Utah (United States) and Chuquicamata in Chile; and the large, low-grade gold mines such as Round Mountain and Goldstrike in Nevada. Similarly, coal deposits that can be mined by the underground longwall method must have large areas of coal with relatively uniform thickness to allow the development and production of large panels that will support the costs of development and purchase of equipment. The depth of a deposit also influences the surface versus underground decision. The depth of the Blue Creek mine requires the use of barrier pillars between longwall panels, at a cost that could probably not be supported by a lower-value coal. In other cases, metal deposits are often mined initially by the open-pit method but switch to an underground method when the costs of removing overburden become too high. This has happened, for example, at Kiruna in Sweden, Northparkes in Australia, and Palabora in South Africa.

Finally, the geologic structure of a deposit must be considered. It is more difficult to generalize about this factor, but a good example is the Homestake deposit in South Dakota (United States). George Hearst, who consolidated the claims and put them into production, is reported to have said to his partners, "Here's to low-grade ore and plenty of it" (Smith 2003). During its 125 years of operation, the Homestake mine produced almost 1.2 million kg of gold and 0.3 million kg of silver. Of course, open-pit mining was unknown when operations began at Homestake, but lacking other information, one might conclude that this large, low-grade deposit was an ideal candidate for that method. However, the deposit was highly folded and faulted, and required selective mining to extract the ore in a manner that could only have been done by underground methods.

Processing Requirements

The processing required to produce an economic product also influences the choice of mining method. It may be possible to mine a low-grade ore at very low cost using a surface method, but the resulting dilution may make processing so expensive that the overall operation is not profitable. In such a case, more selective mining using an underground method may be used to produce a higher-grade ore, which is less expensive to concentrate. Such selective mining can also be used to leave in place portions of the deposit containing impurities or contaminants that can increase reclamation or remediation costs if they enter the process stream.

It is also important to consider the locations of available processing facilities and the ease with which new facilities can be permitted and built. The difficulty of obtaining permits for new operations in built-up areas for aggregate pits and stone quarries was described previously. The same challenge has been encountered in permitting new coal preparation plants in the eastern United States, and in some cases this has been the main factor in deciding how to mine new coal resources.

Political and Social Conditions

Political and social conditions can determine not only whether or not a mineral deposit can be mined, but also the method by which it is to be mined. There may be significant opposition to the large, highly visible disturbance that occurs in surface mining, making permitting too expensive or impossible. In other cases, the legal rights to the minerals in an area may be

separated from the rights to control the surface in the same area, so that accessing and removing the minerals by an underground method is preferable.

Work Force

In general, underground mining methods require a more specialized work force than surface methods. Workers with experience in operating heavy equipment in agriculture or construction can often transfer their skills for use in surface mining operations, but underground mining equipment and processes are significantly different. For a deposit in which there is no clear choice between surface and underground mining, based on other constraints, the presence or absence of a suitably skilled work force can be a deciding factor.

CONCLUSION

Selection of the best mining method for a given deposit, including the choice between surface and underground mining, is a complex process involving the analysis of many interrelated variables. These variables are not just technical; they include consideration of environmental, social, and political conditions and constraints, and of the time and expense required to obtain the required government permits.

The process is usually iterative in nature, looking at many possible approaches and determining how all the variables interact in each. Mining companies and consultants now use detailed and sophisticated models that incorporate all the technical and financial data, and provide detailed output showing mine and mill production, direct and indirect costs, taxes and royalties, cash flows, internal rate of return, and net present value for each alternative considered. These models often incorporate probabilistic routines for sensitivity analysis so that decision makers can look at how the predicted outcomes for each alternative are affected by changes in the values of key variables such as ore grade, labor and material costs, and commodity prices.

CHAPTER 6.2

Mining Methods Classification System

L. Adler and S.D. Thompson

INTRODUCTION

The purpose of a classification system for mining methods is to provide an initial guideline for the preliminary selection of a suitable method or methods. Its significance is great as this choice impinges on all future mine design decisions and, in turn, on safety, economy, and the environment.

The choice of a mining method assumes a previous but cursory knowledge of the methods themselves. It also assumes a brief understanding of ground control and of excavating and bulk handling equipment. In the formal mine design procedure, the choice of mining methods immediately follows geological and geotechnical studies, and feeds directly into the crucial milestone diagram where regions of the property are delineated as to prospective mining methods (Lineberry and Adler 1987). This step in turn just precedes the subjective, complex, and critical layout and sequencing study.

To develop the proposed classification system adopted here, many existing ones (both domestic United States and foreign) were examined and incorporated to varying degrees. The result is deemed more systematic, inclusive, and understandable than its predecessors (i.e., Stoces 1966).

Subsequent parts of this handbook elaborate on the selection and comparison of mining methods.

INPUT STATEMENT

A comprehensive statement has been developed to provide a rapid checklist of the many important input parameters (Adler and Thompson 1987). The three major areas are (1) natural conditions, (2) company capabilities, and (3) public policy (Table 6.2-1). Those parameters appearing early are generally the most important. Natural conditions require that a dual thrust be maintained concerning resource potentials and engineering capabilities. An additional basic distinction occurs between geography and geology. For company capabilities, fiscal, engineering, and management resources must be recognized. This includes the scale of investment, profitability, and personnel skills and experience. Public policy must be considered, particularly as to governmental regulations (especially safety, health, and environmental), tax laws, and contract status. Some of the latter input factors are held in abeyance until near the end of the investigation, and then considered as modifying factors. This organization duplicates but tightens others (Hartman 1987).

SPATIAL DESCRIPTION

Most mineral deposits have been geometrically characterized as to an idealized shape, inclination, size, and depth. Complex or composite bodies are then composed of these elements.

Ideal shapes are either tabular or massive, with chimneys (or pipes) being subordinated. Tabular deposits extend at least hundreds of meters (feet) along two dimensions, and substantially less along a minor dimension. Massive bodies are approximately unidimensional (cubic or spherical), being at least hundreds of meters (feet) in three dimensions. A modification is recommended later to achieve closure with tabular deposits. For tabular deposits, the inclination (attitude or dip) and thickness are crucial. Inclinations range from flat to steep (Table 6.2-2) (Hamrin 1980; Popov 1971).

Table 6.2-1 Input statement categories

Primary Categories (Dependency)	Secondary Categories
Natural conditions (invariant)	Geography
	Geology
	Economic engineering
Company capabilities (variant)	Business administration
	Monetary aspects
	Management aspects
Public policy (semivariant)	Regulations
	Taxes
	Contracts
	Incentives
State of the art (mining engineering)	Salient distinctions
	Total systems (design/control)
	Encumbered (and regulated) space
	Full-spectrum practice (manage/evaluate)
	Professionalism

L. Adler, Professor, West Virginia University, Morgantown, West Virginia, USA
S.D. Thompson, Assistant Professor, University of Illinois at Urbana–Champaign, Illinois, USA

Table 6.2-2 Tabular deposits classified by attitude and related to bulk handling and rock strength

Class	Attitude or Dip	Bulk Handling Mode	Rock Strength
Flat	≤20°	Use mobile equipment (and conveyors)	Weak rock (surficial)
Inclined	20–45°	Use slashers (metal plate can also vibrate—as gravity slides)	Average rock
Steep	≥45°	Gravity flow of bulk solids	Strong rock (at depth)

Table 6.2-3 Surface pit slopes related to rock strength and time

	Maximum Pit Slope	
Rock	Short Term	Long Term
Strong	41°–45°(–70°)*	18°–20°
Average	30°–40°	15°–18°
Weak (soils also)	15°–30°	10°–15°

*Infrequently up to 70°.

Table 6.2-4 Underground deposits classified by thickness

	Deposit Thickness		
Class	Coal	Ore	Comments
Tabular			
Thin	0.9–1.2 m (3–4 ft)	0.9–1.8 m (3–6 ft)	Low profile or narrow mine equipment
Medium	1.2–2.4 m (4–8 ft)	1.8–4.6 m (6–15 ft)	Post and stulls ≤3.1 m (10 ft)
Thick	2.4–4.6 m (8–15 ft) pillar problems	4.6–15.3 m (15–50 ft) can cave (steep dip)	Small surface equipment; crib problems
Massive	≥4.6 m (15 ft)	≥5.3 m (50 ft)	Pillar problems or poor recovery; benching necessary; caving considered

Table 6.2-5 Deposits classified by depth

	Deposit Depth		
	Underground (a measure of overburden pressure)		
Class	Coal	Ore	Surface
Shallow	≤61 m (200 ft) slope entries possible	≤305 m (1,000 ft)	≤61 m (200 ft)
Moderate	122–244 m (400–800 ft) pillar problems	305–457 m (1,000–1,500 ft)	61–305 m (200–1,000 ft)
Deep	≥915 m (3,000 ft) bumps, burst, closure	≥1,830 m (6,000 ft)	≥305–915 m (1,000–3,000 ft) open pit

Table 6.2-6 Deposit classified by geometry and type

Geometric Class	Deposit Type	Comments
Tabular	Alluvium (placer)	Near surface—weak
Flat and inclined	Coal (folded too)	Weak country rock—an erosion surface
	Evaporites (domes too)	
	Sedimentary	Good country rock, thicker
	Metamorphic (folded too)	
Steep	Veins	Can be weakened or rehealed (gouge and alteration)
Massive	Igneous (magmatic)	Strong
	Disseminated ores	Can be weakened

In surface mining, the inclination limits the advantageous possibility of being able to cast waste material nearby, as opposed to hauling it a distance and then storing it. For flat deposits, especially when fairly shallow, an area can be successively opened up and the waste can then be cast into the previously mined-out strips, a substantial economic advantage. Casting, in its normal sense, is not restricted to the use of rotating excavators; broadly, it means relatively short-distance hauling of waste, which can also be done with mobile loaders and/or trucks or with mobile bridge conveyors. For steeper (and deeper) deposits, stable pit slopes become important (Table 6.2-3) (Hartman 1987; Popov 1971). Where the deposit inclination exceeds that of the stable slope, both the hanging wall and footwall must be excavated and the increased waste then handled and placed.

For both surface and underground mining methods, the inclination cutoff values nearly coincide (one for pit slopes, the other for face bulk handling mechanisms, whether mechanical or by gravity). While not identical, they are close enough to use similar values (20° and 45°; see Table 6.2-2).

The thickness of a tabular deposit is also important (Table 6.2-4), with reference primarily to underground work (Popov 1971). When three or more benches are required, the deposit tends to be treated as massive. Primarily in flat underground deposits, thickness governs the possible equipment height (low profile), and in steep ones its narrowness. Also, in underground mining, the deposit thickness becomes a support problem, especially if effective pillars become so massive that recovery is compromised. When the upper limit of any of these concerns is reached (e.g., benching, equipment size, and pillar bulk), closure with massive deposits occurs for all practical purposes. Pillar size vs. recovery can dictate caving except where pillar sizes may be decreased because backfilling is used, such as in postpillar cut-and-fill.

Finally, the depth below the ground surface is important (Table 6.2-5) (Popov 1971; Stefanko 1983). For surface deposits, even flat ones, this can obviate casting and require increased waste haulage and expanded dump sites. For underground mining, earth pressures usually increase with depth, consequently raising the support needs. The ground surface location above a deposit must be clearly identified to evaluate other parameters (see "Input Statement" section previously).

CORRELATING DEPOSIT TYPES

The inclination (dip) can be roughly related to the deposit type (Table 6.2-6). Rocks can also be related to strength (Table 6.2-7) (Hartman 1987). The strength of the deposit and its envelope of country rock can then be related to its type (Table 6.2-8). For determining pit slopes, (surface mining) and support requirements (underground mining), these relationships become important. Some variations are noted, especially for veins and disseminated deposits.

CLASSIFYING SURFACE MINING METHODS

Depth Related to Inclination

The surface mining classification, although based on the crucial ability to cast waste material rather than to haul it, has other features. These are primarily based on the depth of the deposit being a function of its inclination. Flat seams tend to be shallow, and casting is possible; steep and massive deposits trend to depth. From this, a number of relationships result.

Table 6.2-7 Rocks classified by strength

Class	Compressive Strength	Examples
Weak	≤41.3 MPa (6,000 psi)	Coal, weathered rock, alluvium
Moderate	41.3–137.9 MPa (6,000–20,000 psi)	Shale, sandstone, limestone, schist
		Evaporites, disseminated deposit
Strong	137.9–206.8 MPa (20,000–30,000 psi)	Metamorphic, igneous, veins, marble, slate
Very strong	≥206.8 MPa (30,000 psi)	Quartzite, basalt, diabase

Depth Related to Excavating Technique and Stripping Ratio

Because of the effects of weathering and stress release, excavating becomes more difficult and expensive with depth, following a continuum from hydraulic action and scooping through to blasting (Hartman 1987).

As a matter of definition, the stripping ratio (ratio of waste to mineral) usually increases with depth. However, the relatively inexpensive handling of waste near the surface by casting tends to mitigate this increase, permitting higher ratios. The use of mobile, cross-pit, high-angle conveying allows greater pit depths and, along with the mineral value, also influences this ratio.

Surface Mining Classification System

Based on the foregoing factors, a surface mining classification has been developed (Table 6.2-9). The classification incorporates information dependent on the intrinsic characteristics of the geometry of the deposit. Quarrying appears to be anomalous because of (1) relatively steeper pit slopes, (2) specialized means of excavating and handling, and (3) less critical amount of overburden. "Glory hole" mining or its equivalent is making a comeback in very deep open pits using inclined

Table 6.2-8 Deposits related to geometry, genesis, and strength (in order of induration)

Deposits Type	Geometry	Genesis	Strength and Stiffness, Deposit/Country Rock	Examples
Alluvium (placers)	Tabular-flat	Surface-stream action deposition (fans, deltas, meanders, braids)	Poor/poor	Sand and gravel; precious metals and stones (tin)
Erosion surface (swamps)	Tabular-flat and thin (possible folding)	Swamps (possible dynamic metamorphism)	Poor/poor to good	Coal
Disseminated	Massive	Underground channels and multifaceted advance	Poor/poor	Hydrothermal ores (porphyry coppers and sulfides)
Vein (can be rehealed)	Tabular-inclined (pipes, chimney shoots)	Major underground channels (fissures), gouge, alteration (reheal)	Poor to good/good	Hydrothermal ores (porphyry coppers and sulfides)
Evaporites	Tabular-flat-thick	Interior drainage	Good/good	Salt, phosphates
Sedimentary (bedded)	Tabular-flat-thick	Shallow seas	Good/good	Limestone, sandstone
Metamorphic	Tabular-flat-thick	Dynamic and/or thermal	Good/good	Marble, slate
Igneous (magnetic)	Massive	Plutonic emplacement	Good/good	Granite, basalt, diabase

Table 6.2-9 Classification of surface mining methods

Shape, Attitude (dip)	Deposit Characteristics	Stripping Ratio	Excavation		Mining Method
			Waste Handling	Excavation	
Tabular					
Flat	Near surface	Low	Onsite	Hydraulic, scoop, dig	Placers—hydrosluicing, dredging, solution—at depth
	Shallow	Moderate	Cast	Scoop, dig, light blast	Open cast (strip)—area, contour, mountain top
Inclined	Moderate	Moderate (remove hanging wall)	Need highwall	Auger	Auger
			Haul (to waste dump)	Blast	Open pit
	Deep	High (remove both hanging wall and footwalls)	Haul (to waste dump)	—	Open pit
				Saw, jet pierce (joints)	Quarry
Massive	Full range	Depends on depth	Haul (to waste dump)	—	Open pit; glory hole

Note: In-situ mining is always possible.

Table 6.2-10 Structural components located and described for underground mining

Component (time dependent)	Location/(Material)	Loaded by	Supported by	Comments
Roof (can deteriorate, slough, slake—dry and crumble)	Back and hanging wall (envelope)	Main roof—all, especially overburden (cap rock)	Pillars and fill, also arched (1/5)	Spans ~3 m (10 ft) for coal to 30.5 m (100 ft) for rock
		Immediate roof—body	Artificial supports can remove	Spans ~3.1 m (10 ft) (stand-up time)
Pillars and walls (can deteriorate—slough, slake)	Sides, deposit and waste (horses mainly deposit)	All—especially overburden	Floor	Critical: 1. Stiffness: (slenderness ratio: approximately 10/1 [coal] to 1/3 [rock]) 2. Strength (material) 3. Percentage recovery
Floor (can settle and heave)	Footwall (envelope)	All—through pillar watch water	Country rock can be compacted, removed, drained	Critical: 1. Stiffness 2. Strength (bearing capacity especially if water) 3. Heave (deep-seated)
Fill (for permanent stability)	Crushed waste, sand, water	All—especially as pillars are removed	Footwall and floor	Good mainly to support hanging wall. Requires greater than angle of slide and confinement.
Artificial support (limited time)	External: Timber (props, sets, cribs, stulls, posts); concrete gunite (mesh)	Mainly immediate roof	Floor	Deterioration (chemical and stress)
	Internal: Bolts (headers), trusses, cables, grout, cementation	Mainly immediate roof	Anchorage in roof, etc.	Anchorage a concern

hoisting. Glory hole mining utilizes a single large-diameter raise located in the lowest point of the pit, down which all blasted material is dumped. The bottom of the hole feeds into crushers and a conveying system, which transports the material to the surface through a horizontal or inclined drift (Darling 1989).

In contrast to the underground classification, the surface one is not formed into a matrix. This is because depth and therefore the excavating technique, waste handling, and stripping ratio are all functionally related to the deposit geometry, particularly the seam inclination. No preceding classification recognizes this relationship (Hartman 1987; Lewis and Clark 1964; Morrison and Russell 1973; Stout 1980; Thomas 1973).

CLASSIFYING UNDERGROUND MINING METHODS

Normally, two major independent parameters will be considered that form a matrix, unlike for surface methods. These two parameters are (1) the basic deposit geometry, as for surface methods, and (2) the support requirement necessary to mine stable stopes, or to produce caving, a ground control problem (Boshkov and Wright 1973; Hamrin 1980; Hartman 1987; Lewis and Clark 1964; Thomas 1973).

Deposit Geometry

Deposit geometry employs the same cutoff points for tabular deposits as in the surface classification, but for different reasons. Flat deposits require machine handling of the bulk solid at or near the face; steep ones can exploit gravity (Table 6.2-2), with an intermediate inclination recognized. If stopes are developed on-strike in steep seams as "large tunnel sections" or "step rooms" (Hamrin 1980), machine handling can still be used. The resulting stepped configuration causes either dilution or decreased recovery, or both. Because this face can also be benched, stope mining simply reproduces tunneling.

Ground Control

Ground control requires knowledge of the structure (opening), material (rock), and loads (pressures). Structural components are detailed in Table 6.2-10. Earlier tables detailed the deposit by its depth and detailed rocks by strength (Tables 6.2-5 and 6.2-7, respectively). From the point of view of support, the roof, pillars, and fill are of primary concern.

Main Roof

The main roof (sometimes the hanging wall) is distinguished from the immediate roof by being the critical load transferring element between the overburden and pillars. The immediate roof can be removed (mined out) or supported artificially and lightly. The main roof is defined as the first close-in, competent (strong) seam. If it is only marginally competent, heavy artificial support may keep it stable; if not, then caving can be expected. For a flat seam, the vertical (perpendicular) loads on the main roof are largely due to the overburden and its own body load. Horizontal (tangential) loads or pressures will tend to be uniformly distributed, resulting in a low stress concentration. If bed separation occurs above the main roof, this stress uniformity is enhanced; but at depth, overburden loading tends to decrease separation. Body loads are invariant, whereas edge loads—particularly those due to the overburden—can be shifted (pressure arching). The main roof is often sufficiently thick so that it can be arched below 1/5 (i.e., at less than 1 horizontally and 5 vertically) to increase stability. A guideline for coal is that stable spans are usually less than 3 m (10 ft), whereas for hard rock they are generally less than 30 m (98 ft).

For an inclined seam, the main roof is the hanging wall, and the results are similar to a flat seam. Pressures perpendicular to it are more significant then tangential ones, and bed separation due to gravity is less likely.

Table 6.2-11 Deposit and structural components related to underground mining methods

Deposit Geometry	Structural Main Roof and Floor	Components Rated (pillars, walls)*	Underground Mining Methods	Type
Tabular				
Flat (and inclined)	Good	Good	Room-and-pillar (spans ≤6 m [20 ft]); stope-and-pillar (spans ≤31 m [100 ft])	Self-supported
	Good	Poor	Room-and-pillar; stope-and-pillar	Supported
	Poor (roof collapses about free-standing pillars)	Good	Longwall; pillaring	Caved
	Poor	Poor	Immediately above	Caved
Steep	Good	Good	Sublevel stoping (spans 6–31 m [20–100 ft]); large tunnel section	Self-supported then filled
	Good	Poor	Hydraulicking—coal (spans 6–21-m [20–70-ft] arch); shrinkage	Supported then filled
	Poor	Good	Cut-and-fill	
	Poor	Poor	Sublevel caving and top slice spans ≥6 m (20 ft) (for gravity flow)	Caved
Massive	Good	Good	Vertical slices†	Self-supported
	Good	Poor	Vertical slices	Supported then filled
	Poor (cap rock)	Poor	Block caving (spans ~34 m [110 ft] active—end stope used)	

*Rated as to strength (and stiffness of pillar).
†Horizontal slices can introduce the many problems associated with multiple-seam mining.

Pillars

Pillars serve to support the main roof and its loads, primarily the overburden acting over a tributary area. Pillar material consists mainly of the seam itself and sometimes waste incorporated within the seam. Pillars must not only be sufficiently strong but also must be sufficiently stiff, a frequently overlooked requirement. If pillars are not adequately stiff, but still adequately strong, the roof will collapse about the still free-standing pillars, especially when differential pillar (and floor) deflection occurs. The minimum slenderness ratio for pillars to avoid this crippling is inversely proportional to the recovery. The mining of flat, thick seams of coal dramatically reflects this relationship and is a factor in classifying seam thicknesses (Table 6.2-4). For massive deposits, even in strong rock, this makes freestanding pillars of doubtful value. Upper slenderness ratios range from about 10/1 for coal to 1/3 for rock. Continuous vertical pillars are used to separate vertical stopes in hard rock that employ steep, tabular stoping methods. Even with stable ground, these are usually filled soon after mining for long-term stability. When massive deposits along with their cap rock are weak, caving is necessitated, usually performed as horizontal lifts or as block caving. Caving always requires a sufficient span 9 m (30 ft), good draw control, and also risks dilution and/or poor recovery. Soft or nonuniform floors (footwalls) act the same as do soft and irregular pillars.

Fill

Fill, often a sandy slurry consisting of crushed waste, cement, and water, can be readily introduced into confined (plugged), inclined, and steep tabular stopes. When drained and dried, this hardened slurry provides permanent resistance to ground movement, especially for the walls or pillars. It is widely used in all but the caving methods. It is either run in progressively as a stope is mined out or done all at once at the end of stope mining. Because of settlement and shrinkage away from a flat back, it is marginally useful for flat deposits.

When timbering is densely placed, especially with square sets, it rivals pillars. It, too, is usually filled as stoping progresses (overhand mining). These relationships are summarized in Table 6.2-11 and lead into the formal classification.

Underground Mining Classification System

Based on an understanding of bulk handling and ground control, the underground classification system shown in Table 6.2-12 closely follows previous ones. The primary difference is that sometimes shrinkage stoping is considered self-supported rather than supported. However, although the broken mineral provides a working floor, it is still supporting the hanging wall (roof). On the other hand, when the stope is drawn empty, it remains substantially self-supported until fill is introduced. The disadvantages of the shrinkage method are unique: (1) an uncertain working floor, (2) dilution due to sloughing and falls of rock, (3) possibly adverse chemical effects, and (4) tying up about two-thirds of the mineral until the stope is drawn.

Vertical crater retreat mining is included in the classification between sublevel and shrinkage stoping (Hamrin 1980).

OTHER FACTORS

While subordinated, there are additional factors that must be closely evaluated. These deal with the broad impacts on the environment, health and safety, costs, output rate, and others. They are usually evaluated on a relative basis, although numbers may also be employed (Table 6.2-13) (Boshkov and Wright 1973; Hartman 1987). An example of where the environmental considerations on the surface are beginning to affect mining methods is in the use of high-density paste backfilling in order to return most of the tailings back

Table 6.2-12 Classification of underground mining methods based on deposit geometry and support

Deposit Shape, Attitude (dip)	Degree of Support: Unsupported (open stopes)	Supported	Caved
Tabular			
Flat (mobile bulk handling)	Room-and-pillar; stope-and-pillar	Some degree of artificial support for room-and-pillar and stope-and-pillar	Longwall (shortwall); pillaring (especially room-and-pillar)
Inclined (mixed bulk handling)	Above with scrapers	Above with scrapers	Longwall (difficult)
	Large tunnel section (on-strike)	Large tunnel section with artificial support	
Steep (gravity bulk handling)	Coal hydraulicking	Shrinkage stoping; cut-and-fill stoping	Sublevel caving
	Sublevel stoping	Timbered stoping (square sets, stulls, gravity)	Top slicing (control dilution-and-recovery)
	Vertical crater retreat	Fill as needed	
	Shrinkage stoping	Gravity fill as needed	
Massive	Immediately above mine in vertical slices. Fill—gravity placement. To remove pillars, can mine and then fill horizontal lifts.*		Immediately above in horizontal lifts block caving (bulk mining)

*For ground control problems, especially those associated with coal, treat as if they were to be extracted by thick-seam and/or multiple-seam mining. As pressure increases (especially with depth), or as rock strength decreases, shift right for suitable method (toward supported and caved).

Table 6.2-13 Secondary factors to be considered when selecting a mining method

Method	Relative Cost	Flexibility/ Selectivity	% Recovery/ % Dilution	Environment	Safety and Health	Output (t/h) and Productivity (t/employee)	Miscellaneous
Surface Mining							
Placers and dredging	0.05	Low/high	High/low	High impact, and water pollution	Fair	Moderate	Need water; impact of weather
Open-cast	0.10	Moderate/ moderate	High/low	Blasting can lead to frequent claims and water pollution	Fair	High	Flat topography and impact of weather
Open-pit	0.10	Moderate/ moderate	High/low	Ground disturbance, waste piles, and some water problems	Slope stability (slides)	High	Impact of weather
Quarry	1.00	Low/high	High/high	Ground disturbance and waste piles	Slope stability	Very low	Skilled workers and impact of weather
Underground Mining							
Room-and-pillar (coal)	0.30	High/high	50–80/20	Subsidence and water pollution	Ground control and ventilation	High	Pillaring common
Stope-and-pillar	0.30	High/high	75/15	Good	Ground control and ventilation	High	Benching common
Sublevel stope	0.40	Low/low	75/15	Fill to avoid subsidence	Less, blast from long holes	Moderate	Fill common
Shrinkage	0.50	Moderate/ moderate	80/10 plucking during draw	Fill to avoid subsidence	Poor floor (collapse) and stored broken mineral*	Low	Tie up ⅔ of ore
Cut-and-fill	0.60	Moderate/ high	100/0	Fill to avoid subsidence	Some	Low	Sort in stope
Timbered square set	1.00	Moderate/ high	100/0	Fill to avoid subsidence	Smolder, and fall (of personnel)	Very low	Sort in stope
Longwall	0.20	Low/low	80/10	Subsidence and water pollution	Good	Very high	High capital ≤12° dip ≤2.4 m (8 ft) thick
Sublevel caving (top slicing)	0.50	Low/low	90/20	Severe subsidence disruption	Fair and stored broken mineral*	High	Cave width ≥9.2 m (30 ft)
Block caving	0.20	Low/low	90/20	Severe subsidence disruption	Air blasts and stored broken mineral*	High	Tie up mineral

*Can pack (cement), oxidize, and smolder.

underground (in order to obtain mining permits from environmental agencies).

In addition, innovation is always occurring and some is currently of proven value. These include rapid excavation, methane drainage, underground gasification, and retorting (Hartman 1987). Many methods are now automated and robotized.

CHAPTER 6.3

Selection Process for Hard-Rock Mining

Peter G. Carter

INTRODUCTION

The purpose of this chapter is to describe the process for determining which mining methods should be considered by a mine planner when evaluating a hard-rock mineral deposit. (For the purpose of this chapter, hard rock is defined as ores that cannot be mined by mechanical mining machines.) Mining methods applicable to the generic groupings of *open pit* and *underground* are discussed. Quarrying, dredging, methane drainage, and solution mining are covered, along with other mining methods, in more detail in Chapters 6.6 and 10.3 of this handbook, although several of these methods are mentioned here for completeness, because they involve hard rock. The term *mining method* is used to describe a unique combination of variables that describe the process of excavating rock to recover valuable minerals, together with the essential characteristics of the excavation—an open-pit or an underground mine.

Mining in the 21st century is steadily gravitating toward large-scale excavations in either open-pit or underground mining schemes. This is driven by ever decreasing grades and product values (measured in real terms), all of which place pressure on profit margins and drive the requirement for improved economies of scale.

The single most important variable influencing the selection of a mining method will always be the style and geological characteristics of the mineral deposit. Mineralization styles may include, for example, thin, steeply dipping, tabular vein gold deposits or large, disseminated porphyry copper deposits. Typically, more than one mining method or variation, such as open stoping systems with and without fill, will need to be evaluated. Other variables likely to have a material bearing on the selection process include

- Engineering properties of the mineral deposit and host rock mass;
- Required rate of mineral production from the mine;
- Forecasts of the mineral products' value;
- Comparative capital and operating costs of the various mining activities and mineral processing activities necessary to implement the mining method;
- Availability, cost, and skill levels of labor needed to operate the mine;
- Prevailing regulatory environment; and
- Environmental impacts together with the costs of mitigation and, ultimately, mine closure costs.

The optimum mining method will always be the one that maximizes the economic returns while keeping the environmental impact within acceptable levels, maintaining acceptable work conditions (especially in regard to levels of safety risk) for employees, and satisfying statutory obligations (including resource recovery stipulations). Collectively, these goals will also satisfy the objective of efficient use of the mineral resource.

The following sections examine in more detail the key influences briefly referred to here, followed by discussion on the selection and evaluation methodologies that should be considered when planning a mine. Quantitative and qualitative methodologies are examined.

KEY INFLUENCES ON SELECTION OF MINING METHOD

Key influences include the style of the mineralization and the strength and character of the rock mass.

Style of Mineralization

The term *style* refers to the range of geometric attributes and the mechanisms that have controlled and in many cases also determined the distribution of valuable minerals within the deposit. Typically, this information is coded within a geological model for the mineral deposit, based on the quantity of factual data. During the early phases of exploration, the geological model may be substantially conceptual, perhaps based on mapping and remote sensing technologies such as gravimetric or seismic methods and limited drill-hole sampling. The limitations of knowledge about the style of the mineralization must be carefully considered in the selection process.

In some circumstances, dependent on the geological setting, these conceptual models may provide a reliable foundation for considering the applicable mining methods.

Peter G. Carter, Manager of Mining Engineering, BHP Billiton, Melbourne, Victoria, Australia

Improvements in geological knowledge for a coal seam within sedimentary rocks that have not been materially disturbed by faulting are unlikely to cause the mining method selection process to be revisited, whereas additional geological data (drill-hole sampling) of a steeply dipping, tabular gold deposit substantially affected by faulting, folding, or shearing and displaying pronounced grade trends may require a wider range of possible mining methods to be considered.

The method of preparing the geological model will also be a significant consideration for the mine planner. Most of the general mine planning software packages currently available provide powerful three-dimensional (3-D) visualization, wireframe triangulation facilities, and block modeling systems to facilitate the development of sophisticated and often complex geological models. These tools commonly have the facility for preparing long sections illustrating grade isopachs, thickness isopachs, and structurally controlled grade trends, which can be useful in mining method selection processes.

Interpolation of grade distributions applying simple polygonal methods through to complex geostatistical methods incorporating uncertainty are now common. Mineral resource models that reflect the inherent uncertainties provide enhanced assistance for the optimum selection of a mining method.

Strength and Character of the Rock Mass

This section has been adapted from Hoek (2007). Any process intended to aid the selection of an excavation method must consider the strength and character of the host rock mass. One of the more complex tasks for the mine planner is the determination of representative mechanical properties of the host rock mass. Although tests have been devised to quantify many of the properties of laboratory rock specimens, it is a considerably more difficult task to predict the expected behavior of a rock mass. Numerous empirical rock mass classification methods (derived from actual case studies) have been devised to assist mine planners. It is important to understand the limitations of rock mass classification schemes (Palmstrom and Broch 2006) and that their use does not (and cannot) replace some of the more elaborate design procedures or decisions made from economic analyses. However, the use of these design procedures requires access to relatively detailed information on in-situ stresses, rock mass properties, and planned excavation sequence—none of which may be available at an early stage in the project. As this information becomes available, the rock mass classification scheme adopted should be updated and used in conjunction with site-specific analyses.

Open-Pit Slopes

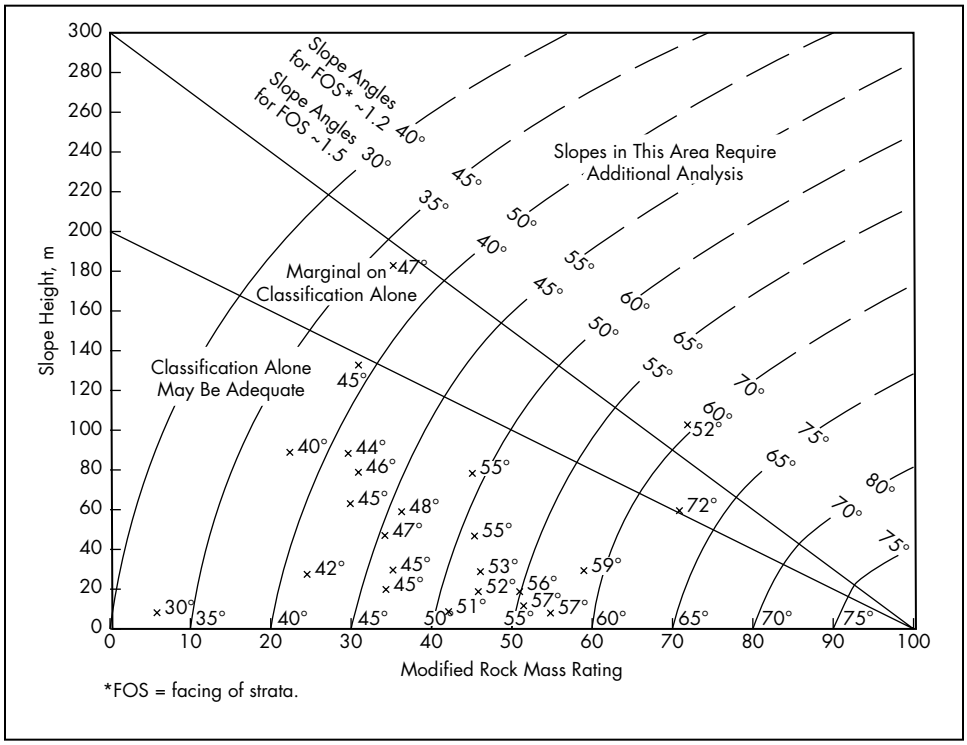
The stability of rock slopes has traditionally been evaluated by limiting equilibrium methods (Hoek and Bray 1981; Wyllie et al. 2004), although probabilistic-based approaches are increasingly more commonly applied, because they acknowledge the implicit uncertainties of limit equilibrium methods. Limit equilibrium models fall into two main categories: (1) models that deal with structurally controlled planar or wedge slides and (2) those that deal with circular or near-circular failure surfaces in homogenous materials. Many of these models have been available for more than 25 years and can be considered reliable slope design tools. Wyllie et al. provide a methodology for assembling basic geological data, rock strength information, and groundwater observations, and integrating this with engineering rules in the form of design charts and graphical methods to permit a nonspecialist engineer to obtain approximate answers suitable for assessing open-pit alternatives.

Several rock mass classification systems have been specifically adapted for rock slope engineering (Haines and Terbrugge 1991; Romana 1995; Chen 1995). These methodologies have been adapted from classification systems for the highly confined rock mass conditions associated with underground mining as distinct from the low-confining stress conditions characteristic of open-pit slopes. These systems, if used with appropriate caution, are useful in specifying a range of slope conditions to assist in mining method selection practices but can never replace the requirement for more rigorous processes such as limit equilibrium and numerical modeling of slopes (Figure 6.3-1).

Numerical modeling of slope deformation behavior is now a routine activity on many large open-pit mines. Software programs such as FLAC and UDEC are typically used for such modeling, although a significant amount of expertise is required to ensure realistic input information and reliable interpretation of outputs. In best practice, a combination of limit equilibrium and numerical modeling approaches are applied to generate an array of solutions for the range of inputs that typically exist at a site, because it is far more reliable to look at the array of results from a parametric study than a single deterministic study.

With the greater depths characteristic of modern open-pit mines, the role of the in-situ stress field in slope stability is becoming an increasingly important consideration. In these cases, mine planners must seek advice from specialists about the applied assumptions when comparing deep open-pit alternatives with underground methods.

In terms of arriving at a suitable set of slope parameters for assessing the applicability of any open-pit method, a process that recognizes the implicit uncertainties and considers a range of slopes as inputs to the evaluation should always be adopted.



Underground Excavations

Rock mass classification systems applicable to underground excavations have been evolving for more than 100 years since Ritter (1879) attempted to formalize an empirical approach to tunnel design for the purposes of determining support requirements.

Terzaghi's rock mass classification. The earliest reference to the use of rock mass classification for the design of tunnel support is in a paper by Terzaghi (1946) in which the rock loads, carried by steel sets, are estimated on the basis of a descriptive classification. It is useful to examine the rock mass descriptions included in his original paper, because he draws attention to those characteristics that dominate rock mass behavior, particularly in situations where gravity constitutes the dominant driving force. The clear and concise definitions and the practical comments included in these descriptions are good examples of the type of engineering geology information that is most useful for engineering design.

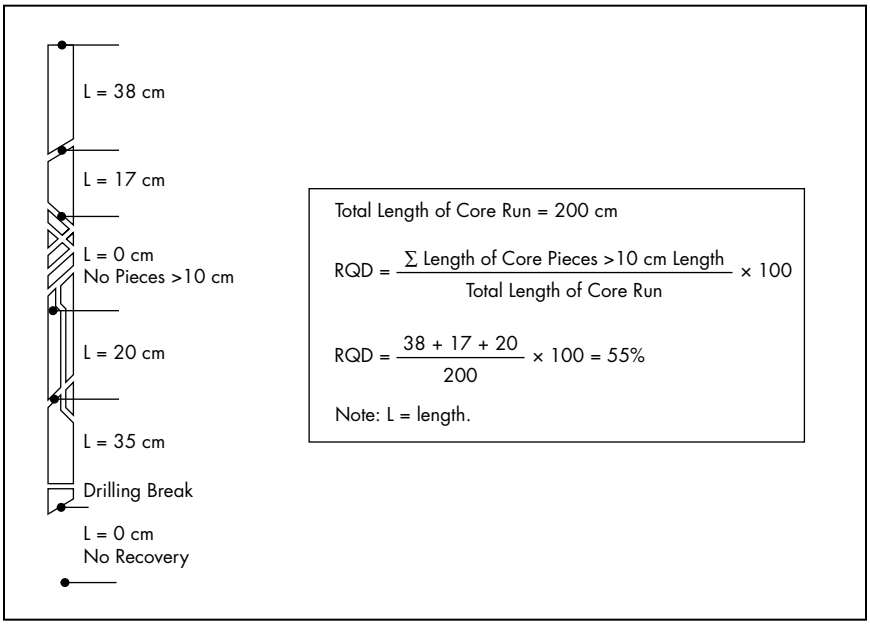
Terzaghi's descriptions (quoted directly from his paper) are as follows:

- Intact rock contains neither joints nor hair cracks. Consequently, if it breaks, it breaks across sound rock. Because of injury to the rock due to blasting, spalls may drop off the roof several hours or days after blasting—known as a spalling condition. Hard, intact rock may also be encountered in the popping condition involving the

Source: Haines and Terbrugge 1991.

Figure 6.3-1 Preliminary slope angle chart

spontaneous and violent detachment of rock slabs from the sides or roof.



- Stratified rock consists of individual stratum with little or no resistance against separation along the boundaries between the strata. The strata may or may not be weakened by transverse joints. In such rock the spalling condition is quite common.
- Moderately jointed rock contains joints and hair cracks, but the blocks between joints are locally grown together or so intimately interlocked that vertical walls do not require lateral support. In rocks of this type, both spalling and popping conditions may be encountered.
- Blocky and seamy rock consists of chemically intact or almost intact rock fragments which are entirely separated from each other and imperfectly interlocked. In such rock, vertical walls may require lateral support.
- Crushed but chemically intact rock has the character of crusher run. If most or all of the fragments are as small as fine sand grains and no re-cementation has taken place, crushed rock below the water table exhibits the properties of a water-bearing sand.
- Squeezing rock slowly advances into the tunnel without perceptible volume increase. A prerequisite for squeeze is a high percentage of microscopic and submicroscopic particles of micaceous minerals or clay minerals with a low swelling capacity.
- Swelling rock advances into the tunnel chiefly because of expansion. The capacity to swell seems to be limited to those rocks that contain clay minerals such as montmorillonite, with a high swelling capacity.

Lauffer (1958) proposed that the stand-up time for an unsupported span is related to the quality of the rock mass in which the span is excavated. In a tunnel, the unsupported span is defined as the span of the tunnel or the distance between the face and the nearest support, if greater than the tunnel span. Lauffer's original classification has since been modified by a number of authors, notably Pacher et al. (1974), and now forms part of the general tunneling approach known as the New Austrian Tunnelling Method.

This method includes a number of techniques for safe tunneling in rock conditions in which the stand-up time is limited before failure occurs. These techniques include the use of smaller headings and benching or the use of multiple drifts to form a reinforced ring inside which the bulk of the tunnel can be excavated. These techniques are applicable in soft rocks such as shales and phyllites, and in which the squeezing and swelling problems, described by Terzaghi, are likely to occur. The techniques are also applicable when tunneling in excessively broken rock, but great care should be taken in attempting to apply these techniques to excavations in hard rocks in which different failure mechanisms occur.

Rock quality designation (RQD). The RQD index was developed by Deere et al. (1967) to provide a quantitative estimate of rock mass quality from drill core logs. RQD is defined as the percentage of intact core pieces longer than 100 mm in the total length of core. The core should be at a minimum size (54.7 mm in diameter) and should be drilled with a double-tube core barrel. The procedures for measurement of the length of core pieces and the calculation of RQD are illustrated in Figure 6.3-2.

RQD is a directionally dependent parameter, and its value may change significantly, depending upon the borehole orientation. The use of the volumetric joint count can be quite useful in reducing this directional dependence. RQD is also intended to represent the rock mass quality in situ. When

Source: Deere 1989.

Figure 6.3-2 Procedure for measurement and calculation of RQD

using diamond drill core, care must be taken to ensure that fractures, which have been caused by handling or the drilling process, are identified and ignored when determining the value of RQD.

Deere's RQD was widely used, particularly in North America, after its introduction. Although various investigators have sought to relate RQD to Terzaghi's rock load factors and to rock bolt requirements in tunnels, the most important use of RQD is as a component of the rock mass rating and Q rock mass classifications covered later in this chapter.

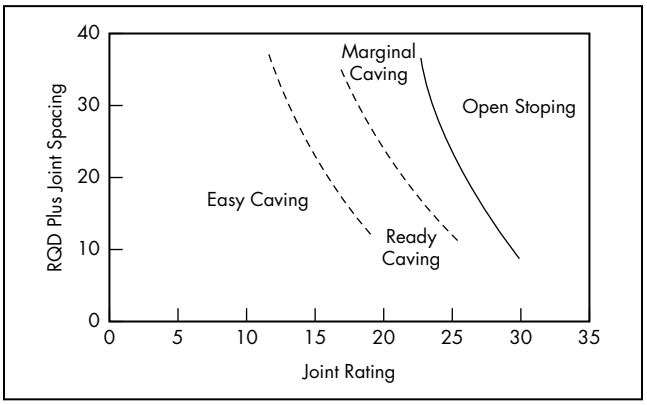
Rock structure rating (RSR). Wickham and Tiedemann (1974) described a quantitative method for describing the quality of a rock mass and for selecting appropriate support on the basis of their RSR classification. Most of the case histories used in the development of this system were for relatively small tunnels supported by means of steel sets, although historically this system was the first to make reference to shotcrete support. Although the RSR classification system is not widely used today, Wickham et al.'s work, in which they devised a basis for rating the geological, geometrical, and joints condition, played a significant role in the development of the classification schemes discussed in the remaining sections of this chapter.

Rock mass rating (RMR). Bieniawski (1973, 1976) published the details of a rock mass classification, called the geomechanics classification or the RMR system. Over the years, this system has been successively refined as more case records have been examined, and the reader should be aware that Bieniawski has made significant changes in the ratings assigned to different parameters (Bieniawski 1989). Bieniawski's RMR system was originally based on case histories drawn from civil engineering. Consequently, the mining industry tended to regard the classification as somewhat conservative, and several modifications have been proposed in order to make the classification more relevant to mining applications. A comprehensive summary of these modifications was compiled by Bieniawski (1989).

Both this and the 1976 version deal with estimating the strength of rock masses. The following six parameters are used to classify a rock mass using the RMR system:

1. Uniaxial compressive strength of rock material
2. RQD
3. Spacing of discontinuities
4. Condition of discontinuities
5. Groundwater conditions
6. Orientation of discontinuities

In applying this classification system, the rock mass is divided into a number of structural regions, and each region is classified separately. The boundaries of the structural regions usually coincide with a major structural feature such as a fault or with a change in rock type. In some cases, significant changes in discontinuity spacing or characteristics within the same rock type may necessitate the division of the rock mass into a number of small structural regions.



Modified rock mass rating (MRMR). Laubscher (1977, 1984), Laubscher and Taylor (1976), and Laubscher and Page (1990) have described an MRMR system for mining. This system takes the basic RMR value, as defined by Bieniawski, and adjusts it to account for in-situ and induced stresses, stress changes, and the effects of blasting and weathering. A set of support recommendations is associated with the resulting MRMR value. In using Laubscher's MRMR system, it should be borne in mind that many of the case histories upon which it is based are derived from caving operations. Originally, block caving in asbestos mines in Africa formed the basis for the modifications but, subsequently, other case histories from around the world have been added to the database. The selection of an appropriate mass underground mining method has been presented by Laubscher (1981) (Figure 6.3-3). The selection process is based on his rock mass classification system, which adjusts for expected mining effects on the rock mass strength.

Laubscher's scheme is aimed at the mass mining methods, primarily block caving and open stoping methods, although

his main emphasis is on cavability. The two parameters that determine whether a caving system is used over a stoping system are the degree of fracturing, RQD (Figure 6.3-3), joint spacing, and the joint rating, which is a description of the character of the joint—that is, waviness, filling, and water conditions. This scheme puts emphasis on the jointing as the only control for determining cavability.

Laubscher (1990) has subsequently modified the MRMR classification to relate the MRMR rating to the hydraulic radius (HR) (Figure 6.3-4). By including the hydraulic radius, cavability becomes feasible for more competent rock if the area available for undercutting is large.

Cummings et al. (1982) and Kendorski et al. (1983) have also modified Bieniawski's RMR classification to produce the modified basic RMR (MBRMR) system for mining. Developed for block caving operations in the United States, this system involves the use of different ratings for the original parameters used to determine the value of RMR and the subsequent adjustment of the resulting MBRMR value to allow for blast damage, induced stresses, structural features, distance from the cave front, and size of the caving block. Support recommendations are presented for isolated or development drifts, as well as for the final support of intersections and drifts.

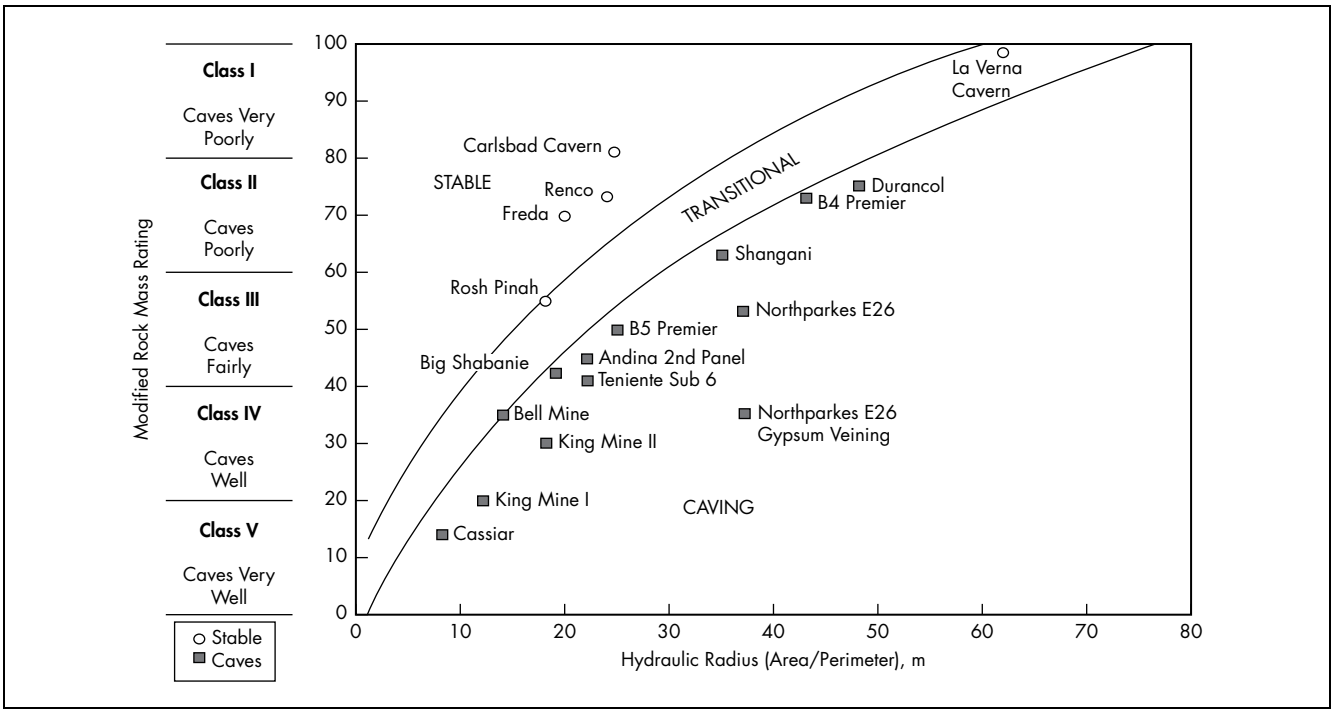
Figure 6.3-3 Laubscher's 1981 classification for cavability

Rock tunneling quality index, *Q*. On the basis of an evaluation of a large number of case histories of underground excavations, Barton et al. (1974), of the Norwegian Geotechnical Institute, proposed a rock tunneling quality index (Q) for the determination of rock mass characteristics and tunnel support requirements. The numerical value of Q varies on a logarithmic scale from 0.001 to a maximum of 1,000 and is defined by



$$Q = \frac{\text{RQD}}{J_n} \times \frac{J_r}{J_a} \times \frac{J_w}{\text{SRF}}$$

where

RQD = rock quality designation
J_n = joint set number
J_r = joint roughness number
J_a = joint alteration number
J_w = joint water reduction factor
SRF = stress reduction factor

In explaining the meaning of the parameters used to determine the value of Q, Barton et al. (1974) offer the following comments:

- The first quotient (RQD/J_n), representing the structure of the rock mass, is a crude measure of the block or particle size, with the two extreme values (100/0.5 and 10/20) differing by a factor of 400. If the quotient is interpreted in units of centimeters, the extreme particle sizes of 200 to

Source: Laubscher 1990.

Figure 6.3-4 Laubscher's cavability related to hydraulic radius and MRMR

0.5 cm are seen to be crude but fairly realistic approximations. Probably the largest blocks should be several times this size and the smallest fragments less than half the size. (Clay particles are, of course, excluded).

- The second quotient (J_r/J_a) represents the roughness and frictional characteristics of the joint walls or filling materials. This quotient is weighted in favor of rough, unaltered joints in direct contact. It is expected that such surfaces will be close to peak strength, will dilate strongly when sheared, and therefore will be especially favorable to tunnel stability. When rock joints have thin clay mineral coatings and fillings, the strength is reduced significantly. Nevertheless, rock wall contact after small shear displacements have occurred may be an important factor for preserving the excavation from ultimate failure.
- The third quotient (J_w/SRF) consists of two stress parameters. SRF is a measure of (1) loosening load in the case of an excavation through shear zones and clay bearing rock, (2) rock stress in competent rock, and (3) squeezing loads in plastic incompetent rocks. It can be regarded as a total stress parameter. The parameter J_w is a measure of water pressure, which has an adverse effect on the shear strength of joints due to a reduction in effective normal stress. In addition, water may cause softening and possible outwash in the case of clay-filled joints. It has proved impossible to combine these two parameters in terms of inter-block effective stress, because paradoxically a high value of effective normal stress may sometimes signify less stable conditions than a low value, despite the higher shear strength. The quotient (J_w/SRF) is a complicated empirical factor describing the active stress.

In relating the value of the index Q to the stability and support requirements of underground excavations, Barton et al. defined an additional parameter, which they called the equivalent dimension, D_e, of the excavation. This dimension is obtained by dividing the span, diameter, or wall height of the excavation by a quantity called the excavation support ratio (ESR). Hence:

$$D_e = \frac{\text{excavation span, diameter or height (m)}}{ESR}$$

The value of ESR is related to the intended use of the excavation and to the degree of security that is demanded of the support system installed to maintain the stability of the excavation.

Modified rock quality index (Q). Barton's Q has been used with a great deal of success in the design of tunnels in rock. However, the SRF parameter is redundant when the classification system is used for the estimation of rock mass properties for the purpose of analytical or numerical modeling for design, because the influence of stress is taken into account within the model. Thus the SRF is set to 1.0, which is equivalent to a moderately clamped but not overstressed rock mass. In addition, in most underground hard-rock environments, the excavations are relatively dry (not considering transient mine water inflows from drilling or backfilling), in which case the J_w parameter can also be set to 1.0.

Along with several other factors (accounting for jointing, stope geometry, and mining-induced stress), Q can then be used to determine the modified stability N′ which is then used with the modified stability graph method (Mathews et al. 1981; Potvin 1988; Bawden 1993; and Hoek et al. 1995) for the dimensioning of open stopes in underground mines.

Modified stability number (N'). Mathews et al.'s empirical method for dimensioning stopes is based on the first and second quotients to dimension each face of a stope together with the HR, where this parameter accounts for the shape and size of the face (Figure 6.3-5). Potvin modified this method and calibrated it using 175 case histories. Nickson (1992) added further case histories, which considered hanging walls, footwalls, endwalls, and backs from a wide variety of mining environments. Other case histories can be found throughout recent literature—Bawden et al. (1989) and Greer (1989). The classification of the rock mass and excavation problem is accomplished in the modified stability graph method, which relates N' to HR where

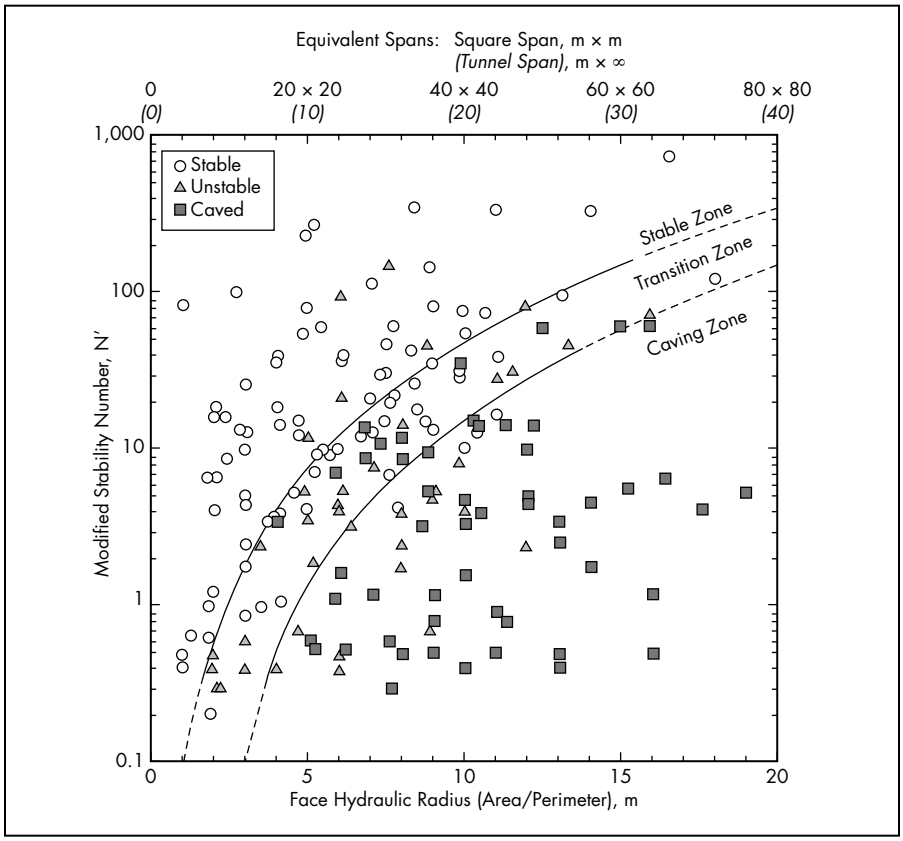
$$N' = Q' \times A \times B \times C$$

where

A = measure of the ratio of intact rock strength to induced stress in the range 0.1–1.0
B = relative orientation of the dominant jointing relative to the excavation surface in the range 0.2–1.0
C = measure of the influence of gravity on the stability of the face being considered in the range 2–8
N' = values in the range 0.0005–8000 with typical values for hard-rock mines of 0.1–1000

Regardless of whether an open-pit or underground mining method is being contemplated, rock mass classification systems can be of considerable benefit, even when little detailed information is available to characterize the rock mass, its strength, and the hydrogeological conditions. At a minimum, these systems can provide valuable insight into the data, which must necessarily be collected following a decision to move the evaluation of a mining method through concept, preliminary, or final feasibility studies.

MINING METHOD ALTERNATIVES



To facilitate the following discussion on mining method selection and evaluation methodologies, a brief discussion to characterize the range of surface (i.e., open-pit) and underground mining methods follows. Additional information in relation to open-pit mining methods can be found in Hustrulid and Kuchta (2006) and Kennedy (1990), while further information on underground mining methods can be found in Hustrulid and Bullock (2001).

Surface Mining Methods

Surface mining methods are defined here as any excavation that commences from the natural surface and does not entail the construction of a tunnel or shaft. Most often, the style of mineralization will significantly impact the features of a surface mining method, particularly the character and thickness of overburden. The type of equipment deployed also commonly affects the classification of a surface mining method.

Open-Cut Mining

Open-cut mining refers to a particular kind of surface mining that most commonly deploys large rope shovels, hydraulic shovels, or excavators together with suitably sized rear-dump trucks and progresses the excavation in a series of slices. For

Source: Adapted from Hutchinson and Diederichs 1996.

Figure 6.3-5 Mathews et al.'s stability graph

Figure 6.3-6 Iron ore open-cut mine in Australia

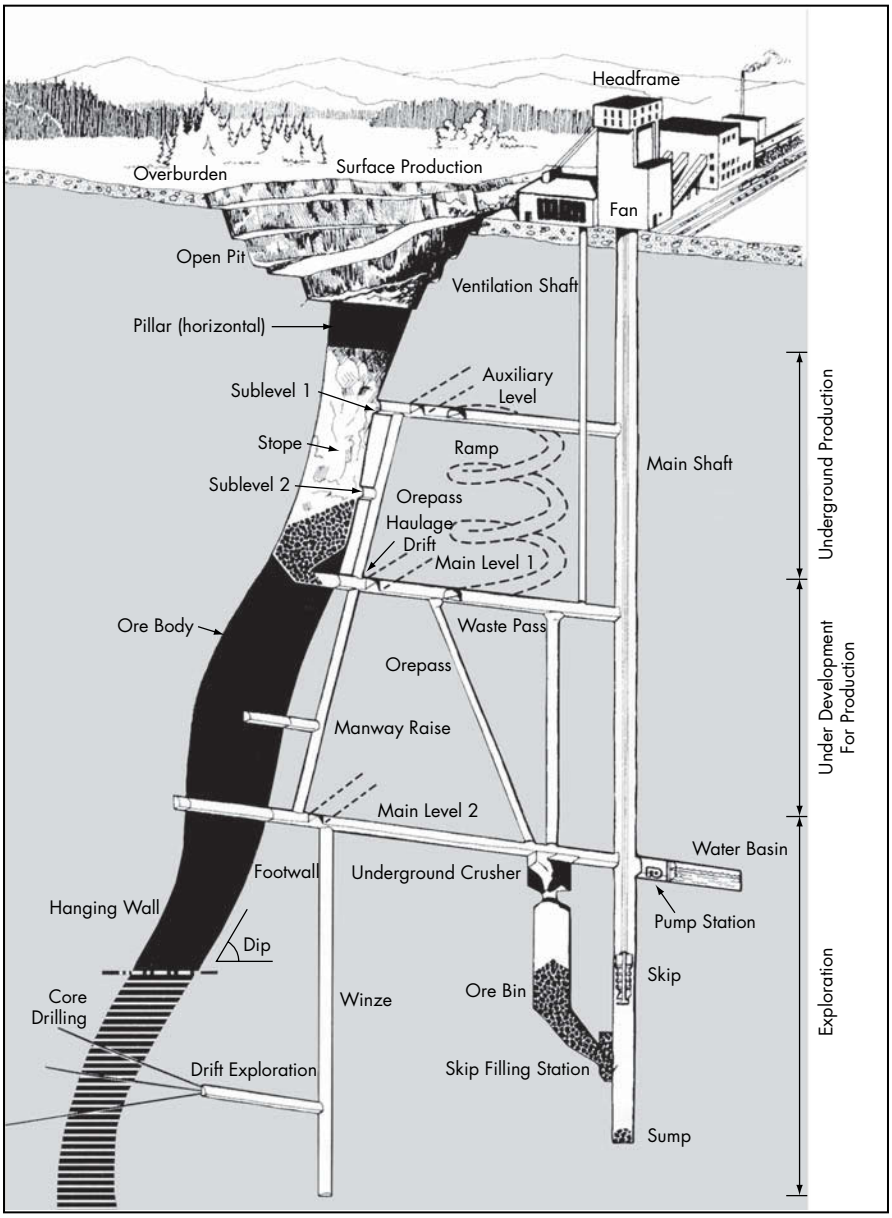

Figure 6.3-7 Strip mine in Australia

hard-rock open-cut mines, drilling and blasting practices are often an integral part of the excavation system. The mining slice height may or may not be consistent with the vertical interval applied to construct berms on a slope. For this method, pit slopes commonly emerge as a sequential series of cutbacks, designed to manage the progressive strip ratios and maximize cash flows. Many of these features are illustrated in Figure 6.3-6.

The term *open-cut mining* is also commonly used to describe excavation in soft rock in which drilling and blasting systems may not be required and continuous excavation technologies such as bucket-wheel excavators are utilized. Truck and shovel systems may well still have a role in these environments.

Strip Mining

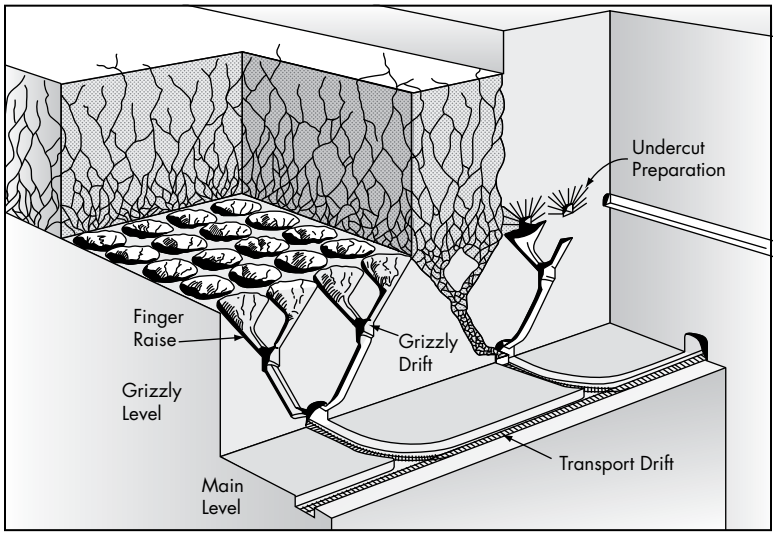
Strip mining describes a particular type of surface mining method that relies heavily on the progressive and sequential disposal of overburden spoil into a previously mined void (Figure 6.3-7). Coal mining often falls in this category, although bauxite miners often adopt a variant of strip mining. Dragline equipment, supplemented by truck and shovel

Source: Hamrin 1998. © Atlas Copco.

Figure 6.3-8 Underground mining terminology

systems, are often observed in strip mines. Strip ratios can be relatively high, and slope angles can be relatively steep, largely due to the relatively low overall height of these slopes.

Underground Mining Methods



Underground mining methods invariably rely on tunneling networks to gain access to the zones of valuable minerals (Figure 6.3-8). These tunnel networks can be linked to vertical shafts equipped with rock-hoisting facilities or inclined ramps, also known as declines, through which rubber-tired equipment can pass, both to facilitate movement of this equipment and also for the transport of rock products to the surface.

Underground mining methods can be divided into three broad classes; caving, stoping, and other methods. The term *caving* implies the controlled collapse of the rock mass under the force of gravity, whereas the term *stoping* implies the excavation of a stable opening of small or large dimensions.

Caving Methods

Three generic methods of removing the valuable minerals and triggering caving processes can be described:

1. **Block caving technologies** are suitable for large low-grade ore bodies, either vertical or inclined, which are undercut over a large area, thereby inducing collapse of the entire rock mass, with the broken rock being extracted via a purpose constructed system of extraction points (Figure 6.3-9). The collapsing rock mass usually propagates to the natural surface and requires careful draw management to contain dilution from unmineralized material. Large scales of operation are possible with

Source: Hamrin 1998.

Figure 6.3-9 Schematic block cave

this technology, which is successfully being applied at increasing depths and on increasingly stronger rocks, compared to reference points in the 20th century.

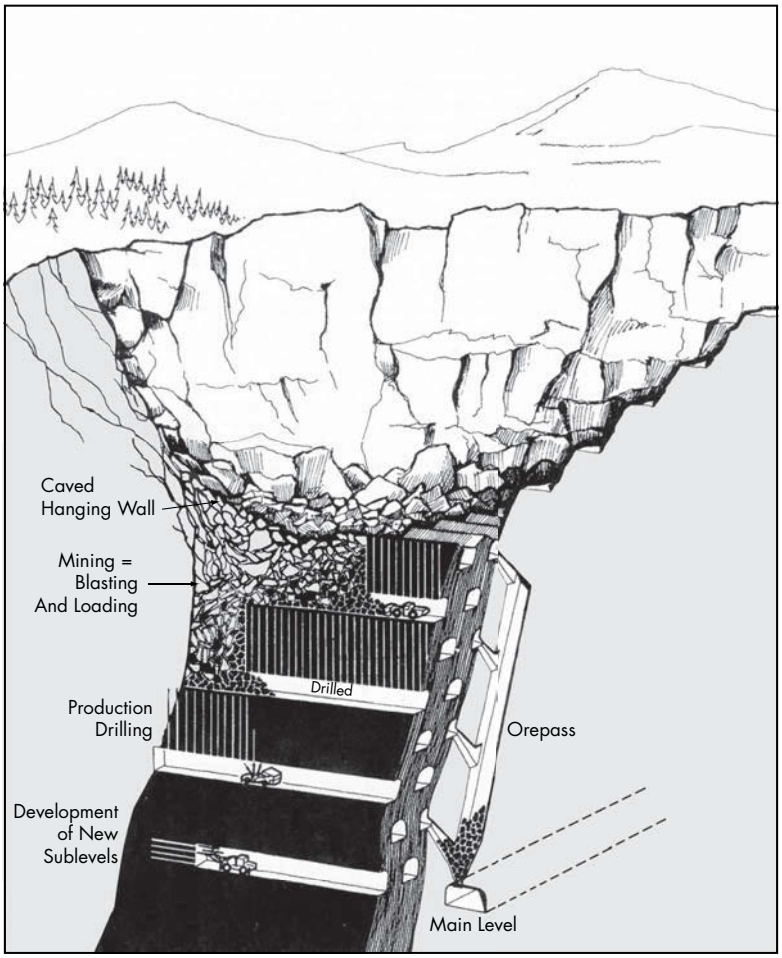
2. **Sublevel caving technologies** are also suitable for large ore bodies of a generally tabular geometry requiring a more selective mining system and extraction by conventional drilling and blasting technologies (Figure 6.3-10). This method differs from block caving in that all of the ore is drilled and blasted, and only the overburden waste rock caves by gravity. Depending on the ore body geometry, this mining method is amenable to high rates of ore production. Sublevel caving is extensively used in the Swedish iron ore mines at Kiruna (26 Mt/a).
3. **Longwall mining systems** are extensively applied to deposits of coal and rely on rock-cutting technologies to excavate the coal using shearers and conveyor transportation systems to deliver the coal to surface. Coal seams are removed in a single slice, which may be 300 to 400 m across and several kilometers long with working heights of between 1.5 and 6 m. The overlying rock collapses into the mining void as the shearing system is advanced. The shearing system is protected by a series of heavy-duty shields operated by means of hydraulic jacks, which provide a movable canopy, thereby preventing the immediate roof over the workings from collapsing onto the shearer. Recent innovations also include longwall top coal caving, which emphasizes coal extraction efficiency in thicker seams.

Stoping Methods

The excavation of a stable void of small or large dimensions may be stoping's first defining feature—that is, the shape of the mineralization and/or the nature of the rock mass—in which the excavation is to be constructed. The term *stoping* infers the excavation of a stable void of small or large dimensions and is a defining feature of these methods (Table 6.3-1). The character of this void is substantially influenced by the shape of the mineralization and/or the nature of the rock mass in which the stope is being constructed.

A second defining feature of the range of possible stoping methods comprises the use of a fill material, which typically falls into two main groups: (1) waste rock or tailings, which may either be unconsolidated and therefore have negligible strength; or (2) consolidated, typically with a pozzolanic material such as cement or fly ash. In this context the term *strength* implies a capacity of the fill material to stand without collapse when otherwise virgin rock confining the fill material to the original void is removed in a second phase of mining.

A third defining feature of stoping methods is the nature of the drilling and blasting technology deployed, which may be characterized as either short-hole or long-hole systems. In this case, short holes are typically less than 4 m in length and consistent with a single-pass tunneling jumbo, while long holes are drilled with purpose designed long-hole drilling machines applying segmented drill strings.



A fourth defining feature occurs where numerous independent stopes and the sequence of creation (and possibly filling) of these voids are contemplated. Collectively, these features give rise to a large number of stoping methods, as in Table 6.3-1, including shrink stopes (Figure 6.3-11) and overhand cut-and-fill stoping (Figure 6.3-12).

A fifth defining feature is the degree to which mineralization that has economic value is not mined so as to maintain the required stability of the stope—thus the principle of pillars such as in the room-and-pillar method, commonly applied to mineralization with low dips and modest heights (4–6 m) (see Figure 6.4-1 in Chapter 6.4). However, it can be applied to heights of more than 30 m.

Vertical crater retreat (VCR) is a term that encapsulates open stopes being developed by applying a particular drill-and-blast methodology but is otherwise similar to conventional open stoping (Figure 6.3-13).

Other Methods

The extraordinary diversity of mineral deposits inevitably leads to innovative mining methods, including combining methods. One such method is postpillar cut-and-fill, where the

Source: Hamrin 1998. © Atlas Copco.
Figure 6.3-10 Sublevel caving

pillars are mined small but immediately backfilled. Another example is the Avoca method, which combines sublevel longhole drilling with immediate backfilling. Other approaches are described in the following paragraphs.

Horodiam. The Horodiam method utilizes a large diameter raise-bored shaft as the access for a drill jumbo to drill horizontal radial blastholes over the entire height of the stope. The method is amenable to remote control technologies and has been patented as a remotely operated excavation system (ROES) by Australia's Commonwealth Scientific and Industrial Research Organisation.

Coal seam methane drainage. The success of this method is a function of the "physical properties of the coal seam (diffusivity, reservoir pressure, permeability, and gas content), mining method (if in progress), and drainage method" (Hartman 1987). The method is used in Europe but only now is gaining widespread acceptance in the United States to produce coal seam methane. This method is a type of borehole mining in which the wells are used to recover the methane.

Coal seam gasification. This method is applied to coal and is also related to borehole mining, in which the coal is burned at one end and the gases given off are recovered at another borehole. Use of this method is based on whether the cost of burning the coal and recovering the gases is cheaper than traditional mining. The key parameters that impact the method are the fracturing and the chemical composition of the coal. This method may become more feasible in cases where the coal seam is too narrow for traditional methods, in the recovery of multiple seams, where the second seam is too close to the first to be recovered in a traditional fashion, or where seam depth or quality precludes the economic application of conventional surface or underground methods. Subsidence considerations apply as for caving methods of mining.

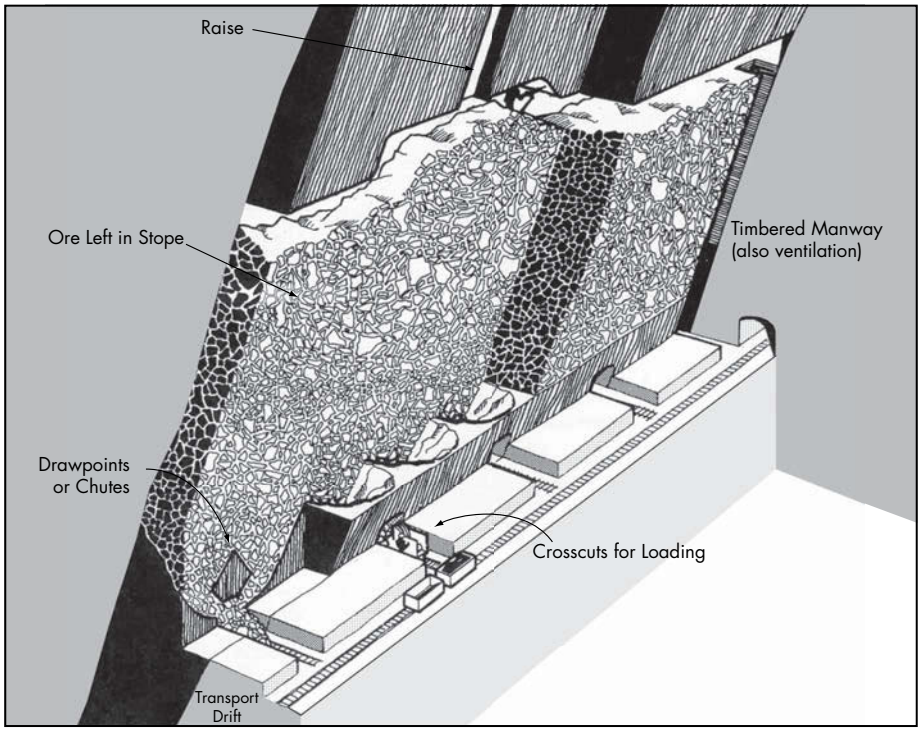
Underground retorting. This method is being tried with oil shales and tar sands. After the area is mined to some extent using traditional drifting techniques and pillar designs, the rock in the stope (retort) is blasted in place. Oil is released from the rock and recovered under the stope. This method is chosen based on the retorting characteristics rather than on the mining parameters. From a mining perspective, the critical factor would be the cost and methodology of fracturing the ground. The degree of fragmentation will impact the percentage recovery of the oil, which is probably the most critical concern.

Surface to Underground Transition Methods

Occasionally, newly discovered mineral deposits are amenable to both a surface mining and an underground method, which presents a particularly interesting challenge to mine planners. Typically, a surface mining method would be applied to

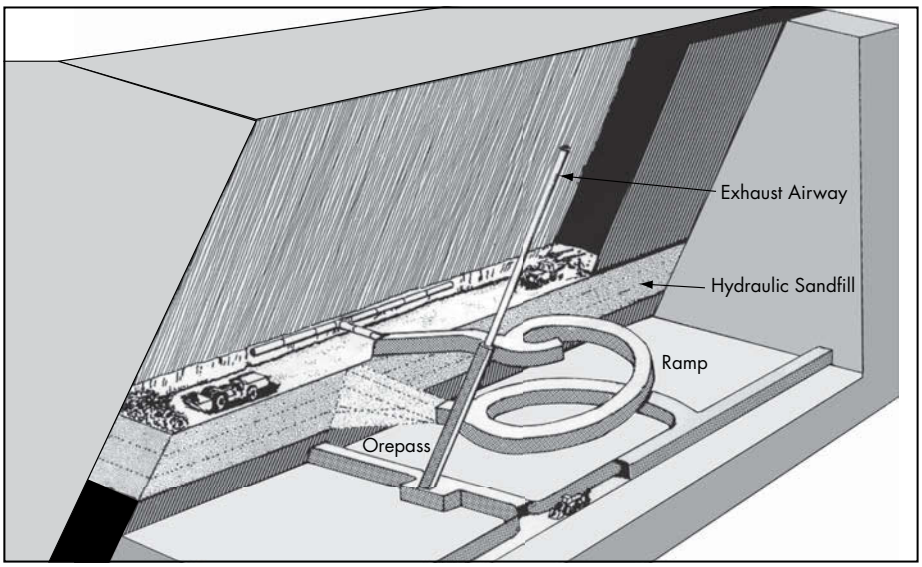
Table 6.3-1 Summary of common stoping methods

Stoping Method	Style of Mineralization	Type of Fill	Drill-and-Blast Solution	Stope Sequencing Method	Use of Pillars	Other Comments
Room-and-pillar	Typically flat tabular	Unusual if applied—unconsolidated	Short holes with tunneling jumbos	Typically unconstrained	Essential feature of method	Typically highly mechanized trackless diesel drilling and ore transportation machinery applied with medium to high productivity outcomes
Square-set stoping	Typically steeply dipping tabular deposits	Timber sets substitute for fill	Short holes drilled with handheld drilling machines	Typically unconstrained	Avoided by substitution of intensive timber works	Poor productivity and expensive mining method rarely used in favor of other modern methods
Sublevel open stopes	Massive and tabular steeply dipping deposits	Can apply either unconsolidated or engineered fills	Long-hole systems with purposed design long-hole drilling machines	Considerable variety of transverse and longitudinal sequences	Secondary stopes may effectively act as temporary pillars if engineered fills are applied; otherwise can be permanent	Typically one of the most productive and lower-cost mining methods applied across many different styles of mineralization
Shrink stopes (Figure 6.3-11)	Typically steeply dipping tabular deposits	Broken ore used as work platform and temporary support of stope walls	Short holes drilled with handheld drilling machines	Usually independent of other stopes	Permanent pillars to separate stopes	Poor productivity, rarely used
Overhand cut-and-fill (Figure 6.3-12)	Tabular, moderately or steeply dipping	Unconsolidated fills	Short holes with tunneling jumbos	Usually independent of other stopes	Permanent pillars to separate stopes	Typically, heavily mechanized method applying tunneling jumbos and load-haul-dump machines accessing the stope from ramp system
Underhand cut-and-fill	Tabular, moderately or steeply dipping	Engineered fills	Short holes with tunneling jumbos	Usually independent of other stopes	Not typically needed as artificial pillars made of engineered fill materials used in lieu	Highly mechanized method applied where minimum stress is anticipated to cause mining to cease, thereby avoiding extensive ramp systems extending into mineralization that may not be able to be mined
Avoca	Tabular, moderately or steeply dipping	Unconsolidated fills	Long-hole systems with purposed design long-hole drilling machines	Typically very constrained, longitudinal advance or retreat systems	Pillars of very low-grade material below economic cutoffs, may be left but usually do not override stope sequence solution	Moderately high productivity solution able to use modern mechanized long-hole drills and load-haul-dump machines. Fill dilutions can be significant factor.
Sublevel retreat open stopes	Tabular, moderately or steeply dipping	Unconsolidated or engineered fills	Long-hole systems with purposed design long-hole drilling machines	Highly constrained by longitudinal retreat sequences in underhand or overhand configurations	Typically avoided in higher stress environments but may be used on regional scale	Highly mechanized mining method used in deposit with lower tons per vertical meter to avoid extensive access development in waste external to mineralization



initially develop the deposit, although instances of an underground development preceding an open-pit development have occurred. The answer to critical questions regarding the depth at which a transition should occur is dependent on many factors, including the relative scale of the surface mine and the underground mine, the lead time required to develop the underground mine, and the optimum underground mining method.

MINING METHOD SELECTION AND EVALUATION METHODOLOGIES



In many cases, the style and geometry of the mineralized system will be the dominant factor in identifying the most appropriate mining method for evaluating the potential economic value of the deposit. It is uncommon, however, to encounter a mineral deposit that is amenable only to a single mining method. Consider, for example, a flat tabular potash deposit within a halite sequence occurring at a depth that unequivocally precludes open-pit methods. In this instance, solution mining and conventional room-and-pillar mining systems should both be considered during the initial appraisal (and carried forward in subsequent appraisals) until such time as a clear economic benefit from a preferred method, after accounting for risk and uncertainty, can be demonstrated.

A second factor that will always have substantial influence on the possible mining methods is the characteristics of the host rock mass and the mineralized rock mass. The quantity and quality of this information will almost certainly be influenced by the status of exploration over the deposit. An all too common problem is the failure in early-stage exploration activities to allocate sufficient funds for the collection of critical rock mechanics data by which the characteristics of the rock mass can be adequately ascertained.

The techniques for evaluating mining methods are only attempts at defining and quantifying in a written format what miners in years past determined through discussion, previous experience, and intuition. Therefore, each of the method selection schemes presented here is similar and yet different, reflecting personal preferences in their emphases. The purpose

Figure 6.3-12 Overhand cut-and-fill stoping (mechanized)

of discussing these techniques is not to critique them but simply to present the alternatives available to aid in selecting the most appropriate.

Most of the schemes are aimed at determining the appropriate underground method, as there are many possible choices. However, the purpose of this chapter is to discuss the selection of the best mining methods, including surface, hydraulic, and more novel methods. The method selection process should first determine whether the deposit should be mined using a more traditional surface, underground, or in-situ leach mining method. A novel method should only be considered if traditional methods are not economically or technically feasible. To start a mine with a novel mining method requires adequate funding and an enormous commitment from the board of directors to technical development; the board must also have the patience to work out the technical problems.

If the deposit cannot be mined using a surface method, then an underground method should be considered. The

Figure 6.3-13 Vertical crater retreat open stoping

mining method selection techniques are limited, because selection is based solely on the known physical parameters and rock strength characteristics. Sometimes several mining methods may appear to be equally feasible. In order to further determine which method(s) is the most suitable, the input variables of mining costs, mining rate, labor availability, and environmental regulations should be considered in more detail.

(Note: None of the mtethod selection systems deal with in-situ stress. Although the techniques account for the vertical stress via depth, none of the methods discuss how a high horizontal stress impacts the choice of the mining method.)

Qualitative and Quantitative Ranking Systems

Boshkov and Wright

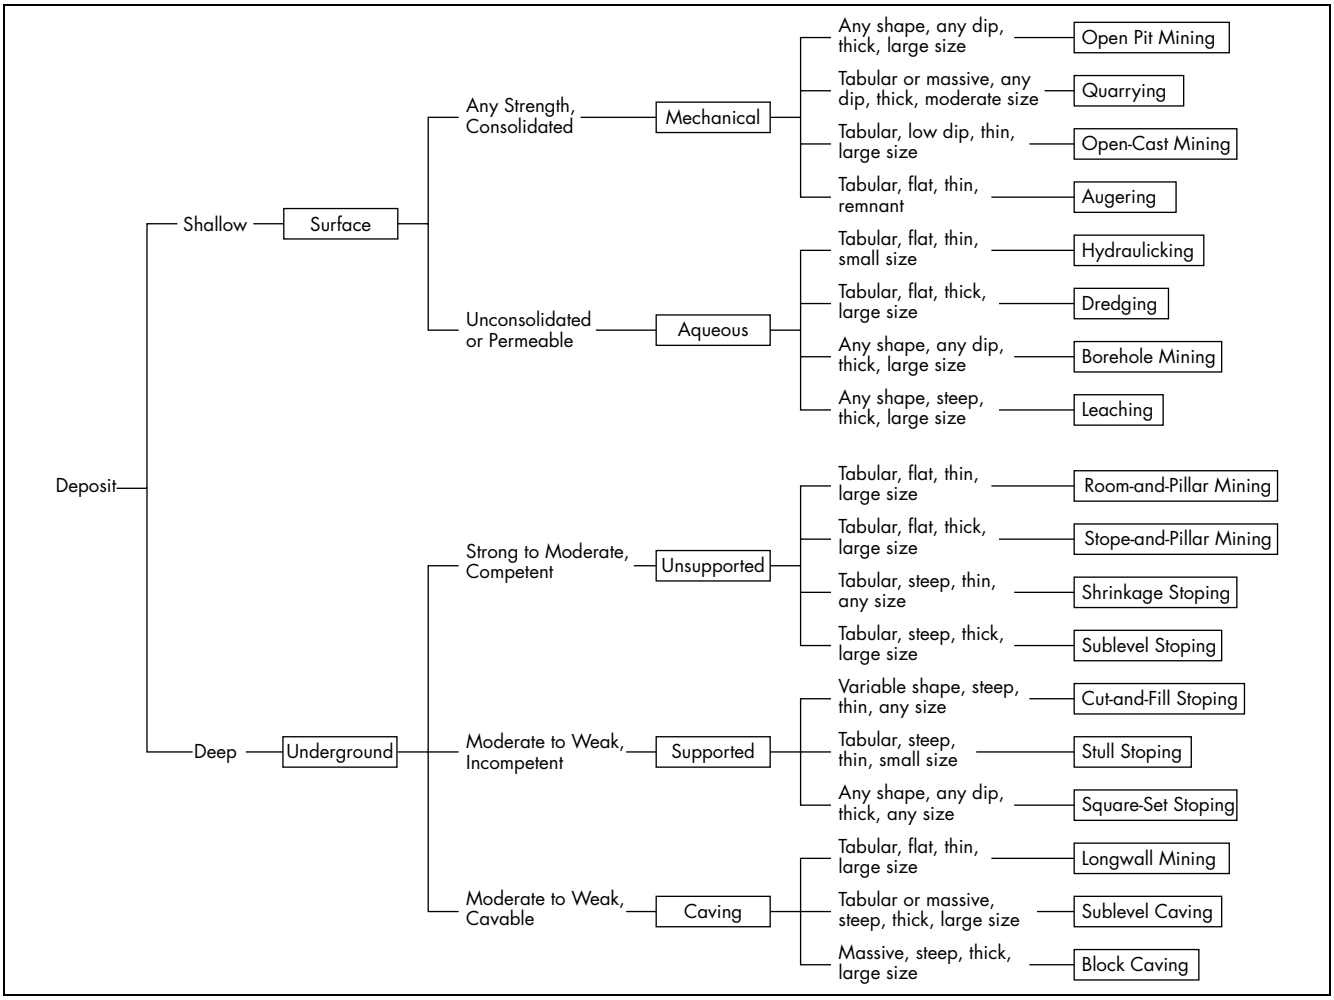
The classification system proposed by Boshkov and Wright (1973) was one of the first qualitative classification schemes developed for underground method selection (Table 6.3-2). Their system, which assumes that the possibility of surface mining has already been eliminated, uses general descriptions of the ore thickness, ore dip, and strength of the ore and walls to identify common methods that have been applied in similar conditions. The results of this classification provide up to four methods that may be applicable.

Hartman

Hartman (1987) has developed a flow-chart selection process for defining the mining method, based on the geometry of the deposit and the ground conditions of the ore zone (Figure 6.3-14). This system is similar to that proposed by Boshkov and Wright but is aimed at more specific mining methods. Hartman admits the method is qualitative and should be used as a first-pass approach. This classification includes surface and underground methods, coal, and hard rock.

Morrison

The classification system proposed by Morrison (1976) divides underground mining into three basic groups: (A) rigid pillar support, (B) controlled subsidence, and (C) caving (Figure 6.3-15). General definitions of ore width, support type, and strain energy accumulation are used as the criteria for determining a mining method. This classification helps to demonstrate the selection continuum, choosing one method over another based on the various combinations of ground conditions. In this system, the ground conditions have already been evaluated to determine the type of support required.



Laubscher

A process for the selection of an appropriate mass underground mining method has been presented by Laubscher (1981). The selection process is based on his rock mass classification system, which adjusts for expected mining effects on the rock mass strength. Laubscher's scheme is aimed at the mass mining methods, primarily block caving versus stoping, and his main emphasis is on cavability. The two parameters that determine whether a caving system is used over a stoping system are the degree of fracturing, RQD, joint spacing, and the joint rating, which is a description of the character of the joint—that is, waviness, filling, and water conditions (Figure 6.3-3). This scheme puts emphasis on the jointing as the only control for determining cavability. More recently, Laubscher (1990) has modified the classification to relate his rock mass rating to the hydraulic radius (Figure 6.3-16). By including the hydraulic radius, cavability becomes feasible for more competent rock if the area available for undercutting is large.

Table 6.3-2 Boshkov and Wright classification system

Type of Ore Body	Dip	Strength of Ore	Strength of Walls	Commonly Applied Methods of Mining

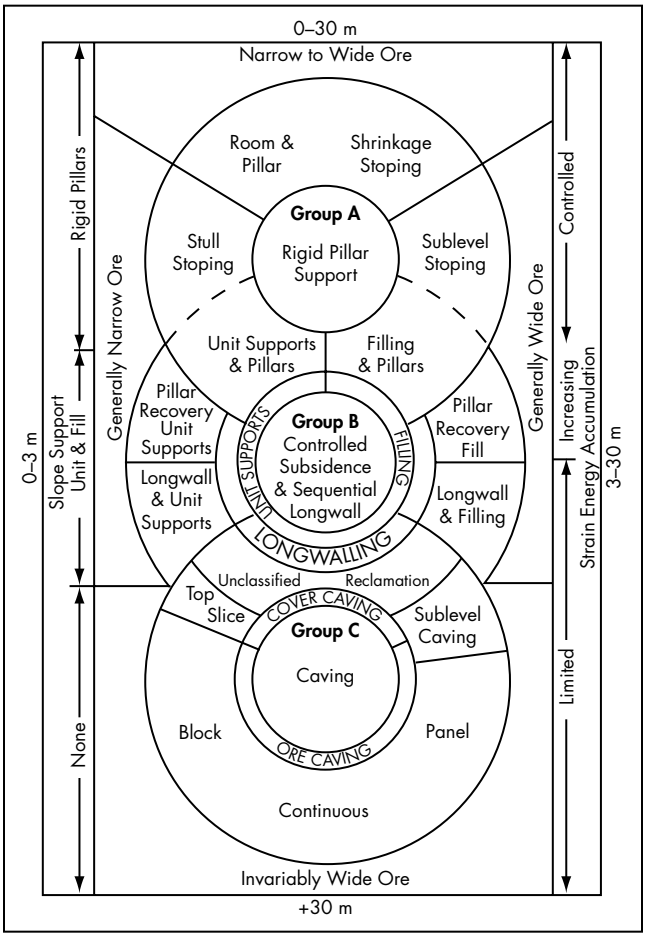
Figure 6.3-14 Hartman chart for the selection of mining method

Nicholas

The classification proposed by Nicholas (1981) determines feasible mining methods by numerical ranking and thus is truly quantitative. The first step is to classify the ore geometry and grade distribution using Table 6.3-3.

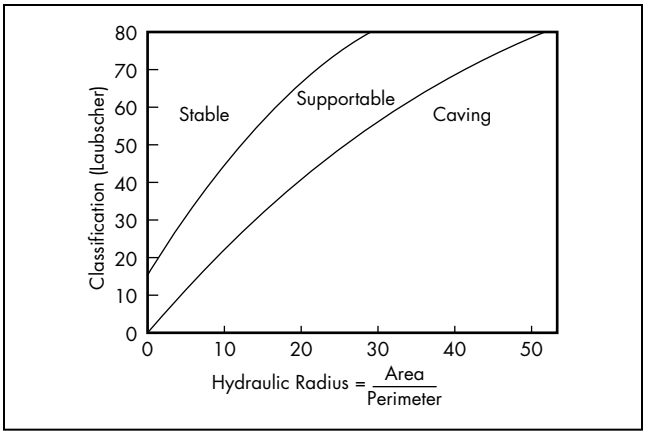
The rock mechanics characteristics of the ore zone, hanging wall, and footwall are similarly classified using Table 6.3-4.



A numerical ranking is then performed by adding up the values of each mining method, using Tables 6.3-5 and 6.3-6. The values of the tables represent the suitability of a given characteristic for a particular mining method. A value of 3 or 4 indicates that the characteristic is preferred for the mining method. A value of 1 or 2 indicates that a characteristic is probably suited to that mining method, while a value of 0 indicates that a characteristic will probably not promote the use of that mining method, although it does not rule it out entirely. A value of –49 would indicate that a characteristic will completely eliminate consideration of that method. A recent modification to the system is the weighting of the categories for the ore geometry, ore zone, hanging wall, and footwall. To give each of these categories equal weight, the ore zone, hanging wall, and footwall need to be multiplied by 1.33. However, the importance of each category is not equal; the ore geometry is more important than the ore zone, which is more important than the hanging wall, which is more important than the footwall.

The proposed weighting for each category, summarized in Table 6.3-7, can be changed based on personal experience. The net weighting is then multiplied by each of the categories. Those two or three (as in the case of Table 6.3-7) mining methods that have the highest overall numerical ranking should be economically analyzed.

The proposed values for the characteristics can be changed as the technical expertise with mining equipment and mining processes improves. In addition, each individual has a different point of view as to the relative importance of the various characteristics for each method.



Numerical Evaluation Methodologies

The continuing development of mineral resource modeling and mine planning technologies in the 21st century is providing a range of sophisticated computer-based tools largely unknown in the latter part of the 20th century. Without exception, these mine planning technologies rely on numerical resource models, most commonly some sort of a block model, whereby the mineral deposit and the surrounding host rock is discretized into uniform orthogonal blocks with grade

Figure 6.3-16 Laubscher's 1990 classification system

Table 6.3-3 Definition of deposit geometry and grade distribution

General shape/width	
Equi-dimensional	All dimensions are on same order of magnitude.
Platy–tabular	Two dimensions are many times the thickness, which does not usually exceed 100 m.
Irregular	Dimensions vary over short distances.
Ore thickness	
Narrow	<10 m
Intermediate	10–30 m
Thick	30–100 m
Very thick	>100 m
Plunge	
Flat	<20°
Intermediate	20°–55°
Steep	>55°
Depth below surface	Provide actual depth.
Grade distribution	
Uniform	Grade at any point in deposit does not vary significantly from mean grade for that deposit.
Gradational	Grade values have zonal characteristics, and the grades change gradually from one to another.
Erratic	Grade values change radically over short distances and do not exhibit any discernible pattern in their changes.

distributions determined by using sophisticated geostatistical analysis and interpolation algorithms.

With rare exception, determination of the mining limits for mineral deposits amenable to open mining methods is evaluated by applying a profit maximization algorithm with the most commercially available packages based on developments of the Lerchs–Grossmann graph theory. The technology relies implicitly on block model representations of the mineral resource and, when combined with linear programming technology to evaluate the optimum mining sequence for the proposed open-pit excavation, represents the minimum acceptable approach to the evaluation of open-pit prospects at any point in the evaluation cycle (concept, prefeasibility, or final feasibility study). Similar technologies are becoming

available for the evaluation of optimized mine plans for underground deposits.

The type of tool selected will depend on the required confidence in the mine planning outcome, which is also typically related to the position in the deposit evaluation cycle. Importantly, all of these technologies facilitate rapid deposit evaluations (compared to classic uncomputerized mine planning methodologies). This speed and facility frequently allows for the analysis of subtle variations within a mining method, which could well mean the difference between a successful or an unsuccessful development for large low-margin deposits.

Risk

Increasingly, business investment decision making requires quantification of the risks and uncertainties associated with a mine plan and particularly with the value of the proposed investment, in which an investment opportunity is competing against many other investment opportunities. Ample evidence within the global mining industry demonstrates that the highest-ranked risk to investment value is the quantity and quality of the mineral resource (the key revenue drivers) on which deterministic mine plans are based.

Consequently, the trend is toward the preparation of probabilistic resource models in mine planning evaluations, both to describe the probability-weighted estimate of the value of a mineral deposit constrained by deterministic limits and to describe the value of a mineral deposit reflecting the probabilities of different mineral limits and grade distributions. These latter techniques, sometimes known as resource range analyses, are particularly useful to investment decision-making processes in the early stages of exploration of a mineral deposit and are supplanted by the probabilistic resource models as the exploration process matures.

In its simplest form, a resource range analysis for a mineral deposit comprises the development of five equally plausible mineral resource models, sometimes characterized as the minimum, low, most likely, high, and maximum cases, with probabilities assigned to each case such that the cumulative probability equals unity. In some instances, three models reflecting the low, most likely, and high cases may suffice. Similarly, a mine plan for each model of the mineral resource is prepared and evaluated with a probability weighting to derive an expected value. The different resource models may well dictate that materially different mining methods are selected for the evaluation. The significant increase in mine planning effort arising from these approaches manifestly relies on the emergence of numerical evaluation methodologies previously described.

Economic Analysis

Every corporation has a range of metrics in which it is interested when evaluating a mineral deposit. These could include issues such as scale and the level of participation in the market for the product, the likely life of the mining project, the size of the investment required to bring the deposit into production, and similar physical metrics. Invariably, this must also include financial metrics. With little exception, the value of prospective future cash flows, discounted at an appropriate rate as a *present value* and netted against the investment required so as to describe a net present value (NPV), will also be required, particularly where competing investment alternatives must be assessed.

In conducting any economic analysis of a mineral project, definition of the future cash flows should consider the four basic cash streams.

1. **Product income:** the incoming cash stream that describes income from the sale of product, perhaps net of royalties, as may be considered appropriate.
2. **Capital cost expenses:** the cash stream representing the outgoing expenditures required to develop the mining project and create an income stream. Sustaining capital expenditures should also be regarded.
3. **Operating cost expenses:** the outgoing cash stream representing the expenditure on inputs to the production process incurred to produce units of output and generate an income stream.
4. **Tax expenses:** the outgoing cash stream representing the payment of income taxes and any offsetting depreciation allowances.

An accumulation of these four cash streams in any accounting period, typically years, provides the basis for describing discounted cash flows and NPV. Probabilistic evaluations should also be completed applying stochastic simulations for the income stream and mine plans that examine optimistic, most likely, and pessimistic scenarios for the capital cost and operating cost streams.

Stages in Application of Mining Method Selection Process

Application of any mining method selection process is necessarily iterative and, as knowledge about the deposit under consideration evolves, may have different conclusions.

Deposit Discovery

The first occasion on which evaluation practitioners may be called upon to provide a business case to justify further exploration expenditure is shortly after the emergence of promising exploration results. Enthusiasm for further drilling is inevitably high and, depending on the prevailing economic environment and the quality of the exploration results, may overshadow a more rational assessment of the potential economic value. This is an ideal time to apply a resource range analysis methodology to establish a range of resource models (and conceptual mine plans for each model) and, more importantly, to establish the business case for further investment in exploration relative to the corporation's business goals and required deposit size.

In this circumstance, the mineral resource models are likely to be simple polygonal models that give some sense of the shape and geometry. The conceptual mine plans are unlikely to be any more than high-level estimates of output that have been extended by relevant unit costs for the expected activities, perhaps applying many rules of thumb for mining and processing activities.

Advanced Exploration Concept Studies

The term *advanced exploration* here implies that preliminary mineral resource modeling has been completed and that the

mineral resource estimates emerging from the process are able to be classified by one of the internationally recognized systems, typically at least as an *inferred mineral resource*. The presumption is that the mineral resource model is based at least on block modeling technology with interpolated mineral concentrations, with the model extended to describe the surrounding host rock (for the purpose of modeling slopes) in the case of deposits requiring open-pit evaluations.

In this case, one of the readily available open-pit optimization software systems should be applied to evaluate the deposit. For underground deposits, similar systems are starting to become available, and these will evolve over time with industry research and development programs.

Many unvalidated critical assumptions may well need to be made about a number of mining method alternatives, derived by applying the methodologies previously outlined. Because of the relatively high levels of uncertainty surrounding many of the key drivers, resource range analysis methodologies are extremely useful in helping to establish the impacts of uncertainty on project value and identifying the priorities for resolving these uncertainties to more acceptable levels. In most circumstances, a risk-weighted NPV greater than zero should be sufficient to encourage further investigation by way of preliminary feasibility studies.

Preliminary Feasibility Studies

In a mineral project development, the advance to a preliminary feasibility study usually signifies a stronger commitment to drilling and sampling the mineralization, complemented by further rounds of mineral resource modeling. Hydrogeological, geotechnical, geometallurgical, and environmental studies are also likely to proceed, welded together under a strategic mine planning umbrella. Improved resource estimate confidence is likely. Mining method studies are likely to be of less significance, as the focus is on variations within the selection of methods identified at the concept study stage. In most cases, the study effort is now focused on ensuring that all reasonable alternatives are investigated with the intent of identifying the best alternative to move forward to a final feasibility study.

Final Feasibility Studies

For final feasibility studies, the focus usually shifts from mineral resource definition to detailed mine and infrastructure planning at a level that is adequate for the capital expenditure approvals necessary to take the project into construction. Evaluation of alternative mining methods should never figure in this stage of project evolution.

CHAPTER 6.4

Selection Process for Underground Soft-Rock Mining

Antonio Nieto

INTRODUCTION

The soft rocks usually are part of the sedimentary minerals classification, which is subdivided into clastic, organic, and chemical. Examples of the soft-rock ores include coal, metalliferous shales, oil shales, potash, salt, trona, and possibly kimberlites. Where coal, metalliferous shales, potash, and trona occur as economic ores, they are typically laterally extensive beds in a nearly horizontal inclination but with, at most, a shallow dip angle. This differentiation is key, because it enables the application of large-scale mechanization to the mining process. The economy of scale that results from mechanization is often the determinant factor for economic success. As the capabilities of mechanical cutting expand into more demanding applications, the possibility exists that ores previously considered hard-rock deposits, such as the platinum-bearing reefs in southern Africa, may be cut instead of blasted.

Coal has its origins in the accumulation of plant debris that becomes buried by sediments. Through a process dependent on time, burial depth, and chemical transformation, the plant debris becomes coal. Therefore, coal is classified as an organic sedimentary mineral. Coal varies in quality from lignite to anthracite, with sub-bituminous and bituminous ranked as intermediate in the progression and the most commonly mined types worldwide.

Coal is primarily used for electricity generation and steelmaking and is commonly referred to, respectively, as *steam coal* and *coking coal*. Coal with attributes such as an appreciable free-swelling index (FSI) is used to make coke, which is used in primary production of steel from iron ore. The scarcity of such coals elevates their value compared to steam coal.

Trona is a carbonate mineral of sodium used to form soda ash, used in glassmaking and other industrial processes, including baking soda. It occurs naturally in a few locations worldwide as laterally extensive evaporite deposits, suitable for underground mining methods. It is a moderate value ore and competes with an alternative process that synthesizes the same product from chemical feedstocks.

Potash is the name loosely applied to a variety of potassium salts, particularly potassium chloride, which are encountered in laterally extensive evaporite deposits found worldwide. These are often associated with intermixed or stratigraphically adjacent halite (sodium chloride). Potassium is key to plant growth, and potash is mainly used as fertilizer, although it is also used to produce soaps, ceramics, and drugs, among others.

Coal, potash, trona, and salt are the principal soft-rock ores and, within limits, share similar production methods that focus on economies of scale. The most common mining techniques for soft-rock ores are longwall, room-and-pillar (R&P), and stope-and-pillar. For water-soluble minerals, solution mining is an alternative. The process of properly selecting an underground mining method for a particular ore deposit is critical to the ultimate success of the operation. An improperly selected method will increase costs, lower productivity, create unnecessary hazards, and reduce resource recovery. Due to the complex nature of ore bodies, no two mines are completely alike, and all operations must adapt to the particular conditions of their deposits.

ORE DEPOSIT CHARACTERISTICS

Numerous considerations must to be recognized when selecting the best method to mine a soft-rock ore deposit. Some of the considerations are based on ore deposit characteristics favorable to the mining method being considered:

- Ore strength
- Host rock strength
- Deposit shape
- Deposit dip
- Deposit size
- Deposit thickness
- Deposit grade
- Ore uniformity
- Deposit depth

Other characteristics are a function of mining method:

- Operating cost
- Capital cost and development timing
- Production rate
- Mechanization
- Selectivity and flexibility

Antonio Nieto, Associate Professor, Energy and Minerals Engineering Department, Pennsylvania State University, University Park, Pennsylvania, USA

- Health and safety
- Environmental effects

Ore Strength

The material properties of the ore often drive mine design decisions. Although there are many mechanical properties, compressive strength is often discussed as an indicative characteristic inferring structural performance and suitability for mechanical cutting. Mining methods such as R&P and stope-and-pillar depend on the strength of the ore rock to support the roof and overburden in order to create a structurally stable excavation. In soft-rock applications, the relative strength of the ore is often weak, with a compressive strength less than 6,000 psi. This low strength is generally associated with a low to moderate specific energy of cutting (kilowatt-hour/ton). This allows the application of mechanized cutting and loading, which is elemental to the success of many modern mines. As the ore strength increases, the options for mechanical cutting are reduced, and the application productivity declines while costs increase. There is a marked difference between the cost and productivity performance of mechanized cutting versus drilling and blasting in the majority of soft-rock applications, with mechanized methods decidedly preferred.

Table 6.4-1 gives the strength designations and ranges of values based on the compressive strength of the material.

It is important to note that the strength and mechanical properties of a rock are significantly affected by fracturing and planes of weakness in the deposit. Fracturing is characterized by small discontinuities in the rock mass and may be caused by heat, vapor expansion (as in porphyry deposits), depositional conditions (i.e., slickensides), or tectonic movement (faults). Cleat is a fracture system ordinarily observed in coal. Two different fracture directions are typically present: face cleat (primary direction) and butt cleat (secondary direction). During exploration, the degree of fracturing should be quantified and utilized to reduce ore structural properties, potentially leading to smaller openings, larger pillars, and increased ground control costs. Limited fracturing may be a positive factor for some mining methods, because it promotes caving, lowers blasting requirements, and aids mechanical cutting. However, excessive fracturing can have a negative influence on ground control, water, and gas inflows.

Host Rock Strength

The strength of the rock enclosing the ore is also an important driver in mining method selection. Temporary and permanent openings must be developed either in the host rock, in order to access the ore, or with the host rock as roof (back or hanging wall) or floor (footwall) for the ore openings (entries or crosscuts). To execute an appropriate design, the material properties must be understood. The behavior of the roof and floor can be pivotal in the success of mechanized mining systems. Floors that become muddy and easily rutted can disable production and send maintenance costs skyrocketing.

It is inaccurate to assume that the ore and host material will have the same characteristics, so each must be independently characterized by geomechanical testing.

Deposit Shape

Ore deposits are classified into two broad categories: tabular and massive. A tabular deposit is flat and thin, and has a broad horizontal extent. This classification typically refers to materials formed by sedimentation. Similar in shape to tabular ore bodies, lenticular deposits are shaped like lenses and lack the large areal extent of most tabular deposits. Most methods designed to exploit tabular deposits may be adapted to mine lenticular ones. The ore materials must often be of higher value than applications such as coal, because production costs are generally higher but reserve tonnages are lower.

A massive deposit may possess any shape. The ore is often distributed in low concentrations over a wide area with varying horizontal and vertical extents. Frequently, the difference between ore and waste may be a function of grade rather than rock type. Massive deposits may be unpredictable and require a considerable exploration investment in order to document and fully understand the resource. For the purposes of mining method selection, massive deposits are often accompanied by a more specific clause like "massive with large vertical extent." These additions are necessary because the shape of a massive deposit is variable and may be unsuitable for certain mining methods. The deposit shape definitions are summarized in Table 6.4-2.

Deposit Dip

Dip is defined as the angle of inclination of a plane measured downward, perpendicular to the strike direction. The deposit dip is more relevant to tabular ore bodies than massive ones, although it may sometimes be a consideration for the latter. Deposit dips are categorized and defined in Table 6.4-3.

Both flat-lying soft-rock ore beds and near-vertical ore veins may be classified as tabular, but the mining methods used to exploit them are dramatically different. Several methods are highly dependent on gravity for material flow and cannot function in flat-lying deposits. Alternatively, low working slopes are a key factor in the application of mechanization for cutting and loading as well as material haulage by rubber-tired, rail, or conveyor-belt methods.

Table 6.4-1 Ore strength definitions

Relative Strength	Example Material	Compressive Strength, psi
Very weak	Coal	<6,000
Weak	Shale, siltstone, sandstone	6,000–14,500
Moderate	Limestone and sandstone	14,500–20,000
Strong	Granite	20,000–32,000
Very strong	Quartzite	>32,000

Table 6.4-2 Deposit shape definitions

Deposit Type	Shape	Width	Extent
Tabular	Flat	Thin to moderate	Horizontal
Lenticular	Flat, elliptical	Thin to moderate	Horizontal
Massive	Any	Thin to thick	Horizontal and vertical

Table 6.4-3 Deposit orientation definitions

Inclination Category	Dip Angle, degrees
Low	0–5
Moderate	5–25
Fairly steep	25–45
Steep	45–90

Table 6.4-4 Tabular deposit thickness definitions

Deposit Thickness (T)	
Thin (small)	T < 5 ft
Moderate	5ft < T < 12 ft
Fairly thick	12 ft < T < 20 ft
Thick (large)	T > 20 ft

Table 6.4-5 Ore grade definitions

Grade	$/ton
Low	10–50
Moderate	50–250
High	>250

Deposit Size

The volumetric size of an ore body must also be considered. Several of the methods discussed in this chapter rely on large deposits with long mine lives to justify their high initial capital costs and promote economies of scale. Other methods simply do not work efficiently in ore bodies, which are either too large or too small. Deposit size is characterized subjectively by the terms *small*, *medium*, and *large*. As a generalization, large ore deposits have tens to hundreds of million cubic yards of ore and suggest mine lives in the 10- to 50-year range.

Deposit Thickness

Deposit thickness refers to the ore thickness of tabular deposits. Thickness plays an important role in opening stability and may prevent certain equipment from functioning efficiently or mining methods from being effective. The deposit thickness (nominally the mining extraction height) definitions are listed in Table 6.4-4. These definitions are most relevant to mechanical cutting and loading applications, such as longwall or continuous miner R&P. The thickness ranges roughly correlate with the types of equipment available to implement a mining system and the cost/productivity that might be expected.

Deposit Grade

Grade is discussed in terms of the amount/value of recoverable/salable material in a unit weight or volume of in-place mineral resource. Where it becomes economically viable to produce the mineral resource, the in-place resource becomes ore. As such, the end-outcome economics of different mining methods may vary the amount of ore that an in-place mineral resource may yield. A gold ore may contain as low as 0.1 oz/ton and still be economic, whereas iron ore grades may approach 60% by weight. Coal is generally characterized by its attributes—that is, energy content (Btu/lb); percentage of ash, moisture, and sulfur; FSI; and so forth. Some mining methods with high operating costs necessitate high-grade ores in order to be economic. Large-scale methods may be suitable for large, low-grade deposits, such as bituminous coals. Ore grades are categorized subjectively and must be investigated on an individual site basis. Ore grade definitions are provided in Table 6.4-5. Value estimates associated with the classifications give some relative sense of the range involved.

Ore Uniformity

The uniformity of the ore in the mineral deposit must be considered, as poor uniformity may render some mining methods unviable. It is undesirable to excavate subeconomic material, unless it is necessary to reach ore or create necessary infrastructure, such as belt-conveyor galleries. A mineral deposit may be segmented by faults, subeconomic mineral occurrence, or legal/environmental issues. Some mining methods are well suited to flexibility because they can selectively extract specific sections of a deposit without disrupting the overall operation. An example of this is the case where an R&P coal mine adapts the panel geometry while in panel to reflect new findings about unsatisfactory coal quality, adverse roof conditions, or insufficient coal thickness.

Other methods, such as longwall mining, limit selectivity and must produce at least some amount of material leading to equipment advance in order to continue to the panel's intended end. Faults with significant displacements compared to the bed thickness can seriously disrupt longwall or R&P operations. In some areas, igneous or sedimentary materials may be injected into tabular deposits, such as dolerite dykes in coal seams, and create impediments to mechanized cutting and loading. An inconsistent feed of material may disrupt processing plant performance or require blending, rehandling, or disposal of mined material. These situations can be anticipated and minimized with a thorough knowledge of the ore body's uniformity. Ore uniformity designations are

- Variable,
- Moderate,
- Fairly uniform, and
- Uniform.

Deposit Depth

Another deposit-related consideration that impacts mining method selection is ore deposit depth relative to the surface. Shallow deposits are generally more suited for surface mining. Deeper deposits may require progressively greater ground control measures (increased costs), larger pillar sizes (lower recovery), or decreased applicability of some mining methods in order to ensure safety and sustainability. Commonly applied variations of R&P or longwall mining occur over deposit depth ranges from 250 to 3,500 ft. The definition of shallow/moderate/deep is relative depending on the value of the ore and the strength of the material. A deep coal mine might have workings to a depth of 3,500–4,500 ft. Alternatively, a deep gold mine producing from a meta-quartzite reef might have workings to nearly triple that depth. Classification for deposit depths are shallow, moderate, and deep.

MINING METHOD CHARACTERISTICS

Every mining method has characteristics that will produce different outcomes based on the ore deposit to be mined. As such, prior to selecting the best mining method, the methods to be applied and their expected outcomes must be clearly understood.

Operating Cost

The operating cost of a mine is the cost associated with the production of ore from the primary mining method. The total cost is higher and incorporates items such as depreciation, depletion, taxes, and royalties. The operating cost divided by the number of salable units of production mined creates a metric used to compare efficiency between competing production alternatives—that is, $/ton. When the total cost is the basis of the metric, it can indicate the potential viability of the project

in total. In mining, the operating cost is composed of fixed and variable expenses. Variable expense totals change in proportion with activity, such as roof-control cost ($/ft) that typically accumulates with the amount of entry development. In comparison, fixed costs, such as labor and ventilation, stay relatively constant over a moderate range of activity variation. Some methods are labor intensive or may require a large quantity of materials in order to operate, thereby necessitating valuable ores to compensate for the greater price of extracting them. Other methods cost little once implemented but have high initial capital costs. These methods, such as longwall mining, may be able to excavate large low-grade deposits economically.

Capital Cost and Development Timing

Initial capital cost is defined as the amount of investment needed before the mine begins to generate revenue. A small quarry excavating an outcropping limestone bed has little capital cost because it can start extracting ore almost immediately with little investment in equipment. Alternatively, a deep potash mine might have to sink one or more shafts beyond a depth of 3,000 ft, build a surface plant, and implement a mechanized mining equipment fleet to produce the first salable ton of product. Thus, first production may come after several years and tens to hundreds of million dollars have been committed.

Higher capital costs are frequently associated with long development or start-up times. Equipment manufacturers often have wait times of months or even years before assembly and delivery of new equipment. Typically, this equipment is customized for the mine-specific application.

Production Rate

The production rate of a mine is highly dependent on the mining method. A high production rate can accommodate a large market and may overcome low-value ore if operating costs are low. The ability to stockpile and blend ores of varying grade in order to maintain a consistent feed to the mill is typically advantageous. Higher production is generally more desirable because mines are rarely opened in areas where selling more product is disadvantageous. The economics of mines that can sell product up to the limit of their production capacity are drastically different than mines that can produce at levels above what their markets can consume. In the latter case, production enhancement proposals readily embraced by the former case, intended to distribute fixed costs over a larger total production, are rejected, and the focus sharpens on costs contributing to the fixed component of operating cost.

Mechanization

Mechanization is a critical element of a modern mine. Utilizing machines to perform production tasks is much safer and more efficient, in cost or production performance, than using manual labor. To justify a large capital investment in equipment, it is common to need a longer mine life and thus a larger ore body. Highly mechanized mining is safer than less mechanized methods because fewer workers will be needed and thus the overall hazard exposure will be lower. Several methods lend themselves to a high degree of mechanization, including longwall and continuous miner R&P methods.

Selectivity and Flexibility

Selectivity and flexibility can significantly contribute to the success of a mining method. It is generally valid to assume that mining conditions, market prices, and technology will change over the course of a mine's life, so the mining method must be adaptable to these fluctuations. Sacrificing optional alternatives in any mining method is not desirable unless there is compelling reason to do so. If commodity prices were to drop substantially, a portion of the ore in a massive deposit may become uneconomic to mine. If the mining method is able to bypass the low-grade sections and continue mining economic material, the mine will continue to be successful.

Health and Safety

The safety and health of a mine's workers should be the top priority of every operator. Several methods are inherently safer than others, because the openings are more stable or personnel are less likely to be subjected to hazardous conditions. Although no modern methods are considered to be unsafe, it bears mentioning that specific health and safety concerns are often mitigated by the mining method selection. Longwall mining is recognized as the safest method of mining applied to soft-rock deposits.

Environmental Effects

The largest environmental impacts of an underground mine typically fall into three categories: subsidence, groundwater, and atmospheric emissions. Subsidence is defined as the sinking of the surface above mine workings as a result of material settling into the voids created by mineral extraction. It is contentious in urban or suburban areas where it can affect homes, schools, and roads. The surface subsidence created by modern longwall mines is largely predictable in its timing and magnitude, in contrast to the unpredictable outcomes associated with some R&P mines. In this way, longwall subsidence is less hazardous to human-made surface structures, because impacts occur soon after mining and rarely change much after initial stabilization. This allows remediation of surface damage in a time contemporary with mining.

Most areas with a history of mining also have developed legal processes to address damage from mining-induced subsidence. High-extraction mining methods will foreseeably induce surface subsidence. If selected, provisions must exist to mitigate or remedy damages.

Water impacts may arise by accidental causes. Acid-generating rock of multiple types in excavated ore, waste, or overlying strata may produce acid mine drainage. Water produced by the rock mass and mining process must be afforded appropriate controls, as it will be necessary to keep the mine drained. In all cases, strict controls must be effectively applied to mitigate groundwater or surface-water impacts by mining-related water discharges.

Air quality in underground mines is typically affected by the natural liberation of mine gases (i.e., methane [CH_4], hydrogen sulfide [H_2S], and carbon dioxide [CO_2]), blasting by-products and equipment emissions (i.e., nitrogen oxides [NO_x], sulfur oxides [SO_x], and diesel particulate matter), and mineral dust from ventilation fans. Generally, exposure and emission thresholds exist for these emissions and are strictly applied. In the case of coal dust and methane, special precautions are followed to avoid the hazards of fire and explosion.

Zero harm is a sustainability principle applied by the foremost mining enterprises in the context of health, safety, environment, and communities where mines in their portfolios actively operate. It is an acknowledged goal that communities will be forever improved because of the global and local activities of these mining enterprises.

MINE PLANNING

Mine planning has three well-defined stages in order to have a successful implementation of the project and operation of the mine: identification, selection, and definition.

Identification

The initial assessment is a review of information about the potential mining site and involves the analysis of geographic, geologic, environmental, technical, and economic data. This assessment helps the mining company to evaluate the advantages and disadvantages of the potential site. In this phase, resource that has potential to become ore is characterized and limited mining methods are considered to aid in a coarse valuation of the prospect. At the conclusion of this phase, a limited number of feasible alternatives for exploiting the opportunity should be identified and adequately framed for further evaluation in the selection phase.

Selection

The reserve determination from the identification phase is the basis for semiquantitative mine plan comparisons. Competing mine design alternatives are compared in pro forma economic evaluations and investment performance measures such as net present value, along with scored risk assessments. Uncertainty that leads to variability of outcomes (risk) will be characterized, and mitigating strategies or controls will be developed should the decision to move into the implementation phase be approved. The preferred mine design (in terms of financial value and technical feasibility) results from this stage of planning. At the conclusion of this phase, a single preferred alternative for the mine plan should be selected for optimization in the definition phase.

Definition

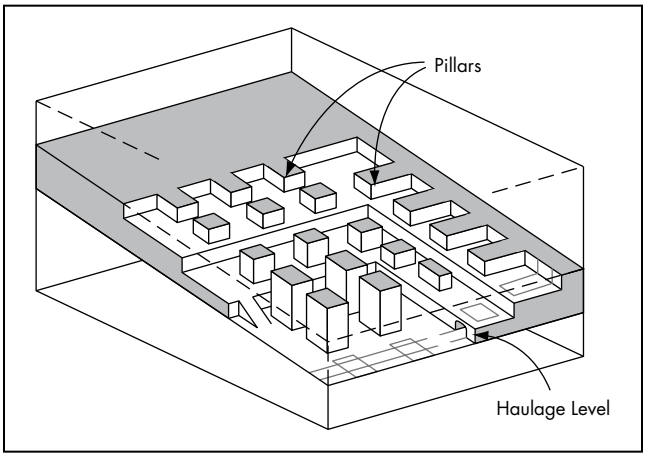
In this phase, all of the detailed planning and resource estimation of the prior phases are refined and optimized to deliver a final plan prior to implementation. The success of this phase will define the success or failure of the venture. Gaps in information, inaccurate planning, or even human resource failures can lead to loss of investment, environmental damage, human injury, and negative community impacts. The key to success in execution is to invest in front-end planning and design prior to implementation, which should follow a rigorous plan that includes sufficient contingency and flexibility to manage the variability that is inevitably encountered.

ROOM-AND-PILLAR MINING METHOD

The R&P mining method is a popular mining method for underground mining in tabular and lenticular deposits, as shown in Figure 6.4-1. It is the dominant choice for noncoal underground mining and is frequently applied in coal mines. The concept is to sink a shaft or construct a slope or drift, depending on depth of ore, to the elevation of the mining horizon and begin excavating the ore laterally within the deposit. Where drilling and blasting are not required, the focus of the operation is the continuous miner (Figure 6.4-2), which utilizes a large rotating drum to break the material in front of it. An internal gathering system then loads the broken ore onto an onboard conveyor.

The onboard conveyor feeds onto a shuttle car or articulated hauler, which takes the product to an optional mobile belt feeder. If present, the feeder meters the product onto a conveyor belt, which in turn carries the ore to the surface. Alternatives to shuttle cars and rubber-tired haulers (battery- or diesel-powered) are generally termed *continuous haulage* systems and include bridge conveyors, composed of multiple independent *bridge carriers*, and flexible conveyor trains using a single continuous belt mounted on a mobile base frame, with bends to follow a producing machine.

Roof support is an integral part of the mining process and is usually done with roof bolts and their relative, the roof truss. In *place-change* continuous mining, the continuous miner makes a cut, and roof bolts are installed with a mobile machine called a roof bolter. Of course, ventilation and face drainage are requirements of any mining method. Alternatively, in very weak roof conditions, continuous miners with roof-bolting equipment onboard are common. These machines, called bolter miners, cut and load the ore simultaneously with the installation of roof bolts. This results in *in-place* mining in contrast to the place-changing method. Another variation of continuous miner has cutting



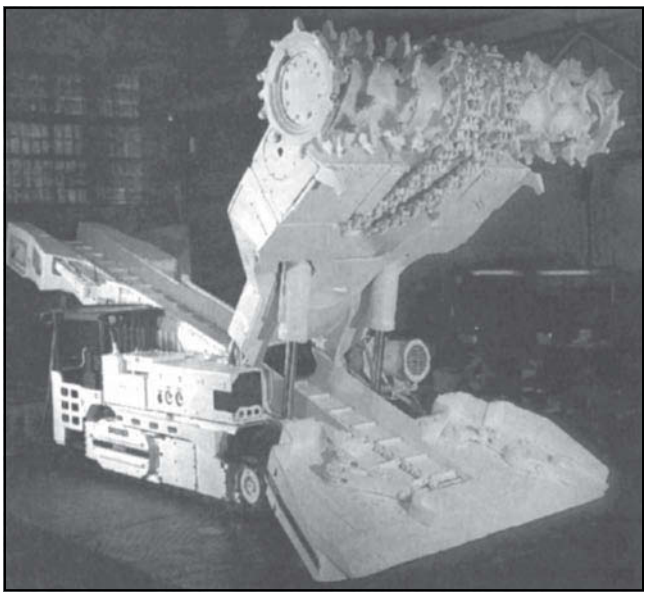


Figure 6.4-1 Room-and-pillar method

Courtesy of Dresser Industries.

Figure 6.4-2 Continuous miner

rotors that rotate parallel to the working face. These *borer miners* are popular in potash and trona mining because of their weight and power. The inability to adequately ventilate methane in the face with borer miners has forced their decline in coal mining. Broken ore haulage can be the same for any of the continuous mining methods, although the combination of in-place mining with continuous haulage methods has some advantages.

In the R&P method, a continuous miner excavates the deposit in a grid-like pattern, driving entries (rooms) approximately 15–20 ft wide at the intended mining height. These openings run parallel to each other along the long axis of the workings. Crosscuts, driven in the same manner at an acute angle to the entries, connect the entries to complete the grid-like pattern. Pillars are left behind to support the roof, hence the term *room-and-pillar*, alternately know as *bord-and-pillar*. The optimal or favorable characteristics for R&P mining are shown in Table 6.4-6.

This mining method is optimal for minerals with lower ore strength such as coal, potash, salt, or trona. R&P mining can be practiced with partial extraction to leave behind larger pillars (lower resource recovery and higher cost) where concerns exist over ground stability or surface subsidence. Alternatively, high-extraction mining can be executed where pillar recovery is done after initial panel development. This method is productive and cost-effective but has rising concerns associated with ground control during the final phases of pillar recovery. Mobile roof supports have been introduced to help mitigate roof-control concerns and reduce logistics related to roof support. Although an improvement, mobile roof supports do not fully address the concern.

Another variation of the R&P method is rib-pillar extraction, where long, narrow pillars are developed and recovered in a progressive process intended to improve safety and productivity. This technique is effective where some attribute of the deposit does not lend itself to efficient longwall operation. Yet another variation of R&P mining, arguably hybridized with longwall mining, is shortwall mining, in which a continuous miner works with shuttle cars and specially designed roof supports similar to longwall shields or chocks. Again, this method has only found successful application in a few cases. For the most part, underground soft-rock operators are migrating to longwall mining, which has left high-extraction R&P mining on the decline where alternatives are available.

The R&P mining method has distinct advantages: the foremost that, with a continuous miner, operations are nearly continuous in nature. Most mining sequences require drilling, blasting, loading, hauling, dumping, and roof support, as well as continuous ventilation and drainage. The invention of the continuous miner eliminated the independent steps of drilling, blasting, and loading, which substantially increases the overall efficiency of the method and improves general productivity. Low operating costs and high production rates are typically associated with modern mechanized R&P mining. Continuous miners can cut through soft-rock deposits, particularly coal, with ease, resulting in rapid development rates. R&P mining is generally more flexible than other methods, because continuous miners can move to other working places within a panel or possibly across a mine with limited difficulty. Also, the grid layout of the mine allows for straightforward ventilation with consistent airflow to all working faces.

The major disadvantage of continuous mining is that it can only be applied to a limited variety of applications. A continuous miner cannot operate efficiently, if at all, in harder rocks like limestone or granite, and, thus, its principal advantages cannot be shared.

Table 6.4-6 Room-and-pillar favorable characteristics

Key Deposit Indicators	Characteristics
Ore strength	Weak to moderate
Host rock strength	Moderate to strong
Deposit shape	Tabular
Deposit orientation	Flat to shallow
Deposit size/thickness	Large, thin
Ore grade	Moderate
Uniformity	Fairly uniform
Deposit depth	Shallow to moderate

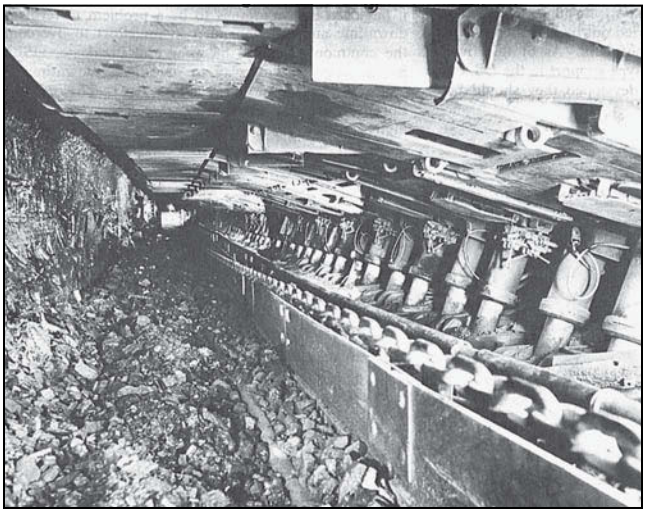

Table 6.4-7 Room-and-pillar advantages and disadvantages

Advantages	Disadvantages
Continuous production	Moderate capital costs
Rapid development rate	Limitation on depth
Excellent ventilation	Moderate selectivity and flexibility
High productivity	Variable subsidence
Moderate operating cost	Higher cost with partial extraction
Good recovery (with pillar extraction)	Moderate recovery (without pillar extraction)

R&P has been used in a variety of soft-rock applications, as well as a few hard-rock mining applications, but on a small scale when compared to coal. To purchase equipment and perform development excavations, R&P requires a moderate capital investment. The method is also limited by depth. The pillar size is dictated by the weight of the overburden above the deposit, so conceptually the deeper the ore body, the larger the pillars must be. Larger pillars result in lower recoveries and overall mining efficiencies. Pillars can be recovered after initial development by utilizing retreat mining (high extraction). The primary advantages and disadvantages of continuous miner–based R&P mining are summarized in Table 6.4-7.

The difference between coal and noncoal production methods are four main factors:

1. **Strength.** Higher strength generally correlates with higher specific energy of cutting and lower productivity in cutting applications.
2. **Scale.** Coal mines are usually larger in throughput than other soft-rock mines because of the need to economically produce a lower value product.
3. **Methane (CH_4).** Where most coal mines are "gassy," many noncoal mines are free of that hazard. In most countries, coal mines and their related equipment are governed by strict regulations designed to prevent methane or coal dust explosions. Large mine explosions are often the product of methane explosions, which entrain coal dust in the air, leading to subsequent and more energetic coal dust explosions in rapid succession. Worldwide, systems involving water or incombustible dust (rock dust) are implemented to prevent coal dust explosions. Spontaneous combustion is also a hazard in many coal mines worldwide and is an attribute of some coal seams, but not all.
4. **Coal workers pneumoconiosis, more commonly known as black lung.** This chronic, debilitating disease is related

Source: Hustrulid 1982.

Figure 6.4-3 Klockner Ferromatik shield roof supports on U.S. longwall faces

to excessive exposure to respirable coal dust, usually during employment in coal mining. The management of dust in coal mining is subject to strict regulations but continues to be an area of industry and regulatory focus.

LONGWALL MINING METHOD

Longwall mining is combined with R&P mining to create some of the most efficient and highest-producing underground mines in the world. First, the main entries are driven with the conventional R&P techniques using continuous miners. A series of panels branching perpendicular from the mains or submains are outlined by a 2–3 entry R&P border, leaving a very large solid block (panel) of ore within its confines. Typical panel dimensions in contemporary coal mines are 800 to 1,400 ft of face length (width) with 6,000 to 15,000 ft of panel length. In coal, panel tonnages of almost 12.1 million metric tons are possible. In modern longwall faces, a shearer, armored face conveyor (AFC), stage loader, and line of powered roof supports (shields) are assembled in a setup room at the beginning of the panel before longwall mining commences (Figure 6.4-3). Utilities used by a longwall include emulsion pumps with capacities of 300–500 gpm at 4,000 to 4,800 psi. Electrical controls powered by 3,300 to 14,400 V provide power to the longwall face equipment at 1,000–4,160 V.

The shearer moves back and forth across the coal block, excavating 100% of the ore within its height capability, causing the material to fall onto the AFC and be transported to the main belt conveyor system via the stage loader, which normally has an integral crusher to provide suitably sized material for conveyor belts. The shields advance sequentially following the shearer to hold up the roof directly above the face equipment and advance the AFC to repeat the cutting cycle. The excavated area behind the shields is allowed to collapse. Retreat of the longwall progresses, as continuous miners develop additional adjacent longwall panels. When the longwall reaches the end of the panel, specialized activities are executed by a carefully choreographed plan to withdraw the longwall equipment from the completed panel and reinstall it in the next panel. During this process, key elements of the equipment are refurbished or exchanged with machine

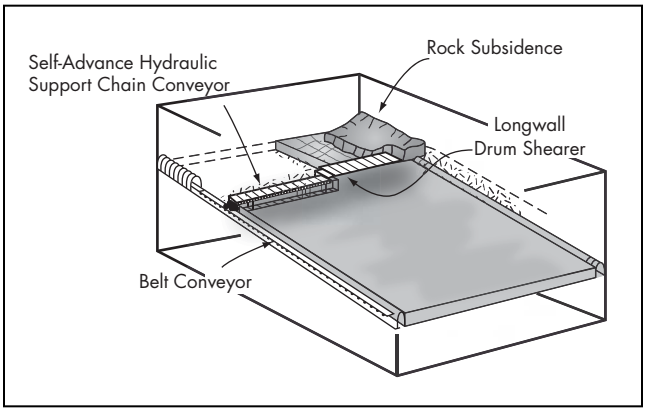

Figure 6.4-4 Longwall method

manufacturers for an already refurbished machine or component. Commonly, shearers, AFC and stage loader components, pumps, and selected electrical equipment are refurbished as necessary to allow high availability in service during the new panel. For world-class longwalls, production can range from 6.6 to 13.2 million tons per year, with unplanned production outages resulting in lost opportunity costs estimated to range from $200 to $1,000/min. A sketch of the longwall mining method and the components used are shown in Figure 6.4-4.

In coal seams lower than 60 in., thick plow-type longwalls are sometimes applied. These systems do not have the productivity of higher-height shearer-based systems and are more vulnerable to abnormal geologic conditions or roof falls on the face or in the tailgate. However, they are a viable alternative if mining heights below the limits of shearers are required.

Alternatively, interest is emerging in mining very thick seams, more than 18 ft in height, by longwall methods. This has led to development of some very large single-pass longwall systems; multilift longwalls, with limited success; and top-coal caving longwalls, which seem to offer good potential.

Although both retreating and advancing style longwall systems have been used in the past, most installations worldwide are now retreating faces. This choice causes higher initial development but minimizes the huge task of maintaining gate roads in the caved area behind the face (gob/goaf).

The largest number of longwalls is composed of dated equipment styles, including low-capacity chock-type roof supports, or even the earliest style, prop-and-bar or timber roof support. These are notable only because many such installations still exist worldwide but are clearly inferior to modern technology from productivity and safety perspectives.

It is of passing interest that a variation of the longwall method is also applied to hard-rock gold and platinum reef deposits in southern Africa. There, drilling and blasting break the rock, and low-production conveying systems and slushers clear broken ore from the face. Nonexplosive rock breaking or cutting is being evaluated but is not yet commercialized.

Not all soft-rock ores are suited for longwall mining, which works best in deposits that are laterally extensive, flat lying, of fairly uniform thickness, and primarily free of discontinuities such as faults. Coal beds deeper than 1,000 ft usually must be extracted by way of longwall mining, because using R&P methods would require the use of much larger pillars to support the roof and thus reduce the amount of coal that can essentially be recovered.

Table 6.4-8 Longwall favorable characteristics

Key Deposit Indicator	Characteristics
Ore strength	Low
Host rock strength	Weak to moderate
Deposit shape	Tabular
Deposit dip	Flat to shallow
Deposit size/thickness	Large, thin
Ore grade	Low and above
Uniformity	Uniform
Deposit depth	Shallow to deep

Rock bursts, mountain bumps, and outbursts are all manifestations of stored energy release where R&P or longwall mining has been conducted with some combination of the following conditions present:

- Depth greater than 1,500 ft
- Strong ore or stiff/strong rock members in the nearby underlying or overlying strata
- Unexpectedly high in-situ horizontal stresses or stress increases from interaction between workings
- Substantial reservoir or pore pressures of pressurized fluids, particularly CO_2 or CH_4

These events can range from mild thumps of little significance to catastrophic events capable of serious equipment damage and fatal injury to personnel. Expert assistance should be enlisted to assist the mine planning process where such events may occur.

The optimal characteristics for longwall mining are shown in Table 6.4-8.

Even more so than R&P mining, the longwall method is exceptionally efficient and has outstanding production rates and low operating costs. The operation is almost completely mechanized and recovers an extremely high percentage of the ore body. The working face is also safe since the roof is directly supported at all times by heavy-duty shields. Electronic controls and automation allow personnel to position themselves away from most of the recognized hazards. If conditions allow, longwall mining is the most effective way to excavate a thin tabular deposit with lower ore strength.

Over the years, significant improvements to longwall mining equipment have been made to help yield higher production rates. Shields with high-yield capacities and electro-hydraulic controls have replaced manually operated frames and chocks. AFCs have become more robust and powerful with increased size and speed of the chains, allowing higher conveyor capacities. The shearers have also become much more powerful and reliable, which enables more production, less downtime, and greater equipment longevity.

There are, however, a few disadvantages to longwall mining. First, it requires a substantial capital investment to purchase the highly specialized equipment to create a longwall section. The development time is significant because the continuous miners have to progress the main entries and develop gate roads for the longwall panel before the longwall can be installed. Finally, there is little selectivity or flexibility after mining commences. Longwall mines should be large, long-lived operations, with high production rates, in order to make certain of an adequate return on the mine operator's investment. The primary advantages and disadvantages of longwall mining are summarized in Table 6.4-9.

Table 6.4-9 Longwall advantages and disadvantages

Advantages	Disadvantages
Low operating cost	High capital investment
High productivity	Significant advance development
High recovery	Low selectivity
Safest method	Predictable subsidence
High production rate	Low flexibility
High mechanization	
Continuous method	

SMALL-SCALE MINING METHODS

Typically, in small-scale mining operations, a more traditional mining method is favored, where pneumatic drills are used to drill holes to be charged with explosives, and the ore is then blasted and hauled away. Small-scale coal mines may use this method because access to capital is difficult and the cost of equipment for a continuous miner section is prohibitive. Where conditions and capital availability permit, some operators employ continuous miners in small R&P mines. The evolving regulatory and socioeconomic climate is likely to systematically diminish such small operators in preference for larger-scale operations.

CONCLUSIONS

The process of selecting the optimum mining method for a given deposit is complex and requires extensive collection of geological, metallurgical, and mining-related data. In addition to the analysis of multiple alternatives, a thorough understanding of the sociopolitical setting, pertinent environmental concerns, and applicable regulations is critically important. This chapter has discussed the primary deposit characteristics and the mining method performance variables that are involved when selecting a mining method for soft-rock extraction. Because mineable ore deposits exist in all shapes and sizes and no two are alike, the best method selection process is not always evident. However, several key tasks should always be undertaken during method selection for any ore deposit. The first step is to identify the mineral resource available. The second step is to match the most suitable mining method to the ore body. As part of this step, it is important to identify pertinent economic or environmental factors that may constrain methods selection.

Above all else, it cannot be overemphasized that mine planners must value the principle of zero harm, which encompasses health, safety, environment, and community impacts. Failure in any of these areas can affect the sustainability of a mining operation just as seriously as a planning or execution failure. A review of numerous case histories of success and failure highlights the fact that failed projects are usually due to inadequate deposit characterization, inadequate risk assessment and consequent acceptance of elevated risk, inadequate planning or overestimation of operating performance, or inadequate capital to correctly implement plans. There are many paths to failure, and the paths to success are few and normally difficult.

CHAPTER 6.5

Comparison of Underground Mining Methods

Richard L. Bullock

An overview of the planning required for an underground mine is necessarily complicated by the availability of many different types of underground mining methods. For a detailed description of these mining and development methods and associated case studies, see Hustrulid and Bullock 2001.

The major objective when deciding upon and planning a mining method should be to maximize value, which is achieved after consideration of the following (R.L. Grayson, personal communication):

- Safety of all personnel
- Lowest production cost per metric ton
- Maximum productivity
- Required quality and quantity of the final product
- Maximum recovery of reserves
- Optimal environmental considerations

There are obviously trade-offs in trying to reach these non-aligned objectives.

ROOM-AND-PILLAR MINING METHOD

Room-and-pillar (R&P) mining is a system where a series of rooms (horizontal openings) are extracted, leaving ore, rock, or coal—called pillars—in place between the rooms. These rock/ore/coal pillars can be smaller horizontally than the rooms typical for hard-rock mining (see Figure 13.1-5 in Chapter 13.1) or larger than the rooms typical for soft-rock or coal mining. Normally rooms and pillars are of consistent size and shape and are laid out in a uniform pattern. However, for some metal mining, because the ore is not uniform, pillars can be varied in size and location to enable placement in low-grade areas of the stope. This is sometimes called stope-and-pillar mining.

The term *room-and-pillar* mining has been applied to metal mining in the United States for more than 150 years in the vast mining districts of the Missouri Lead Belts, the Tennessee Zinc District, and the Tri-State Zinc District of southwestern Missouri, southeastern Kansas, and northeastern Oklahoma. Considering the number of underground mines of coal, dolomite, gypsum, limestone, potash, salt, and trona, as well as all of the Mississippi Valley–type lead and zinc mines, it should not be surprising to realize that approximately 60% to 70% of all underground mining in the United States is some form of R&P mining. This amounts to nearly 340 Mt/a (370 million tons/yr) (Zipf 2001). For the aggregate industry alone, according to NIOSH there are 90 to 100 underground mines, all of them R&P (Iannacchione 1999). In today's permitting environment, at any given time there are probably between 20 and 40 R&P underground aggregate mines being planned.

Access to the R&P Mine: Hard-Rock and Coal Mining Methods

Although the access to a mine is not always influenced by the mining method, some discussion is warranted on the various approaches to the initial mine and production opening where R&P mining is to be applied:

- If it is possible to develop the resource from a hillside adit, doing so obviously provides the least expensive and most complete method of entry. In coal mining, this is called a drift entry.
- If a shaft is sunk (Bullock 1973), it should be
  - Sunk somewhere close to the center of gravity of the ore body, unless the ground is going to be allowed to cave, in which case it should be placed well outside the cone of subsidence;
  - Sunk to a depth that allows most of the ore that is be hauled downgrade to reach the shaft storage pockets;
  - Sunk deep enough to accommodate adequate storage pockets, skip loading, and a crusher station (if needed); and
  - Located, for aesthetic reasons, such that the headframe is out of sight of the public.
- If a decline is to be driven, the maximum grade of the decline depends on the equipment that will be driven on the decline. For truck haulage, the decline gradient should be matched to the gearing and optional power train of the trucks. Here are a few planning guidelines, depending on how a decline will be used for truck haulage:
  - For trackless haulage, 12.5% is the maximum grade recommended for normal mine trucks. If

Richard L. Bullock, Professor Emeritus, Mining & Nuclear Engineering, Missouri University of Science & Technology, Rolla, Missouri, USA

super-powered trucks are planned, then grades up to 17% may be acceptable.
– For conveyor-belt haulage where rubber-tired trackless equipment must negotiate on a regular basis, 15% is the maximum grade recommended. For conveyor-belt haulage only, the theoretical maximum grade is approximately 0.17 to 0.31 radians (10° to 18°), depending on the type of material (CEMA 1994). Beyond these recommended angles of incline, material will slide down the belt en masse and internally on top of itself, and lumps will roll down the belt and over the top of the fines. However, equipment must be able to access the belt to occasionally clean up spill rock unless hand shoveling for cleanup is planned.

Room-and-Pillar Stoping for Hard Rock

The differences in strength, hardness, and abrasiveness of rocks such as limestone, dolomite, or sandstone as compared to those of the soft materials coal, potash, salt, or trona necessitate different extraction methods.

Primary Extraction Methods

One advantage of modern R&P mining systems is that every task can be mechanized to some degree, provided that it is economically sound to do so. Mechanization minimizes the operating labor force and simplifies staffing. The high-capacity equipment for modern R&P operations is relatively simple to operate.

Although most R&P mining is done by drilling and blasting, particularly for aggregates and metals, some mining is done by mechanical excavation, usually with roadheaders (Bullock 1994). With the power of today's mechanical excavating machines and with improvements that are being made in tools such as disk and pick cutters, the possibility of mechanical excavation should be at least considered during the feasibility study for any rock under 100 MPa (15,000 psi) or even up to 136 MPa (20,000 psi) if it contains fractures and is low in silica content. Where mechanical excavation is truly viable, its use equates to higher production rates and reduced operating cost. The following are advantages of mechanical excavation where it is viable (Ozdemir 1990):

- Improved personal safety
- Minimal ground disturbance
- Reduced ground support needed
- Continuous, noncyclic operations
- Low ground vibrations and no air blast
- Uniform muck size
- Less crushing and grinding in the mill
- Reduced ventilation requirements
- Conducive to automation

Room Width

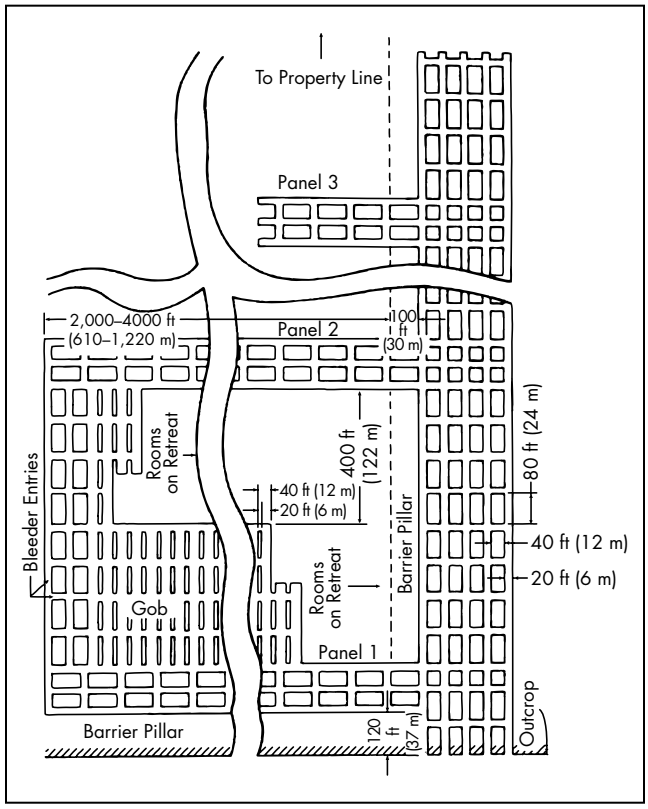
For productivity reasons, rooms should be as wide as is practical and safe. The wider the rooms, the more efficient the drilling and blasting, and the larger and more efficient the loading and hauling equipment. However, room width is always limited by the rock mass strength of the ore body, back, and floor compared to the stress levels induced into the rock. It is inappropriate to design room widths simply from elastic theory, without taking into account rock-mass strength. However, since rock and pillars can be reinforced to increase the effective rock-mass strength, final room width may be a matter of economics.

Many discussions have been written on how to design a roof span. For further insight into the rock mechanics of R&P roof spans, see Hustrulid and Bullock 2001. What is important at this point is to determine what information is needed for the design and how much of the needed information is already at hand. Chapter 12.1 contains a general summary of geological and structural information that should have been determined during exploration of an ore body. Unfortunately, most exploration groups spend little time or money in determining the information that is needed to construct a rock-mass classification of the mineralized areas and rock surrounding the mineralization. A best-guess rock-mass analysis may have to be done with nothing but the exploration information. In any case it is hoped that mapping of underground structures from core logs, surface mapping, possibly mapping of surface outcrops of the same underground structures, and geophysical information, along with the rock quality designation (RQD) of the rock core, are sufficient for a crude rock-mass classification to be constructed.

Pillar Width

The overall strength of a pillar is related to its height; that is, the ratio of pillar width w to pillar height h is important. The amount of load that a pillar can safely carry is proportional to the ratio w:h. Thus a pillar of ratio 4:1 has a much larger safety factor than does a pillar of ratio 1:1 or 1:5. Ratios of 1:3 to 1:4 are not uncommon in some competent hard-rock metal mines.

The theoretical load as calculated by the overburden load distributed to the pillars may or may not be the load that is actually carried. There is a good chance that the load may arch over some of the interior pillars of the stope and transfer load to barrier pillars or waste areas. In some such cases, interior pillars can be made smaller as yielding pillars. If a stopes mine is very wide, a row of large, rectangular barrier pillars should be retained at regular intervals. In areas of very large lateral extent, this prevents cascading pillar failure of the entire area in a domino affect (Zipf and Mark 1997).



For more information, the reader is referred to case studies on R&P stoping in Hustrulid and Bullock 2001. These studies describe how different mines approach these design problems as well as catastrophic failures that have occurred when proper precautions were not taken.

Secondary Extraction Methods

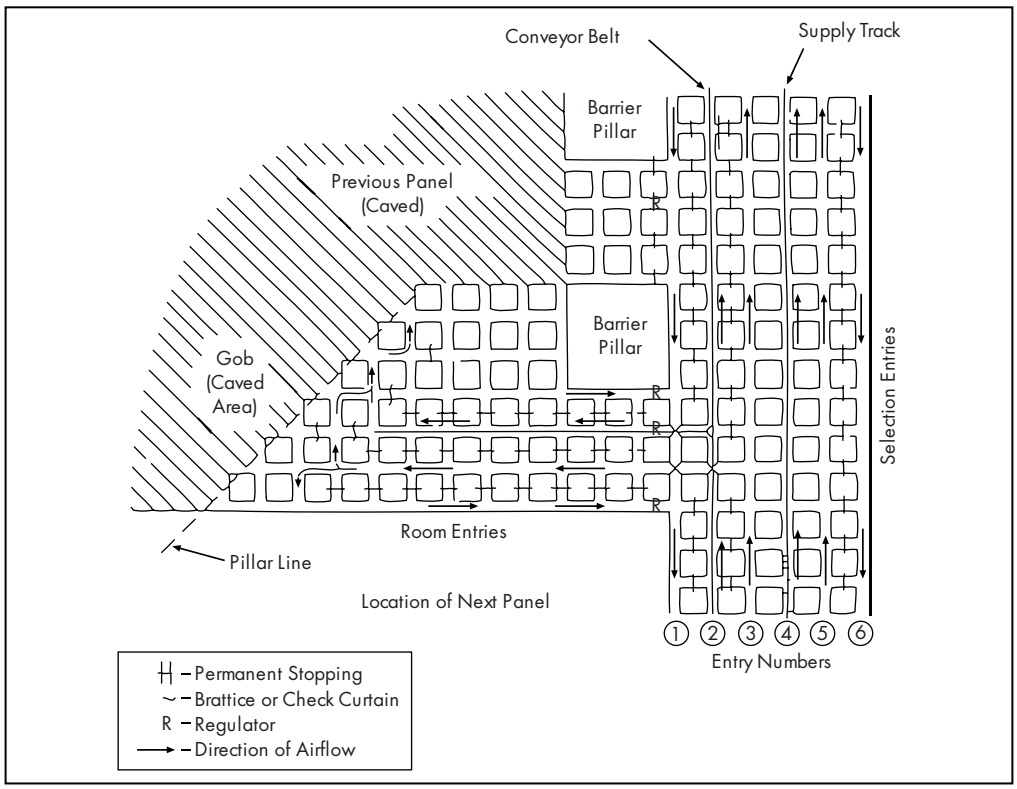
Pillar removal should be planned as part of the overall mining of areas where the economic value of what remains warrants the extraction of some or all pillars. For example, it is not uncommon for some very-high-grade pillars in the lead/zinc/copper mines of the Viburnum Trend in Missouri to have a value of more than $1 million per pillar.

For optimum recovery, the initial pillar design must be correct and include barrier pillars to prevent catastrophic failures. There are five basic approaches to removing pillar ore after completion of primary mining:

1. Partially extract, by slabbing, the highest-grade part of each pillar.
2. Remove a certain number of the high-grade pillars completely, but leave enough to support the back.
3. Encapsulate pillars with fenced cemented rock fill or paste backfill, then come in underneath the pillar and drop it into the sublevel below.

Source: Stefanko and Bise 1983.

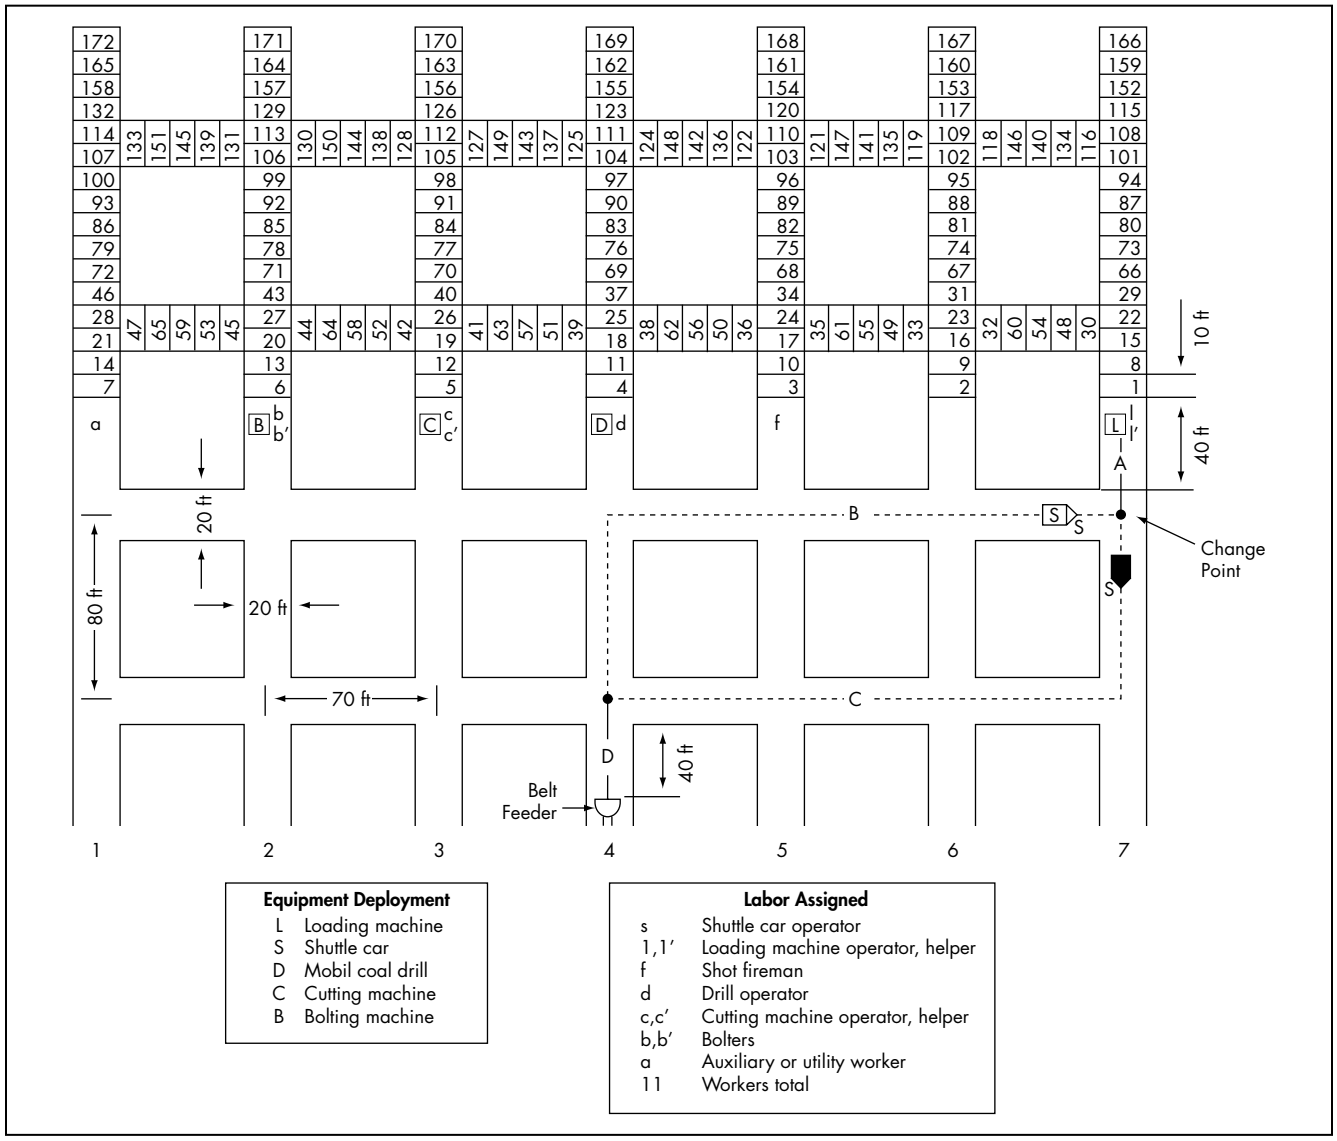
Figure 6.5-1 Typical soft-rock or coal R&P mining system with five entries



4. Encapsulate low-grade pillars with fenced cemented rock fill or paste backfill to form a barrier pillar, then remove the surrounding pillars (Lane et al. 1999, 2001).
5. For narrow areas and strong/reinforced back, remove all pillars.

Room-and-Pillar Mining for Coal and Soft Rock

For the typical R&P mine layout for mining of bituminous coal shown in Figure 6.5-1, five main entries allow access to the production panel through panel entries. Coal-mine dimensions are generally as follows:



- Entry widths (in the United States) can be up to 6 m (20 ft) and are generally driven 18.3 to 30.5 m (60 to 100 ft) apart, center to center.
- Panel widths can be 122 to 183 m (400 to 600 ft), limited primarily by the cable reach of the electric shuttle cars that are usually used to move the coal. Panel lengths generally vary from 610 to 1,220 m (2,000 to 4,000 ft) but can be longer.

In Figures 6.5-1 and 6.5-2, note that the panel pillars are being mined. In the United States this is called pillaring or caving; elsewhere it is called stoping. Normal practice in pillaring is to drive rooms and crosscuts upon advance (mining into the virgin coal seam in a panel) and to pillar upon retreat (mining while moving back out of the panel). In the United States, the caved area is called the gob; elsewhere it is called the goaf. Pillars are not removed if the surface must be supported; pillaring is often omitted for other reasons as well (Hartman and Mutmansky 2002).

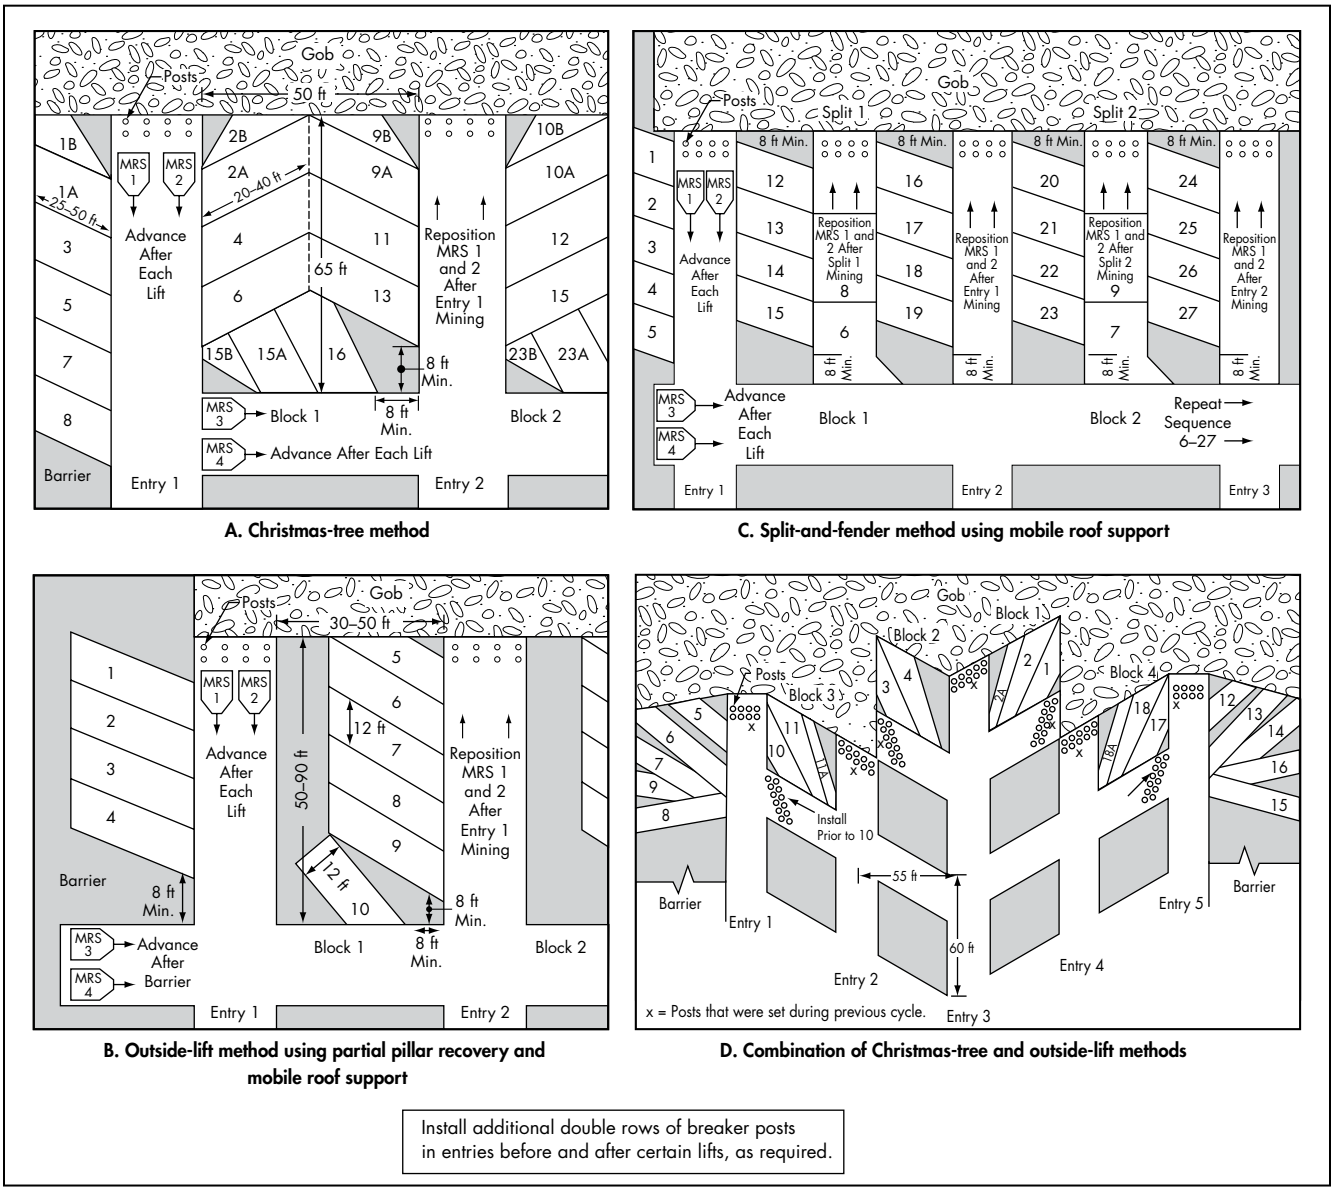
Figure 6.5-2 Typical soft-rock or coal R&P mining system showing retreat minivng with six entries

Source: Stefanko and Bise 1983.

Figure 6.5-3 Conventional R&P section with seven entries showing auxiliary operations

Mining Methods

Two methods of R&P coal mining exist: conventional and continuous. Conventional operation involving drilling and blasting of the undercut coal seam is an antiquated method practiced in <5% of coal mines in the United States. Conventional operation using conventional equipment is cyclic, with the following sequence:



1. Undercut a kerf of 127 to 178 mm (5 to 7 in.) to improve coal breakage during light blasting.
2. Drill blastholes with an electric rotary drag-bit auger drill.
3. Charge the holes lightly with permissible explosive and then blast.
4. Load the coal with an electric gathering-arm loader into a shuttle car for transport away from the face.

Auxiliary operations of roof control, ventilation installation, and cleanup must also be performed. A typical mining section that uses this system is shown in Figure 6.5-3, which shows a seven-entry development. The numbers represent the sequence of faces where each crew member performs their function of the cycle.

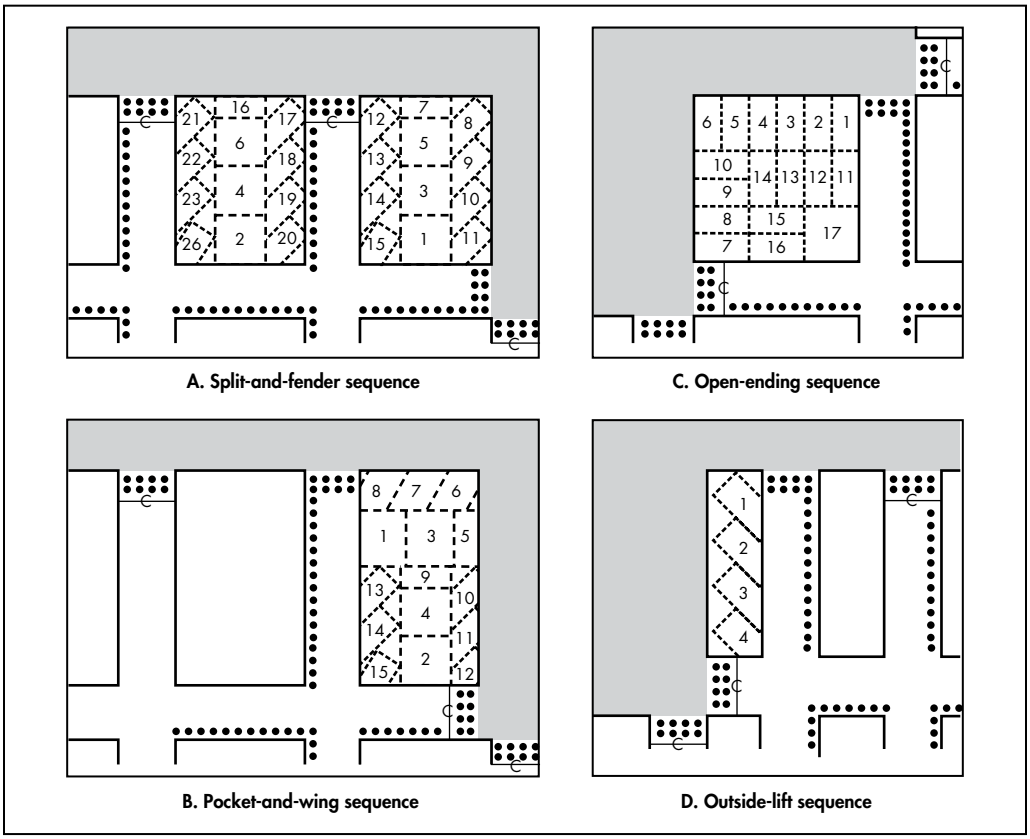
Continuous operation is so named because a mechanical excavating drum miner continuously extracts the coal. Coal is mined continuously and then hauled from the face, usually by electric shuttle car but sometimes by conveyor belt or diesel scoop machine. There is usually some waiting between the loading of each shuttle car or scoop. As with conventional operation, auxiliary operations of roof control, ventilation installation, and cleanup must also be performed. The plan view in Figure 6.5-2 shows section entries, room entries, and rooms associated with a production panel within a mine. Room entries, rooms, and associated crosscuts are mined upon advance, and pillars are mined upon retreat. In the figure, note the numbering on the entries in the section entry set.

Retreat Methods

Retreat mining methods vary greatly in the coal industry. The method used can depend on seam height as well as local mining

Source: Feddock and Ma 2006.

Figure 6.5-4 Pillar-extraction methods



conditions, availability of mining equipment, pillar size, success of similar methods in adjacent mines, opinions of mine engineers, and state and federal roof-control specialists. Pillar-extraction methods widely practiced in the industry include Christmas tree, outside lift, split and fender, and combinations thereof, as shown in Figure 6.5-4.

In a study by the U.S. National Institute for Occupational Safety and Health (NIOSH; Mark et al. 2003), it was estimated that, nationally, about 60% of retreat mining used the Christmas-tree method, 35% used the outside-lift method, and only 5% used the split-and-fender method. The Christmas-tree method is usually favored because it does not require placing changes and bolting.

Using 150 case histories, NIOSH has developed a methodology that has proved successful in generating and validating the Analysis of Retreat Mining Pillar Stability (ARMPS) method and program developed by Mark and Chase (1997). The method aids in the correct design of retreat mining and helps show potential problems such as bump- (seismic-) prone areas (Chase et al. 2002). An excellent review of all current practices in the United States has been written by Mark (2009).

The Christmas-tree method (Figure 6.5-4A) is also called left–right or twinning. Cuts are taken both left and right on both sides of the entry. A continuous miner removes most of the coal on each side until a chevron-type pillar—typically a corner wedge-shaped remnant pillar—is left. The figure shows a common sequence in which lifts are extracted during barrier and production pillar extraction using mobile roof support (MRS) units.

The outside-lift method (Figure 6.5-4B) is the original method developed for use with MRS units. This method is suitable for narrow pillars when combined with extended cut mining. There are many variations, depending on conditions, pillar dimensions, and coal-haulage equipment. Generally the

Source: Kauffman et al. 1981.

Figure 6.5-5 Pillar-extraction cut sequences

pillar is sized so that lifts taken from one side of the pillar are sufficient to extract the pillar without going beyond the supported roof. Cuts are taken starting from the pillar near the gob (goaf) and moving toward solid coal. The sequence of cuts shown in the figure is typical, and MRS units are moved in a retreat mining process or adjacent entry with supplemental support generally provided by posts, mechanical chocks, or MRS units. Multiple pillars are usually extracted simultaneously to provide an adequate number of working places and so avoid production delays.

The split-and-fender method (Figure 6.5-4C) involves a specific cut sequence for continuous mining equipment, as shown by the numbers in the pillars. Again, supplemental support in the form of MRS units is used.

The disadvantages of MRS units are twofold: costs for their initial purchase and for recovery if they are trapped by a rock fall are high, and their operating range is usually limited to seams thicker than approximately 1.1 m (42 in.).

Typical Retreat Mining Methods Using Breaker Posts or Mechanized Chocks

The vast majority of thin-seam mines (seams ≤1.3 m or 52 in.) in the United States use wooden breaker posts (Mark et al. 2003). In a 2002 survey of mines in southern West Virginia (United States) by NIOSH (Mark 2002), the vast majority of thicker-seam mines were already using MRS units. But of the 54 thin-seam mines, only 7 (13%) were using them. In thin-seam mines, a timber plan that requires an adequate number of posts installed at the proper times and locations is essential.

More than 100 roadway, turn, and breaker posts can be required to extract a single pillar. Where hardwood timber is not abundant, mechanical chocks can be used, as is often the case in Europe, Australia, and South Africa. Typical examples of this application are sited in the following paragraphs.

In very low (i.e., thin) seams where continuous haulage is used, the Christmas-tree and outside-lift methods have been used in combination for pillar systems developed with continuous haulage (Figure 6.5-4D). When using mobile bridge conveyors—the most common type of continuous haulage—crosscuts are driven at ~60° angles to facilitate movement of bridges and carriers. The parallelogram-shaped pillars create a panel configuration that is usually referred to as a herringbone or turkey-foot design. Each mining cycle starts with recovery of the two central pillars (blocks 1 and 2) left standing out in the gob by the previous cycle. Each pillar is extracted by the outside-lift method. After cutting lifts 1 and 2 in block 1, the continuous miner is maneuvered to cut lifts 3 and 4 in block 2. A variation is to cut the two central pillars using the Christmas-tree method. The extraction sequence removes the left barrier and block 3 followed by the right barrier and block 4, and then the sequence repeats (Feddock and Ma 2006).

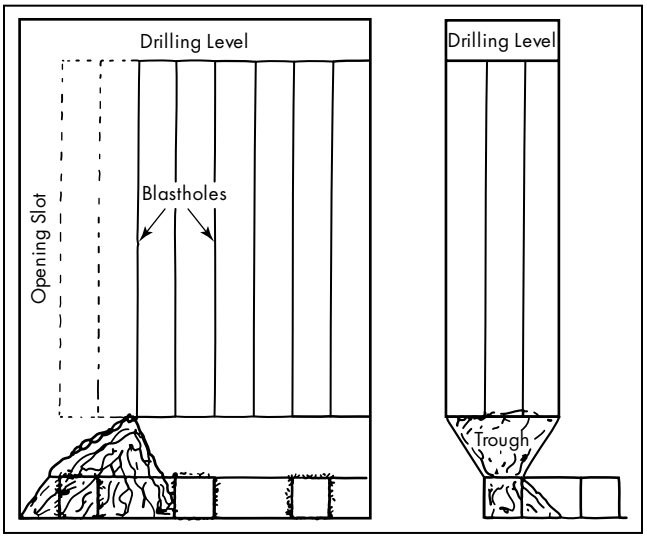
In the low-seam coal mines of Appalachia (United States), many mines still use the four basic pillar-extraction cut sequences described by Kauffman et al. (1981) and shown in Figure 6.5-5: split and fender, pocket and wing, open ending, and outside lift. The numbers in the figure represent the sequence of cuts made by a continuous miner. Temporary prop supports are shown as rows of black dots.

There are several disadvantages to using posts rather than MRS units (Mark et al. 2003):

- Setting posts exposes miners to ground falls.
- Posts have a limited load-bearing capacity; a typical hardwood post 152 mm (6 in.) in diameter can carry about 45 t (50 st).
- Posts have limited roof-convergence range—from 25 to 51 mm (1 to 2 in.)—before they break.
- Because of their weight and bulk, posts can cause material-handling injuries, particularly in high coal.

SUBLEVEL OPEN-STOPING MINING METHOD

R&P methods are often used for subhorizontal ore bodies of relatively uniform thickness. As strata dip and/or ore-body thickness increases, other extraction methods are usually used. For example, a moderately thick, flat-dipping deposit would normally be mined by R&P methods. But for a dip of 90°, loading on the pillars is from the horizontal direction and blasted ore falls down for collection at the bottom of the stope. Although the general geometry is the same as that for R&P methods, the generic name given to this system is sublevel open stoping. Blasthole stoping, vertical crater retreat mining, and vein mining fall under this general heading.



A special form of sublevel open stoping is called shrinkage stoping. In general, the method is applied to ore bodies having dips greater than the angle of repose of broken material (~50°) so that material is transported to the collection points by gravity. For massive deposits, stopes with vertical walls are created and the overall dip of the deposit is immaterial. The criterion for applying the method is that, during extraction, the openings created must remain open. After extraction, the openings may be filled or left open, and the pillars left between stopes may be extracted or left in place. This section presents some typical layouts used for extracting ore. It is assumed that mobile equipment is used with ramp access.

Throughout planning, it is important to be aware of the potential for ore dilution or ore loss when drilling long holes and when mining undulating veins. In feasibility studies, the value of dilution for sublevel long-hole stoping should be ≥15% and ore loss ≥5%. However, for short-blasthole methods such as shrinkage methods, dilution and ore loss might be <5%.

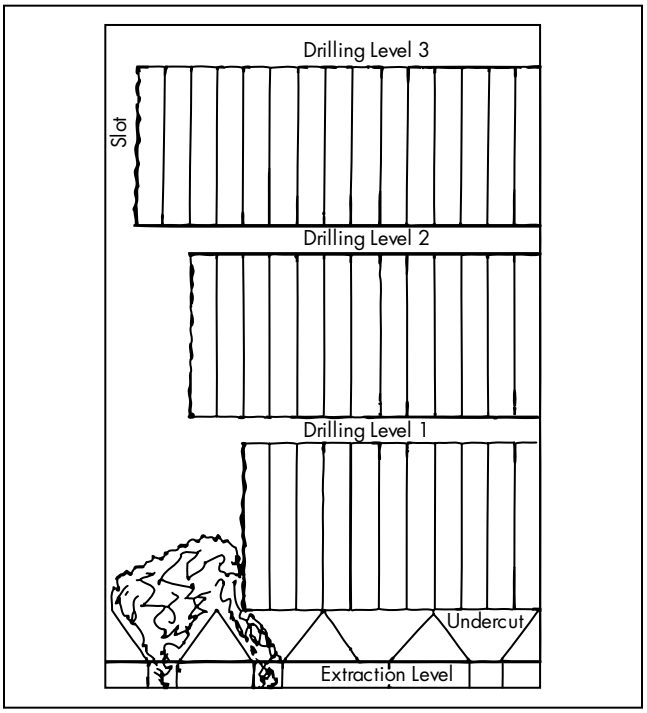
Extraction Principles

One can consider an ore block of width w = 1 to 10 m (3.3 to 33 ft), length l = 10 to 40 m (33 to 131 ft), and height h = 20 to 30 m (66 to 98 ft). For simplicity, it can be assumed that the block is vertical, although for this method the dip of the block is immaterial since, if the block is thick enough, a stope can be developed that will flow by gravity and can be mined by a number of sublevel stoping techniques. Blasted ore falls to the bottom of the block and is removed with load-haul-dump (LHD) equipment. There are various designs for the extraction level. It can also be assumed that a trough is created using fans blasted toward an opening slot. The LHD units travel in a footwall haulage drift running parallel to the trough. Access to the trough is from the side. The location and number of access drawpoints are such as to provide full extraction coverage.

With the availability of remote- or teleremote-operated LHD units, it is now common to design stopes with flat bottoms rather than trough undercuts. Final cleanup of up to 20% of the stope ore is done by remote control, which simplifies stope layout and makes drilling and blasting more efficient. With remote LHD units, there may be no requirement for a footwall haulage and crosscuts, because the stope is accessed along the strike within the ore, reducing waste-development costs.

Source: Bullock and Hustrulid 2001.

Figure 6.5-6 Blasthole stoping method, starting with a slot opening



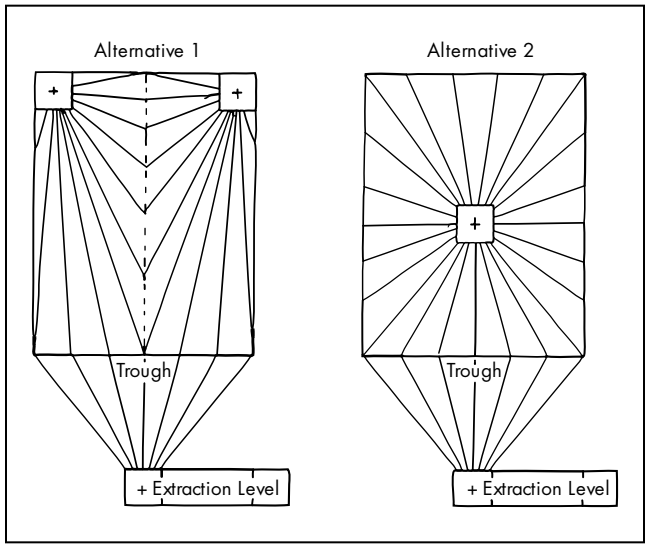
Blasthole Stoping (End Slicing)

Because it is the simplest and usually lowest in cost, blasthole stoping (also called end slicing) is the first method considered for mining a block (Figure 6.5-6). From the drilling level at the top of the block, rows of parallel blastholes are drilled down to the top of the extraction trough. A raise is driven at one end of the block and is slashed to full stoping width to form a slot. Holes are blasted one or several rows at a time toward the open slot. The blasting design and layout is similar to that used in bench blasting. Hole diameters vary widely but are typically in the range 76 to 165 mm (3 to 6.5 in.). For wide blocks, diameters of 165 mm (6.5 in.) are often used.

Hole straightness is an important design consideration that affects fragmentation, ore loss, and dilution. In general, the largest hole diameter possible for the stope geometry is selected, because straight hole length is strongly dependent on hole diameter. The amount of development required to exploit a certain volume of ore is inversely proportional to block height, and, because the cost of development is significantly higher than that of stoping, the tallest extraction blocks possible should be planned for the stope.

Sublevel Stoping

If geomechanic studies indicate that very tall blocks (those whose height exceeds the straight drilling length from one drill location) can be extracted using the same extraction level, then several drilling levels at various heights within the block can be created by a method called sublevel stoping (Figure 6.5-7). The layout is similar to that for blasthole stoping with an extraction level and an opening slot, but now there are multiple drilling levels. Mining is done either overhand (lower drilling blocks are extracted first) or underhand



Source: Bullock and Hustrulid 2001.

Figure 6.5-7 Sublevel stoping method, showing a typical parallel-holes drill pattern

(upper drilling blocks are extracted first); overhand stoping is usually assumed. The simplest approach is to repeat the drilling layout for one-level blasthole stoping. Ore-body thickness is assumed to be such that the full width is undercut and becomes available for drilling access, in which case parallel holes can be drilled.

An alternative approach is to drill fans of holes rather than parallel holes from the sublevels (Figure 6.5-8). There can be one or multiple drill drifts on each sublevel and the rings can be drilled downward, upward, or in full rings. There are many variations of drill pattern, based on a number of factors. For example, the distance between sublevels needs to be maximized so as to minimize the amount of development per ton of ore broken. But the accuracy of the drilling equipment in that particular rock determines how long holes can be without excessive drill-hole deviation, which causes boulders, ore loss, ore dilution, or so-called misbreaks (rock that breaks incorrectly or not at all) in blasting. Likewise, the width of the ore block to be taken can determine whether sublevel drifts are placed on the hanging wall and the footwall, or, if the ore is narrow, whether a single drift in the ore might approach the limits of the ore. Another variable is hanging-wall strength. If a hanging wall needs support, then some of the sublevels need to be on the hanging-wall side so that sublevel drifts can also be used in place of cable bolts for support as well as for drilling long blastholes. Yet another variable is whether a primary stope or a pillar between two previously mined filled stopes is being mined. In the latter case, the blastholes break more easily to the free face of the rock–fill interface. For a guide to these planning decisions, see Chapter 13.4.

Use of sublevel stoping assumes good stability of the openings created. Stability surprises can mean partial or even full collapse of partially extracted stopes. Production can be

Source: Bullock and Hustrulid 2001.

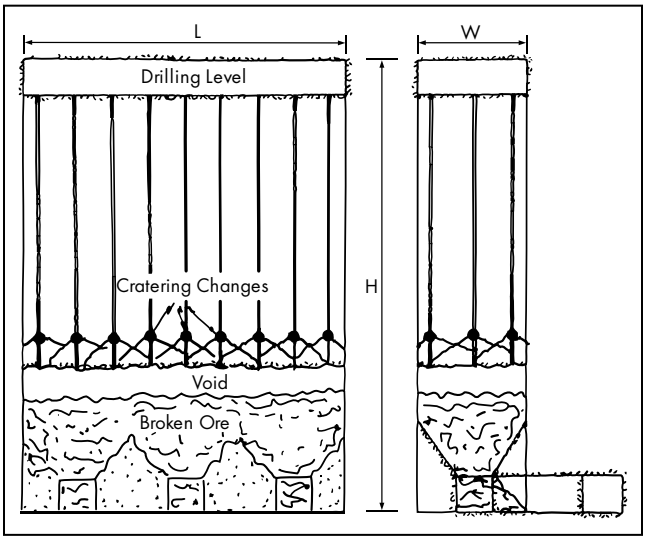


Figure 6.5-8 Multilevel sublevel stoping method, showing typical fans-of-holes drill patterns

stopped fully because of the presence of large blocks in the drawpoints. Even in the best-case scenario, there is likely to be some ore loss and dilution. The footwall, hanging wall, and roof can be reinforced before or during mining. Extraction blocks (stopes) can be oriented parallel or perpendicular to the ore body, depending primarily on the width of the ore body and how the mine planners want to drive the access drifts to support extraction of the stope block.

Vertical Crater Retreat Stoping

In the cases discussed previously, rings of holes are blasted toward a vertical slot. In vertical crater retreat (VCR) or vertical retreat mining (VRM) systems, the need for a slot connecting the drilling and extraction level has been eliminated, simplifying development (Figure 6.5-9). Rather, the slot is replaced by a horizontal slot (undercut) created at the bottom of the block on the extraction level. A real trough can be created but is not necessary. From the drilling level, large-diameter (~165 mm or 6.5 in.) parallel holes are drilled downward to the undercut level. Short explosive charges (length = 6× the hole diameter) are lowered to positions slightly above the top of the undercut. These "spherical" charges are detonated, dislodging a crater or cone-shaped volume of rock into the underlying void. As each layer of charges is placed and detonated, mining of the stope retreats vertically upward in a VCR.

The design of the blasting pattern is based on full coverage of the block cross-section by the adjacent craters. Normally the blasting pattern is tighter (holes are spaced closer) than for large-hole blasthole stoping, and hence the powder factor is larger. During blasting under these confined conditions, fragmentation is generally finer than it is for blasthole stoping. Prior to charge placement, care must be taken in determining the location of the free surface. In some cases, ore blocks can overbreak vertically along fractures or faults and leave a vertical opening for the next round to break to, in which case the next round in a nearby hole will break sideways to any nearby free face. Thus observations and measurements are essential prior to planning every blast. In this system, the level of broken rock remaining in the stope can be controlled to provide

Source: Bullock and Hustrulid 2001.

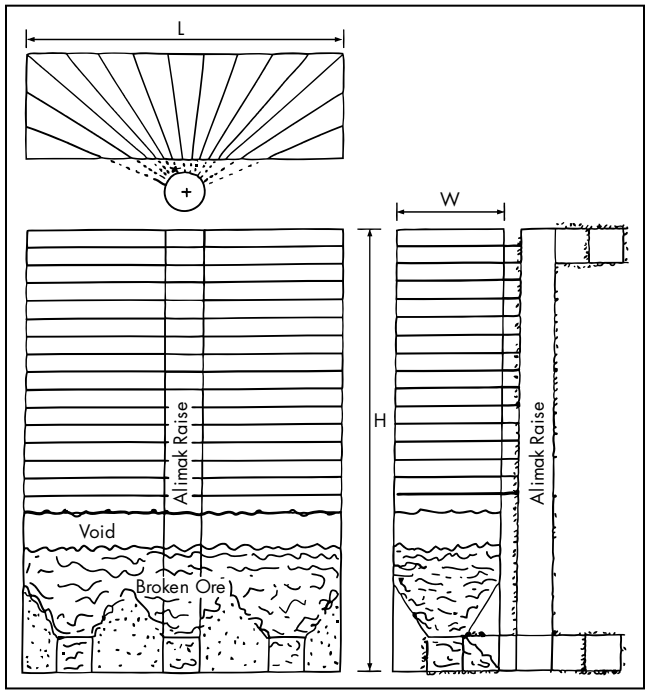

Figure 6.5-9 Vertical crater retreat stoping method

varying levels of support to the stope walls. If the stope is kept full except for a small slot to provide a free surface and swell volume for the blasted rock in the slice, the method used is classified as a shrinkage method and the remaining ore is drawn out at the completion of mining.

Vein Mining

Another approach to extracting the ore block is called vein mining (Figure 6.5-10). At the highest level of the block to be extracted, a connection is made to the ore body. Access is assumed to be via the footwall side, and connection is made in the middle of the extraction block. On the extraction level, an undercut or extraction trough is prepared. A raise is driven between the extraction level and the upper access point from which long blastholes can be drilled. Using a Boliden-type cage or the Alimak technique (Ovanic 2001), a raise is driven upward in the footwall a small distance from the ore-footwall contact. The next step in the process is the drilling of subhorizontal fans of blastholes using the Alimak platform or Boliden-type cage in such a way that the plan area of the extraction block is fully covered. The hole diameter is determined by the capacity of the drilling machine but should be as large as possible since the toe spacing and the burden (distance between fans) is determined by the hole diameter and the explosive used. When drilling of the entire extraction block is complete, the fans are charged and blasted one or more at a time, working off the raise platform. Access to the block is now only from the upper level as the stope is retreated upward. The ore in the stope can be removed after each blast or can be left in place and only enough removed to provide swell volume for the next one or more slices. Rock reinforcement can be installed in the hanging wall if required from the raise platform during the drilling of the production holes.

An advantage of this method is that it enables extraction of very high ore blocks with a minimum of development (upper access point, extraction level, and connecting raise). The overall length of the extraction block is determined by the straight-hole drilling length of the available drilling equipment. However, if larger blocks are more economically mined, then multiple raises can be used and this possibility should

Source: Bullock and Hustrulid 2001.

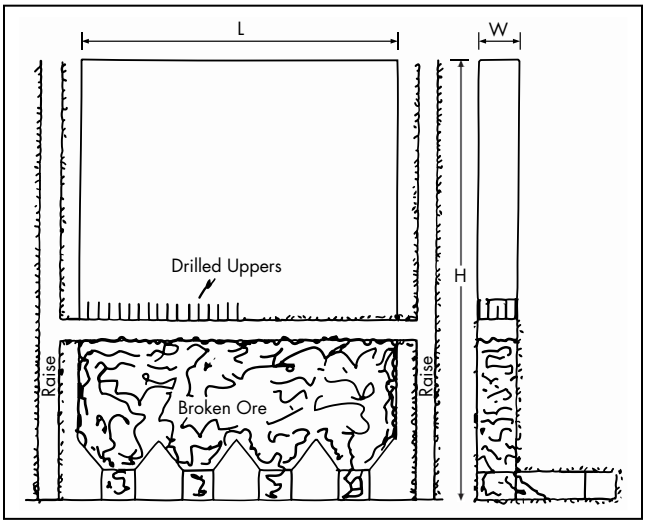

Figure 6.5-10 Vein mining method using long holes

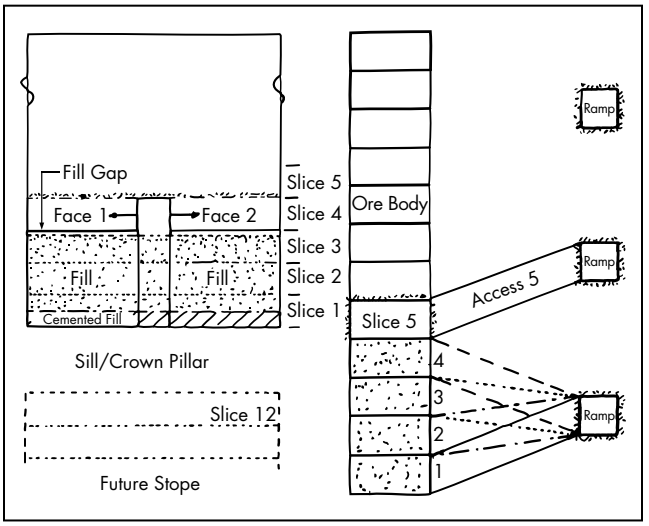
be considered in the feasibility study. A disadvantage is that drilling and charging must be done from a raise environment, which can be hazardous unless well managed. However, major advances have been made in the mechanization and automation of rigs used for drilling.



Shrinkage Stoping

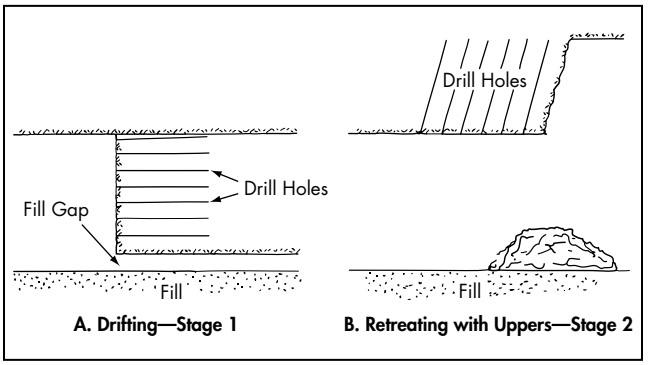
Although normally considered as a separate method, it is logical to also discuss shrinkage stoping at this point, since it is an open-stope method (Figure 6.5-11). The method is generally applied to very narrow extraction blocks that have traditionally not lent themselves to a high degree of mechanization. It has been applied successfully in high-grade precious metal mining because of its low dilution and low ore loss. The extraction block is laid out longitudinally due to the very narrow nature of the ore body recovered. An extraction drift is located in the footwall with loading crosscuts positioned at regular intervals. Raises are driven at each end of the extraction block connecting to the above-lying level. An initial horizontal extraction slice is driven across the block from raise to raise. Extraction troughs are created by drilling and blasting the rock between this level and the underlying extraction points. When the extraction system has been created, short vertical holes are drilled into the roof of the first extraction slice using the raise access. The miners stand on the broken ore that forms the working floor. Jackleg or stoper drills are used to drill small-diameter holes. The holes are charged and then ore is extracted from the stope to provide room for the blasted material. The blast is initiated and the miners reenter the newly created void to bar down loose material before drilling out for the next slice. The process continues, working upward one slice at a time. When the upper end of the extraction block is reached, the ore is drawn out. Until that time, the stope is filled with broken ore.

A severe disadvantage of this method is that it is among the most hazardous of mining methods. The miner is exposed to

Source: Bullock and Hustrulid 2001.
Figure 6.5-11 Shrinkage stoping method

Source: Bullock and Hustrulid 2001.
Figure 6.5-12 Overhand cut-and-fill mining sequence

freshly blasted unsupported ore while working on rough broken ore. In addition, voids can be created in the ore being drawn, which can suddenly collapse in areas where miners are working. For these reasons as well as the relative high operating cost, its use is limited in the United States. However, it is still used fairly extensively in developing countries and in Canada.



Summary of Open-Stoping Sublevel Mining

Depending on the geometry of the ore body, several varieties of sublevel stoping can be used. However, the ore bodies must all have strong wall rocks and competent ore, either naturally or by means of reinforcement, since in the process of ore removal large openings are created.

The extraction block used to illustrate the layouts for the different mining systems can now be duplicated and translated laterally and vertically in the ore body, leaving pillars to separate adjacent blocks. The size and shape of the extraction block can be adjusted to fit the ore-body geometry and the mine infrastructure. Openings created during this primary mining can be filled with various materials or left unfilled. The filling materials can be cemented or left uncemented, depending on the next stage of recovery envisioned. Various methods can be used to recover remaining reserves tied up in the pillars. During the feasibility studies, these secondary recovery methods should be examined at the same time as the primary system is designed. Although for simplicity the basic extraction block was considered to be vertical, the process can obviously be repeated for ore bodies having various dip conditions.

CUT-AND-FILL MINING METHOD

Where ore and/or wall rocks are weak, and hence both opening size and allowable time between ore removal and filling of the excavation is strictly limited, a number of extraction designs can be applied, all of which fall under the general category of cut-and-fill mining. This versatile method can be adapted to the extraction of any ore-body shape. With some exceptions, all of the ore is removed via drifts that are then filled. As a result, mining costs are higher than for other methods. But when the method is applied correctly, recovery is high and dilution is generally low. Thus it is appropriate for the extraction of high-grade ore bodies.

Figure 6.5-13 Two-pass cut-and-fill mining sequence

Extraction Principles

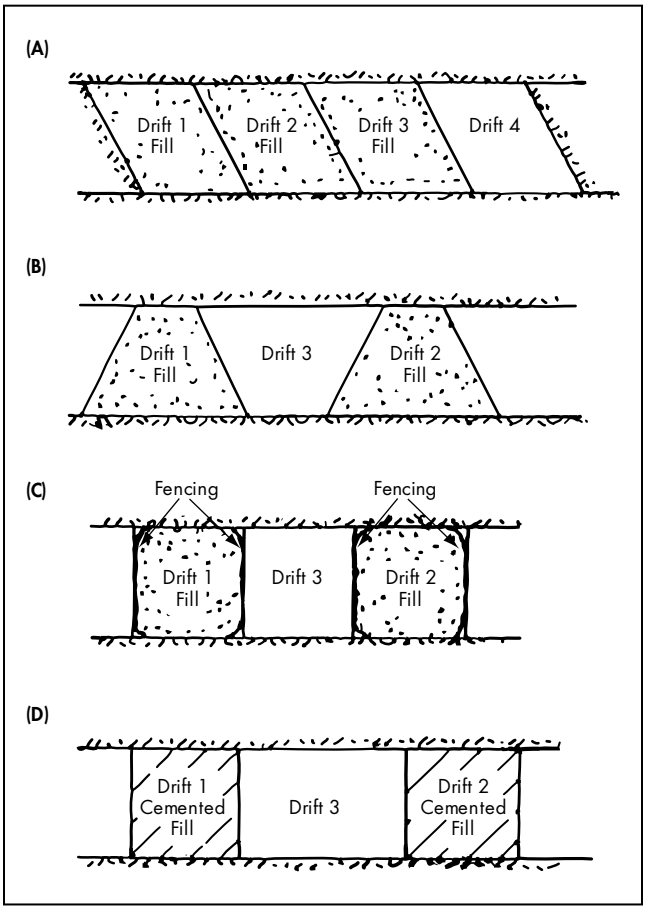
For simplicity, an extraction block of the same type used in the previous section is assumed. Access is via a ramp driven in the footwall, and mobile equipment is used. Typically, drifts used in mechanized cut-and fill mining are about 5 m (16.4 ft) high. The ore block to be extracted is assumed to be vertical and of a width that can be removed by means of normal drifting. When ore-body strength is fairly good, overhand cut-and-fill mining is normally applied (Figure 6.5-12).

Ideally, access to each level is via crosscuts originating at the midlength position of the block such that two headings can be operated at one time. Typical drift rounds consisting of drilling, blasting, loading, scaling, and installation of rock reinforcement are used. This progression of operations can lead to delays unless carefully planned. Drilling of heading 2 is carried out while other operations are being done at heading 1. When the extraction slice is complete, backfilling takes place. Fill is placed so as to leave a small gap to the overlying ore (Figure 6.5-13A) such that a heading 5 m (16 ft) high recovers about 4 m (13 ft) of ore. On the next slice, this gap forms the free surface for blasting. The process continues upward, slice by slice, to the top of the block.

Source: Bullock and Hustrulid 2001.

Figure 6.5-14 Avoca mining sequence

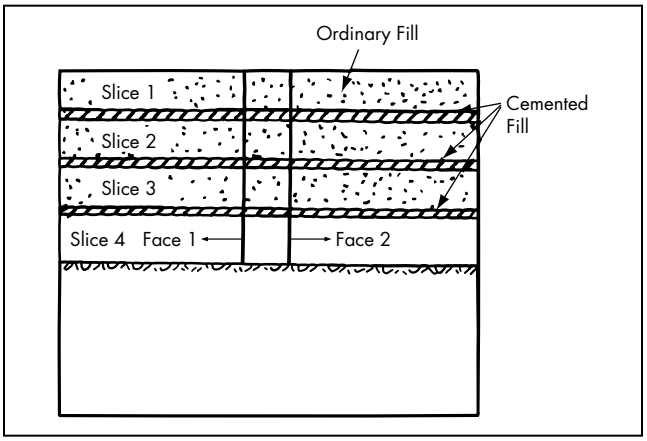
Several extraction blocks can be operated simultaneously to meet production requirements. The horizontal pillar created between two such stacked extraction blocks is called the crown pillar for the underlying stope and the sill pillar for the stope above. Normally the first cut of the extraction block above the sill is filled with cemented fill to facilitate later extraction of the pillar.



In some cases, the wall rock is strong enough to allow a double slice to be open at any given time. The first slice is mined by drifting and then, rather than filling directly, upward-oriented drill holes, called uppers, are drilled the length of the slice (Figure 6.5-13B). When drilling is complete, several rows of holes are charged and blasted, beginning at the ends of the extraction block and retreating toward the access. Ore is extracted by an LHD unit after each blast and transported to the orepass. Efficiency can thus be improved by changing the typical cycle to one in which all drilling is done first, followed by charging and loading. Then either one lift can be backfilled followed by the drilling of uppers, or both lifts can be backfilled, followed by drifting and then drilling of uppers.

Access to this one-drift-width cut-and-fill stoping is via an access ramp in the footwall. Often, where the wall rock is fairly competent, four slices are accessed from a given point on the ramp (Figure 6.5-12). In overhand cut-and-fill stoping, crosscut 1 is made first. When the slice is complete, the roof of the crosscut is slashed down to form crosscut 2. This continues for the four slices, at which time a higher point on the ramp is selected as the origin of the crosscuts. Generally the maximum crosscut inclination is limited to about 20°, although 12° to 15° is more normal. This sets the position of the ramp with respect to the ore body.

There are several variations of overhand cut-and-fill stoping using so-called ramp-in-stope development. This method has the advantage that development is in ore, although some development must still be done in the footwall. It can be applied to lower-grade deposits for which the development cost of conventional mechanized cut-and-fill mining cannot be justified, although overall operations are usually less efficient. One such mine development is the Bruce copper mine in Bagdad (Arizona, United States), described by Johnson et al. (1998). Another general description of ramp-in-stope cut-and-fill mining is in Pugh and Rasmussen (1998).



If the strength of the wall rock and ore is quite good, spans of more then two lifts can be created by means of the Avoca (rill mining or benching) mining method (Figure 6.5-14). In the figure, slices 1 and 4 are extracted by drifting (stage 1). Rows of vertical blastholes are then drilled from the floor of slice 4 to the roof of slice 1. A vertical slot is created and rows of holes are blasted one or more at a time toward the slot. Ore is extracted by an LHD unit operating in slice 1. At the same time that retreat extraction is under way, filling is being conducted from the opposite end of the stope (stage 2). A gap is maintained between the extraction and filling fronts to minimize dilution. When completed, slice 7 is removed by drifting (stage 3). Slices 5 and 6 are now removed using slice 7 as the drilling level and slice 4 as the extraction level.

If the extraction block is quite wide, the cut-and-fill method can still be used but now several drifts are driven side by side (Figure 6.5-15). This is similar to R&P (rib pillar) mining with the rooms being filled and the pillars then being extracted. Various techniques can be used to shape the drifts; the most common is shown in Figure 6.5-15C. Here, straight walls are used and every other drift is removed in a primary mining phase. Cemented fill is used to avoid dilution during removal of the interlying drifts. Another variation is to make the primary drifts narrow and the secondary drifts wide to minimize the use of cemented fill.

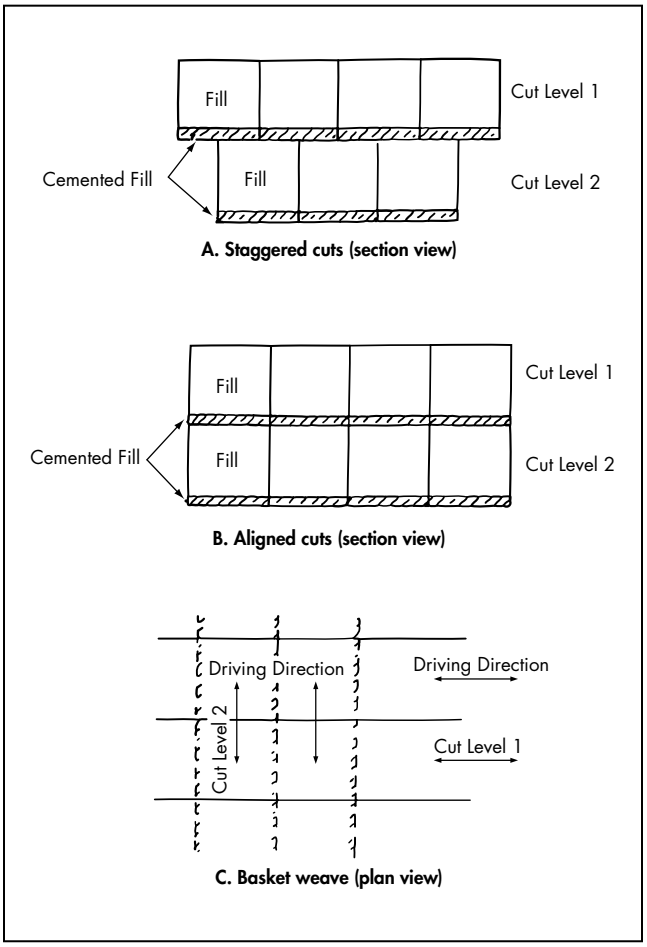
Figure 6.5-15 Drift-and-fill mining techniques

Source: Bullock and Hustrulid 2001.

Figure 6.5-16 Underhand cut-and-fill mining method

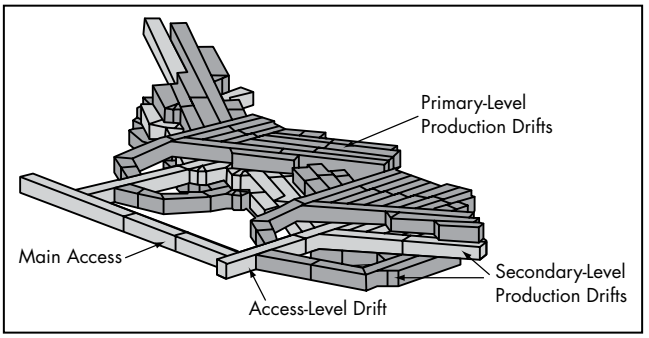
If the strength of the ore or hanging wall is very poor (e.g., in the range of rock mass rating [RMR] = 20 to 40, which might be the equivalent of a standup time [depending on the roof span] of 1 to 100 hours), then the underhand cut-and-fill mining method—often shortened to *undercut and fill*—can be used (Figure 6.5-16). The first slice is taken and then various techniques are used to prepare a layer that becomes the roof when the slice below is extracted. In the past, the most common mining method involved a timber floor pinned into the walls. It is now more common to pour a layer of cemented fill with or without reinforcement. The remainder (upper portion) of the drift can be left open or filled with uncemented fill. The next slice is then extracted under the constructed roof. A more common practice in North America is to use engineered cement or paste fills. When they are used for mining wide ore bodies, the material must be jammed tight to the back or previous floor.



From the same development access level, some mines use the overhand cut-and-fill method to work upward from this level and the undercut-and-fill method to work downward. This doubles the number of working faces in operation at any one time from a given level. Whether or not this is advisable depends on the ore/rock strength. Wide ore bodies can also be mined using the underhand cut-and-fill method (Figure 6.5-17A and B). The process is the same as described earlier but now cold joints occur between the individual drift floor pours. Generally, whether it be engineered fills, cemented fill, or a paste fill, it is better to avoid positioning drifts of the underlying layer directly under those above. It is acceptable to shift the drifts sideways or drive them at an angle to those above; the latter case results in a basket-weave pattern (Figure 6.5-17C). Undercut drifts are developed usually not on 90º angles but more commonly on 45º or 60º angles (Figure 6.5-18).

In thick, inclined, or very wide ore bodies that are appropriate for overhand cut-and-fill mining, vertical pillars are sometimes left to provide additional support between the hanging walls and footwalls in a method called postpillar mining (Figure 6.5-19). If possible, the pillars are located in internal waste or low-grade areas. On the lowest slice, an R&P mine is created and the rooms are then filled. A second slice is taken continuing along the vertical upward extension of the pillars and this level is then filled. The process continues thusly. This method is so named because the pillars appear as vertical posts surrounded by fill. Some consider it to be a subset of R&P mining, others to be a subset of cut-and-fill mining.

There are no set dimensions for the pillars and rooms in this mining method. In Figure 6.5-19, the small post pillars can vary from only 1.8 to 6 m (6 to 20 ft) square, and the rooms from 7 to 15 m (24 to 50 ft), depending on the rock-mass strength of the back. The idea is to maximize the extraction ratio while maintaining a safe working area. Because of the presence of the surrounding fill, even very tall and slender pillars can be quite strong. The method is often used to maximize initial recovery from R&P mining, and therefore no additional recovery is expected by means of retreat mining or pillaring. Of course, in all such cases, measures must be taken to ensure that the pillars are correctly aligned and vertical.



SUBLEVEL CAVING MINING METHOD

Sublevel caving was used initially in the United States for extracting soft iron ores in the iron ranges of Minnesota and Michigan. The method as practiced today differs significantly from that used earlier and should probably be given another name such as sublevel retreat stoping, continuous underhand sublevel stoping, or something similar that better reflects the process. Sublevels are created at intervals of 20 to 30 m (66 to 98 ft) beginning at the top of the ore body and working downward. On each sublevel, a series of parallel drifts is driven

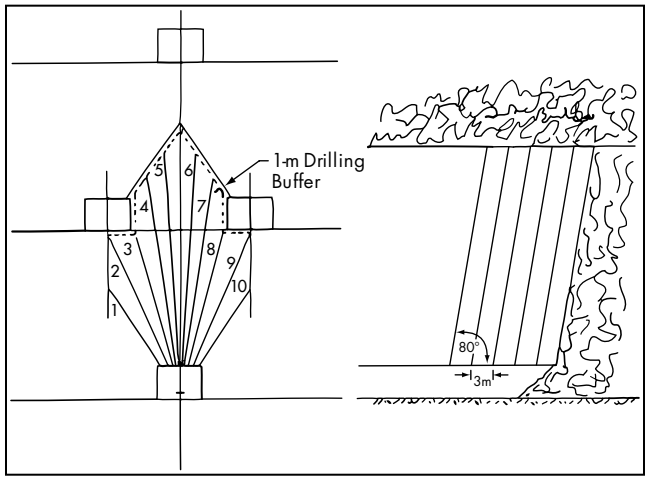
Figure 6.5-18 Undercut drift-and-fill mining method, showing a primary level and underlying secondary levels to be mined under backfill (Murray mine, Jerritt Canyon, Nevada, United States)

Note: Pillar and room dimensions vary according to the rock-mass strength of the back.

Figure 6.5-19 Postpillar cut-and-fill mining



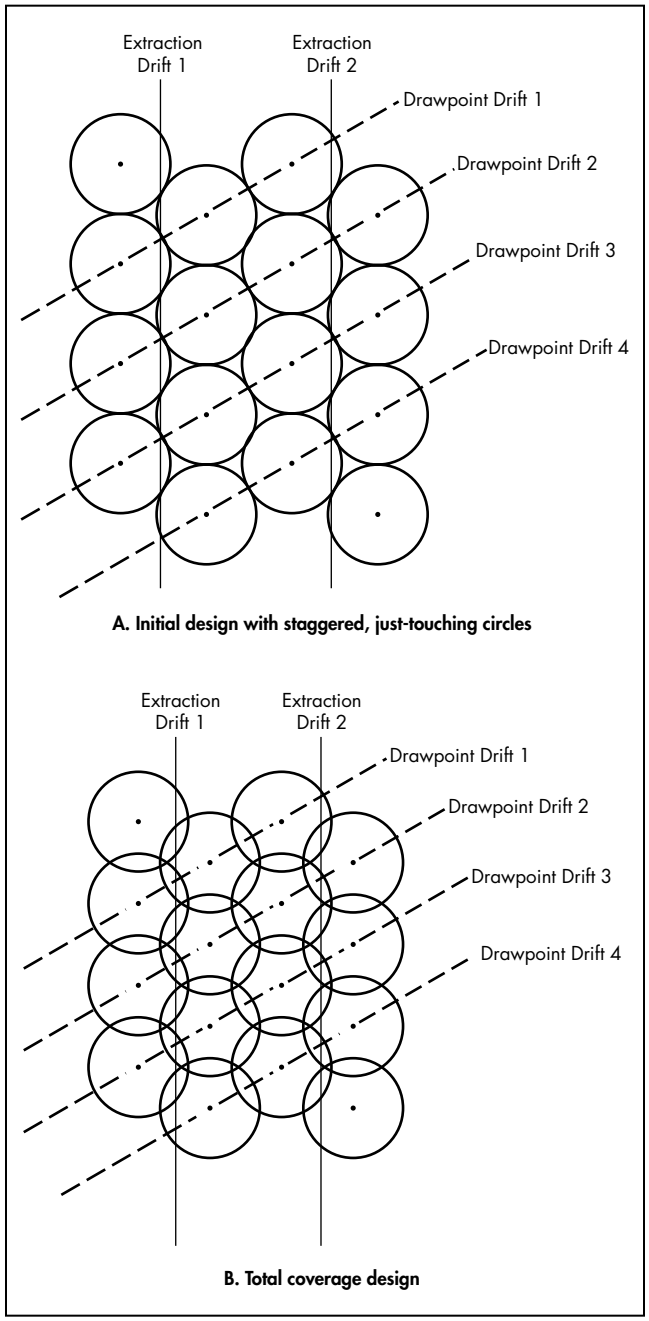
at a center-to-center spacing on the same order as the level spacing. From each sublevel drift, vertical or near-vertical blasthole fans are drilled upward to the immediately overlying sublevels. The distance between fans (the burden) is on the order of 2 to 3 m (6.5 to 10 ft). Beginning typically at the hanging wall, fans are blasted one by one against the frontlying material consisting of a mixture of ore from overlying slices as well as the waste making up the hanging walls and/or footwalls. Extraction of ore from the blasted slice continues until the total dilution reaches a prescribed mineral cutoff level. The next slice is then blasted and the process continued. Depending on ore-body geometry, the method can be used with transverse or longitudinal retreats.

Today, sublevel caving is used in hard, strong ore materials from which hanging-wall rocks readily cave. The key layout and design consideration is to achieve high recovery with an acceptable amount of dilution and ore loss. The uncertainties of fragmentation and ore cavability present in panel caving (discussed in the following section) are removed since each ton of ore is drilled and blasted from the sublevels. The method has been used most for mining magnetic iron ores, which can be easily and inexpensively separated from waste. However, it has been and can be applied to a wide variety of other ore types.

Sublevel Caving Layout

Ore is recovered by means of both drifting and stoping. Because the cost per ton for drifting is several times that for stoping, it is desirable to maximize stoping and minimize drifting. Thus, through the years, sublevel heights have steadily increased until today stopes are up to 30 m (98 ft) high. Whereas, in early designs, approximately 25% of the total volume was removed by drifting, today, in the largest-scale sublevel cave designs, that value has dropped to about 6%. Similarly, sublevel intervals have increased from 9 to nearly 30 m (30 to 98 ft). Key to this development is the capability to drill longer, straighter, and larger-diameter holes. Sublevel caving is an underhand method with all blastholes drilled upward. The ore moves down to the extraction/drilling drift by gravity.

A number of factors determine sublevel cave design. Sublevel drifts typically have dimensions (width × height) of 5 × 4 m (16 × 13 ft), 6 × 5 m (20 × 16 ft), or 7 × 5 m (23 × 16 ft) to accommodate LHD equipment. In the example used to illustrate the layout principles, the drift size is assumed to be 7 × 5 m (23 × 16 ft). The largest possible blasthole diameter, from the viewpoint of drilling capacity and explosive charging, is normally chosen. The maximum hole size in use today is 115 mm (4.5 in.), based largely on the capability to



Source: Bullock and Hustrulid 2001.
Figure 6.5-20 Sublevel caving ring design

charge and retain explosive in the hole. These large holes can be drilled using either in-the-hole or top-hammer drills. The large diameters and large drift sizes permit the use of tubular drill steel of relatively long lengths, which minimizes the number of joints and maximizes joint stiffness, so that the required long, straight holes can be produced. The largest ring designs incorporate holes with lengths of up to 50 m (164 ft).

A sample sublevel caving ring design is shown in Figure 6.5-20. The sublevel drift interval is decided largely based on the capability to drill straight holes. In this example, it is assumed that the sublevel interval based on drilling accuracy is 25 m (82 ft). When the sublevel interval has been decided, it is necessary to position the sublevel drifts. In this example, drifts are placed so that the angle from the upper corner of the extraction drift to the bottom center of the drifts on the overlying sublevel is 70°. This is about the minimum angle at which the material in the ring moves to the drawpoint. The resulting center-to-center spacing is 22 m (72 ft). A single-boom drill is assumed to drill all of the holes in the ring. The inclination of the side holes is chosen as 55° although holes somewhat flatter than this can be drilled and charged. The function of holes drilled flatter than 70° is largely (1) to crack the ore, which is then removed from the sublevel below; and (2) to reduce the maximum drill-hole length. Holes flatter than 45° are difficult to charge because of the angle of repose of the ore at the extraction front. In the final configuration of drill holes shown in the figure, a buffer zone 1 m (3.3 ft) wide has been left between the ends of the blastholes and the boundary to the overlying drifts and outer fan holes. The layout is similar to that obtained using the theory of bulk flow described by Kvapil (1982, 1992). The fans can be drilled vertically or inclined from the horizontal at an angle, typically 70° to 80°. Inclining the fans improves brow stability and access for charging the holes. In the example, the inclination of the fans is 80° and the burden is 3 m (10 ft).

To initiate mining of a new sublevel, an opening slot must be made toward which the fans can be blasted. Several techniques can be used, including blind hole boring and slashing, fan drilling with increasing inclination angles until the production fan inclination is reached, and creating an opening slot longitudinally along the hanging wall. For transverse sublevel caving, upon reaching the footwall, the inclination of the

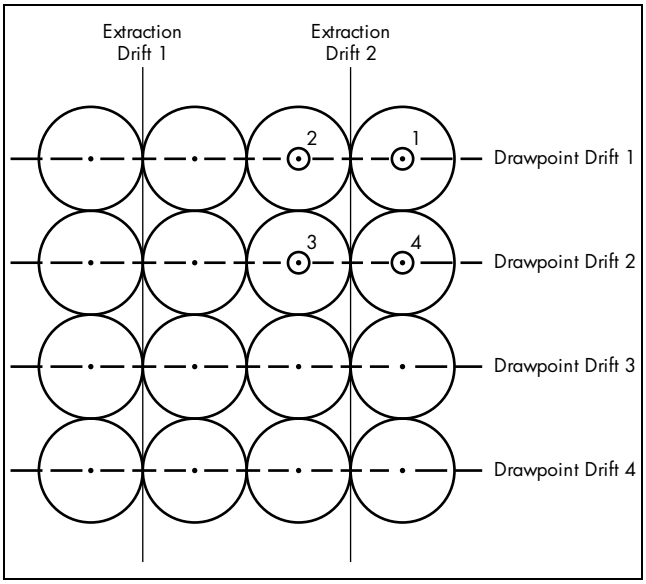
Source: Bullock and Hustrulid 2001.
Figure 6.5-21 Panel caving method

fans is sometimes steepened to permit recovery of additional ore and to minimize waste extraction. Figure 6.5-20 shows the importance of good drilling precision. If the forward or backward angular position due to incorrect initial alignment or in-hole deviation exceeds 2°, the ends of the longest holes find themselves in the wrong ring. Side-to-side angular deviations can mean that fragmentation is poor due to too little explosive concentration, dead-pressing of explosive, and so on. Thus, careful drilling is of the utmost importance for successful sublevel caving. (*Dead-pressing of explosive* means that the explosive density has increased, by detonation of another nearby blasthole, to the point that the explosive can no longer

detonate. This is most likely to happen with fairly insensitive explosives. More sensitive explosives are more likely to detonate sympathetically rather than become dead-pressed.)

Recovery and Dilution

Sublevel caving lends itself to a very high degree of mechanization and automation. Each of the different unit operations of drifting, production drilling, blasting, and extraction can be done largely without disturbance from the others. Specialized equipment and techniques have been developed leading to a near-factory-like mining environment. As indicated earlier, because every ton of ore is drilled and blasted, there are no longer the uncertainties regarding cavability and degree of fragmentation as occur with block caving. However, a very narrow slice of blasted ore surrounded by a mixture of waste and ore must be extracted with high recovery and minimal dilution. As is easy to visualize, the ore at the top of the ring in the example is more than 40 m (130 ft) away from the extraction point, whereas the waste–ore mixture lies only the distance of the burden in front of the drill ring pattern, on the order of 3 m (10 ft). With care, recoveries on the order of 80% with dilution held below 25% can be achieved.



PANEL CAVING MINING METHOD

The term *panel caving* here represents block caving (suggesting the mining of individual blocks) as well as panel caving (used today mostly to indicate a laterally expanding extraction). As one would expect, the system has a great number of variants.

For panel caving, the three most important elements of the extraction system are (1) the undercut level that removes the support from the overlying rock column, (2) the funnel through which rock is transported downward to the extraction level, and (3) the extraction level itself. The basis for system design and performance is the degree of fragmentation present as the rock blocks enter the top of the funnel. In the early days of block caving, it was always considered essential that the materials be soft and cave readily. Today, the trend is to use cave mining on ever harder and tougher ores. As a result, the engineer must thoroughly evaluate the ore body and tailor the design so that successful extraction will result. This is the least expensive mining system, as measured by extracted tons. However, it requires a large amount of testing during the feasibility study, and thus only an engineer who is experienced in panel caving design should attempt to design a panel caving system.

Extraction Principles

Assuming the use of LHD equipment, the major development on the extraction level consists of extraction drifts, drawpoints, and extraction troughs/bells. To simplify discussion, it is assumed here that all drifts have the same cross section. Design is iterative and it is not always obvious where to begin. In this case, one begins with knowing or assuming the size of the material that must be handled. The physical size of the loading equipment is related to the required scoop capacity, which, in turn, is related to the size of the material to be handled. If fragmentation is expected to be coarse, a larger bucket and larger machine are required than if the extracted product is expected to be fine. Knowing the size of the machine, one arrives at a drift size. The orepass diameter should be 3 to 5 times the anticipated largest block size in order to avoid hang-ups. By this rule, the extraction opening should be about 5 to 7 m (16 to 23 ft) for block sizes up to 1.5 m (5 ft). Depending on density and shape, such a block would weigh 5 to 10 t (5.5 to 11 st). A large piece of equipment is required to handle such blocks. It is typical for extraction drifts to be sized according to width/height ratios $w{:}h$ = 4:3, 5:4, and 6:5. For the machine in the example in this section, the drift size would be about 5 × 4 m (16 × 13 ft) or larger.

Source: Bullock and Hustrulid 2001.

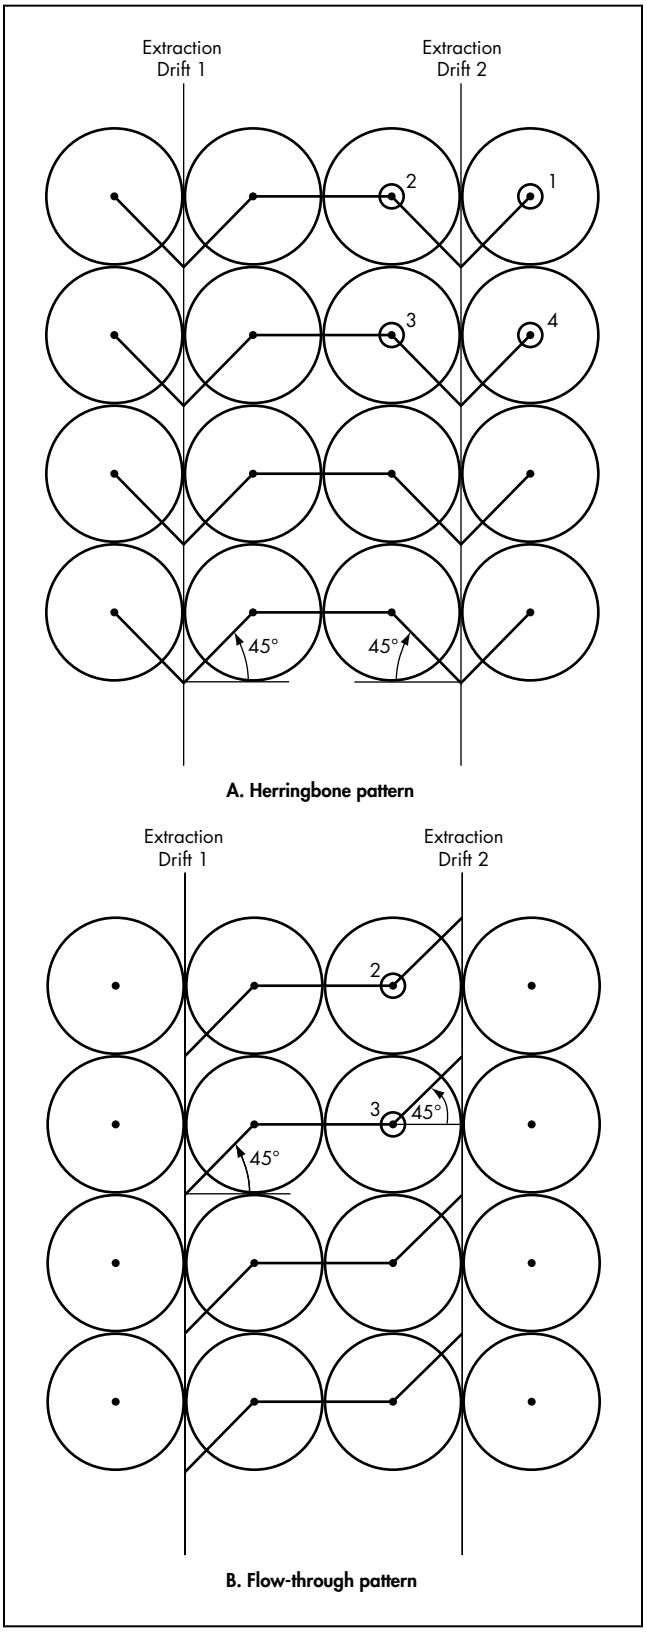


Figure 6.5-22 Panel caving method, showing square layout of extraction and drawpoint drifts

To begin the design of the extraction level, one creates a grid of extraction drifts that are to be traversed by LHD units and the lines of the associated drawpoints. In practice, a series of circles of radius R corresponding to the draw radius of influence on the undercut level are first drawn. Figure 6.5-21 shows two such patterns for staggered coverage with the locations of the extraction drifts superimposed. The value of R depends on the degree of fragmentation, and is larger for large fragments and smaller for finer fragments. This presents a design problem, since fragmentation is generally larger in the initial stages than at the later stages of draw.

The degree of desired coverage is an important design factor. The case of "just-touching" (Figure 6.5-21A) shows that triangles between the circles are not covered. Moving the circles to achieve greater overlap gives, finally, the case of total coverage (Figure 6.5-21B). In this example, it is assumed that R = 7.5 m (25 ft) and a square just-touching drawpoint pattern is used.

Figure 6.5-22 shows the locations of the extraction drifts, drawpoint drifts, and drawpoints on the extraction level. For extraction drift 2, drawpoints 1 and 2 are associated with drawpoint drift 1 and drawpoints 3 and 4 are associated with drawpoint drift 2. The figure shows that two draw circles are associated with each drawpoint in this design. For drawpoint 1, the draw circles are 1 and 4; for drawpoint 2, the draw circles are 2 and 3.

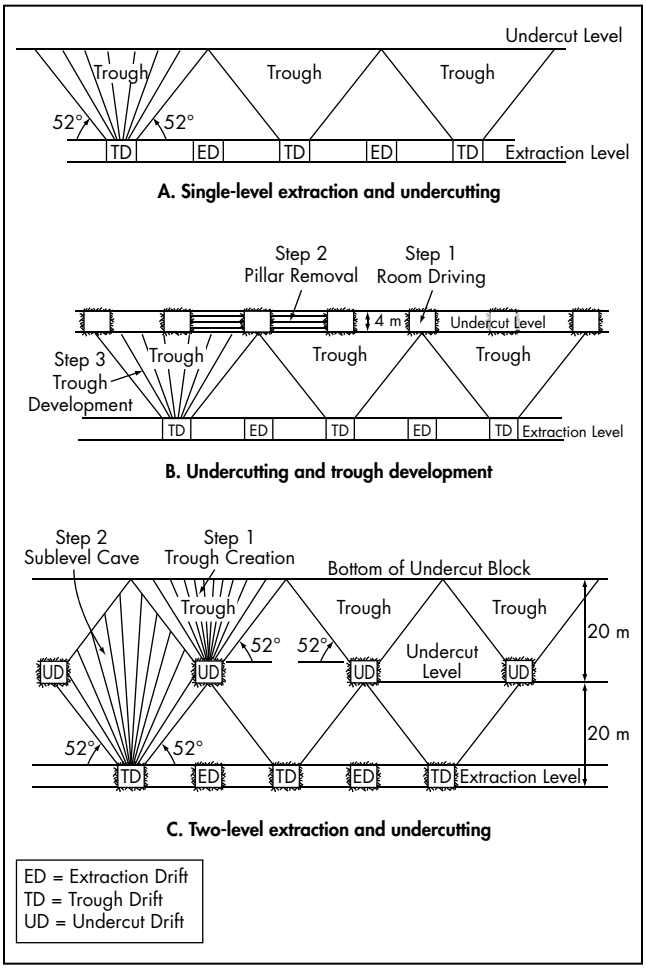
In continuing the design example, one must decide the orientation of the drawpoint drift with respect to the extraction drift. Figures 6.5-23 shows two possibilities involving the use of a 45° angle. Careful examination reveals that the choice affects both loading direction and ease with which openings

Source: Bullock and Hustrulid 2001.

Figure 6.5-23 Panel caving method, showing drawpoint drifts

can be driven. A drawpoint entrance made at 60° to the axis of the extraction drift is at a very convenient angle from the loader operator's point of view. Some designs use 90° angles (square pattern), enabling loading to be done from either direction; however, although 90° pillars provide good corner stability, loading is more difficult. When considering different drawpoint design possibilities, loading machine construction must be taken into account. It is important for the two parts of the LHD unit to be aligned when loading to avoid high maintenance costs and low machine availability.

As mentioned previously, the extraction level must be designed according to the degree of fragmentation expected, so that the openings are large enough to permit extraction. However, large openings are prone to stability problems and, because openings must last for the time required to extract the overlying column of ore, it is important that design, creation, and reinforcement of the openings be done with care. Fortunately, for harder rocks yielding coarser fragmentation, although one expects the ore to be coarse, the host rock is also strong and provides good construction material. For softer rocks yielding finer fragmentation, the openings should be smaller. Protecting the integrity of the openings is of the highest importance and is discussed in more detail in the next section.



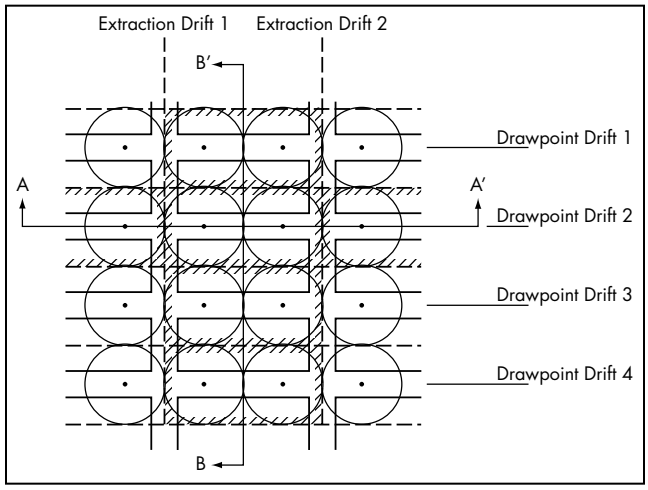
There are a large number of design possibilities for the extraction level. All involve the basic components of fragmentation, radius of influence, draw coverage, machine size, and drift size, which should be examined in roughly that order.

Undercutting and Formation of the Extraction Trough

In the undercutting process, a slice of ore forming the lower portion of the extraction column is mined. As this drilled and blasted material is removed, a horizontal cavity forms beneath the overlying intact rock. Because of the presence of this free surface, subhorizontal side stresses, and the action of gravity, the intact rock undergoes a complex process involving loosening, crushing, and caving. The ease with which intact rock transforms into a mass of fragments is called its characteristic *cavability*. One approach to addressing a material's cavability is to describe the size and shape of the area that must be undercut to promote caving. The other, and more important, approach is to describe the fragment size distribution. The latter is much more difficult to predict, but ultimately more important from a design viewpoint. In this section, both the undercutting process and the design of the trough required to deliver the resulting fragments to the extraction level are described.

The simplest design is to combine undercutting and trough formation into a single step. As described in the previous section, a series of parallel extraction drifts are driven. The center-to-center spacing of the drifts is determined by the size of the influence circles. This example uses the plan layout of Figure 6.5-22. The center-to-center spacing of the extraction drifts is 30 m (100 ft) (4*R*). A series of parallel trough drifts are now driven between the extraction drifts. Starting at the far end of the extraction block, fans of holes are drilled and then blasted toward opening slots.

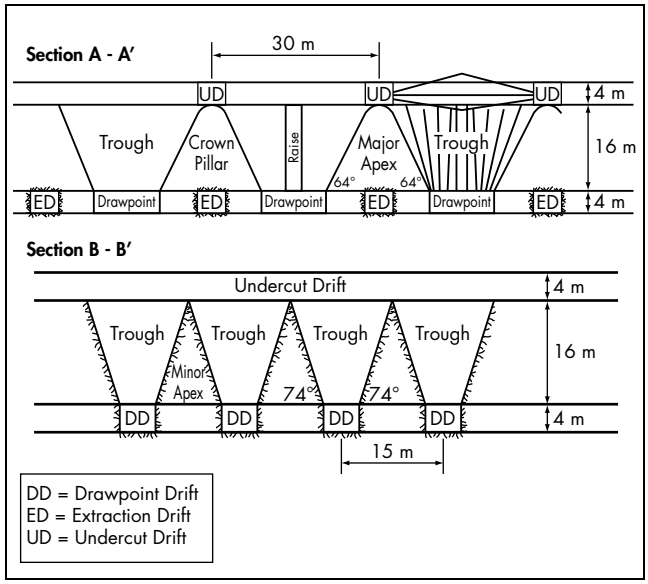
Figure 6.5-24A shows an example in which the side angles of the fans are 52° and the resulting vertical distance between the extraction level and the top of the undercut is 20 m (66 ft). The trough drifts and troughs can be created either before or after the extraction drifts are driven. The latter case is called



Source: Bullock and Hustrulid 2001.

Figure 6.5-24 Panel caving methods

advance or pre-undercutting. An advantage of this design is that all development is done from one level. An example of the use of this design has been presented by Weiss (1981).



Most mining companies using panel caving have separate undercut and extraction levels. Figure 6.5-24B shows the undercut level designed as a rib pillar mine. The rooms are 5 × 4 m (16 × 13 ft) and the room center-to-center spacing is 15 m (50 ft). In step 2, the interlying pillars are drilled and blasted. In step 3, extraction troughs are created to complete undercut/trough development. It is possible and often desirable to develop the undercut level first, followed by the extraction level.

Figure 6.5-24C shows an alternative design for the same basic extraction-level layout. A separate undercut level has been used with the undercut drifts spaced 30 m (100 ft) center to center. From these drifts, fans of holes are drilled to form a trough. The angle of the side holes has been chosen as 52°. The undercut drifts are positioned directly above the underlying extraction drifts. When the undercut has been created, a sublevel-caving-type fan pattern is drilled from the trough drifts on the extraction level. This completes development. The total height of the undercutting in this case is 40 m (132 ft), which has some advantages in the caving of harder rock types because it greatly increases the undercut volume, thus inducing caving, and the greater volume improves secondary breakage of the harder rock.

Figure 6.5-25 Panel caving showing plan view of traditional bell development

Source: Bullock and Hustrulid 2001.

Figure 6.5-26 Panel caving showing sectional views of traditional bell development

Figures 6.5-25 and 6.5-26 show plan and section views of a more traditional undercutting and bell layout for panel caving. The previous examples use primarily extraction troughs to demonstrate the principles involved. A trough has the advantage of simplicity of construction but the disadvantage that additional rock is extracted during development. This rock, if left in place, can provide extra stability to both the extraction drifts and the drawpoints. Drawbells are created rather than troughs. The first step in drawbell construction is to drive a drawpoint drift connecting adjacent extraction drifts. A raise is driven from this drift up to the undercut level. Fans of drill holes are then drilled from the drawpoint drift around the opening raise to form the bottom of the drawbell.

Fans of holes are also drilled from the undercut drifts to complete bell formation. A disadvantage of this method is that the amount of development and level of workmanship required is higher than for trough design. As a result, it is more difficult to automate.

For all designs, it is important that a complete undercut be made. If this is not done, very high stresses can be transmitted from the extraction block to the extraction level, causing major damage. Traditionally, the extraction level has been prepared first, followed by creation of the undercut and completion of the drawbells. This procedure has a number of advantages.

Unfortunately, however, very high near-vertical stresses are created just ahead of the leading edge of the undercut. These stresses are transmitted through the pillars to the extraction level and can induce heavy damage to the newly completed level. The result is that repairs must be made before production can begin. The concrete used for making the repairs is generally many times weaker that the rock that has been broken, and the structural strength can never be completely restored.

An alternative to this procedure is to create the undercut first (advance undercutting), thereby cutting off the vertical stress. The extraction level is then created under this stress umbrella. Where this has been done, conditions on the extraction level are markedly improved over those where undercutting was done afterward. Both techniques have advantages and disadvantages, but advance undercutting is preferred for most future mines.

Block Size

The size of a block refers both to the height of the extracted column and its plan area. In the early days of block caving, block height was on the order of 30 to 50 m (98 to 164 ft). With time, this has increased to the point that extraction heights of several hundred meters are now being used or planned. Obviously, because specific development is inversely proportional to the height of the block, there are incentives to make the extraction units as high as possible, within the restrictions imposed by factors such as ore-body geometry and mineral type. Limits are also imposed by the life of the extraction points. If the anticipated life of the extraction point is, for example, 100,000 t (110,000 st), there is no point in selecting a block height yielding 200,000 t (220,000 st) per drawpoint.

Drawpoints can be rebuilt but it is best if they can last the life of the draw. As mentioned earlier, most caving today is done in the form of panel caving rather than the caving of individual blocks. After the initial cave is started, the lateral dimensions are expanded. Cavability affects the size of the undercut that must be created to get a sustainable cave. Relationships have been developed among rock-mass characteristic, hydraulic radius (area/perimeter), and ease of caving. It is possible, unfortunately, to begin initial caving and then for a stable arch to form. The undercut area must then be expanded and/or other techniques such as boundary weakening must be used to get the cave started again. With a sufficiently large undercut area, caving can be induced in any rock mass, which is necessary but not sufficient for successful block caving. Another factor that affects the size of the undercut is the degree of fragmentation that results. Because panel caving is being considered for application to ever stronger rock types, both of these factors—cavability and degree of fragmentation—must be satisfactorily addressed before any method is selected. Unfortunately, the database upon which such decisions must be taken is very limited.

Cave Management

Cave management refers to maintaining control over how much is extracted from each drawpoint each day. It involves a number of different factors. The rate of draw is an important parameter in planning the required area under exploitation. Loosening of fragments appears to be a time-dependent process and must be recognized in planning the draw. The rate must not be so rapid that a large gap results between the top of the cave and the bottom of the block. Sudden collapse of the rock above can result in disastrous air blasts. In high-stress fields, too-rapid draw can cause rock-bursting conditions. In the drawpoint area, there is a zone in which the height of the column under draw increases from near zero (where extraction is just beginning) to the full column height. This is followed by a zone in which the ore-column height decreases to near zero where extraction is complete. It is important to maintain the proper ratio of draw height to slope distance to avoid early introduction of waste from above. Poor cave management can also mean buildup of high loads in various areas and subsequent stability problems. Typical rates of draw, taken from the available literature, are on the order of 0.3 to 0.6 m/d (1 to 2 ft/d).

The proper sequencing of undercut and extraction is a very important aspect of cave management. Unfortunately, relevant design guidelines are difficult to obtain from the literature.

An important design consideration for the extraction level is the means by which oversize is handled. There are a number of different problems to address. The first concern is the management of true hang-ups at the extraction points. Sometimes these can simply be blasted down by careful placement of explosives. At other times the boulders must be drilled first. This is not a simple procedure and involves danger to both machines and humans. The second concern is where and how to handle the movable oversize. These blocks can be (1) handled at the extraction points, (2) moved to a special gallery for blasting, (3) moved to an orepass equipped with a grizzly and handled there, or (4) dumped directly into an orepass for later handling. All variations are used and each company has its own procedures.

Initially, the sizes of blocks arriving at the drawpoints are defined by natural jointing, bedding, and other weakness planes. As blocks separate from the parent rock mass, they displace and rotate with the loose volume, occupying a larger volume than does the intact mass. The swell volume is extracted from the extraction points, providing expansion room for the overlying intact rock. Loosening eventually encompasses the entire column. As the column is withdrawn, the individual blocks abrade and split, resulting in finer fragmentation than in the early part of the draw. The initial fragmentation due to initial fractures in the rock is called primary fragmentation. As the column moves downward and new breakage occurs, the resulting fragmentation is called secondary fragmentation. Data concerning this transition from primary to secondary fragmentation are very difficult to obtain.

CHAPTER 6.6

Comparison of Surface Mining Methods

Ernest Bohnet

INTRODUCTION

Each mining operation is unique in some aspect—ownership; ore-body location, size, geometry, grade, mineralogy, hydrology, or geotechnical parameters; or constraints such as environmental regulations. However, all mining operations are alike in one way—the prime objective of any mining project is to maximize the return on investment. This is the golden rule, or in the language of mining, the investor's "Law of Conservation."

A mineral resource, by definition, does not become a mineable reserve unless the mineral or minerals can be extracted economically (and legally). The choice of the most economic method is dictated primarily by the type of deposit to be mined, the mining rate, and the physical characteristics of the deposit.

A comparison of surface methods must take into consideration two prime objectives of mine planning: to develop the most economic plan for the overall project that will maximize the return on the monies invested and to maximize the recovery of the resource. Surface mines can be subdivided into various classes and subclasses, which can be illustrated as follows:

Class	Subclass	Method
Mechanical	—	Open-pit mining
		Quarrying
		Strip mining
		Auger mining
Aqueous	Placer	Dredging
		Hydraulic mining
	Solution	Surface techniques
		In-situ leaching
		Evaporite processing

The purpose of this chapter is to discuss the relative advantages and applications of one method versus another, as well as some of the more important evaluation parameters that must be considered in any method comparison.

FACTORS AND CONDITIONS

Open-pit mining and strip mining are the two most dominant types of surface mining methods in the world, accounting for approximately 90% of the surface mineral tonnage. Strip (open-cast) mining is used for large, tabular, flat-lying ore bodies or mineral seams, such as coal, that are relatively close to the surface. Backfilling of these mines is usually economically feasible and desirable as part of the concurrent reclamation requirements.

Open-pit mining is typically applied to disseminated ore bodies or steeply dipping veins or seams where the mining advance is toward increasing depths. Backfilling usually cannot take place until the pit is completed; even then, the prohibitive cost of filling these pits with all of the waste rock removed at the end of the mine life would seriously jeopardize the project's economics. Very few large open pits in the world could support such a costly handicap.

Aggregate mines produce a bulk commodity for local markets. These quarries employ the same mining methods as other open-pit mines.

Seam deposit mining, like coal, uses different planning methods and terminology as compared to open-pit mining for base and precious metals. However, all surface mining methods have one common element: mining proceeds until the economic or legal limits are reached. The method of determining the economic limit is different for the two types of deposits. Coal, for example, in most instances, is readily distinguished from waste rock and is of a near-uniform quality and value per ton mined in each seam. Therefore, mine design limits are determined by the break-even strip ratio, commonly defined as cubic yards (cubic meters) of waste to tons (metric tons) of coal that can be mined. Since 1 ton of coal is approximately equal to 1 yd^3 (1 t ≈ 0.84 m^3), the ratio is similar to a volume ratio.

The pit limits for a disseminated deposit, such as base or precious metals, is determined by a break-even economic analysis of the value of a finite incremental pit expansion. This economic analysis is a two-step process where first the net operating value is determined for each ton of material in a

Ernest Bohnet, Vice President of Mining and Geological Services, Pincock Allen & Holt, Denver, Colorado, USA

block model, above and below the ore cutoff grade. Second, the pit limits are determined by expanding the pit shape in increments to a break-even point where the net operating margin equals the cost of waste stripping. Given that each ton of ore has a different grade and net value, a break-even stripping ratio cannot be used in the determination of the pit limits.

As a final test, the increment between an existing pit wall to the economic limit must have sufficient width for the proposed mining method. Complicating this matter further is the potential for multiple ore processes, such as milling and leaching of the same ore type. Milling is a higher cost process method used to increase metal recoveries, whereas leaching is a slower process with correspondingly lesser recoveries and lower costs.

Therefore, the mining engineer must have sufficient knowledge of the overall project, from ore geometries to the process extraction methods, in order to maximize the project return on investment. This includes an awareness of all cost and recovery parameters, as well as the factors that affect the value of the salable product. For example, where process capital and operating costs are high, ore selectivity and the choice of appropriate mining method play important roles in mine design. Mining cost increases that may be required to optimize the project's return can be more than offset by reduced process capital and operating costs per unit of salable product.

The total amount and type of material to be moved per time period, coupled with ore-body geometries, are the prime criteria in selecting the most economic and applicable mining method.

Other factors that affect the type of mining method as well as type and size of equipment include

- Topography;
- Remoteness of operation;
- Support infrastructure;
- Availability and cost of skilled labor;
- Climate and altitude;
- Environmental, legal, or physical boundary restrictions;
- Groundwater quantities;
- Slope stability and ground conditions;
- Investment risk;
- Blasting restrictions;
- Life of operation; and
- Waste rock disposal.

Topography can play a major role in selecting the most appropriate mining method. Generally, the more rugged the topography, the more limited are the choices of mining method and level of overall production.

Remote operations require substantial infrastructure to maintain the standard of living needed to attract a well-qualified work force. Therefore, the mining and processing methods selected must result in high productivities per employee shift. Better ore selectivity in the mine will reduce process plant requirements and could, therefore, reduce overall staffing requirements. If the ore grade can be raised sufficiently, the ore may be transported off-site for processing at a less remote location. Large equipment can be used for the bulk of the waste stripping and small equipment employed to selectively mine the ore.

Where labor costs are high, the same philosophy can be applied. Lower labor costs and the level of labor skills available can also affect the choice of mining method. For example, front-end loaders and mechanical drive trucks will require less diverse maintenance skills as compared to the labor force needed to maintain electric/hydraulic shovels and electric haul trucks.

With adverse climatic conditions, mining operations may be seasonal. Seasonal and short-life operations may use contractors for all mining operations or for only the bulk waste stripping.

Environmental and social considerations play an increasingly important role in the type of mining operation permissible. Open pits in populous areas may require backfilling, whereas the same type of operation in a remote location may have minimal environmental constraints. For example, hydraulic mining, outlawed in California (United States) in 1884, was used to remove the unconsolidated overburden at the Bougainville Copper mine (Papua New Guinea) in 1969–1971. Environmental and aesthetic conditions may be so restrictive in some areas as to eliminate surface mining options altogether. In some cases, this forces the use of underground mining, which will result in reduced mineral resource recovery.

Groundwater conditions and slope stability can play an important role in mining method options, mine design, production scheduling, and equipment selection. A large dragline may not operate safely where ground conditions are wet and unstable and the risk of slope failure is high. If large water inflows are anticipated, mining may have to be accelerated to avoid high pumping costs from a lengthy operation. Ore can be stockpiled at the processing plant and treated months (or even years) after the mine is completed.

The risk of investment varies from country to country; however, if risks are high, then capital expenditures are usually minimized. Front-end loaders, with shorter useful lives and lesser capital costs, are preferred over large shovels and draglines. The larger the project and the longer the development period, the greater the investment risk.

Blasting restrictions due to the operation's proximity to populous areas or in foreign countries with explosive use constraints can also affect mining method selection. Continuous mining machinery similar to pavement cutters or ripping can be used in some circumstances as an alternative to drilling and blasting.

Available waste disposal areas may be located a significant (trucking) distance from the surface mining operation. A viable alternative in this situation is crushing and transporting of the waste via a line of conveyor belts, and this in turn can affect the mining methods. Where the ore has a high value per ton, in excess of 100 times the cost of mining, very high strip ratios can be economically justified, as well as underground mining methods. The surface mining method in these circumstances is designed to be primarily a waste removal operation. Ore mining is a small cost component of the overall operation, and great emphasis must be placed on efficient waste production and mining methods. Given that most open-pit and strip mines have waste-to-ore ratios higher than 1:1, the majority of surface mines are waste rock operations. It is, therefore, important to ensure that any effort to reduce ore mining costs does not increase waste mining costs. For example, in a coal stripping operation using shovels and trucks, usually a slot is left on one side of the backfilled pit for coal haulage to minimize coal mining costs. This slot prevents efficient waste haulage around both sides of the pit, thereby increasing waste haulage distances and costs significantly. As strip ratios increase, the mining method and haul road system will require modification to allow more effective waste transportation and reduced overall mining costs. Digging conditions including the size

of the broken material will impact the choice of hydraulic/cable shovel, dragline, bucket-wheel excavator, and front-end loader.

Quarrying is a special type of open-pit mining used to produce aggregates and dimension stone products. In dimension stone quarries, rock joint fractures are infrequent, and, therefore, the bench faces are vertical. The lack of fractures often permits near-vertical highwalls that can approach up to 1,000 ft (300 m).

Auger mining is primarily used to remove coal from under a final highwall. The final highwall position is determined by economic stripping limits, property boundaries, or physical constraints such as a body of water.

In the case of physical constraints, auger mining may be the only alternative to increase the amount of coal recovered. However, if the highwall position was determined using a break-even stripping ratio analysis, the cost of stripping the final 100 to 300 ft (30 to 100 m) break-even increment should be compared to auger mining costs and profitability.

Aqueous surface mining methods, uniquely involving the use of water for extraction, can be used in special circumstances. The mining of placer-type deposits that contain concentrations of heavy metals in unconsolidated overburden are particularly suitable to dredging and hydraulic mining if an adequate water supply is available and the mining operation can comply with the applicable environmental regulations.

Hydraulicking, now often termed *hydraulic mining*, ideally requires the presence of a natural gradient away from the deposit to facilitate hydraulic transport of the resultant ore or waste slurry to the process or disposal area.

Dredging can be used if a natural or human-made body of water overlies the placer deposit. Dredging machines can be classified as mechanical, bucket-line, bucket-wheel suction, and dipper; or hydraulic, suction, and cutterhead. The type of dredging equipment selected depends on the type of material to be excavated.

Solution mining using surface or in-situ techniques is applicable to deposits of minerals that can be recovered usually by dissolution, but also by melting, leaching, or slurrying. The two methods are similar and are differentiated primarily through the location and the type of minerals recovered. Surface leaching generally employs heap (or dump) leaching of mineral values; copper, gold, silver, and uranium are common examples.

In-situ mining uses barren solution, introduced down one set of wells, and the loaded solution returns to the surface through concentric or another set of wells. This mining method is primarily used with sulfur, evaporite, or water-soluble minerals. In-situ leaching uses chemical or bacteriological reagents, usually mixed with water, to selectively dissolve the valuable minerals. Drill holes are typically used to inject and recover the solution. Extraction may also be enhanced by rubblization of the ore zone prior to solution application. Solution mining will increase in the future as more effective reagents are developed and application methods are improved.

The preceding discussion has focused primarily on factors and conditions that can affect surface mining options. New technologies will result in a greater range of alternatives in the future. Therefore, the mining engineer needs to continually review these developments as applicable to each old and new situation encountered. Basic assumptions must be revisited to ensure that past assumptions of extraction are still the most economically viable in light of new developments. Mining is dynamic in nature; therefore, mining methods will continue to evolve to meet new economic, social, and environmental conditions.

DEVELOPMENT VERSUS THE PRODUCTION SEQUENCE IN OPEN-PIT AND STRIP MINING

Selection of the most suitable mining method and the most appropriate size and type of equipment are closely associated. The following discussion primarily addresses loading and hauling fleets, as applied to quarries, strip mines, and open-pit operations.

The size of the operation over time has a direct bearing on the type of equipment selected. Loading and hauling fleets are dependent fleets, and, therefore, the effectiveness and availability of each affects the fleet requirements of the other. For example, if a mining operation had only one large shovel, the truck production would only be effective when the shovel is operable and broken rock is available at the shovel face for loading. Therefore, to have an effective operation, more than one unit per equipment fleet is desirable. A mining operation should have at least one drill per shovel and at least one backup shovel/loader to load trucks when a shovel breaks down or has to undergo a scheduled maintenance shutdown.

Large mining operations require time to develop sufficient working areas for effective use of the equipment. Therefore, the equipment selected for full production may not always be suitable for the development period of each pushback. The development (or preproduction) period may require different mining methods because of lesser material movements and different types of material to shift. During the development stage, access haul roads need to be constructed, and in rugged terrain, bench widths may be much narrower than those available during production. Therefore, smaller equipment may be needed during this stage of mine development.

Sufficient time must be allowed in the production schedule to drill, blast, and remove the material from the mine. Narrow benches do not allow continuous mining unless access for drilling and blasting is provided in the plan.

During preproduction and during the stripping phase of each mining sequence, taller benches may be used. For example, stripping may be accomplished on 40-ft (12-m) benches and ore production on 20-ft (6-m) benches to minimize ore dilution. The advantages of higher benches include the use of larger equipment, minimal access construction, and overall cost reductions. However, taller benches will also increase the vertical lift for all material below the pit exit elevation.

Large open-pit and strip mines are subdivided into smaller phases that are sequenced to optimize project economics. The objectives of dividing a surface mine into a development phase and then production phases are to

- Minimize preproduction stripping requirements to obtain sufficient stripped ore reserves to sustain production;
- Shorten the time between stripping and ore production;
- Develop the highest net-value ore first and mine the lowest net-value ore later;
- Avoid high stripping peaks that result in excessive equipment purchases and labor requirements;
- Blend the ore (or coal) to produce a less variable product; and
- Optimize equipment fleets for each of the development and production phases.

The development and production sequencing requirements must be considered in selecting the most appropriate mining equipment types and mining method.

METHOD ADVANTAGES AND DISADVANTAGES

The advantages and disadvantages of one type of surface mining versus another are often related to the types of equipment used and the associated costs and benefits derived from their use. In the following discussion, emphasis is placed on the mechanical extraction methods generally used in open pits, quarries, and strip mining.

Strip mining has the greatest choice of equipment, particularly for the mining of relatively flat-lying coal seams in gentle topography. In the following discussion, the various types of mining methods and equipment applications for strip mining (using draglines, shovels, bucket-wheel excavators, conveying systems, and combinations of these types of systems) as well as those for open-pit mining (usually limited to shovel/truck or front-end-loader/truck-type operations) will be discussed. (Shovel/rail-type operations of the past have almost been phased out in favor of the greater flexibility of mining with truck haulage.)

Open-pit loading equipment is usually matched with haul trucks that can be loaded in four to six passes. The choice of loading unit is dependent on total production requirements, the minimum number of active work areas, ore selectivity, and blending requirements. Additional factors to be considered are the type of material to be loaded and the ground and digging conditions. In hard digging or with sharp rock in wet climates, tracked shovels are preferable over rubber-tired loaders. However, if the mine production requirements are relatively small or the mine life is short, the lower capital cost of front-end loaders must be considered, particularly in high-risk investment areas.

The rubber-tired loader is commonly used to load material that is described as easy to medium digging and for operations requiring less than 100,000 tons (90,000 t) of daily material movement. Loaders are highly mobile and, therefore, are ideally suited for situations requiring frequent movement from one mucking face to another for ore blending requirements. Loaders also can be used to load, haul, and dump material into a crusher from blending stockpiles dumped near the crusher. Some operations have a mismatch of large shovels and a small crusher. A mismatch occurs when the crusher rating of tons per hour is much less than what the shovel can produce through the truck fleet. If this situation occurs, there are advantages to stockpiling the material at the crusher to avoid truck dumping delays and thereby maximize shovel and truck productivities. The extra cost of a stockpile-rehandling loader is more than offset by the increase in shovel and truck productivities and their respective reduced fleet requirements.

Loader cycle time is approximately 25% to 50% greater than a shovel's cycle time. Therefore, a loader has to be 25% to 50% larger (bucket capacity) than a shovel to attain the same productivity. In addition, loader availabilities are typically less than a shovel's, and this factor also needs to be considered in sizing the loader fleet. The loader bucket-fill factor is usually less than a shovel's in medium to hard digging. Hydraulic shovels have similar limitations and advantages as a cable shovel. The hydraulic shovel is typically not used in very hard digging. Hydraulic shovels are available in a range of sizes comparable to front-end loaders. However, because the larger sizes over 30 yd^3 (23 m^3) are not common, large cable shovels are used as the prime loader at mines where production requirements are in excess of 200,000 tpd (180,000 t/d).

Hydraulic shovels can effectively load from smaller bank heights than can cable shovels; therefore, if ore selectivity is very important, these shovels can improve ore selectivity and minimize dilution. A hydraulic shovel has additional advantages over a cable shovel in the sense that the bucket can be vertically positioned anywhere in the mucking face and selectively load from either the top half or bottom half of the face. This advantage is particularly useful in mining seam deposits where waste separation from the seam is necessary, or in some precious metal (gold) deposits that have highly variable grades and/or oxide–sulfide mineralization contacts. Hydraulic shovels are also more mobile and require less infrastructure because they are diesel versus large electric cable shovels with trailing cables, cable crossings, and power lines in the pit. There are capital and operating cost trade-offs as mentioned.

Hydraulic shovels can also be equipped with a backhoe-type loading bucket. This permits the shovel to sit on top of the bench and load trucks that are positioned on the same bench or on the bench below. Backhoe loading is particularly useful for loading a dipping seam or wedge of material where loading with a cable shovel would be impossible. Backhoe loading is also very useful in wet conditions, permitting the trucks to travel on a drier bench above the water, with correspondingly increased tire life.

The useful life of loaders, hydraulic shovels, and cable shovels varies according to the application, maintenance standards, and the company's general replacement policy. However, life for a front-end loader is typically in the 3- to 4-year range, hydraulic shovels in the 8- to 12-year range, and cable shovels are usually replaced at 20-year intervals. The longer the useful life, the more obsolete the equipment becomes in comparison to new technological advances. In order to combat this technological aging factor, many equipment manufacturers are progressing toward complete modular part replacement designs. These designs allow the mine operator to exchange older components for new, more reliable modules that may have more advanced features.

Another factor that influences the choice of loading equipment is the trade-off between lower and higher capital costs versus higher and lower operating costs. Complicating this analysis is the difference in useful life. Given that the prime objective in mining is to maximize the return on investment, the time value of money must be taken into consideration in any trade-off analysis. Discount rates of 10% to 15% are commonly used to convert future costs into a net present value (NPV). The higher the discount rate, the greater the emphasis on reducing current costs (capital). Expenditures after 10 years have less significance on the total NPV. This method of ranking alternative fleets can be applied to all choices: dragline versus a shovel-and-truck fleet in a coal stripping operation, or cable shovels with 170-ton (150-t) trucks versus front-end loaders with 85-ton (76-t) trucks, trucking versus crushing and conveying. However, other tangible and intangible factors may be present that often are overlooked in this capital-versus-operating-costs analysis. An example of this would be greater ore selectivity, which means less ore dilution and less ore discarded as waste, thereby resulting in higher-grade ore to the processing plant. A small-grade change can significantly affect overall project economics.

As an example, project economics are very sensitive to changes in commodity price. However, grade changes and recovery changes have nearly the same effect as a commodity price change. Therefore, if ore selectivity can improve the ore grade by 10%, this is more significant than a 10% increase in both mine capital and operating costs. This factor must be taken into consideration in any equipment trade-off economic analysis.

Other factors that influence the choice of equipment (and therefore mining method) are less tangible. As previously discussed, these include mobility requirements, ore blending, hard or easy digging, maintenance skills of the available work force, size of the operation, working area, and advance rate required.

In respect to this last point, open-pit mines are subdivided into phases. Each phase is somewhat independent of the following phases; however, the object is to remove waste rock that exposes ore in a timely manner before the ore reserves (from the prior phase) are exhausted. Circumstances exist where the advance rate or number of benches to be mined each year in a phase requires more than one loading unit. If the working width of a bench is too narrow to permit more than one unit, then larger equipment may be required.

An example of this situation is a mine that was using 15-yd^3 (11-m^3) hydraulic shovels as the prime loading fleet. The mine plan indicated that after the tenth year of operation, the fourth mining phase required the movement of 15 million tons (13.5 Mt) of material per year for 5 years to expose ore. Given that one shovel could not move this material and since two shovels could not effectively work on the bench, the alternatives were to purchase a large 40-yd^3 (30-m^3) cable shovel or start mining the phase earlier. A discounted cash-flow analysis indicated the better choice was to purchase one 40-yd^3 (30-m^3) shovel for the bulk of the waste stripping and to use the smaller shovels for ore production.

The purpose of subdividing an open pit into phases is to improve the project economics. This can also mean that material movement requirements through time will change significantly. It does not mean that mining quantities will change dramatically each year. An effective mine production schedule must be developed to consider equipment and personnel requirements. A smooth schedule will give the mine operations and maintenance departments sufficient time to build up their organizations without significant annual variances. If total material movements are increased during the life of the mine, these increases should be smoothed to form a new production level that remains constant at a higher level for a number of years.

During preproduction, or at some point in the life of the mine, this may not always be feasible, and an alternative to this is contract stripping. Contract stripping can be justified if the mine life is short or the stripping peak is of fairly short duration (i.e., between 3 and 4 years). Again, the trade-off is lower capital costs versus higher operating costs. The intangible benefits include the avoidance of hiring and training a large work force for a relatively short time period, greater assurance that the stripping will be carried out on time and per the contract terms, as well as fewer management resources being required. An intangible disadvantage is less control over the operation, as it must be recognized that a contractor's goal is to move a volume of rock, not necessarily to separate ore and waste in the mine owner's best interest. Adequate ore control procedures must be conducted as part of the mine owner's responsibility to minimize ore dilution and loss. It is also the mine owner's responsibility to ensure that the mine plan is accurate and well understood, otherwise extra costs will be charged by the contractor for scope deviations.

The life of a mining project plays an important role in selecting the most appropriate mining method, equipment fleets, and whether to use a contract miner. Smaller companies may have more capital constraints and therefore favor contract mining.

The lack of available capital also may force the mine operator to look for used equipment for its initial mining. This equipment may be replaced within a few years with new equipment if mine life is sufficiently extended and positive cash flow has been demonstrated to the lending agency's satisfaction. Any economic analysis of used versus new equipment is extremely subjective. Equipment maintenance costs are composed of maintenance labor and repair parts. The amount of maintenance required is related to the condition of the equipment purchased and also to the operating hours on the equipment. If the equipment has been overhauled adequately, maintenance costs will be similar to that of a piece of equipment that has been in operation for a relatively short time. The maintenance requirements of rebuilt equipment will increase at an aging rate that is approximately double that of a new piece of equipment.

In order to adequately explain this factor for economic analysis, consider the following example of haul trucks that normally have a useful life of a maximum of 75,000 hours. If the average maintenance cost during the life of a truck has a value of 1.0, then the relationship of maintenance costs to life can be stated as follows:

Operating Hours	Maintenance Cost Factor	Mechanical Availability, %
0–5,000	0.30	85
5,000–20,000	0.70	80
20,000–40,000	1.00	75
40,000–60,000	1.20	70
60,000–75,000	1.35	65

If a truck with 60,000 to 70,000 hours is overhauled, maintenance costs should drop to the equivalent of a new truck with 5,000 operating hours. However, after operating only 30,000 hours, the overhauled used truck would have the same maintenance requirements as a truck with 65,000 hours.

Used equipment availabilities are also much less than that for new equipment. New equipment usually will have manufacturers' warranties and close field support.

The effect of purchasing used equipment with lower availabilities is that more units are needed to obtain the same production level, and the maintenance work force has to be significantly larger. Nonetheless, if capital funding is limited, used equipment or a contract miner may be the only viable options.

The comparison of one type of mining method versus another should also compare the various types of equipment that are dependent on another type, such as loading and hauling equipment, loading productivity versus crusher capacity, and drilling unit capacity versus scheduled shovel production.

For any analysis, it is better to have the first unit in the chain of production with greater capacity than the downstream

unit. Therefore, drill capacity should exceed shovel/loader capacity, shovel capacity should be slightly higher than crusher capacity, or the capacity of two shovels should be matched with the capabilities of one crusher.

A mismatch occurs when there are only a few units in production and the capacity of one unit dependent on the production of another is significantly different. For any comparison of different mining methods or equipment types, it is very important to conduct the economic analysis using accurate and correct assumptions.

Two of the major expense areas in any open-pit or stripping operation are the functions of loading and hauling. Typically, 30% to 50% of the total mining cost is related to hauling all material types out of the pit. A cost comparison of equipment sizes and alternatives must be based on an optimum selection of loading and haulage fleet sizes, otherwise the comparison may be unfairly skewed one way or the other.

The first step in any comparison is the determination of unit productivities per operating shift or per hour. Loader productivities can be estimated by using the anticipated load time per specified truck size and dividing this into the estimated effective minutes per shift. Productive minutes per 8-hour shift (with no downtime) will vary from 330 to 420 minutes, depending on the efficiency of the assignment systems used and the balance between loading and haulage units. Industry standards without a computerized truck dispatch system typically use 350 effective minutes per 8-hour shift as a basis for comparison.

Truck productivities can be determined from haul profiles for each specific time period. For initial studies comparing one system to another, average productivities per time period can be used to determine fleet requirements.

One method that can be used to more accurately analyze the loading and haulage fleet requirements is the binomial method. The best way to explain this method is by using a simple case to demonstrate its use in determining dependent fleet production.

Example 1. Consider a fleet consisting of

- One loader, 80% mechanical availability and an estimated productivity of 9,000 tons (8,200 t) per operating shift, and
- Three haul trucks, 70% mechanical availability and an estimated productivity of 4,000 tons (3,600 t) per operating shift.

Determine the fleet capacity.

Solution. Assume that the fleet is scheduled 100% of the time and will only be inoperable if either the loader or all the trucks are down for repairs.

One could incorrectly assume that the average loader production would be 80% of 9,000 tons (8,200 t) per shift, or 7,200 tons (6,500 t) per shift. However, because the loader production is dependent on available haul trucks, the truck downtime distribution must be considered.

Table 6.6-1, developed using the binomial formula, shows the fraction of time that x units are available out of a fleet of n units with a given availability of p where this fraction equals

$$\frac{n!}{x!(n-x!)} \times p^x \times (1-p)^{(n-x)} \qquad (6.6\text{-}1)$$

Table 6.6-1 indicates that 34% of the time, all three trucks are available (row 3, column 3); 44% of the time, two are available; 19% of the time, only one is available; and 3% of the time, the whole truck fleet is down. When less than three trucks are operating, the loader production will drop to the amount that the trucks can haul—in this case, 8,000 tons (7,300 t; i.e., 44% of the time) and 4,000 tons (3,600 t; i.e., 19% of the time).

Table 6.6-1 Fraction of time that (*x*) units are available out of a fleet of (*n*) units that have a probable availability of 70%

	Number of Units Available, *x*						
Fleet Size, *n*	0	1	2	3	4	5	6
1	0.30	0.70					
2	0.09	0.42	0.49				
3	0.03	0.19	0.44	0.34			
4	0.01	0.08	0.26	0.41	0.24		
5	0.00	0.08	0.13	0.31	0.36	0.17	
6	0.00	0.01	0.06	0.19	0.32	0.30	0.12

In summary, the fleet capacity can be stated as follows: The loader operates 80% of the time and during this time, 34% will be at 9,000 tons (8,200 t)/shift, 44% will be at 8,000 tons (7,300 t)/shift, and 19% will be at only 4,000 tons (3,600 t)/shift. Total fleet capacity would average

$$0.80 \times 0.34 \times 9{,}000 = 2{,}448 \text{ tons/shift}$$
$$0.80 \times 0.44 \times 8{,}000 = 2{,}816 \text{ tons/shift}$$
$$0.80 \times 0.19 \times 4{,}000 = \underline{\quad 608 \text{ tons/shift}}$$
$$\text{Total} = 5{,}872 \text{ tons/shift (5,340 t)}$$

From this simple example, one can see that production from the loader would be 18% short of the initial estimate of 7,200 tons (6,500 t) per shift that was determined without consideration of the haul fleet. The same analysis holds true for haulage truck requirement determinations. For example, if only the number of haul trucks needed was examined, the following could result.

- Annual target objective: 1,800,000 tons (1,636,000 t)
- Shifts scheduled: 250
- Tonnage requirements per shift: 7,200 tons (6,500 t)
- Average truck productivity: 4,000 tons (3,600 t)/shift
- Operating trucks needed per shift: 1.80
- Three trucks at 70% availability will average 2.1 shifts

Therefore, it could be incorrectly assumed that three trucks would be sufficient. However, from the previous discussion it is known that if the loading fleet contained only one loader, then 20% of the time the haul fleet would be idle waiting for the loader to be repaired. It is also known that the loader could not keep up with three trucks, and production would be limited to 9,000 tons (8,200 t) per shift, not the 12,000 tons (10,900 t) per shift indicated by the haulage capacity. Therefore, haulage capacity would be

$$250 \text{ shifts} \times 0.80 \times 0.34 \times 9{,}000 = \quad 612{,}000 \text{ tons}$$
$$250 \text{ shifts} \times 0.80 \times 0.44 \times 8{,}000 = \quad 704{,}000 \text{ tons}$$
$$250 \text{ shifts} \times 0.80 \times 0.19 \times 4{,}000 = \quad 152{,}000 \text{ tons}$$
$$= 1{,}468{,}000 \text{ tpy}$$
$$(1{,}335{,}000 \text{ t/a})$$

The solution in this case would be to purchase another loader or work more shifts. With larger fleets, the shortfalls caused by calculating fleets independently are not so easy to quantify without using a computer program that considers

Table 6.6-2 Equipment operating shifts attainable per shift with a probable availability of 70%

	Number of Operators, *x*					
Fleet Size, *n*	**1**	**2**	**3**	**4**	**5**	**6**
1	0.70					
2	0.91	1.40				
3	0.97	1.76	2.10			
4	0.99	1.91	2.56	2.80		
5	1.00	1.97	2.80	3.33	3.50	
6	1.00	1.99	2.92	3.66	4.08	4.20

the availability interaction of the two fleets. Haulage truck productivities can be averaged for these calculations; however, in reality, haul distances will vary, and this can be used to counter some of the production shortfalls that would otherwise occur when there is a shortage of trucks or loading units. For example, if the mine were short of trucks, then the shortest haul distances would be used; and conversely, if the mine were short of loading units, longer hauls would be used to counterbalance the shortfalls that would otherwise occur. This may not always be possible, but haulage distance flexibility should be one objective of a good mine plan.

The lack of a loading unit more severely impacts haulage capacity than the lack of one truck. For this reason, it is better to have slightly more loading standby capacity and use an under-trucking philosophy to minimize both capital and operating costs. Haulage costs per ton of material mined will typically be several times the loading cost.

It is not always in the miner's best interest to have operators for each piece of loading or haulage equipment. In fact, as the fleet sizes increase or availabilities decrease, the extra operators are more of an operating cost liability.

Binomial distribution can be used to determine the most likely number of operating shifts that will be obtained for a given fleet size based on the number of operators or equipment scheduled, where x is the number of assigned operators, n is the number of units in the fleet, and b is the binomial probability of n things taken one at a time (see Table 6.6-2).

Table 6.6-2 is derived from the following formula:

operating shifts/shift =

$$x\frac{\sum_{j=x}^{n} bj}{} + 1(b_{(x-1)}) + x - 2(b_{(x-2)}) + \ldots 1(b_1) \qquad (6.6\text{-}2)$$

For example, the anticipated operating shifts for five pieces of equipment with 70% availability and four operators is 3.33. Adding one more operator to the payroll would only increase loader operating time by 0.17 shifts. From another viewpoint, if a truck fleet was purchased to cover five operating loading units, then the trucks purchased for the fifth loading unit would only operate 17% of the time. During the remaining 83%, the trucks and their drivers would be wasted capacity unless the remaining loading units could handle the extra trucks effectively.

In order for the remaining loading units to handle the extra trucks, the operation must be initially designed to be under-trucked when all the scheduled loading units are operating.

The following example is taken from an actual case in China for which the initial fleet specified for review was severely over-trucked.

Example 2. Initial production plans indicated an overburden stripping requirement of 160,000 tons (145,500 t) per shift. Production rates for the shovels and trucks were estimated to be 20,000 tons (18,200 t) and 2,500 tons (2,300 t) per operating shift, respectively. It was proposed to purchase and schedule 10 shovels to operate at 80% availability to give a loading capacity of 10 × 80% × 20,000 tons (18,200 t) = 160,000 tons (145,500 t). In order to cover each shovel, it was proposed to purchase 10 trucks and schedule 8 of them to operate at 80% availability, giving an average capacity of 10 × 80% × 2,500 tons (2,300 t) = 20,000 tons (18,200 t) per shift, thereby matching each shovel's productive capacity.

Solution. The devised production plan assumed that trucks and their drivers, due to physical constraints, were not transferable between the various loading units and the haul distances were always the same length. Therefore, the total equipment requirements were estimated to be 10 shovels and 100 trucks, of which 10 shovels and 80 trucks would always be scheduled to operate.

By applying the binomial function to a group consisting of one shovel and 10 trucks, the anticipated output would be approximately 15,000 tons (13,640 t) per shift, or 150,000 tons (136,400 t) for 10 shovels. This is 10,000 tons (9,100 t) short of the objective and is caused by the fact that there will be times when less than eight trucks are available, resulting in lost shovel production. Situations will also occur when more than eight trucks are available, but given that the shovel can use only eight trucks, no increase in production can be gained to counterbalance the shortfall.

Referring to Table 6.6-3, if the trucks could be transferred from shovel to shovel in order to balance the truck shortfalls (Case 3), then production will be increased by approximately 10,000 tons (9,100 t) and the target attained. However, this is avoiding the real problem, over-trucking. The 160,000-tons (145,500-t)-per-shift target can be obtained with different shovel/truck fleet combinations with a lower capital expenditure and at a reduced operating cost. Table 6.6-3 illustrates various fleet sizes that would produce 160,000 tons (145,500 t) per shift. For comparison, operating and capital costs of each fleet are listed, and the basis of these estimates is provided in Table 6.6-4. Case 1 is the base as originally specified; Case 2 is the base case but with the equipment increases that would actually be needed to reach 160,000 tons (145,500 t) per shift with the same constraints as Case 1. Case 3 is the production obtained if trucks can be transferred from one shovel to another, Case 4 is an optimum fleet balanced to minimize costs with fixed hauls, and Case 5 is an ideal case where haul distances can be flexed to accommodate truck or loading equipment shortages and maintain peak production efficiencies. In this last case, production efficiency is increased by changing the mine plan to allow flexible haul distances. Instead of a fixed 2,500 tons (2,300 t) per truck shift, dump points can be varied to shorten or increase haul distances to give a truck productivity range of 2,100 tons (1,900 t) to 2,600 tons (2,400 t) per shift but still average 2,500 tons (2,300 t) per effective truck shift.

This example shows the magnitude of the savings that can be achieved by selecting the optimal fleet size and removing some of the high-cost constraints.

Table 6.6-3 Optional fleets vs. cost (Example 2)

	Case				
Equipment Characteristics	**1**	**2**	**3**	**4**	**5**
Shovels in fleet	10	11	10	11	11
Shovels scheduled	10	11	10	9	9
Trucks in fleet	100	107	100	85	81
Trucks scheduled	80	85	80	70	70
Truck productivity, tons					
Minimum	2,500	2,500	2,500	2,500	2,100
Maximum	2,500	2,500	2,500	2,500	2,600
Fleet production, tons	150,340	160,049	159,544	160,498	160,240
Shovel operating shifts	8.00	8.80	8.00	8.39	8.39
Production per shovel operating shift, tons	18,792	18,187	19,943	19,125	19,094
Truck operating shifts	75.20	80.05	78.41	67.34	64.71
Effective truck shifts	60.10	63.98	63.82	64.20	64.13
Production per truck effective shift, tons	2,500	2,500	2,500	2,500	2,499
Operating cost per ton*	$0.4438	$0.4447	$0.4364	$0.4118	$0.4085
Fleet purchase cost ($ × 10^6)	$230	$249	$230	$215	$210

*Loading and haulage cost only.

A computer program that models the dependent fleet interactions can generate and investigate a large number of loader/truck combinations, select those that meet the production goal, and finally determine which combination will give the lowest overall combined cost per ton of material mined.

This type of evaluation is also a very useful tool for sensitivity analyses to investigate how changes in parameters such as availabilities, depreciation, and equipment and labor operating costs change the optimum fleet size.

The methods described using the binomial distributions were developed to quickly and easily analyze various loading/haulage fleet combinations with respect to costs, capacities, and the optimal fleets for comparing one mining method and equipment choices to another alternative.

There are obvious limitations to the accuracy of this method in its application to a true mining situation. This evaluation, for instance, cannot recognize the difference between the expected output from an operation that has a well-functioning computerized truck dispatch system as compared to one that is run with batch assignments. This simple method also does not consider the total picture in the sense that there are multiple haul profiles and that the loading equipment may have varying productivities and/or targets according to the material being mined. Only a fully developed mine simulation program can analyze an operation accurately to reflect all of the numerous variables applicable to one point in time.

The desired accuracy level and the complexity of the operation to be studied dictate the depth of study and method that should be used. The numerical examples illustrate the importance of correctly selecting the best loading and truck fleet sizes.

This case study of equipment proposed in a large strip mine has been given as a good example of comparing nonoptimal equipment fleets with other types of mining. If the comparison were made between a dragline versus a shovel/truck combination and that comparison indicated $10 million in capital cost savings, the mine owners would have made the wrong choice of mining method and equipment. Therefore, it is of significance to correctly analyze the proposed equipment fleet to ensure that any comparison is valid and the proposed savings of one system over another are real.

Table 6.6-4 Basic assumption for all cases (Example 2)

Equipment Characteristics	**Shovels**	**Trucks**
Mechanical availability	80%	80%
Maximum productivity per operating shift	20,000 tons	As noted
Operating cost per effective shift	$1,500	$665
Operating cost for nonproductive shift (waiting time)	$300	$220
Operating labor cost per shift	$240	$120
Capital cost per unit ($ × 10^6)	$8.0	$1.5

SUMMARY

In all surface mining operations, where there is a choice of mining method and equipment, the optimal alternative is often difficult to choose because the differences may be within the degree of accuracy of the trade-off study.

The five most important criteria in selecting the best mining method and equipment are

1. Type of deposit, seam or disseminated;
2. Geometry of the deposit and terrain;
3. Total material movement per time period;
4. Projected project life; and
5. Geographic location.

Other factors of lesser importance include

- Climatic conditions and altitude;
- Availability and cost of a skilled labor force;
- Environmental and legal restrictions;
- Slope stability and groundwater;
- Investment risk and available capital funding;
- Blasting restrictions;
- Method of waste rock disposal, external or backfilling;
- Availability of support services and infrastructure; and
- Availability of electric power versus the local cost of diesel fuel.

of the advantages and disadvantages of each surface mining method is presented in Table 6.6-6.

In conclusion, many factors need to be considered in selecting the best mining method coupled with the most economic fleet of equipment. When there is more than one option, it is best to select the alternative that gives the mining operation the greatest degree of flexibility. Mining is dynamic, and the operation that can adjust the easiest to changing conditions is the operation that will survive future crises.

Successful analysis of the options available ensures that the proposed project will operate at its competitive peak. The ideas presented in this chapter will hopefully help the mine operator meet the prime objective, that is, the investor's law of conservation.

PART 7

Rock Breaking Methods

CHAPTER 7.1

Mechanical Rock Breaking

Jamal Rostami

INTRODUCTION

One of the main components of mining activities and unit operations is rock breakage, which has increasingly shifted toward mechanized systems in the past few decades. Mechanical excavation refers to methods of rock breakage where the rock is entirely removed from the mine face by the action of mechanical cutting tools. In recent years, mechanical excavation has become increasingly common, especially in underground mining and construction. Mechanical rock excavation is traditionally compared to drill-and-blast operations. The inherent advantages of mechanical excavation are increased safety, higher production rate, less labor-intensive operation, higher degree of automation, minimum damage to the walls, better control over the process, uniformity of product size, elimination of blast vibrations, and better ventilation in underground openings.

Many improvements have been made in the process of rock breakage, and several world records have been set at various operations. This includes drilling and excavation systems across the board and sizes ranging from 50 mm to >15 m (2 in. to >50 ft) in diameter. Mechanical excavators are well positioned in underground construction and mining but are less common in surface operations. However, excavators such as surface miners and road milling machines are becoming more common in surface mining operations, especially in soft to medium-hard rocks.

The most common types of mechanical excavators are tunnel boring machines, raise boring machines, roadheaders, continuous miners, and longwall drum shearers. However, mechanical excavation methods also include unconventional techniques such as laser drills, microwave rock-breakage systems, projectile impact, flame jets, and water jets. Of these techniques, water jetting is the only one that is used on a regular basis for precision rock cutting and occasionally in drilling operations. The mechanism of rock cutting by water jet can be considered erosional, somewhat different from the other methods listed. The use of electric shock to induce stresses, or "plasma explosion," has also been investigated but has not yet been used in mining applications or rock excavation.

Using the physical, chemical, and mechanical properties of rock formations can induce rock breakage. This is to say that the breakage occurs when bonds between the constituent grains and minerals in rock are broken using one of these forms of energies. This can be done by using chemical processes to weaken and break the bonds, or by inducing stresses between the particles to separate pieces or chunks of rock from the ground or from each other. Optical, thermal, and mechanical properties of rocks can also be used to generate stresses.

The most efficient form of breaking such bonds is by the use of force via a mechanical device or tool. This has been the most dominant method of rock breakage since the industrial revolution, when high-quality steel became available at reasonable prices. The rock-cutting tools, coupled with various types of machinery that could deliver concentrated forces, allowed indentation and penetration into the rock surface to drill the holes for blasting operation or for large-scale excavation. Other means of rock breakage are still being explored and experimented on. At this stage they are considered to be "novel techniques." This includes using a laser beam for melting rock or using oscillating laser beams for breakage of rock into pieces through resonance of the grains.

New methods and techniques, as well as new tools for rock fragmentation, are being developed every day. Some of these ideas will find acceptance in practical applications relatively fast, while others will not. In addition, manufacturers continue to develop new machinery, and as such, miners gradually adopt new systems into their design and operation. As one expert put it, this is "a subject that in general has as many exceptions as rules" (W. Hissem, personal communication). This means that the information provided in this chapter on the tools and the norms/rates indicated for different types of machinery are likely to change within a few years. Although this information is provided to offer a brief background and basic understanding of the techniques, it is imperative that users look up the most recent development to obtain quantitative values for their design and engineering estimates.

Jamal Rostami, Assistant Professor, Energy and Mineral Engineering, Pennsylvania State University, University Park, Pennsylvania, USA

ROCK/BIT INTERACTION AND ROCK INDENTATION PROCESS

Mechanical rock breakage involves using a tool to create a high-stress area within the rock to cause failure and disintegration. As such, the tool penetrates the formation when sufficient forces are applied. This process is called indentation and can be accomplished under static or dynamic loading. Static loading is used primarily in excavation, while dynamic or impact loading is mostly used for drilling applications. The distinction between the two is that impact loading primarily involves a reciprocating hammer that delivers impact energy to the tool, whereas with static loading, a bit is dragged or rolled across the surface, which causes rock chips to spall from the rock surface.

In mechanical rock excavation (static loading), the cutters or bits can be categorized into the following two main groups: drag-type tools and roller-type tools. Each group is associated with particular ground conditions, rock properties, and machine types. Thus, it is important to understand the relationship between the rock properties and the selection of proper or optimum tools. Intact rock properties have the most pronounced impact on bit or cutter selection. These properties include the following:

- Rock strength (compressive and tensile)
- Abrasiveness or hardness of the rock and its constituent minerals
- Rock texture, grain size, and shape
- Ductility or plastic behavior

Several rock mechanics tests are commonly used to characterize the rock type and potential behavior pertinent to excavation and breakage. The following is a list of the typical tests used for this purpose:

- Unconfined compressive strength
- Indirect ("Brazilian") tensile strength
- Point load index
- Abrasiveness measured by the Cerchar abrasivity index (CAI) or by the Taber abrasion test
- Siever's J-value (SJ), brittleness (S_{20}) index, and abrasiveness value, as measured by Norwegian drillability tests (Bruland 2000)
- Elastic moduli measurements (Young's modulus and Poisson's ratio)
- Thin-section analysis

To successfully select a cutter type, measurements of the values for some of these properties are required.

Mechanical breakage starts with rock indentation by a bit or part of a bit that is in contact with the rock surface. This process involves a hard and relatively stiff object applying concentrated load on the brittle medium or rock formation. The process starts with elastic deformation of the rock, followed by localized failure of the rock in the area of high tensile stresses, which forms the initial cracks in the directions of maximum tensile stresses. The process of fracturing causes irreversible deformations. A continued increase in the stress at the point of contact results in crushing of the material under the contact area forming a fine powder. The grain size of the crushed zone gradually increases as the distance from the point of contact increases until the crushed zone gives way to radial cracks. A detailed study of this phenomenon was performed by Lindqvist (1984). In Lindqvist's analysis, the approach offered by Lawn and Swain (1975) was adopted,

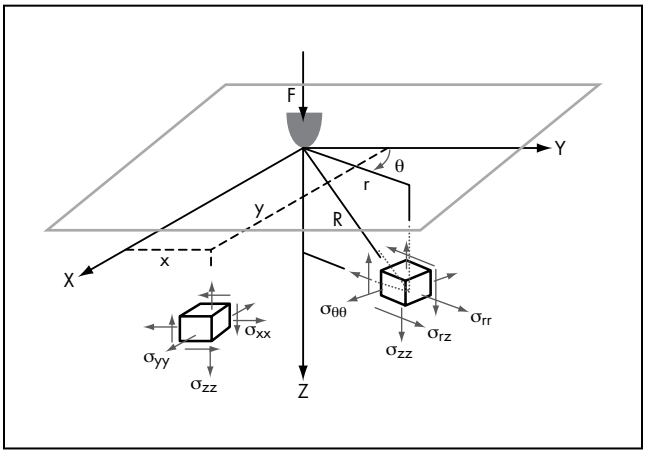

Figure 7.1-1 Coordinate system for indentation stress field

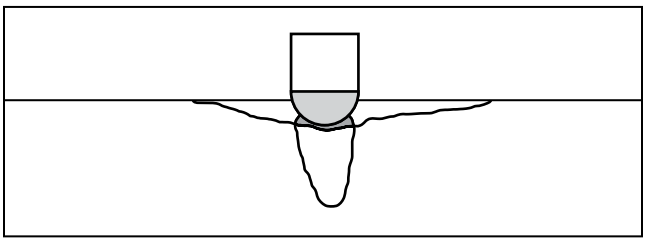
and stresses in the rock were estimated using the Boussinesq solution for the stresses in a plane from a concentrated load. These stresses can be expressed by the following equations (Fung 1965):

$$\sigma_{rr} = \frac{F}{2\pi R^2}\left[\frac{3r^2 z}{R^3} - \frac{R(1-2\nu)}{R+z}\right]$$

$$\sigma_{\theta\theta} = \frac{(1-2\nu)F}{2\pi R^2}\left[\frac{z}{R} - \frac{R}{R+z}\right]$$



$$\sigma_{zz} = \frac{3Fz^3}{2\pi R^5}$$

$$\sigma_{rz} = \frac{3Frz^2}{2\pi R^5}$$

where

σ_{rr}, $\sigma_{\theta\theta}$, σ_{zz}, and σ_{rz} = stresses in various directions, including radial, tangential, and shear (see Figure 7.1-1)
F = applied load
R = radius vector from the stress point to the force application point, which equals $(r^2 + z^2)^{1/2}$

As can be seen in these equations and in Figure 7.1-1, the stress in the rock is proportional to the applied force and inversely proportional to the square of the distance from the point of contact. These equations, and all similar sets of equations for estimation of stresses using other coordinate systems (i.e., the Cartesian system), indicate that the stress reaches a singularity at $R = 0$; however, the indenter actually has a finite width and the load is distributed over a small area. This setting creates an area of concentrated compressive stresses in the radial direction developed directly under the indenter, and the resulting deformation creates tensile stress in tangential directions. The stress field quickly loses its magnitude as the points get further away from the load. The area of concentrated compressive stresses is best represented by the powdered rock that forms under the cutting tool. This powder is often referred to as pressure bubble. The process of indentation is followed by formation of the chips as radial cracks extend from the pressure bubble in all directions, especially toward the adjacent cut or toward an existing free surface or surfaces.

Source: Gertsch 2000.

Figure 7.1-2 Schematic of a sample after an indentation test

Gertsch (2000) defines two parameters—specific penetration (SP) and specific energy (SE)—to express rock cuttability. SP is defined as the amount of indentation obtained for a given applied force, and SE is defined as the energy required to excavate a unit volume of rock. Figure 7.1-2 shows a schematic drawing of a rock specimen after an indentation test. Thus, the response of a rock to indentation can be represented by a force–penetration curve. A sawtooth shape, resulting from rapid loading and unloading, indicates brittle behavior, whereas a steadily increasing curve with no unloading or a drop in the force indicates a rather plastic or ductile rock. If an indenter is dragged across a face at a certain depth, simulating the action of a drag bit, it will create a sawtooth curve; however, the magnitude of forces will not increase over time, as it does in an indentation test.

BIT MATERIALS

Bits or cutting tools are the most important components of any system of mechanical rock breakage. Tools must be very strong to resist high-stress concentrations without failure, but they must also be able to resist abrasion and rapid wear by hard minerals in the rock formation. A tool is subject to impact loading; however, most materials that are hard and abrasion resistant are also brittle and fracture under impact loading. The best cutting tools are strong and ductile on the inside with a hard surface, which is typically obtained by chemical or heat treatment of steel.

The most common materials used in rock-cutting tools are special types of steel and tungsten carbide. Tungsten carbide is stronger, harder, and more impact resistant than steel, and it is commonly used as an insert at the cutting end of a steel bit (bit tip). Rock-cutting tools are manufactured from high-grade steel that is machined and heat treated to increase the surface hardness to a range of 54 to 56 on the Rockwell hardness scale. As for the carbide, various grades of carbide can be used for manufacturing of the bit tips. This includes the size of the grains used in the mix and the amount of cobalt used in the mixture to prevent carbide from becoming brittle at higher temperatures.

Through extensive testing and field trials, the optimum percentage of cobalt in carbide mix has been considered to be around 10%. This gives the best combination of hardness, strength, and toughness to the carbide inserts for application in rock excavation. In certain applications, polycrystalline diamond is used to coat the cutting tips of tungsten carbide bits. Polycrystalline diamond tools have shown excellent resilience in various applications, but they are still rather expensive and are only used for special applications such as oil-well drilling bits or diamond drilling for deep rock exploration, where the extended life and higher tool costs are justified due to operational considerations and typically very high rig/operational costs.

BIT TYPES

Mechanical rock excavation tools are classified into the following two main categories: drag tools and roller tools. Drag tools scrape rock from a face by dragging the cutting edge of the tool across the rock surface. These tools have rather sharp edges to reduce the forces for penetrating, thereby cutting the rock in tensile and shear mode. The amount of force (and thus energy) that can be transferred to the rock by these tools is limited by the strength of the material used for the tip of the tools. The use of stronger, harder materials such as tungsten carbide at the tips of drag-type tools has resulted in increased bit life and an ability to cut harder rocks. Although using carbide can increase the range of application of the drag-type tools, it cannot withstand the extreme forces and heat generated while cutting harder rocks (especially those with high quartz content). Drag bits are generally limited to cutting rocks with strengths less than 100 MPa (15,000 psi). For higher-strength rocks or rocks with higher hardness and abrasivity, roller tools are often used.

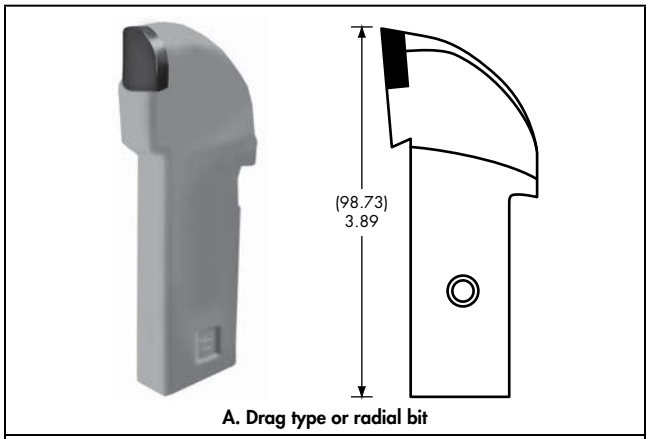


Figure 7.1-3 shows some of the typical drag bits used in the industry. These tools are very common on partial-face machines used to mine soft to medium-strength rocks. There are two types of tools in this category—drag bits and conical picks. Drag (or radial) bits are used in very soft and nonabrasive rocks and are very efficient. However, they lose their efficiency very rapidly as the sharp edge of the tip erodes.

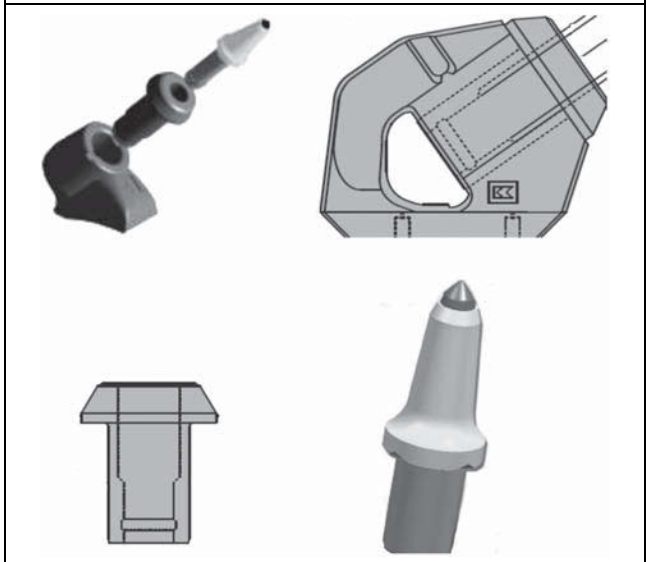
Drag bits are gradually being replaced by conical picks, which are used for higher-strength and more abrasive rocks. Rotation of the bit, which allows for uniform wear on the tip and the sustaining of its profile during the excavation, is an important function of the system. The new sleeve system allows for better performance and longer bit life due to improved rotation. Sleeves provide additional surfaces for rotation and protection of the bit block. When sleeves experience high deformation or are damaged, they can be easily replaced. In contrast, replacement of a bit block involves cutting out the damaged block with a torch and welding on a new one, which can result in inaccurate placement of the block on the cutting drum and subsequent problems. The use of sleeves often results in higher productivity and lower maintenance in excavation systems.



In harder rocks, roller-type cutters, including disc cutters and strawberry or multi-row tungsten carbide cutters, are used. Figure 7.1-4 shows disc cutters with the front- and back-loading mounting assembly that uses the wedge-lock system. Back-loading cutters are used in tunneling applications and allow for cutter changes from within the cutterhead, which is safer than changing cutters at the front of the cutterhead, where the ground is unsupported. The new cutter material and assembly system affords longer life, better accessibility of the cutters (especially in bad ground), and reduced time for cutter change. Figure 7.1-5 shows "strawberry" cutters with multiple rows of tungsten carbide buttons that are used in extremely hard and abrasive rocks and in applications where cutter change is very difficult and longer cutter life is intended. An extensive review of mechanical excavation and rock-cutting tools can be found in Roxborough (1985).

BIT SELECTION

The selection of the right tool for a given application is a function of several parameters, including rock strength and abrasivity, machine type and size, and accessibility of the face. It must be stressed that using the right tool can influence the overall success and the economics of using mechanized excavation in an operation. Figure 7.1-6 is a simple chart for the

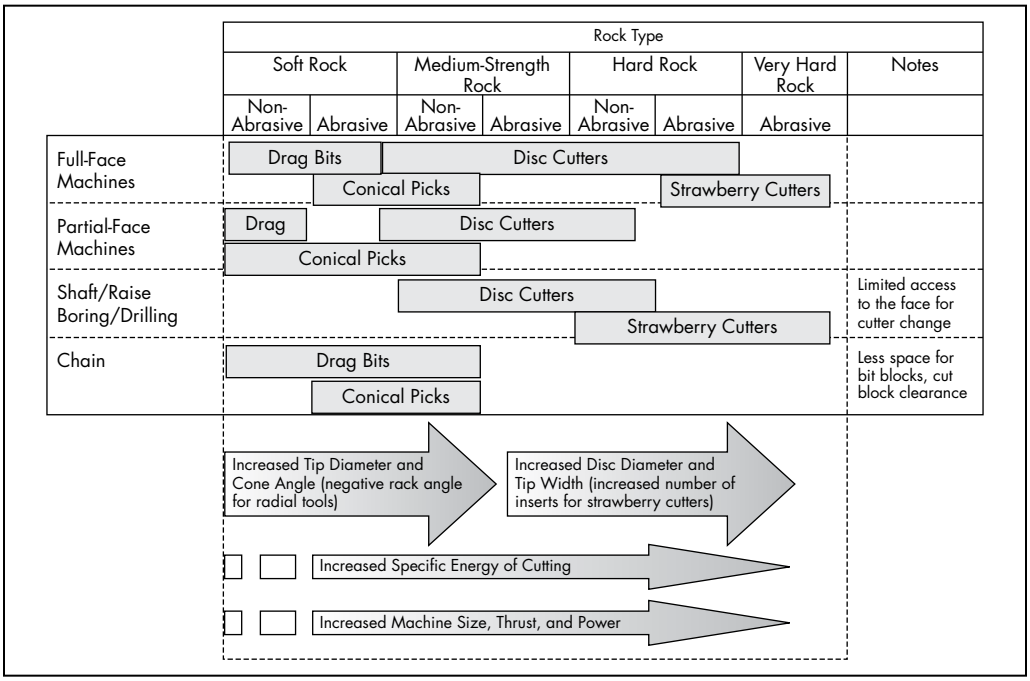

Figure 7.1-5 Strawberry cutters with multiple rows of tungsten carbide buttons

selection of rock-cutting tools. Additionally, selecting a correct strategy for cutter change can have a major impact on the cutting efficiency, machine productivity, and excavation costs. Proper tool selection should result in optimal overall machine performance and minimized excavation cost and not just minimized cutter cost.

Briefly, radial or drag bits are recommended for soft, nonabrasive rocks, and conical or point-attack bits are the most suitable for soft but more abrasive and medium-strength rock, which is typically <100 MPa (<15,000 psi). For harder and more abrasive rocks, disc cutters are preferred, but strawberry cutters with tungsten carbide buttons are also used. A more detailed discussion on selection of cutting tools and bits including criteria for bit selection, cutting force estimation, and bit life estimates can be found in Rostami (1998) and Rostami (2001). Anderson and Rostami (1998) discussed the selection of drag-type bits, and Roby et al. (2009) presented a more recent review of disc cutters and their applications and improvements.

EXCAVATION

Mechanical excavators can be grouped according to various parameters associated with their application, including size (small, medium, or large), direction (horizontal, vertical, or inclined), ground conditions (soil/soft ground, hard rock, or mixed face), shape of the excavation (circular or noncircular), whether surface or underground, and finally the cutterhead system used (partial-face or full-face). Full-face machines are machines where all the cutters are engaged and cut the face simultaneously. Partial-face machines are those where the cutterhead cuts a portion of the face and only portion of the cutters contact the face at a given instant. Unlike the full-face machines, partial-face machines can excavate openings of different shapes and sizes. A third category of machine consists of rock breakers and impact hammers.

Source: Rostami 2001.

Figure 7.1-6 Simplified chart for selection of rock-cutting tools for mechanical excavation

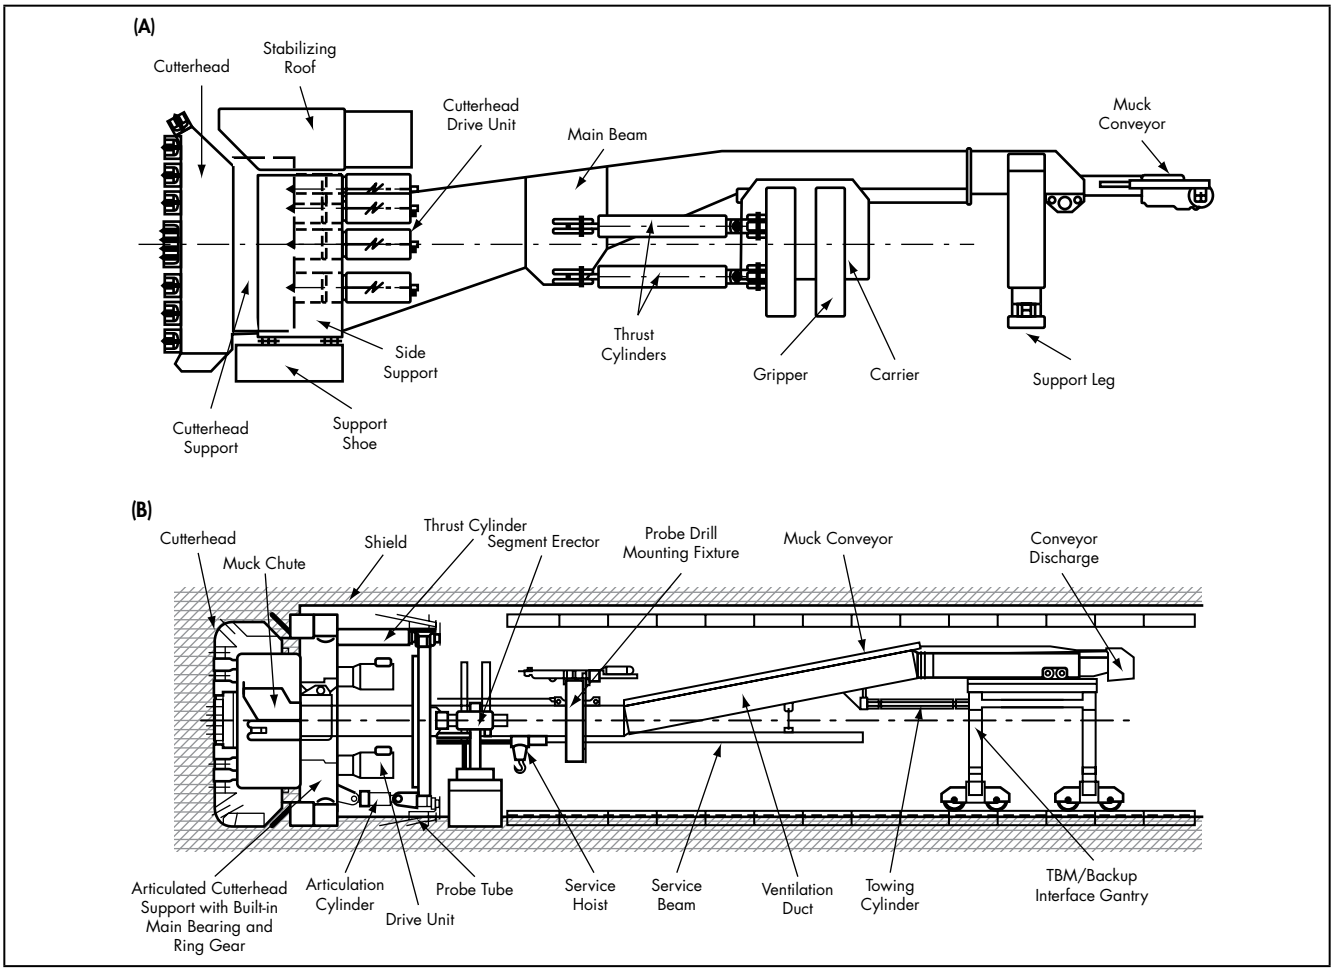
Full-Face Machines

With one exception, full-face machines excavate circular-shaped openings. The best example and the most popular full-face machine is the tunnel boring machine (TBM). Other types of full-face machines include raise borers, shaft-drilling machines, and full-face continuous miners. These four types of machine are described in more detail as follows.

Tunnel Boring Machines

TBMs have enjoyed amazing growth in popularity since 1990 and have set remarkable performance records, the best of which being the excavation of 174 m (~540 ft) of tunnel in one day by a 5-m- (16-ft-) diameter machine through medium-strength sandstone in Australia. A functional TBM is comprised of a cutterhead, a cutterhead support and drive unit, the main frame/shell/beam of the machine, a propulsion system that typically consists of a set of grippers and thrust cylinders, a face conveyance system, a towing section or bridge, and a backup system (Figure 7.1-7).

These machines can be steered and can negotiate a bend with a radius of around 300 m (1,000 ft). The main cutting tools on rock TBMs are disc cutters. Machines range from 1.8 to 15 m (6 to 50 ft) in diameter. TBMs of various sizes have been used to advance numerous water storage tunnels in limestones and dolomites in Chicago, Milwaukee, and other major U.S. cities. A 15-m- (50-ft-) diameter TBM has recently been used in a hydroelectric project under Niagara Falls, Canada. The following types of machines are in use today.



- **Open-type TBMs:** These machines are used for more competent rock, and they push off the walls with their grippers.
- **Shield machines:** Shield machines are used in broken, unstable rock or in soft ground/soil, and they install a segmental concrete lining behind the face to support the ground and provide a solid base for the jacks propelling the machines forward.
- **Double-shield TBMs:** These TBMs have been successfully used in many projects where mixed-face ground conditions are anticipated. These machines can grip on the walls and move forward in good ground, while simultaneously erecting a concrete segmental lining where needed. They can also advance through bad and broken ground by pushing off the segmental lining in a similar manner to regular shield machines. This provides for higher efficiency and flexibility, especially for fast-track projects where the nature of the ground has not been fully explored.

A simplified chart for making a preliminary selection of the type of TBM needed for project based on the rock mass rating for the project ground conditions is presented in Figure 7.1-8.

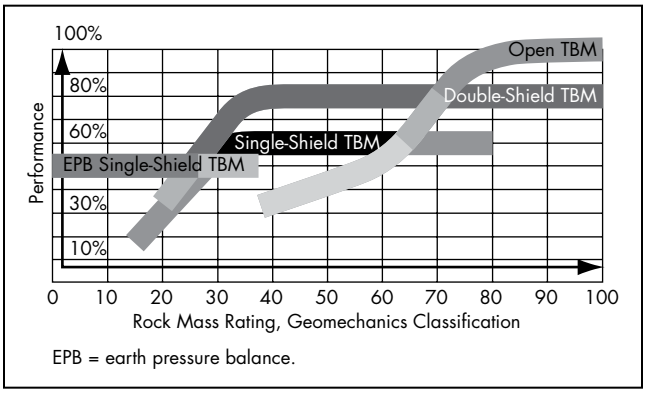
Shaft Boring Machines

For vertical or inclined openings, shaft boring, shaft drilling, raise boring, or raise drilling machines can be used depending on whether access is available at the top or bottom of the proposed opening or both. A shaft boring machine is a self-contained machine similar to a TBM, but it is used for driving vertical openings. It can sink large-diameter, blind shafts where the ground is reasonably good and the machine can grip on the walls to propel the cutterhead into the face. The cutterhead is powered by onboard electric or hydraulic drives. A vacuum system is used to remove broken muck from the bottom of the shaft and transfer it to the main hoisting system of the shaft.

At the time this chapter was written, shaft boring machines had been used to depths of around 1,000 m (~3,000 ft), but this is not a fixed limit and could be exceeded if needed. The

Courtesy of The Robbins Company.

Figure 7.1-7 Components of (A) typical open-type TBM and (B) shielded TBM



diameter of a shaft boring machine can be up to 10 m (30 ft), with the controlling factor being the velocity of the cutters at the circumference of the opening similar to TBMs. The penetration rate of these machines ranges from 1 to 2 m/h (3 to 6 fph), and various types of ground support can be installed simultaneously in the upper decks of the machine.

Shaft Drilling Machines

Shaft drilling refers to blind shaft excavation where the cutterhead hangs from a headframe and is rotated from the top head through the drill string. The thrust force for advancing the machine is provided by a series of deadweight segments directly behind the cutterhead at the bottom of the drill string. This allows the drill string to be in tension rather than compression (thereby avoiding buckling of the drill string), provides for better control of the straightness of the shaft, and minimizes deflection from the alignment. In effect, the system uses gravity to advance and steer the head. The limiting factor for shaft drilling is the amount of torque that can be transferred through the drill string, so the potential depths and diameters of the shafts are limited by the breakout torque delivered by the drill string (the Euler buckling stress varies inversely as the square of the slenderness ratio [length/diameter], and this imposes the limit on the amount of torque that can be transferred to the head).

Typical drilled shaft diameters range from 1.5 to 4 m (5 to 14 ft). Recently, a shaft drilling operation with a diameter of 6 m (20 ft) was begun for a 450-m- (1,475-ft-) deep shaft in Indiana (United States). The top head is capable of lifting up to 400 t (440 st) and can deliver high torque through a turntable to a cutterhead fitted with disc cutters. Formulas for estimating machine thrust, torque, and power requirements are found in a later section of this chapter.

Smaller-diameter shafts have been successfully drilled to depths of 1,000 m (3,300 ft) (A. Zeni, personal communication). The muck generated at the face is removed using reverse circulation. A typical excavation rate for a shaft-drilling machine is 2 to 3 m/h (6 to 10 fph), and setup time for the machine can be achieved within 3 to 4 weeks. During the operation, the cutterhead is submerged and the entire shaft is filled with drilling fluid to provide support for the shaft walls. When the excavation is complete, the cutterhead and drill string is retrieved and the same headframe is used to lower a steel lining into the drilled shaft. After the lining is in place, it is anchored by pumping concrete into the annular space between the lining and the walls, which displaces the drilling mud. Only a limited number of these machines exist worldwide and only a few specialty contractors have experience using these machines. Figure 7.1-9 shows a typical shaft-drilling machine.

Courtesy of The Robbins Company.

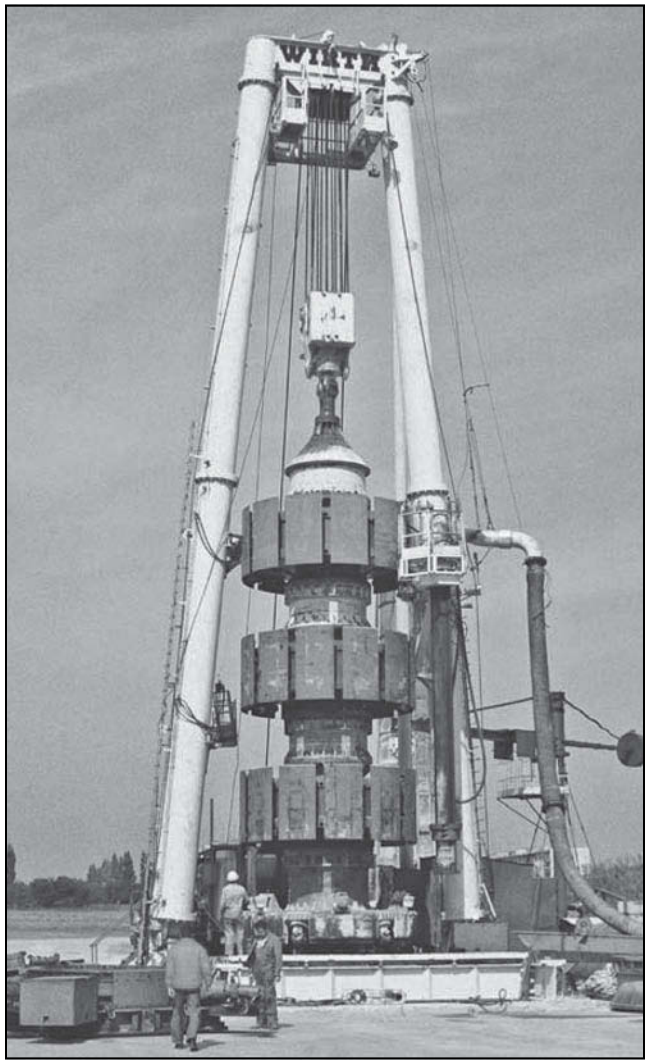


Figure 7.1-8 Preliminary selection and performance chart for various TBMs

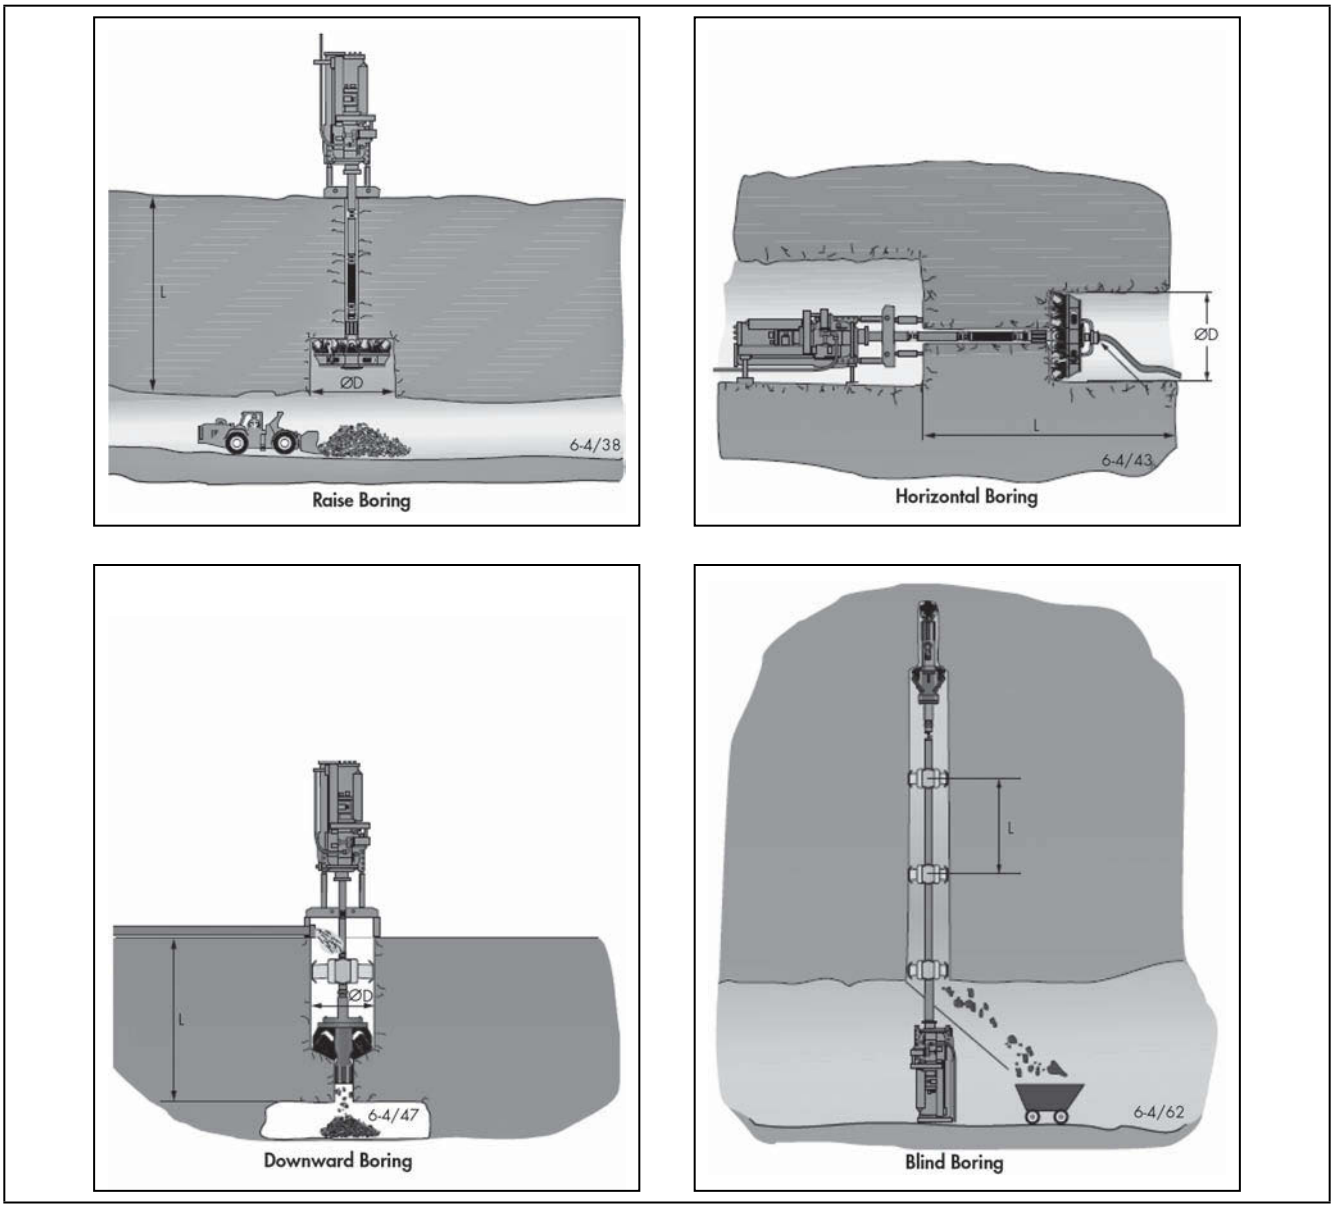
Raise Boring Machines

Where access to a lower level is available, vertical and inclined shafts can be excavated by raise boring. This operation is shown in Figure 7.1-10 and includes drilling a pilot hole, removal of the bit, installation of the reamer head, and reaming of the shaft back to the upper level or toward the machine. The pilot hole is typically in the range of 200 to 350 mm (8 to 14 in.) in diameter, depending on the size of the drill string needed to provide sufficient thrust and torque for the intended final size of the bored shaft. The pilot hole is typically drilled using a tricone bit. However, when raise boring from the surface, the pilot hole can be drilled with any drilling machine capable of drilling a pilot hole of the required size. For long raises, use of a down-the-hole rotary percussion drill rig for the pilot hole could result in schedule and cost advantages compared to using a raise borer.

The raise can be vertical or inclined, and recently there have been several applications of this system in a horizontal direction, where a raise-bored tunnel was driven between two access tunnels. The limitations of the raise boring machine regarding size and length of the excavation are the same as for shaft drilling machines. Raise boring machines can be used to drive larger diameters if reaming is performed in multiple passes. This operation can be repeated several times with the size of the reamers selected to conform to the drill string and machine power. Low-profile raise boring machines have been developed that can be set up in a room with around 6 m (20 ft) of head clearance.

During pilot drilling, the muck is removed by circulating drilling fluids. While reaming, the muck drops down to a lower level where it can be removed by a loader. In horizontal raise boring, the muck is picked up by a loader. Ground support for raise-bored openings (for ground that is competent enough to stay open while the reaming operation is in progress) is installed after completion of the reaming, usually by a robotically controlled shotcrete spraying system that is lowered into the hole, or ground support can be installed by lowering a work platform from which the crew can work and install required additional ground support under the protected areas. This system can be considered for ground that is competent enough to stay open while the reaming operation is in progress. Typical rates of penetration for raise borers are from 3 to 5 m/h (10 to 16 fph) for pilot drilling and from 1 to 2 m/h (3 to 6 fph) for reaming. (An equation for predicting penetration rate as a function of rock strength and machine parameters for both pilot drilling and reaming is presented in a later section of this chapter.)



Courtesy of Aker Wirth.

Figure 7.1-9 Shaft drilling machine at surface showing the cutterhead

Raise Drilling Machines

Inclined shafts/raises can also be developed by raise drilling machines. This involves drilling upward using a cutterhead, where the drill string is pushed to drive the head and provide the torque. The muck flows down by gravity, and at the collar it is diverted onto the floor or into a muck car through a pan or a muck chute (Figure 7.1-10). The head can be up to 1.8 m (6 ft) in diameter, and the machine can drill a blind raise of around 100 m (300 ft). The limit on the size and length of section is imposed by the fact that this machine uses the drill string in compression to drive the head upward, in which case the torque that can be transferred to the cutterhead is more limited than that in a shaft drilling (or raise boring) operation. Raise drilling operations are very common in underground metal mines where a large opening is required for initial blasting of the stope. The typical drilling

Courtesy of Sandvik Mining and Construction.
Figure 7.1-10 Types of raise boring operations

rate is around 1 to 2 m/h (3 to 6 fph), similar to reaming from an overhead machine setup.

Stope Boring Machines

The stope boring system or BorPak is used for blind-hole raise boring. It comprises a guided boring machine, a power unit, a launch tube/transporter assembly, a conveyor, and an operator's console (Atlas Copco 2010). The BorPak operates like a micro-boring machine, climbing up the raise as it bores. Cuttings pass through the center of the machine, falling down the raise and launch tube onto a conveyor.

This machine has the potential to bore openings from 1.2 to 2.0 m (3.9 to 6.6 ft) in diameter at inclinations as low as 30°. This system is a miniature TBM, where instead of a gripper, an inflatable packer is activated to hold the walls while the head turns and is pushed against the face. At the end of the boring cycle, the steering shoes are pressed to the walls to hold the head against the face while the packer is deflated and moves up for regripping.

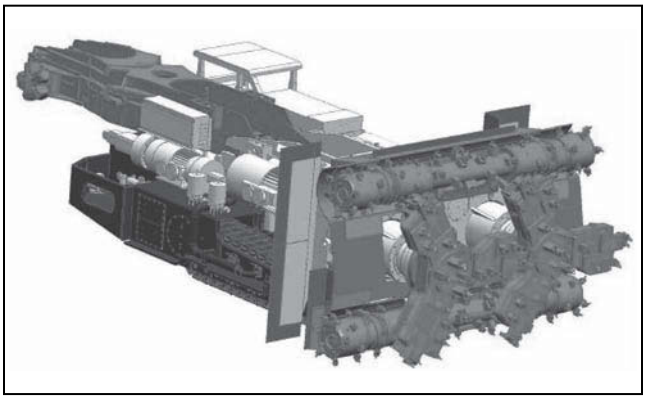
The machine has excavated holes with lengths of up to 150 m (450 ft). A preliminary design for a boring unit that can use a vacuum pickup system for mucking was developed to allow these units to be used for excavation in a horizontal or a slightly declined opening. However, operational units have not yet been manufactured. The BorPak system has been extensively used to excavate slot raises for sublevel stoping in underground hard-rock mines.

Full-Face Machine Cutters

The cutting tools on most, if not all, of the above noted full-face rock-cutting machines are roller-type cutters. TBMs and BorPaks generally use disc cutters. Conversely, some shaft

and raise boring and drilling machines use strawberry cutters to achieve longer cutter life. This is because changing cutters in these operations is difficult if not impossible and can significantly delay heading advance because it is necessary to pull the machine or reamer away from the face. Significant improvements have occurred in recent years with respect to cutter materials, cutter load capacity, cutter life, and computer monitoring and control technology on the cutters that allows for monitoring of cutter rotation.

Machine Transport



An important issue when planning to use full-face machines is transporting them to a site and then to the workplace. The minimum dimensions of these machines are typically such that it will be necessary to ship them in pieces with erection at the site. It is customary to specify the largest size and heaviest piece of the machine during the procurement phase so that the pieces can be delivered to the site through the available roads and bridges and be hoisted down the shaft if necessary. Most machine manufacturers design and fabricate their machines to comply with size and weight specifications to facilitate transportation and assembly, as well as decommissioning and dismantling the machine when a project is complete. With shield machines, the split cutterhead design and collapsing shield allows them to be withdrawn from within a lined tunnel they have just constructed.

Full-Face Continuous Miners

As noted previously, the only noncircular full-face mechanical excavators are the full-face continuous miners, which are often known as borer miners or "Marietta miners." These machines, which excavate rectangular openings with semicircular ends, are common in underground mining of potash and trona. The machines contain one or two pairs of counterrotating cutting drums that are 2.5 to 3.6 m (8 to 12 ft) in diameter, and depending on the number of drums, the machines can be 5 to 10 m (15 to 30 ft) wide. The triangular area between the circular cuts created by the drums is excavated either by a chain or by special cylindrical-shaped cutterheads (known as "cob cutters" due to their shape).

These machines are highly productive and can produce more than 1,000 t/h (1,100 stph) in trona and potash. They can be equipped with drag bits, but more commonly use conical picks, and they typically have 400- to 1,000-hp cutterhead power for high production rates. Excavated materials fall on the machine's front apron, from which they are pushed onto a chain conveyor that discharges onto a panel conveyor belt that feeds the main conveyor system. Panel belts are typically extensible and fed from belt storage magazines. These machines can excavate 500 m (1,500 ft) of entry per day. The ground support requirement is typically met by installing a single row of roof bolts over the operator's cabin. Some versions of these machines can install roof bolts while the machine is excavating, allowing for continuous production and face advancement.

These machines have high utilization rates of around 40% to 50% and have very high production rates. However, due to the limited applications and number of machines and manufacturers, they are gradually being replaced by drum-type continuous miners and roadheaders. Figure 7.1-11 shows a new generation of borer miner. These machines are slightly larger than their predecessors, reaching around 250 t (275 st) on the single-pair (two-drum) machines.

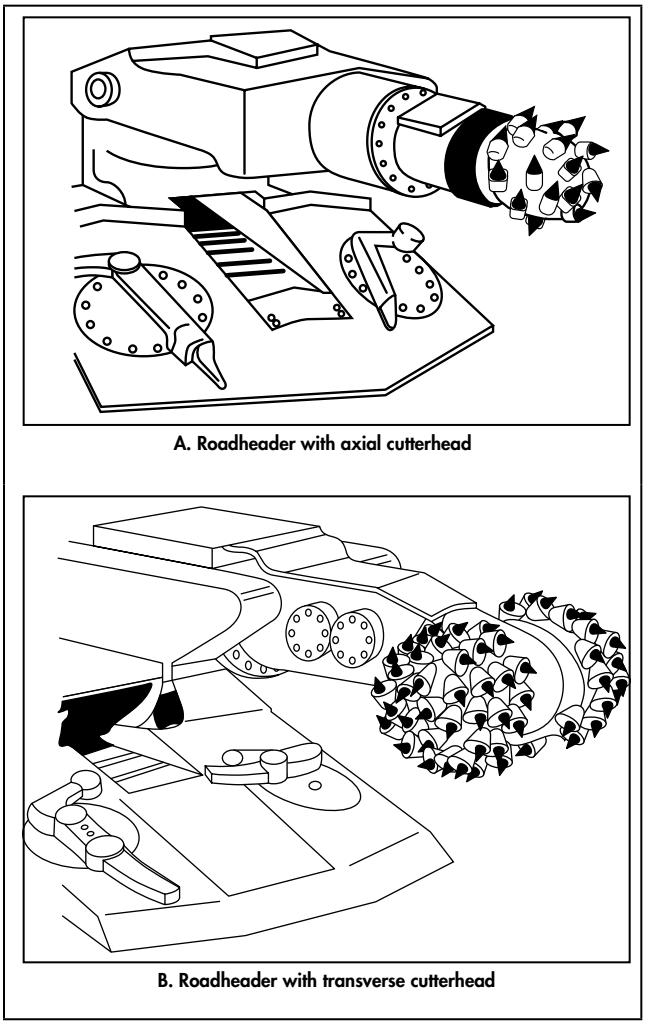
Partial-Face Machines



Partial-face machines are used for development and production in a variety of activities in underground or surface mines. These machines have traditionally been used in soft to moderately hard rocks using drag bits and conical picks. Owing to the need for rapid development in underground mines, several hard-rock partial-face machines have been developed and used for excavation of noncircular openings. However, they have only had limited success.

Partial-face machines are the most popular and most frequently used machines for underground mining of softer rock types, such as coal, salt, gypsum, potash, trona, and the softer variations of limestone. This group of machines includes roadheaders, continuous miners, longwall drum shearers, plows, road milling machines, surface miners, trenchers, and some variations of hard-rock mining machines. Bucket-wheel excavators (BWEs) can be considered a partial-face machine, but they are primarily used to excavate and load very soft soil-like material. Similarly, dredges may occasionally excavate rock but are generally used for removing partially consolidated material from the bottom of rivers or lakes. Because they generally do not excavate rock, BWEs and dredges are not covered in this chapter.

Roadheaders

Roadheaders were primarily developed for the driving of tunnels or mine entries. They use drag bits on a cutting head mounted at the end of a boom, which moves side to side and up and down to excavate the face of the tunnel. Along with TBMs, roadheaders are the most popular mechanical excavators in use. Over the years, two types of roadheaders have been developed and used. One, known as an "axial," in-line, or milling machine, has a cutterhead that rotates around the axis of the boom. The other, known as a transverse or ripping machine, has a cutterhead that rotates in a plane perpendicular to the boom axis. Figure 7.1-12 shows both types of roadheaders.

Axial roadheaders are typically favored in softer rock types, whereas transverse machines are preferred in harder rocks. Roadheaders are generally limited to use in rocks with unconfined compressive strengths of 100 MPa (15,000 psi) or less. Roadheaders are mostly used in mine development, especially in evaporites (salt and potash), and may also be used in production. Roadheaders have also been used to drive

Figure 7.1-12 Two types of roadheaders

large-sized shafts as the primary excavation system, where the cutterhead and boom are reconfigured to excavate the floor.

A typical work cycle includes sumping the head into the bottom of the face to begin a new cut, followed by motion of the head laterally and up and down to remove the rest of the face. Roadheaders take advantage of weaknesses in the rock and perform better in jointed rocks. Their performance drops in abrasive rock types due to the need for frequent bit replacement. The production rate of a roadheader is a function of its size, cutting power, weight, rock strength and abrasiveness, and operator skill in maneuvering the boom. The larger, more powerful machines can produce more, but their size requires a minimum opening dimension to allow for efficient operation. A major limiting factor for roadheaders is their ability to react to side forces as the cutterhead moves from side to side. This so-called limit on slewing or arcing forces determines how deep the head can be plunged into the face and how fast it can be moved from side to side in the production cycle before the machine starts to slide on its track.

Roadheaders are divided into three classes: small, medium, and heavy duty. Small roadheaders are typically less than 45 t (50 st) in weight and have cutterhead power of 70 to 110 kW (100 to 150 hp). Medium roadheaders range from 45 to 75 t (50 to 83 st) and have cutterhead power of up to 200 kW (260 hp). Heavy-duty roadheaders typically weigh more than 75 t (83 st) and can have a cutterhead power of 300 kW (400 hp). There are several variations of machines with low profiles for cutting harder rock types and those with an extended reach for cutting softer rock in large-size tunnels with high ceilings. Production rates for roadheaders can range from as little as 10 to 20 t/h (11 to 22 stph) to more than 200 t/h (220 stph).

Machine setup consists simply of connecting it to an electrical cable. Broken rock is removed from an apron on the front of the machine by means of gathering arms or rotating stars and a chain conveyor from which it is transferred to trucks, panel conveyors, or shuttle cars for haulage away from the face. Machines often come with additional equipment, ranging from bolters to steel set erectors, for the installation of ground support. Various types of mucking arrangements have been tried in the past to move the muck from the apron onto the chain conveyor, but the most efficient system appears to be rotating discs, rotating stars, or clam arms. Formulas for estimating performance and production rate of the roadheaders are provided in a later section.

Continuous Miners

Continuous miners (CMs) are the most popular machines in underground coal mines, but they are equally important in salt, potash, trona, and gypsum mines. These machines were invented in the mid-1950s and have evolved into robust and reliable mining machinery. Although several variations of CMs have been used over the years, currently available machines use solid heads that combine three cutting drums to form a cylindrically shaped cutterhead.

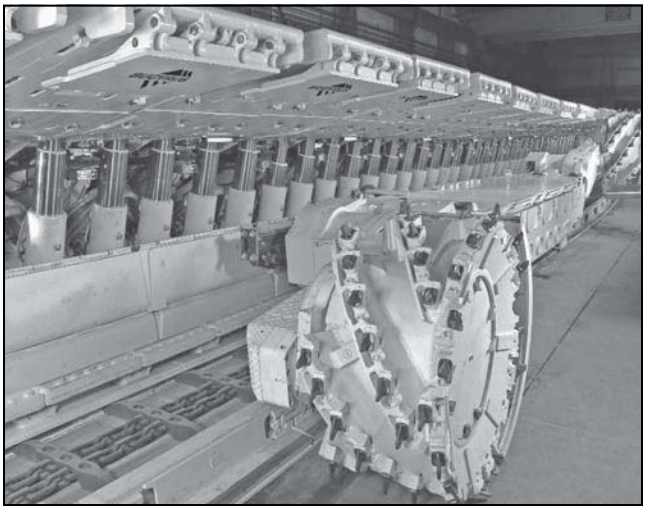
These machines operate by sumping at the upper part of the face near the roof and shear downwards. Because of the shape of the cutterhead, CMs cut a rectangular face. CMs can operate in seams as low as 1 m (3.3 ft) to as high as 5 m (15 ft). Cutterheads are typically 3 to 4 m (10 to 13 ft) long and 0.8 to 1.4 m (2.3 to 4.5 ft) in diameter, and they are generally fitted with conical bits for cutting the rock. The machines vary from 60 to 110 t (66 to 120 st) in weight and cutterhead power varies from 200 to 400 kW (260 to 530 hp). CMs are primarily used in room-and-pillar (R&P) operations, although they can be used in shortwall mining as well. In R&P operations, machines are used to drive multiple entries and crosscuts. However, the time required to move the machine between faces cuts into production time and is avoided as much as possible. Some new CMs have onboard bolting systems to reduce the need for maneuvering and relocating of the machines between working faces, which can improve machine utilization and daily production.

Typical R&P (or "CM panels") mining can produce in the order of 4 to 5 kt (4,400 to 5,500 st) per shift. In soft, thick coal seams, production can reach more than 1,000 t/h (1,100 stph) with larger, more powerful equipment. CMs used for driving headgates for longwall panel development can advance a three-entry development panel about 30 m/d (100 fpd) in a typical well-coordinated operation. An important aspect of using the CMs is the dust-control issue, which has resulted in most if not all cutterheads to be fitted with water sprays or so-called "wet" heads. Some of the sprays are phased, meaning that they only work when the bit is engaged and cutting. This allows for lower usage of water and prevents the sprays from creating a turbulence that pushes the dust back. Machines are

also fitted with dust scrubbers that collect the air right behind the head on both sides to reduce the amount of dust that gets into the air circulation.

Longwall Drum Shearers

Drum shearers are the backbone of longwall operations in coal and provide high productivity and high reserve recoveries of up to 80% when used on bedded ore bodies such as coal. Longwall mining accounts for slightly more than 50% of the total underground coal production in the United States. Longwalls in the United States generally use double-drum, ranging-arm shearers. Similar to CMs, drum shearers can work in seams as low as 1.5 m (5 ft) and as high as 6 m (20 ft). Drums are fitted with conical bits arranged in a helical (spiral) pattern. The excavated material falls onto the face (chain) conveyor. The installed power of the arms on the drum shearers has gradually increased over the years and currently machines with cutterhead power of 750 kW (1,000 hp) per drum (or per arm) are available on the market.



Recent advances in the shield and machine automation have resulted in considerable increases in machine cutting speeds. Cutting speeds of up to 0.83 m/s (150 fpm) have been achieved, while the automated shields will maneuver behind the fast-moving drum to advance the face. With such efficient systems, longwall faces have grown as wide as 450 m (1,500 ft), and panels can consistently advance 15 m (50 ft) per day. At high cutting speeds, drum shearers can produce in excess of 5,000 t/h (5,500 stph) at peak production. However, to avoid overwhelming the face and panel conveyors, drums take half cuts or work at lower speed to allow for a more uniform and sustainable production rate. A typical longwall panel can produce about 10 to 12 kt/d (11,000 to 13,200 stpd) in a 3-m- (10-ft-) high coal seam in two 10-hour shifts. Figure 7.1-13 shows a typical longwall drum shearer.

Drum diameters are chosen to be 0.5 to 0.6 times the seam height. Therefore, diameters range from 0.8 m (2.5 ft) to more than 3 m (10 ft). Drum widths are often limited to 0.75 to 1.0 m (2.4 to 3.3 ft) to avoid cantilever forces on the arm from the weight or cutting forces. Counterrotating drums are used in alternating lead-and-tail drum positions, and the machine is maneuvered back and forth along the headgate or tailgate to advance the face in a "snaking" motion.

To minimize airborne dust and improve visibility, water is sprayed on the cutterhead. Cutting drums are replaced or overhauled after 2 to 3 Mt (2.2 to 3.3 million st) of production (the same is true for CMs). Longwall systems are capable of passing through fault zones. Special drums are used along with stronger bits and lower cutting speeds to handle harder roof and floor formations. Longwall drum shearers are also used in some trona and potash mines, but they produce slightly less than in coal because of higher energy requirements for cutting such formations.

Plow Systems

Coal plows are also used in longwall operations mainly in Europe, and they work by being dragged along the face to take small 100- to 150-mm- (4- to 6-in.-) deep cuts between the headgate and tailgate. The motion of the plow along the face is controlled by a set of high-strength cables. At speeds of between 2.5 and 3.6 m/s (490 to 710 fpm), these systems can be highly productive, especially in low seams, where drum shearers are not very effective. Plow systems can work in seams as low as 0.5 m (2 ft) and as high as 2 m (6.5 ft).

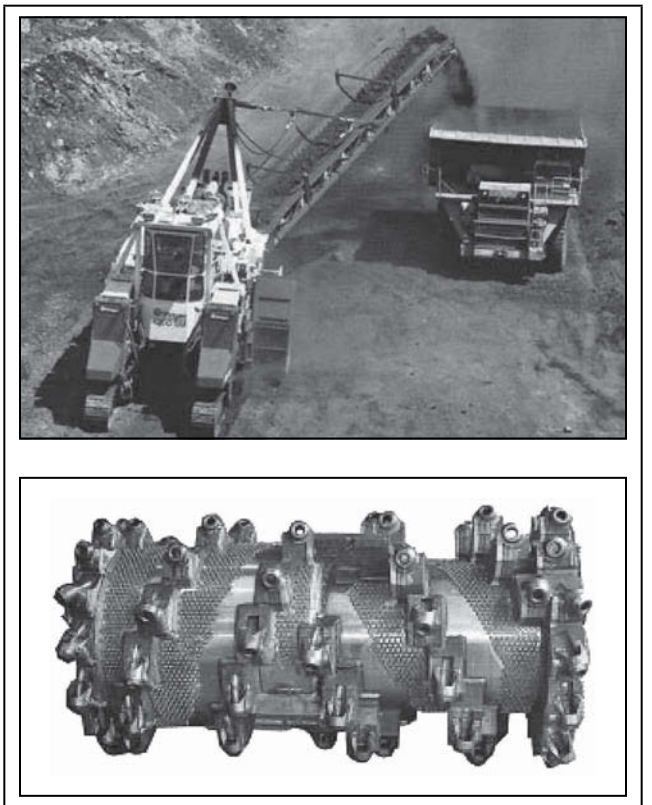
Figure 7.1-13 Drum shearer in a longwall face

Machines can maneuver and follow the seam, cutting up or down relative to the pan, which can negotiate vertical seam curvature along the face. To increase productivity, higher-power cutting systems have been installed on some machines. The available models have total installed power ranging from 800 to 1,600 kW (1,080 to 2,160 hp). Production rates can be estimated from the speed of cutting and depth of slice with production rates of more than 1,200 t/h (1,320 stph) possible.



Road Milling Machines

Road milling machines, which are used to remove road pavement prior to resurfacing, have in recent years been adopted for mining operations such as coal, gypsum, oil sand, and limestone. These machines are highly productive and allow for selective mining in flatly bedded ore bodies. The machines primarily consist of a chassis mounted on three to four independently controlled suspension systems that carry a cylindrical cutting drum. The depth of the cut can be controlled by adjusting the height of the legs.

In mining applications, the cutting drums are about 1 m (3.3 ft) in diameter and 2 to 4.2 m (6.6 to 13.8 ft) in length, and they can cut a slice of about 150 to 200 mm (5.9 to 7.9 in.) into the rock. Cutting speed depends on the hardness of the material as well as depth of slice, and speeds can reach up to 1.3 m/s (240 fpm). Machines can load mining trucks or a surface conveyor by means of bridge conveyors. Machine production is typically around 400 to 500 t/h (440 to 550 stph) with a single machine and fleet of four or five trucks, but new records have been set by larger machines in recent years, reaching production rates of around 2,100 t/h (2,300 stph). With recent restrictions on blasting in quarries near urban areas, the use of these machines has become more common.

Road milling machines are often powered with onboard diesel engines with power ratings as high as 1,200 kW (1,600 hp) on machines with gross operating weights up to 180 t (200 st). The cutting drums used in larger mining operations are fitted with conical bits at a higher bit spacing to increase the size of the product and minimize fines. Compared to the milling machines used in typical road applications, the drums on machines used for mining have fewer bits and use less energy to cut the material but leave a slightly rougher

surface. Small machines weighing about 10 to 15 t (11 to 17 st) and fitted with cutting drums as small as 0.5 m (<2 ft) in diameter and 0.5 m (<2 ft) in length can be used to pave underground roadways to remove floor heave and improve the road surfaces. Partial-Face Machines for Hard-Rock Applications

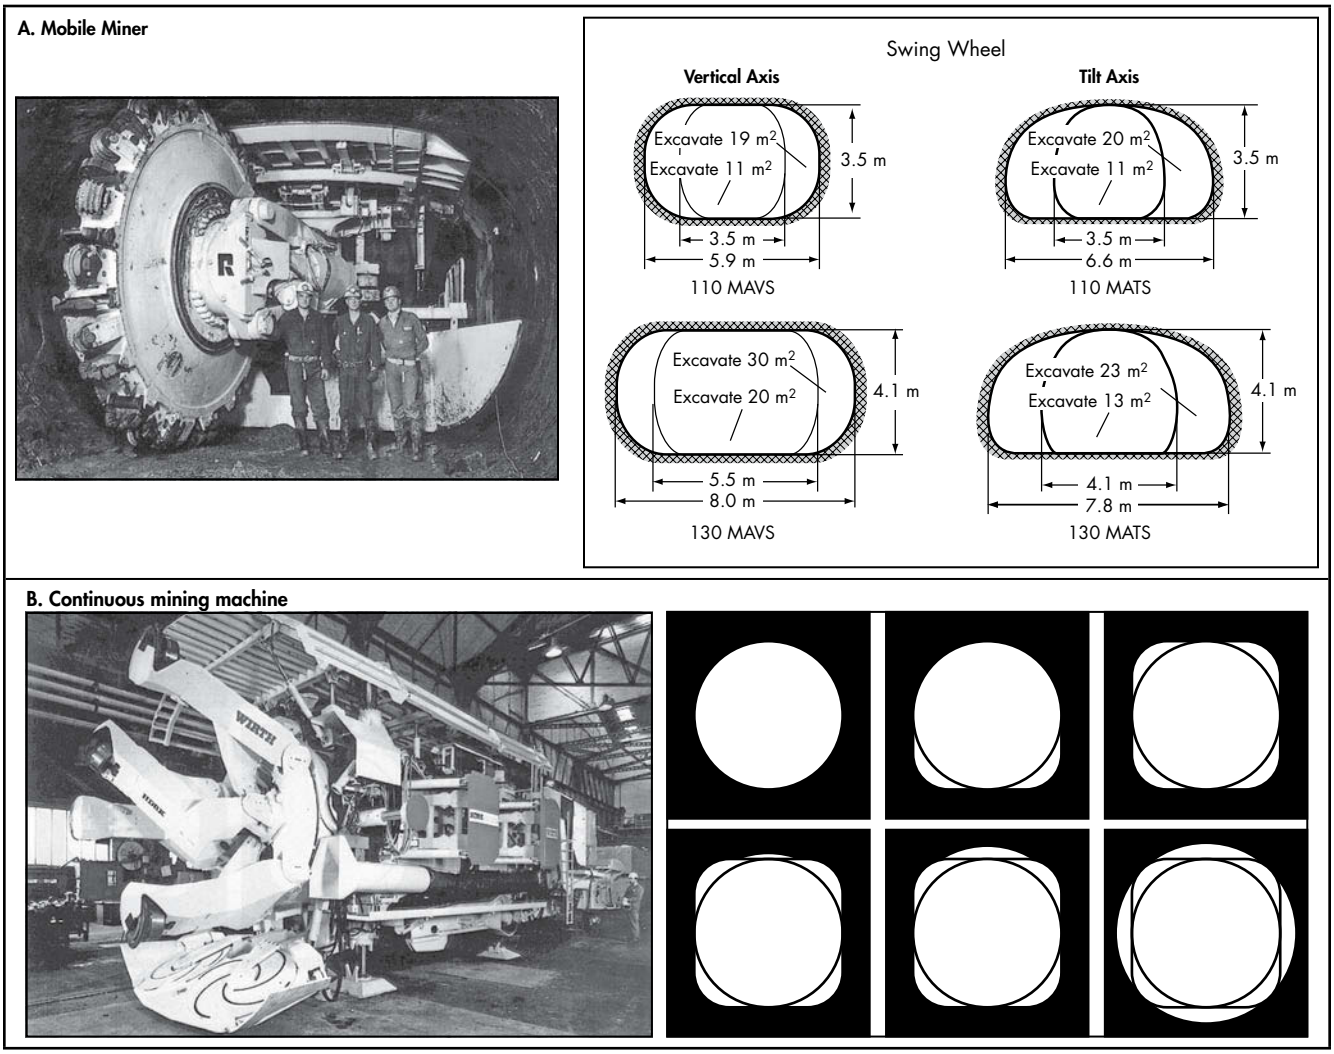
Underground hard-rock miners seek mechanical excavation systems that can excavate noncircular openings, preferably horseshoe-shaped drifts with a flat floor. Because of the strength and (often) abrasiveness of hard rock, the only feasible cutting tools for hard-rock excavation have been roller-type cutters, particularly disc cutters, which require high thrust forces in the 10-to-30-t (11-to-33-st) range. As a consequence, having several cutters in contact with rock means that there are several hundreds of tons in forces at the face. TBMs can provide reaction forces for such high-thrust forces by applying pressure to the circular walls of the opening because the resulting thrust force is directed along the axis of the tunnel. In contrast, partial-face machines have been limited in the thrust they can deliver at the end of the cutting boom, because excessive force will make the machine slide on its tracks.

Over the years many concepts have been tried, but none has been fully accepted in mining operations. In the mid-1970s, an Atlas Copco Mini Fullfacer was tested at the Craigmont Mine in British Columbia, Canada, and was considered but not tested in Sudbury, Canada.

The Robbins Mobile Miner was developed in mid-1980s and was used in the Mt. Isa and Pasminco mines in Australia, as well as in a tunneling operation in Japan. It consisted of a cutting drum fitted with disc cutters (or multi-row carbide cutters) that could be moved from side to side while the drum rotated to excavate a profile with a flat floor and roof and arched sides (Figure 7.1-15). To provide for the reaction forces, the machine weight was gradually increased, and additional gripping mechanisms were added to the system to the point where, in the smaller version, the gross weight of the machine exceeded 200 t (220 st).

Although the Mobile Miner was considered successful in the excavation of hard and abrasive rock and could offer a consistent advance rate of more than 1 to 1.5 m/h (3.3 to 4.9 fph), it has not been used in any mining application since its use in the aforementioned Australian mines in the early 1990s.

Another machine of this class was developed by Aker Wirth. This continuous mining machine was designed based on the concept of undercutting the rock face using disc cutters pushed sideways to break the rock in shear toward a free face. The machine has four arms with 500-to-600-mm (20-to-24-in.) disc cutters at the end of each arm (Figure 7.1-15). For excavation, one arm starts at the middle of the face and moves toward the center while the other three arms move outward as the cutterhead rotates. The outward cutting arms are designed to move independently and push out of their projected cutting circle to excavate corners of an opening, creating a variety of profiles, such as circle-, horseshoe-, and square-shaped openings. The machine was successfully tested in a sandstone quarry in Germany. However, the field trial in an underground hard-rock mine in Sudbury, Canada, did not produce the anticipated results. No continued performance record is available on the machine.



A heavy-duty roadheader has also been tested for possible application in hard-rock mines. This machine, which was developed by Eimco Inc., was an axial roadheader that was modified with higher power, higher weight, and additional gripping system for added stability and control of vibration as well as increased arcing force. The cutting tools on this machine were conical bits with a larger tip and improved bit design to withstand higher cutting forces needed for excavation of hard and abrasive (igneous) rocks. Nevertheless, the trials at the underground hard-rock mine in Sudbury, Canada, seem to have been unsuccessful.

A Voest-Alpine (now Sandvik) roadheader with the ICUTROC cutter system has driven declines for two underground mines in dolomite in the Chicago area and is currently driving perimeter development drifts in one of the mines. The contractor, who owns the machine, has made a number of modifications to the machine to improve productivity. The compressive strength of the dolomite encountered by the machine has ranged from 62 to 120 MPa (9,000 to 17,500 psi).

Other Types of Mechanical Breakers and Excavators

Rock Breakers, Impact Hammers

One group of mechanical excavation equipment that does not fit either of the aforementioned groups and is inherently different in its cutting mechanism is the impact hammer or hydraulic breaker. These tools convert oil flow into the linear and reciprocating motion of a ram that impacts against a replaceable steel rod. Hydraulic breakers are mounted in place of digging buckets on construction equipment such as track or wheel excavators, backhoe loaders, and skid-steer loaders. The breaker is connected to the hydraulic system of the host

Figure 7.1-15 Hard-rock excavation machines for noncircular openings and their excavation profiles

carrier to receive the input pressure required for operation. The steel rod, whose tip may be a chisel, moil, or blunt tip, delivers percussive force to the material to be broken. Common uses for hydraulic breakers include breaking oversize boulders on orepass grizzlies and scaling to remove loose material on rock faces. Hydraulic breakers are also used for breaking concrete, brick, and asphalt. In some cases, impact hammers have been used to excavate jointed rocks and, in conjunction with water jets, to trim tunnel perimeters.

Miscellaneous Cutting and Excavation Machines

Several partial-face machines not used in mining operations on a regular basis have been developed over time. One such machine is the surface miner by Voest-Alpine. The surface miner is a heavier version of a continuous miner without the height limit that the CMs in underground mines have to comply with. These machines could be used for bench mining and for cut benches as high as 5 to 6 m (16 to 20 ft). The cutting tools of these machines are conical picks, which restricts their cutting medium to rocks with compressive strength below 100 MPa (14,500 psi).

Another machine is the trencher, which can excavate rock trenches as wide as 1 to 1.5 m (3 to 5 ft) and as deep as 10 m (30 ft). The cutting system includes a large crawler-mounted tractor chassis with a cutting boom at the end of the machine. The cutting boom is fitted with a cutting chain laced with conical bits. Trenchers can cut soft to medium-strength rocks.

Similar to trenchers, rock saws are also available in a variety of sizes for different mining applications. These rock saws are used for cutting stress-relief cuts and trenches of 100 to 200 mm (4 to 8 in.) in width and up to 3 m (10 ft) in depth. Rock saws are also fitted with drag bits and conical bits, and they can be used in soft-rock applications, mainly in coal and evaporites.

Diamond-wire saws are also available and very popular in dimension-stone quarries around the world. The diamond- or carbide-impregnated wires are very efficient in cutting large blocks of limestone and marble and are used to a lesser extent in granite quarries. The operation of these saws is very simple and straightforward. Guide holes are drilled on the sides of the blocks in orthogonal directions and the wire is passed through the holes and looped. The wire loop is then driven by a drive

unit and gently tensioned while making a straight cut on the side of the block as it moves out. This operation is repeated on each side until the block is cut from all sides and released.

Another type of rock cutting and excavation system used in mining applications is a water jet. Although the cutting action of water jets does not involve the use of mechanical tools, they are typically grouped with mechanical excavators. The cutting ability of a water jet is controlled by the water pressure, the rate of motion across the rock surface, and the rate of water flow (which is a function of the nozzle size). The jet pressure used in rock cutting typically varies from 10 to 310 MPa (1,450 to 45,000 psi), and the flow rate can range from a few liters per second to thousands of liters per second.
